Preface

Welcome to the GEOMATE 2019 - The Ninth International Conference on Geotechnique, Construction Materials and Environment, GEOMATE 2019, will be held in Hotel Continental Fuchu, Tokyo, Japan in conjunction with the Japan Association for Pulling-out Existing Piles, Mie University Research Center for Environmental Load Reduction, The GEOMATE International Society, The Society of Materials Science, Japan, The Useful Plant Spread Society, Japan, Glorious International, AOI Engineering, HOJUN, CosmoWinds and Beppu Construction, Japan.

On Friday 11 March 2011, at 14:46 Japan Standard Time, the northeast of Japan was struck and severely damaged by a series of powerful earthquakes which also caused a major tsunami. This conference was first dedicated to the tragic victims of the Tohoku-Kanto earthquake and tsunami disasters. The Geomate 2018 conference covers three major themes with 17 specific themes including:

- Advances in Composite Materials
- Computational Mechanics
- Foundation and Retaining Walls
- Slope Stability
- Soil Dynamics
- Soil-Structure Interaction
- Pavement Technology
- Tunnels and Anchors
- Site Investigation and Rehabilitation
- Ecology and Land Development
- Water Resources Planning
- Environmental Management
- Public Health and Rehabilitation
- Earthquake and Tsunami Issues
- Safety and Reliability
- Geo-Hazard Mitigation
- Case History and Practical Experience

Alike earlier conferences, this year we have received many paper submissions from different countries all over the world, including Australia, Bahrain, Bangladesh, Brazil, Canada, Colombia, Czech Republic, Egypt, France, India, Indonesia, Iran, Iraq, Israel, Japan, Kazakhstan, Lebanon, Malaysia, Nigeria, Pakistan, Philippines, Russia, Saudi Arabia, Singapore, South Korea, Taiwan, Thailand, Tunisia, Uganda, United Kingdom and Vietnam. The technical papers were selected from the vast number of contributions submitted after a review of the abstracts. The final papers in the proceedings have been peer reviewed rigorously and revised as necessary by the authors. It relies on the solid cooperation of numerous people to organize a conference of this size. Hence, we appreciate everyone who supports as well as participate in this joint conference.

Last but not least, we would like to express our gratitude to all the authors, session chairs, reviewers, participants, institutions and companies for their contribution to GEOMATE 2019. We hope you enjoy the conference and find this experience inspiring and helpful in your professional field. We look forward to seeing you at our upcoming conference next year.

Best regards,

Prof. Zakaria Hossain, Prof. Mie University, Japan

Prof. Dr. Shinya Inazumi, Shibaura Institute of Technology, Japan

Dr. Jim Shiau, University of Southern Queensland, Australia

Organization

Conference Honorary Chairmen:

Emeritus Professor Dr. Sohji Inoue, Mie University, Japan
Emeritus Professor Dr. Teruo Nakai, NIT, Japan
Emeritus Professor Dr. Fusao Oka, Kyoto University, Japan
Emeritus Professor Dr. Bujang B.K. Huat, UPM, Malaysia

Scientific Committees:

Conference Chairmen:

Prof. Dr. Shinya Inazumi, Shibaura Ins of Tech, Japan
Prof. Dr. Zakaria Hossain, Mie University, Japan

Conference Organizing Committee:

Prof. Dr. Shinya Inazumi, Shibaura Ins. of Tech., Japan (Chair)
Prof. Dr. Zakaria Hossain, Mie Univrsity, Japan (Chair)
Dr. Jim Shiau, USQ, Australia (Assiatant to General Chair)
Prof. Dr. M Ibn Ibrahimy, Prof., Int. Islamic Univ. (Co-Chair)
Prof. Dr. Toshinori Sakai, Mie University, Japan (Co-Chair)
Prof. Dr. Takamitsu Kajisa, Mie University, Japan (Co-Chair)
Dr. Vivi Anggraini, Lecturer, Monash Uni Malaysia (Co-Chair)
Dr. Masaaki Kondo, Mie University, Japan (Co-Chair)

National & International Advisory Committee:

Prof. Dr. Fumio Tatsuoka, Tokyo University of Science, Japan
Prof. Dr. Junichiro Takeuchi, Kyoto University, Japan
Prof. Dr. Kingshuk Roy, Nihon University, Japan
Prof. Dr. Sai Vanapalli, University of Ottawa, Canada

THE INFLUENCE OF TEMPERATURE AND MOISTURE ON THE BEHAVIOR OF FINE-GRAINED SOILS

Xingyi Wu[1], Junping Ren[1] and Sai K. Vanapalli[1]
Department of Civil Engineering, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT

The most widely used construction materials for various civil infrastructures is the naturally available, compacted and modified soils. Their behavior is influenced by environmental factors such as precipitation, evaporation and variations associated with the natural ground water table. The stability and deformation behavior are typically two key criteria that govern the design of these infrastructures. Soil is a complex material with different phases both in an unfrozen and frozen condition. The moisture content within the unfrozen and frozen soils is influenced by a wide range of negative and positive temperatures. The soil can be in a frozen or thawed, saturated or unsaturated condition or combinations of them due to the variations in temperature and moisture content. In other words, the hydro-mechanical behavior of soils is significantly influenced by freezing/thawing and wetting/drying processes. In this paper, the influence of variation of temperature and moisture content on the soil behavior is explained using the soil-water characteristic curve (SWCC) and soil-freezing characteristic curve (SFCC). The SWCC and SFCC are respectively used as tools in the prediction and interpretation of the behavior of unfrozen unsaturated soils and frozen soils. The focus of this paper is directed to understand the influence of wetting/drying, freezing, and freeze-thaw cycles on soil properties such as void ratio, hydraulic conductivity, shear strength, microstructure change and swelling behavior of expansive soils. Finally, the influence of temperature and moisture on the design of pile foundations in expansive soils is succinctly highlighted.

Keywords: Soil, Moisture, Temperature, Wetting-Drying, Freezing-Thawing

INTRODUCTION

The most widely used material in the construction of various engineered infrastructure is the soil, in its natural, compacted or modified form. For example, soils are compacted to form dams, canals, roads and railway subgrades, and waste containment structures such as soil covers and liners. The infrastructure constructed is typically in a state of the unsaturated condition during their service life. The variation of moisture content within the soil has a significant influence on the performance of these infrastructures.

The pore water in unfrozen unsaturated soils typically has a lower free energy in comparison to free water due to the interactions between soil particles, pore water and pore air. The soil-water characteristic curve (SWCC) defines the relationship between the free energy of pore water (or soil suction) and its amount in the unsaturated soil. The quantity of pore water can be represented by either gravimetric or volumetric water content or degree of saturation. The SWCC is a conceptual and interpretative tool for understanding the behavior of unsaturated soils [1]. For example, the SWCC has been used for predicting the hydraulic and mechanical properties of unsaturated soils, such as the hydraulic conductivity [2], shear strength [3], and modulus of elasticity [4].

The environmental impacts on soil behavior would be incomplete if only the influence of the variation of moisture content is considered. This is because phase changes of pore water (from liquid to solid or vice versa), which is the result of freezing and thawing of soils, has a significant impact on various soil properties are not considered. In the permafrost and seasonally frozen regions, frost penetration generally results in the freezing of the top layer of the soil which is close to natural ground level. For example, the frost penetration in northern Ontario, Canada can be deeper than 3 m; however, it is typically around 1 to 2 m in southern Ontario [5]. Similar or close to similar trends are observed in many other cold regions of the world.

The unfrozen water and pore ice typically coexist within a frozen soil. The relationship between unfrozen water content and the subzero temperature is defined as the soil-freezing characteristic curve (SFCC). Several researchers during the past five decades have investigated the similarity between SWCC and SFCC behavior [6], [7]. This background has provided a foundation for using SFCC as a tool for cold regions engineering applications by extending the mechanics of unsaturated soils, which will be highlighted and succinctly discussed in later sections of this paper.

There is an urgent need for both the researchers and engineers to better understand the influence of climate change and global warming effects on the engineering properties of unfrozen and frozen soils.

Lu et al. [8] estimated the possible variation of moisture contents within the soils of various regions of the world for the 21st century. Their study suggests significant widespread drying effects in most regions (e.g., Australia, America, Europe, and East Asia), while significant wetting is expected in some regions of East Africa, and central and south Asia. They also suggested that drying is related to precipitation reduction and temperature increase. In addition, soils in humid regions may undergo several wetting/drying (W-D) cycles due to high intensity rainfalls followed with periods of high temperature that contribute to significant evaporation. In addition, global warming effects are expected to contribute to widespread temperature variations in cold regions resulting in freeze-thaw (F-T) cycles. The focus of this paper is directed to understand the influence of freezing, F-T, and W-D cycles on soil properties which include void ratio, hydraulic conductivity, shear strength, microstructure change, and swelling behavior of expansive soils. Finally, the influence of variation of temperature and moisture content on the design of pile foundations in expansive soils is succinctly highlighted.

EFFECT OF FREEZING ON SOIL BEHAVIOR AND THE USE OF SFCC

Hydraulic Conductivity

The hydraulic conductivity of frozen soils near zero temperature is a key property required in water balance calculation in cold regions and is useful information in both engineering applications and agricultural management. It is also an important property in artificial ground freezing techniques. Ice crystals form in the pore spaces of the soil when it is subjected to freezing and block the pathways for water flow. As a result, the hydraulic conductivity of frozen soils is much lower in comparison to unfrozen soils. If the soil temperature falls further below subzero values, more ice will form in the soil pores. Due to this reason, the available unfrozen water films that facilitate free flow of water will substantially decrease. Therefore, hydraulic conductivity decreases further with a decrease in subzero temperature (or unfrozen water content). Fig. 1 summarizes the hydraulic conductivity behavior for various frozen soils.

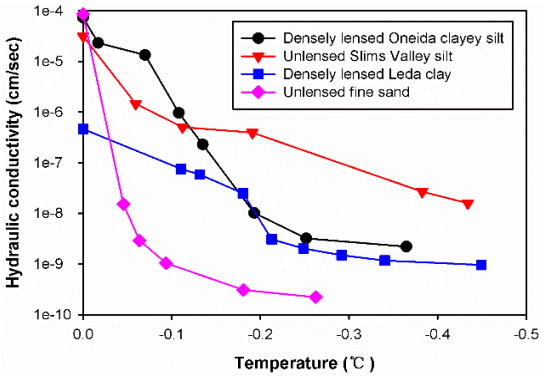

Fig. 1 Hydraulic conductivity of frozen soils [9].

The hydraulic conductivity of frozen soils is strongly dependent on the soil type. This is because the unfrozen water content, pore size distribution, void ratio, particle size, and surface area are dependent on the type of soil and influence the hydraulic conductivity. For example, most water available in sand freezes close to 0 °C. The amount of water in unfrozen sand below 0 °C is small; due to this reason the hydraulic conductivity of sand below 0 °C is low. On the other hand, an unfrozen clay has a low hydraulic conductivity. However, at temperatures below 0 °C, the hydraulic conductivity of clay is still relatively high in comparison to its unfrozen value since the clay contains unfrozen water and has continuous paths available for flow of water [9]. These observations can also be derived from the experimental results summarized in Fig. 1.

There are limited experimental studies in the literature that focus on the measurement of hydraulic conductivity of frozen soils. This may be attributed to difficulties associated with conducting and obtaining reliable experimental results. For this reason, hydraulic conductivity of frozen soils is estimated using relatively simple yet reliable models. The SFCC can be used as a tool for estimating the relationship between frozen hydraulic conductivity and subzero temperature. For example, Azmatch et al. [10] proposed a permeability function for partially frozen silt by using the saturated hydraulic conductivity and SFCC following two steps; which include; (i) the laboratory SFCC data points are fitted with the Fredlund and Xing [2] SWCC equation; and, (ii) the fitted curve is then used together with saturated hydraulic conductivity to estimate the hydraulic conductivity function for partially frozen silt by employing the Fredlund et al. [11] empirical equation.

Resilient Modulus

The resilient modulus (M_R) has been widely used as a key parameter for rational characterization of the resilient behavior of unbound base/subbase and subgrade soils subjected to traffic loading. These

unbound soils are porous media and contain a certain amount of water in their pore spaces. The phase change of pore water has a significant impact on the M_R of these soils. When pore water freezes, ice binds adjacent soil particles together, resulting in a dramatic increase in M_R. For example, Bigl and Berg [12] highlight the M_R of subbase and subgrade soils can increase approximately two orders of magnitude for frozen soils. Bosscher and Nelson [13] report a 20-fold increase in modulus for one type of frozen sand. Similar increases in moduli for frozen granular base soils were also observed by Cole et al. [14]. The pavement structure has relatively high stiffness and bearing capacity during the freezing process and at frozen state; due to this reason, overloading of the pavement structure is allowable in frozen soils without damages.

The SFCC has been used for estimating the M_R of frozen soils. Ren and Vanapalli [15] proposed a semi-empirical model for predicting $M_{R(\text{frozen})}$ for saturated soils. The model exploits the similarity between SWCC and SFCC, and uses cryogenic suction (ψ_{cryo}) and degree of unfrozen water saturation (S_u, which is the ratio of the volume of unfrozen water to the total water volume) for prediction. It is assumed that the rate at which ψ_{cryo} contributes towards frozen M_R can be related to S_u. The value of S_u varies from unity to a small value at large ψ_{cryo}. The semi-empirical model is expressed as:

$$M_{RSAT(\text{frozen})} = M_{RSAT(0℃)}(1+\chi\psi_{cryo}S_u^{\delta}) \quad (1)$$

where $M_{RSAT(0\ ^\circ C)}$ is the saturated M_R at 0 °C (MPa); χ and δ are fitting model parameters.

The above model works well for different types of saturated soils (e.g., see Fig. 2) and has a theoretical basis. However, the model is only applicable to saturated soils.

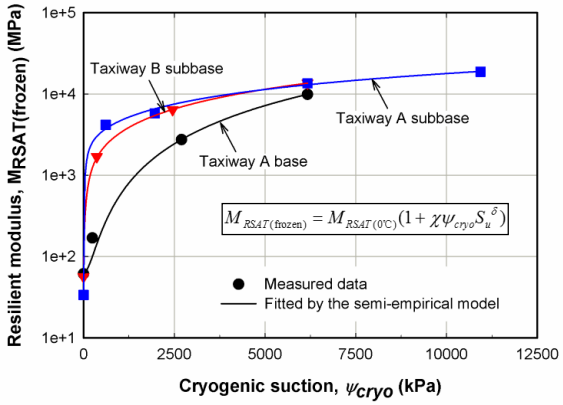

Fig. 2 Prediction of M_R of frozen saturated soils using the SFCC [15].

EFFECT OF F-T CYCLES ON SOIL BEHAVIOR

The effect of F-T cycles can be compared to the natural weathering process that has a significant influence on the behavior of various infrastructures that include the pavements, railroads, pipelines, and building constructions. The F-T cycles considerably change the soil physical property as their void ratio (density) and hydro-mechanical properties of soils; namely, hydraulic conductivity, shear strength, and stiffness.

Void Ratio (Density)

Previous studies show that F-T has a dual influence on soil density, i.e. loose soils tend to densify and dense soils become looser after F-T cycles [16]. Viklander [17] proposed a new term residual void ratio to explain this behavior associated with F-T cycles. The void ratios of different specimens show significant change after one F-T cycle; however, there is little or no change in void ratio for later F-T cycles. The initially loose soil experiences volume increase during freezing (due to ice-lensing) and decrease during thawing (due to the consolidation of soil matrix). Therefore, the density will increase and larger soil particles will come closer. On the other hand, the void ratio of an initially dense soil increases due to F-T, since particles of the soil cannot fall back to the same position after thawing, resulting in a net volume increase. Therefore, the soil structure is slightly looser in comparison to soil prior to soil freezing. The void ratios of the specimens reach a residual value after a certain number of F-T cycles, as shown in Fig. 3.

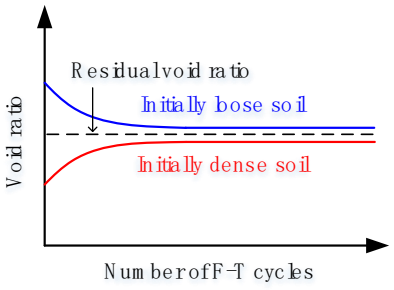

Fig. 3 Effect of F-T cycles on void ratio.

Hydraulic Conductivity

The F-T cycles typically weaken soil structure and contribute to more cracks and fissures. This leads to higher hydraulic conductivity after the soil is subjected to several F-T cycles. Fig. 4 highlights the effect of one- and three-dimensional F-T cycles on the hydraulic conductivity of three Wisconsin soils. The hydraulic conductivity test indicated that there was an

increase in vertical hydraulic conductivity of different types of fine-grained soils [18]. The increase in the hydraulic conductivity was attributed to the formation of polygonal shrinkage cracks and/or the reduction in the fine content in the pores of coarse fraction. The cracks and other structural changes can be observed using the scanning electron microscope (SEM). At low magnification, distinct cracks spaced at 0.5 mm were observed. However, at higher magnifications, voids of 0.005 mm were observed within the aggregates formed during the freezing process [19]. These results suggest F-T cycles can cause changes in both the macro- and micro-structure of fine-grained soils.

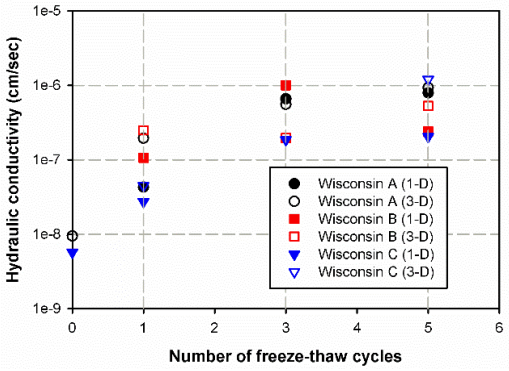

Fig. 4 Effect of F-T cycles on hydraulic conductivity [20].

Shear Strength

The soil particles are forced to separate from each other when water within the soil pore changes its phase to ice. This characteristic contributes to an increase in pore volume which results in swelling of frozen soils. The soil particles have a tendency to re-position to their original locations when the pore ice melts. However, this is not possible in dense soils. As a result, the original soil structure is typically weakened. In other words, the mechanical properties of soils are significantly influenced by F-T cycles.

From their studies, Formanek et al. [21] highlighted the loss of more than half of its original shear strength after the first F-T cycle for a silt loam. The second and third cycles contributed to a further loss, however, the lost of shear strength was not significant. Aoyama et al. [22] found the reduction in soil cohesion increased with a decrease in temperature, whereas little change was observed in friction angle after F-T cycles. Lerouil et al. [23] conducted shear strength tests on nine Champlain Sea clays after one F-T cycle. Results showed that freezing typically led to a drastic decrease in the undrained shear strength, and the frozen-thawed specimens presented a dilatant behavior similar to granular soils. Graham and Au [24] found that the F-T cycles produced increased compressibility and pore water pressure, and reduced strength at low stresses compared with the behavior of undisturbed Winnipeg clay. Kamei et al. [25] found that the unconfined compressive strength and durability decreased with an increase in the number of F-T cycles. The greatest reductions in both strength and durability were observed during the second F-T cycle; however, later F-T cycles only had a limited influence.

Wang et al. [26] investigated the mechanical properties of Qinghai-Tibet clay subjected to a maximum of 21 closed-system F-T cycles. The experimental results suggest a strong relationship between the failure shear strength and the number of F-T cycles. Figure 5 shows variations in cohesion and friction angle of the soil with respect to F-T cycles. These results suggest that the cohesion decreases dramatically with an increase in the number of F-T cycles, from 0.55 MPa to about 0.25 MPa after 15 cycles. On the other hand, the friction angle shows a dramatic increase. Similar trends of results were also reported by Ogata et al. [27].

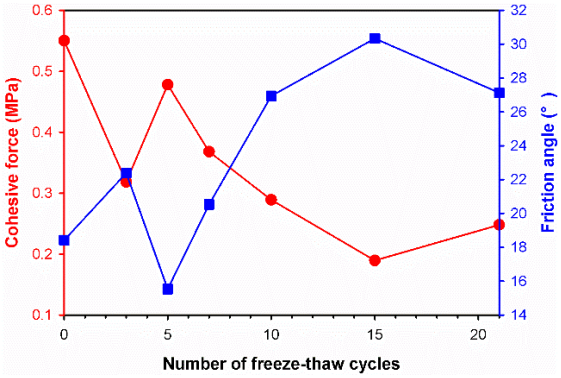

Fig. 5 Effect of F-T cycles on shear strength [27].

Resilient Modulus

The resilient response of compacted soils under cyclic loading is significantly influenced by soil structure. The M_R of soil typically decreases as F-T cycles weaken the soil structure. Culley [28] investigated the resilient strains and M_R of till specimens subjected to F-T cycles in a one-dimensional closed-system. The specimens were compacted to various densities and water contents. At water contents lower than the optimum water content, the decrease in M_R resulting from F-T cycles decreased as density increased. However, at water contents of optimum and higher, the detrimental F-T effect increased with an increase in the density. The water content at which the maximum F-T effect occurred increased as density increased, ranging from 1.5% less than optimum at 93% density to 1.5% greater than optimum at 100% density. These trends were also consistent for resilient strain.

Lee et al. [29] concluded from the M_R tests performed on five cohesive soils sampled from in-

service subgrades that the stress at 1% strain in the unconfined compression test ($S_{u1.0\%}$) was a good indicator of M_R, and proposed an empirical relationship between M_R and $S_{u1.0\%}$. The proposed relationship is applicable to both as-compacted and in-service subgrade soils. There was a negligible effect of F-T on M_R, when there was no ice lens formation, for soils having values of $S_{u1.0\%}$ less than approximately 55 kPa. The effect of F-T increased as the value of $S_{u1.0\%}$ increased. It was observed that a single cycle of F-T caused a 30% - 50% reduction in M_R. The M_R of various coarse- and fine-grained subgrade soils subjected to F-T cycles were presented by Simonsen et al. [30], the results indicated that all the soils exhibited a substantial reduction in M_R (approximately 20% - 60% depending on soil type) after F-T cycles.

Wang et al. [26] studies suggest decreases by 18%-27% for unfrozen soil M_R depending on confining pressure. The greatest changes in M_R in all the four soils studied with various confining pressures (i.e., 200, 400, 600, and 800 kPa) were obtained after the first F-T cycle (as shown in Fig. 6), suggesting significant disturbance during the first F-T cycle.

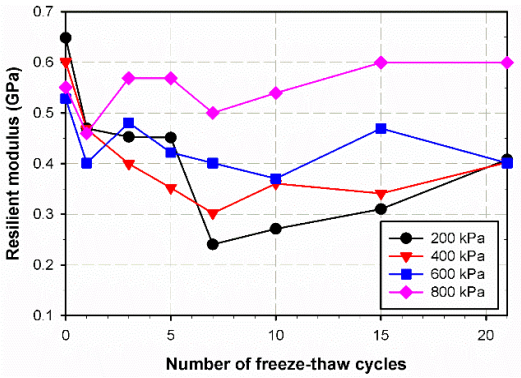

Fig. 6 Effect of F-T cycles on resilient modulus [26].

EFFECTS OF TEMPERATURE AND MOISTURE CHANGE ON THE BEHAVIOR OF EXPANSIVE SOILS

The Structure of Expansive Soil

The structure of expansive soil has a significant influence on its mechanical behavior. Tang et al. [31] studied pore size distribution (PSD) of an expansive soil by mercury intrusion porosimetry (MIP). The results of this study summarized in Fig. 7 shows two peaks suggesting it is bimodal in nature. The two peaks are around 30 μm and 7 nm, respectively. These two sizes of pores can be considered as macropores and micropores, respectively. Studies on different types of expansive soils showed similar results [32]–[34]. The soil structure with micro and macropores is typically referred to as the double structure in the literature.

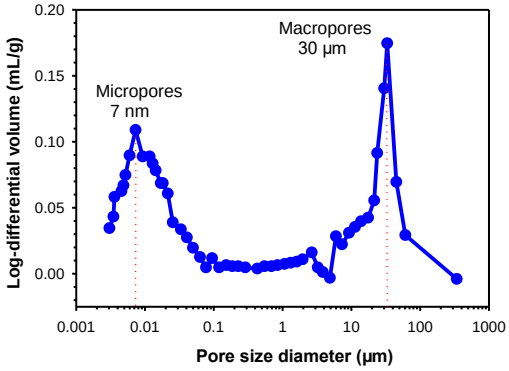

Fig. 7 Pore size distribution of an expansive soil [31].

The double structure can typically be attributed to the aggregation of elementary soil particles. For fine-grained soils, several factors including the water content and interparticle forces can facilitate particle aggregation. The soil particles get closer to each other during the drying stage due to an increase in suction associated with a decrease in water content. The positive ions of water (i.e., hydrogen ions) can be attracted to the negatively charged soil particle's edges when the distance between adjacent soil particles is smaller enough. In addition, the interparticle forces (e.g., van der Waals attraction and electrical double repulsion) contribute to the formation of aggregates. During the drying process, the water content decreases and the air content increases, resulting in an increase in the van der Waals attraction and drop of the electrical double repulsion. This results in the aggregation of clay particles [35]. On the contrary, during the wetting process, soil suction and van der Waals attraction between soil particles will decrease, and the electrical double layer repulsion will increase. In other words, the wetting process will destroy soil aggregates.

As shown in Fig. 8, the micropores are defined as pores in aggregates or intra-aggregates pores. The pores between aggregates (inter-aggregates) are the macropores. The double structure concept has been widely accepted to describe the behavior of expansive soils [36]–[38]. The micropores and macropores sizes are not unique values. Many factors including the soil type and the specimen preparation method may contribute to the different pore sizes.

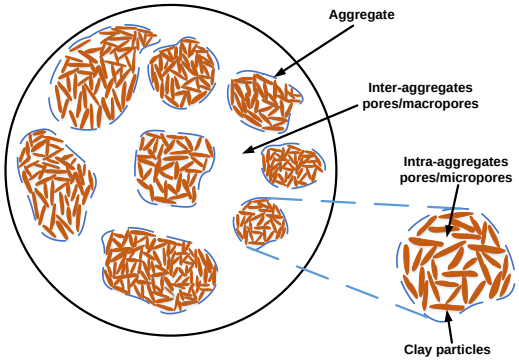

Fig. 8 The structure of aggregated soil [39].

The Volume Change Behavior of Expansive Soil

The effect of high temperature

The effects of high temperature (from 20 °C to several hundred degrees) on the deformation behavior of expansive soils have been studied by several researchers [40]–[42]. These studies suggest the influence of temperature on volume change behavior of expansive soils is affected by confining pressure and suction.

Romero et al. [40] used the Boom clay to study the volume change behavior by subjecting it to different stresses and temperature paths. The non-isotropic tests at constant suction and confining pressure were performed. The volume change of specimens under different thermal cycles is shown in Fig. 9. It can be seen that significant dilation occurs when temperature increases from 20 °C to 80 °C under both the values of suction investigated. However, when the temperature decreases from 80 °C to 20 °C, shrinkage was observed in the two specimens for both the suction values. It is of interest to note that the shrinkage is less in comparison to dilation.

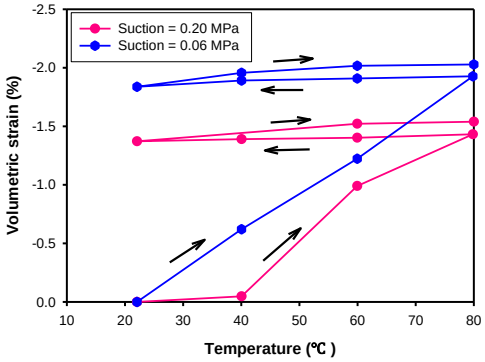

Fig. 9 Volumetric strain due to thermal cycling [40].

The temperature variation can contribute to significant changes in the soil structure. The clay minerals in the expansive soil typically expand and the adsorbed water could also enhance due to an increase in the temperature [43]. Romero attributed the irreversible strain to the possible rearrangements of particles at the macrostructural scale [40]. However, Tang et al. [42] found the effect of temperature depends on the stress state in the soil (e.g., confining stress and suction). The dilation phenomenon occurs under high suction and low confining pressure, and the volumetric strains are reversible. On the other hand, under low suction and high confining pressure condition, the test specimen contracts due to the influence of thermal cycles. The volumetric strain associated with this phenomenon is also irreversible.

Typically contraction is observed in a saturated soil with a low overconsolidation ratio when it is subjected to heating; however, the saturated soil with a high overconsolidation ratio will expand due to heating [43]. The effect is similar to that of the confining pressure on the unsaturated expansive soil. Tang et al. [42] suggested that soil aggregates weaken when soil is tested at low suction value; such a behavior may be attributed to an increase in water content.

An increase in temperature can result in expansion when the confining pressure is low and the suction is high. On the contrary, unsaturated expansive soil can be compressed under high confining pressure at low suction values.

The effect of wetting-drying (W-D) cycling

The volume change behavior of expansive soils resulting from W-D cycles is influenced by the number of W-D cycles, and W-D cycling pattern [44].

Tripathy and Subba Rao [44] conducted different swelling-shrinkage tests on a highly plastic expansive soil by controlling the height of samples. Samples were allowed to fully swell to the saturation and allowed to shrink to initial height or partially shrink to several predetermined heights that were larger than the initial heights of samples in each cycle. The height of samples after equilibrium condition was allowed to change from a smaller to a larger value (less shrinkage) or from a larger to a smaller value (greater shrinkage). From these studies, they found that if the greater shrinkage was applied to sample, a new swelling potential would establish, which means more swelling strains occurred along the first swelling path after the change. The swelling strains along the first swelling path were irreversible. The irreversible strains were reduced with an increase in the number of swell-shrink cycles. Only reversible strains occurred after five cycles. However, if the less shrinkage was applied to the samples, only reversible strain would immediately occur, without any irreversible strains.

The differences in the behavior of expansive soils can be attributed to changes in microstructure associated with the W-D cycles. Water was

progressively absorbed by the soil aggregates during the wetting process. The aggregates expanded due to an increase in water content, which closed the macropores. Therefore, during the wetting process, the volume of macropores decreased. The volume of micropores, however, did not change significantly. Therefore, during the hydration, the structure of the soil is going to be homogenous [32], [45].

The soil structure change that occurred due to hydration during W-D cycles may be considered as permanent. Therefore, the volumetric strain was reversible or elastic at each W-D cycles after equilibrium [46]. Seiphoori et al. [46] used MIP to test the microstructure of an expansive soil at several different stages of W-D cycles. The results summarized in Fig. 10 suggest that during wetting, the volume of the macropores decrease rapidly. However, the micropores were not affected by the hydration. The micropores in the soil were increased when it was close to the saturation condition. In the subsequent W-D cycles, three curves, C, D, and E were close to each other, which means the soil structure of the test specimen did not change significantly. In other words, the structure of the expansive soil was kept as homogenous during W-D cycles. Only reversible volumetric strain that occurred after W-D cycles can be attributed to the homogenous nature of the soil structure.

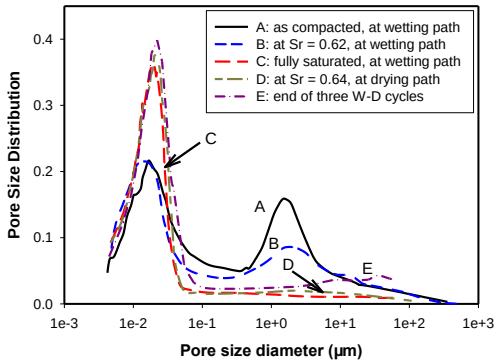

Fig. 10 Evolution of microstructure due to W-D cycles [46].

The Shear Strength of Expansive Soil

The effect of high temperature

The effect of high temperature on the shear strength of expansive soil is predominantly dependent on the degree of saturation and dry density [47], [48].

Wiebe et al. [48] conducted undrained triaxial shear tests on sand-bentonite mixtures with different degrees of saturation (i.e. 50%, 65%, 80%, and 98%) and under different temperatures (i.e. 26°C, 65°C, and 100°C). Fig. 11 summarizes these experimental results. The shear strength reduced with an increase in temperature when the soil was in a state of unsaturated condition. When the soil was nearly saturated, the effect of temperature on the strength can be considered negligible.

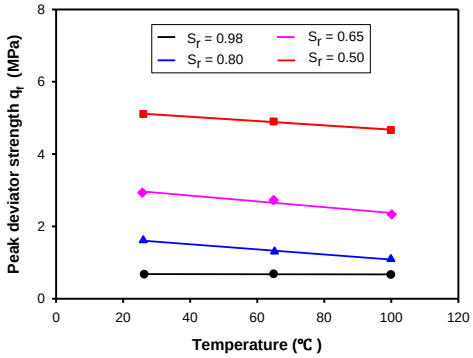

Fig. 11 Strength reduction due to temperature [48].

Gu et al. [47] used the micropenetrometer equipped with a series of penetration probes with different diameters ranging from 0.3mm to 1.0mm to test the resistance of a high liquid-limit clayey soil. The resistance can be used to indicate the structural strength of the soil. It is found that when the soil had high dry density, the resistance was reduced evidently with an increase in the temperature. For the soil at lower dry density, the resistance was only slightly influenced by temperature. Therefore, it can be concluded that the structural strength of dense soil decreases due to an increase in the temperature, while that of loose soil is not significantly influenced by temperature.

The soil strength originates from the strength of soil aggregates and forces between soil aggregates. Gu et al. [47] pointed out that soil aggregates will soften as a result of expansion and increase the intra-aggregate pore water pressure due to heating. This translates into a reduction in the soil strength. Another reason is that soil suction is reduced due to an increase in the temperature.

Wiebe et al. [48] suggest that soil pores and aggregates are small when the degree of saturation is relatively low; for this reason, suction in intra-aggregate pores will be high. The high suction is sensitive to the change of temperature, which contributes to a reduction in shear strength of the soil at low degrees of saturation.

For dense soils, the interparticle forces are significant due to the closer distance between soil particles. The effects of temperature on the interparticle forces will be more evident in dense soil in comparison to loose soil. Therefore, the shear strength of soil specimens at high dry density decreases significantly with an increase in temperature. However, the shear strength of specimens at low dry density is not significantly influenced by temperature [47].

The effect of W-D cycles

Yang et al. [49] found that the shear strength of expansive soils reduces due to the influence of W-D cycles. Zeng et al. [50] showed that soil cohesion decreases due to W-D, while the friction angle is relatively constant. They concluded that soil particles aggregate during the W-D cycles; due to this reason, the bonding between soil particles reduces and the shear strength decreases.

Goh et al. [51] measured the shear strength of sand-kaolinite mixtures at several different stages of W-D cycles. Some of the key results are summarized in Fig. 12. The peak soil strength after the first drying process is much higher in comparison to that after the first wetting. Although soil strength during the drying stage for the following subsequent cycles is higher than that during the wetting stage, the differences are not as significant as in the first cycle. The drying strengths of the second and third cycles are lower than that of the first cycle. On the other hand, the wetting strengths of the second and third cycles are higher than that of the first cycle. Tse and Ng [52] reported similar trends of results from their studies.

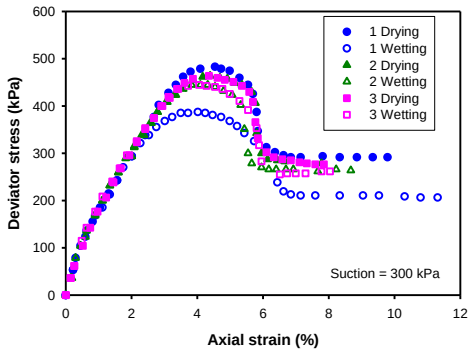

Fig. 12 Stress-strain relations during three W-D cycles [51].

Such a behavior may be attributed to the hysteretic characteristic of SWCC. The water content during the wetting stage is lower than that at the drying stage at the same suction. In other words, the area of water menisci that are in contact with soil particles or aggregates at the wetting stage is less than that at the drying stage. Therefore, the contribution of suction to soil strength during the wetting stage is lower in comparison to the drying path.

For obtaining SWCC, the boundary drying and wetting curves are obtained respectively by draining the initially saturated specimen to a totally dry condition and the initially dry specimen was wetted to saturation. The scanning curves were obtained from further drying or wetting cycles. The scanning curves are between the boundary drying and wetting curves. This means that at the same suction condition, soil water content on the scanning curves is higher and lower than that on the boundary wetting and drying curve, respectively [53]. The soil specimen followed the boundary curves under the first W-D cycle, while followed the scanning curves under the subsequent W-D cycles. As discussed earlier, more water menisci (or larger suction) contribute to an increase in soil strength. Therefore, soil strength during the subsequent W-D cycles was higher than that at the wetting path of the first cycle but lower than that at the drying path of the first cycle.

However, some other researchers suggest that soil strength increases with W-D cycles [54], [55]. Liu and Sun [55] studied the influence of W-D cycles on the loading and unloading behavior of a silty clay. It is found that the cyclic strength of the specimens subjected to W-D cycles is higher than that of the specimens at the initial state. Khoury and Miller [54] observed that the strength of the specimens that were subjected to W-D cycles is greater than that of specimens only subjected to drying at the same net normal stress and matric suction. Liu and Sun [55] suggested that the irreversible compaction due to W-D cycles increases as the interparticle forces contribute to higher shear strength. They also suggest that the strength may reduce due to an increase in water content; however, the influence of irreversible compaction outweighs effects of water content. Therefore, the shear strength was reinforced by W-D cycles.

In summary, there is no consensus about the influence of W-D cycles on the soil shear strength behavior. Further studies are necessary for a better understanding of the influence of W-D cycles on the microstructure and shear strength of expansive soils.

DESIGN OF PILE FOUNDATION IN EXPANSIVE SOILS CONSIDERING TEMPERATURE AND MOISTURE CHANGES

The energy piles are being used in some engineering practice applications; these piles use the thermal properties of the ground soils to exchange heat or cold energy between the ground soils and the superstructure. There is evidence from experimental studies that there will be thermal expansion or contraction of energy piles and surrounding soils due to the changes in temperature. This volume change can result in relative deformation along the soil-pile interface, which contributes to modifying the stress between piles and the surrounding soils. When soil expands due to an increase in temperature, positive friction typically occurs along the surface of the piles, resulting in the uplift of the pile foundations and damage the superstructure. These practical problems should be properly addressed when designing energy pile foundations [56].

Expansive soils expand with an increase in water content and contribute to an increase in the external lateral earth pressure, positive friction and pile uplift. Liu and Vanapalli [57], [58] proposed a simple constitutive framework for rational design piles in

expansive soils taking account of the variation of water content induced by infiltration. However, to date, the change in the behavior of soil and soil-pile interface due to W-D cycles has not been considered in the design of pile foundations in expansive soils extending unsaturated soil mechanics framework. The hysteresis of SWCC should also be considered to analyze the shear strength of soil and soil-pile interface. Although the hysteresis of SWCC has been considered in interpreting the strength of expansive soils [51], the strength of soil-pile interface considering different stages of SWCC has not been studied. Reliable behavior of pile foundations in expansive soils is possible by taking account of the influence of W-D history considering the hysteresis effects of SWCC.

SUMMARY

The soils and infrastructures are exposed to the influence of various environmental factors such as precipitation, evaporation, and temperature change. In other words, soils are likely to be subjected to freezing/thawing (F-T) and wetting/drying (W-D) cycles. It is anticipated that there will be frequent F-T and W-D cycles due to the anticipated climate change and global warming effects in the near future on our planet. In this paper, the influences of temperature and moisture variations on the soil behavior are succinctly reviewed. It is necessary to consider these influences for the rational design of infrastructures such as pile foundations. In addition, reliable constitutive models that take into account climate change and global warming effects should be proposed to facilitate reliable analysis of the behavior of soils and pile foundations.

The freezing process, W-D, and F-T cycles significantly influence the frozen and unfrozen soil properties. For example, frozen soils have low hydraulic conductivity, and high strength and stiffness, due to the formation of ice in soil pore spaces. The F-T cycles typically weaken soil structure and contribute to the formation of cracks and fissures within the soil mass. As a result, frozen-thawed soils typically have higher hydraulic conductivity and lower stiffness and bearing capacity. The temperature and W-D cycling have a significant influence on the behavior of expansive soils (e.g., swelling and shrinkage characteristics), and therefore on the design of pile foundations in expansive soils.

ABSTRACT

The compression behavior of ultra-soft soil with and without the prefabricated vertical drains (PVDs) at various water contents (w_i) was studied via a series of consolidation test and large-scale model tests. The compression curve of ultra-soft soil show an inverse S-Shaped due to the yield stress resisting deformation, which is similar to the pre-consolidation pressure for natural soil. Large settlements with the delay of excess pore pressures were observed, which is a distinct behavior of ultra-soft soil, especially at very high water content. The higher initial water content resulted in the longer delay of excess pore pressure dissipation. The ultra-soft soil was significantly improved by ground improvement with PVD, as evident by the significant reduction in w and increase in undrained shear strength (S_u). The S_u at various degree of consolidation could be approximated by the vertical effective stress (σ'_v) based on the SHANSEP and Asaoka's method. The outcome of this research will facilitate the geotechnical design of reclamation of ultra-soft dredged soil in Mae Moh mine and other similar soils.

Keywords: Ultra-soft soil; Large-scale model test; Prefabricated vertical drains; consolidation

INTRODUCTION

The Mae Moh mine is largest open-pit lignite mine in Southeast Asia, situated at Mae Moh district, Lampang province, Thailand. It is operated by the Electricity Generating Authority of Thailand (EGAT). Sump1 C1 is a low-lying area, located in the north of the Mae Moh mine with the total area of 80,000 m2. The soil erosion caused by the discharge of surface water along the mine slope were finally collected and formed up to approximately 38 m thickness of dredged soil deposits under water in sump 1 C1 for over decades.

According to the mine planning and development of EGAT, the mine will be excavated to a depth of approximately 500 m from original surface in the next 40 years. As a result, this mine will become the deepest open-pit lignite mine in the world. The excavated soil from mining activity will be transferred to dump in the Sump 1 C1. It will be subjected approximately 300 m of overburden material in the next 40 years. However, the dredged soil in the Sump 1 C1 is ultra-soft soil and possesses very low bearing capacity. Therefore, it is imperative to improve the existing ultra-soft dredged soil before commencing any construction activities in order to prevent any failure due to the mud flow.

Soil improvement techniques generally include soil replacement, preloading, stone column, and cement column, etc [1]-[4]. Among these methods, the preloading with prefabricated vertical drains (PVDs) is cost-effective and commonly used in land reclamation projects on ultra-soft soil deposits [5]-[8]. However, a few laboratory testing and field instrumentation have been conducted to study the performance of PVDs improved ultra-soft soil in dredged sump [2], [8]-[10]. The previous studies showed that the PVDs accelerate settlement, enhance shear strength, and reduce moisture content of the ultra-soft clay for a particular water content. However, the compression behavior of ultra-soft improved by PVDs at various initial water content have not been well examined.

In this study, the consolidation behavior of ultra-soft dredged soil with and without PVDs were studied. The distinct consolidation behavior especially excess pore pressure dissipation of ultra-soft clay was presented. The research outputs will facilitate geotechnical engineers to assess the compressibility of ultra-soft soil with and without PVDs, which can be applied to the ground improvement of ultra-soft soils in future dredging projects.

LABORATORY TEST

To study the consolidation behavior of the ultra-soft soil with and without PVDs, a series of consolidation test and large-scale model tests were conducted on the ultra-soft soil at various initial water contents.

Soil sample

The ultra-soft soil samples were obtained from a dredged pond - Sump 1 C1. The disturbed samples were collected from 1.5 m depth below the soil surface.

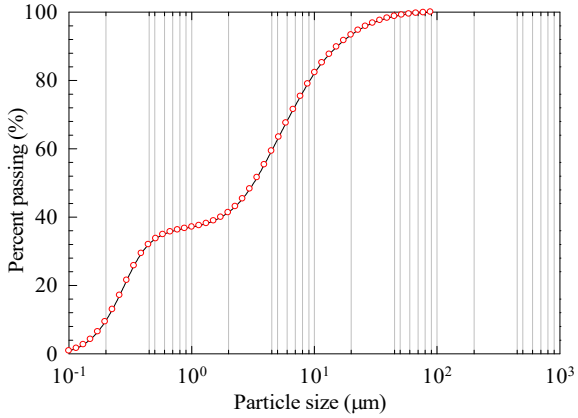

Fig. 1 Grain size distribution curve

The grain size distribution curve of the soil sample is shown in Fig. 1. The soil sample contained 41% clay and 58% silt with 1% sand. The liquid limit and the plastic limit were 57% and 26%, respectively. The specific gravity was 2.57. The natural water content was in the range of 114% - 170%. The in-situ strength was extremely low.

Consolidation test

The consolidation behavior of the sedimentation soil without PVDs were studied by conducting the Oedometer tests. Six samples were prepared by mixing the slurry thoroughly with a quantity of distilled water to reach the target initial water contents, which were 1.45, 1.79, 1.84, 1.97, 2.10, and 2.28 times the liquid limit. The remolded sample was then transferred into the consolidation ring. The consolidation sample was 105 mm in diameter and 20 mm in nominal height. After that the samples were then subjected to both low and high loads. A very low effective vertical stress of 0.5 kPa was first applied and gradually increased with following vertical stresses of 1 kPa, 1.5 kPa, 2.5 kPa, 3.5 kPa, 5.5 kPa, 7.5 kPa, 9.5 kPa, 12.5 kPa, 25 kPa, 50 kPa, 100 kPa, 200 kPa, 500kPa, 1000 kPa, 2000kPa, 4000 kPa. The duration of each loading step was fixed at 24 hours.

For each loading increment, the coefficient of permeability, k, was calculated by the following equation.

$$k = c_v \times m_v \times \gamma_w \quad (1)$$

where c_v is the coefficient of consolidation determined using the root time method proposed by Taylor (1942), m_v is the coefficient of volume change, and γ_w is the density of water.

Large – scale consolidation test

To investigate the compression behavior of ultra-soft soil improved by PVDs, the large-scale consolidation tests were conducted at the initial water contents of 120% and 180%.

The consolidation tank was made of stainless steel with an inside diameter of 495 mm and a height of 1200 mm, as shown in Fig. 2. During the test, the settlement was measured by two Linear Variable Displacement Transducers (LVDTs). Six saturated miniature pore pressure transducers (PPTs) were installed to measure excess pore water pressures at different positions. A total earth pressure cell was placed on the steel plate in order to control the pressure acting on the sample during the test. To reduce wall friction, the inner surface was smeared with lubricating oil beforehand.

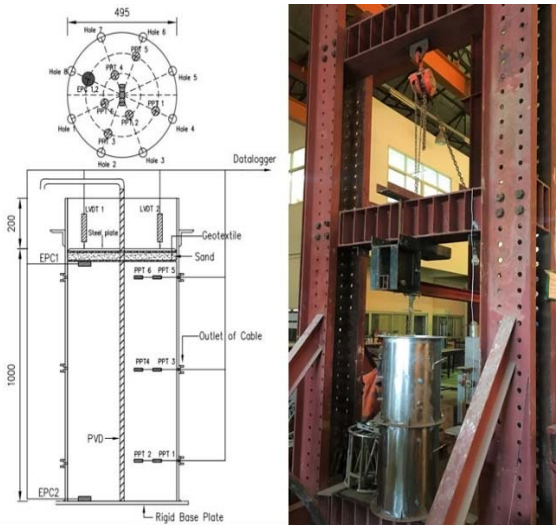

Fig. 2 Large scale of consolidation tank

For each test, the remolded sample was prepared by adding a sufficient amount of water to obtain the initial water content greater than its liquid limits and then thoroughly mixed by a mechanical mixer. The remolded soil was hence poured into the tank for about 1 month for sedimentation process. The final height of the soil in the consolidation tank was approximately 95 cm while the water contents of the soil in the 2 tested cases were respectively 120%, 180% after sedimentation time.

In this study, PVD Ali-drain type AD250 having 100 mm width and 5mm thickness was selected. After

the 1 month of sedimentation, a small aluminum mandrel with PVD inside was penetrated vertically into the ultra-soft soil. When the mandrel touched the bottom of the tank, it was slowly withdrawn from the soil. A 10 cm thick sand layer was then spread on the geotextile layer to prevent the soil squeeze out of the tank under the loading condition. A steel plate was placed on the top of soil to impose the same displacement.

After the assembling of the tank, three incremental vertical pressures (20 kPa, 40 kPa, and 80 kPa) were applied on the top of the soil layer. The step loading applied at the top of the soil is shown in Fig. 3. The large-scale consolidation test was allowed to drain only in one direction to the top surface. During the test, the settlement and the pore water pressure were automatically recorded in real-time with a data logger. The undrained shear strengths were measured after the end of consolidation at each loading step using a mini vane shear test apparatus.

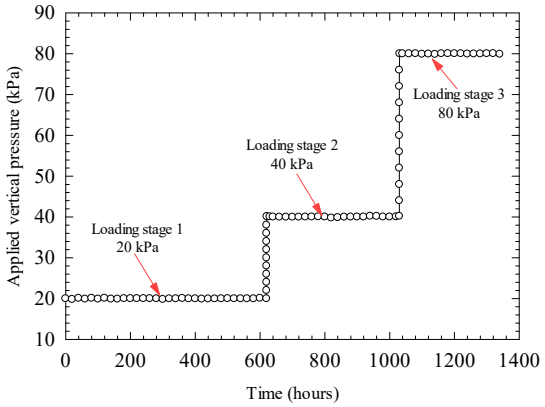

Fig. 3 Loading stages in 3 tested cases

RESULTS AND DISCUSSION

Consolidation test results

The consolidation curves in term of void ratio versus effective vertical stress in a semi-logarithmic (e vs log σ'_v) for six samples at different initial water contents are shown in Fig. 4. The consolidation behavior of the soil at various water content is an inverse S-shape, which is similar with Lianyungang, Baimahu clay and Kemen clay reported by [11]. The transitional stress separating small and large change in void ratio is defined as yield stress or suction pressure, which is similar to the pre-consolidation pressure for natural soil [11].

The relationship between the coefficient of permeability and void ratio of the ultra-soft soil at various water contents is shown in Fig. 5. The permeability significantly reduces with the reduction of void ratio. The non-linear relationship between e and log k for the Mae Moh soil samples can be represented by the following equation.

$$e = 141.84 \times k^{0.239} \quad (2)$$

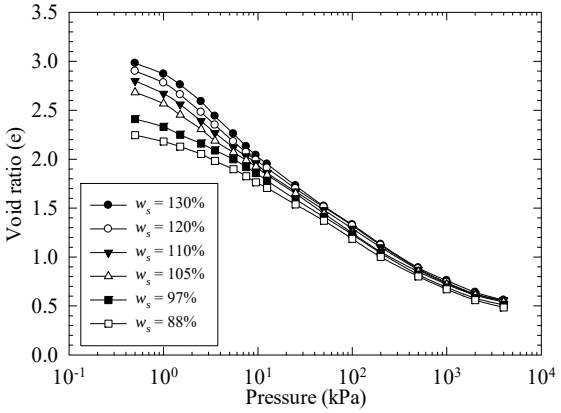

Fig. 4 Consolidation curve of sediment soil at different initial water contents

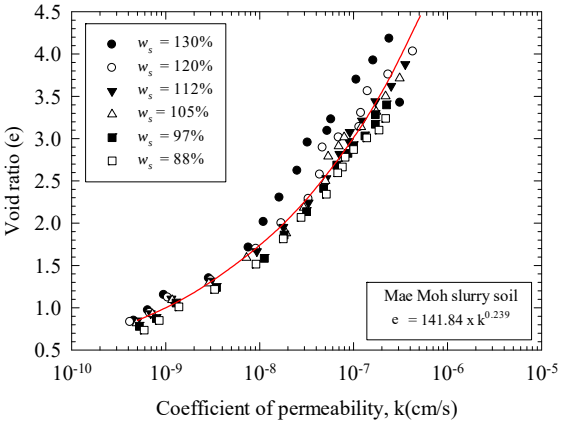

Fig. 5 e- log(k) relationship of sediment soil at different sedimentation water contents

Model test results

Settlement results

The relationship between the settlements versus time of two tested cases is shown in Fig. 6. The settlement occurred in the first loading stage (20 kPa) was much higher than the settlement induced in the second loading (40 kPa) and the last loading (80 kPa), respectively in both cases. The value of settlement reduced as the consolidation stress increased due to non-linear compression behavior of the ultra-soft soil [12]-[14].

The large settlements were observed in 2 cases, especially for case 2 with the initial water content of 180% that exhibited the highest value. The settlement of case 1 was in the order of 240 mm, which was about 27% of strain under the vertical consolidation stress of 80 kPa. The final settlement and the degree of consolidation of the soil at each stage of loading were predicted by using Asaoka's observational method [15], as presented in Fig. 7. The soil in case 1

achieved more than 90% the degree of consolidation in all stages of loading, which was about 90.65%, 94.33%, and 96.24% for consolidation stresses of 20 kPa, 40 kPa, and 80 kPa, respectively.

The measured settlements in case 2 were much higher than those in case 1, which was approximately 393.02 mm after 1362 hours of testing. A very large vertical strain of approximately 42% was developed at the end of consolidation test. Large settlements induced by PVDs in both cases proved the effectiveness of PVDs in improving the ultra-soft soil at different initial water contents. The degree of consolidation in case 2 in each loading stage was smaller than that in case 1. This indicates that the higher initial water content leads to the higher final settlement and the lower rate of consolidation settlement.

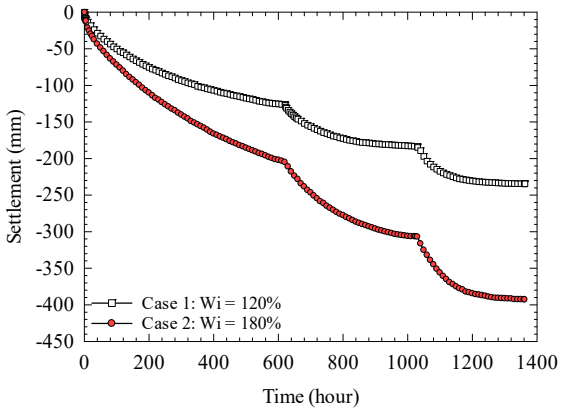

Fig. 6 Settlement versus with time curve measured from the model test of 2 cases under 3 loading stages.

Excess pore water pressure

The dissipation of excess pore water pressures from six transducers of case 1 and case 2 are shown in Figs. 8-9. In both cases, the initial excess pore water pressures (at time t = 0) measured from 6 PPTs were slightly lower than the total vertical stress. On the other hand, the excess pore water pressures recorded at the top (PPT 5, PPT 6) were different with those measured at the bottom of the tank (PPT 1, PPT 2), showing the different distribution of pressures on the soil along the depth possibly due to different drainage conditions.

It is of interest to note that only minimal pore pressure dissipation was recorded at six transducers in the early of loading stages, although the settlements took place during this time (Figs. 8-9). For instance, Fig. 6 shows that the settlement in case 2 after 50 hours was 53.61 mm, which was 30.89% of degree of consolidation, with the delay of excess pore water pressure during the first loading stage. The delayed time is defined as the transitional point from small change to large change in excess pore pressure. The delay of excess pore water pressures was also observed in the second and the last loading stage. It is noted that the delayed time tended to reduce with the increase of vertical consolidation pressure. The higher initial water content resulted in the longer delay of excess pore pressure dissipation. The delayed time observed in PWP 5 and PW6 of case 2 (Wi = 180%) was approximately 50 hours in the first loading, which was approximately 20 hours longer than that of case 1 (Wi = 120%). This delay in excess pore pressure dissipation with progressive settlement is the distinct behavior of ultra-soft clay which diverts from natural soft clay. This similar behavior was also noticed in the previous research reported by [6] , [8].

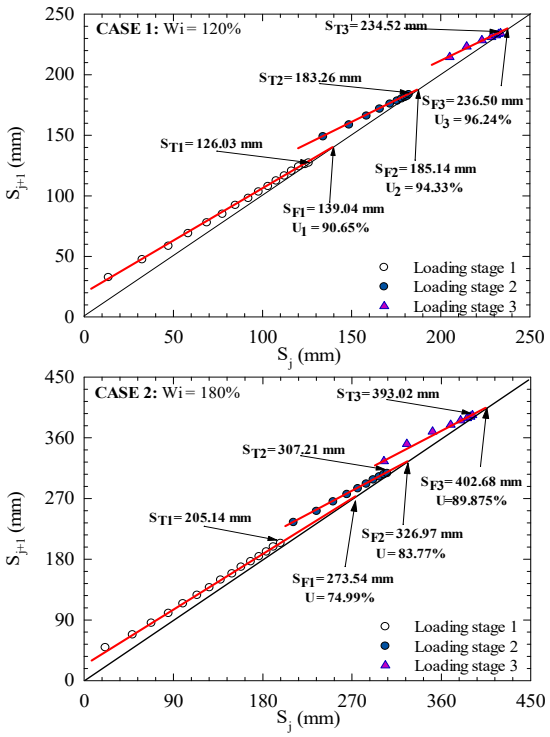

Fig. 7 The final settlement of each loading stage predicted by using Osaka's observation method

Beyond the delayed time, the pore water pressure reduced significantly (Figs. 8-9). At the same depth, the excess pore water pressures close to the PVD (PPT 2, PPT 4, and PPT 6) indicated a faster rate of dissipation than the others. Because the consolidation tank was tested under one-way drainage, the decrease of excess pore pressures observed from 2 PPTs at the bottom of tank (PPT 1 and PPT 2) were lower than those measured on the top of the tank.

Water content and undrained shear strength

The water contents of the ultra-soft soil in 2 cases were measured at various distances from the center of the vertical drains after the end of consolidation test at vertical stress of 80 kPa and compared with the initial water contents (w_i %), as shown in Fig. 10. A

significant reduction of the water content was noticed in both cases. The lowest water content was found near the PVDs, and the water content increased with the increasing radial distance from the PVD. For case 1 (w_i = 120%), the final water contents varied from 42.01% to 52.66%. It is noted that the reduction of water content in case 2 (w_i = 180%) was very large, which reduced by approximately 129% near the vertical drain.

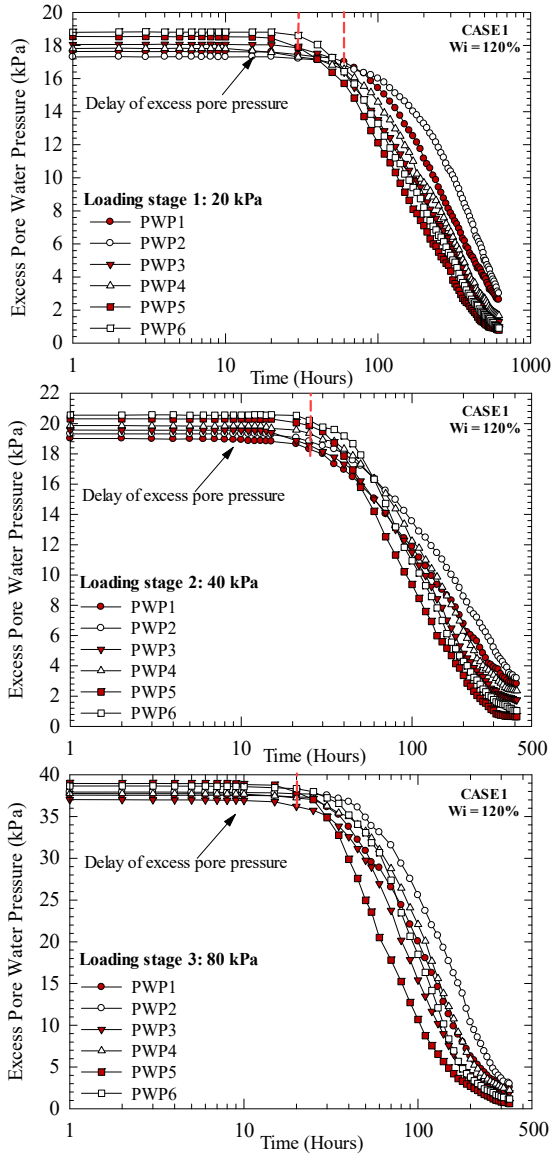

Fig. 8 Excess pore water pressure dissipation versus with time measured by pore pressure tranducer in case 1 (Wi = 120%)

The undrained shear strength (Su) of the soil in the middle of the soil layer in the tank was measured by using mini vane shear equipment. The higher water contents and lower initial undrained shear strengths were observed in case 2 when compared with the results in case 1. On the other hand, Fig. 10 shows that the undrained shear strength, S_u, versus the vertical effective stress, σ'_v. The vertical effective stress at the end of test of each vertical consolidation pressure was a product of the total vertical stress (σ_v) and the degree of consolidation (U) calculated using the Asaoka's observation method. It was evident that the undrained shear strengths is directly related to vertical effective stress ($\Delta\sigma'_v$). The Su versus σ'_v relationship was therefore developed based on the SHANSEP equation proposed by [16]:

$$\frac{S_u}{\sigma'_v} = 0.22 \quad (8)$$

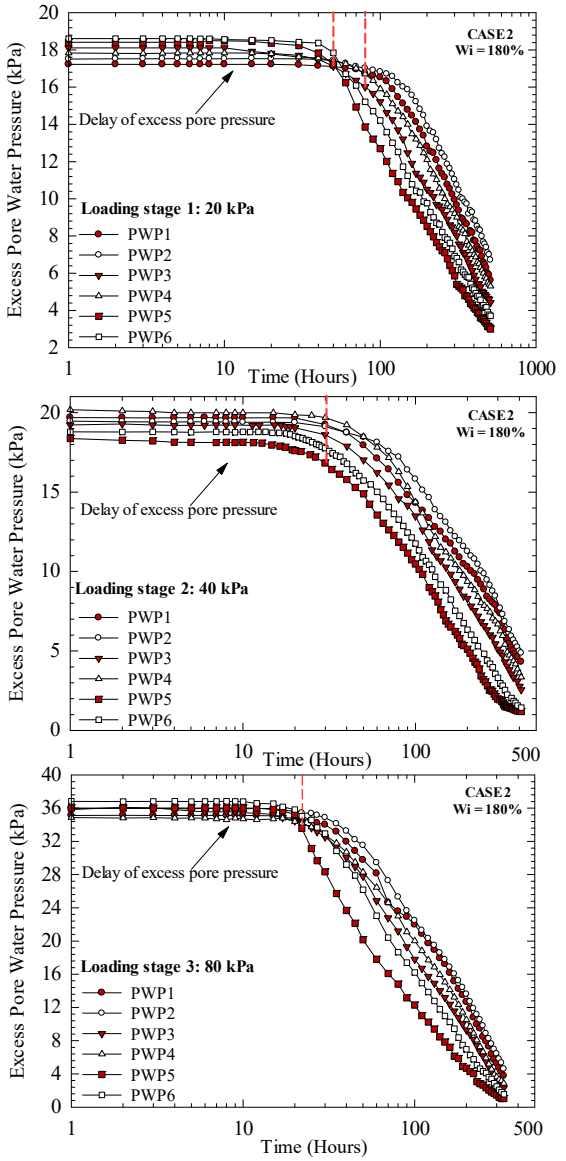

Fig. 9 Excess pore water pressure dissipation versus with time measured by pore pressure tranducer in case 2 (Wi = 180%)

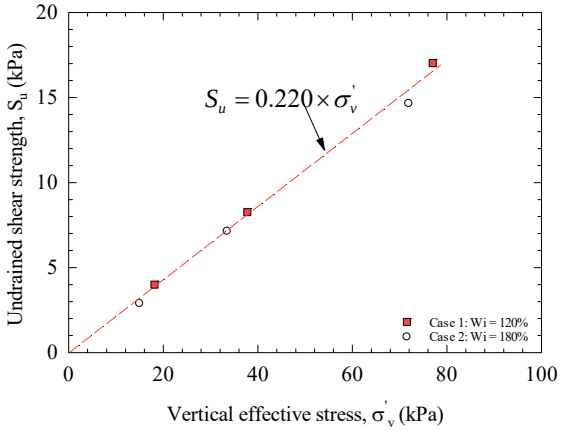

Fig. 11 Measured and predicted undrained shear strength in kPa during the consolidation process

CONCLUSION

This research studied the compression behavior of ultra-soft soil with and without using PVDs in Mae Moh mine, Thailand. The following conclusions can be drawn as follows:

- The consolidation curves of sedimentation soil without PVDs can be represented by the inverse S-shape from a very low (0.5 kPa) to very high vertical effective stresses.
- The large settlements for all cases were observed, especially for case 2 that exhibited the highest value after the consolidation stage of ultra-soft soil improved by PVDs. The test results indicated that the higher initial water content resulted in the higher settlement and the lower rate of consolidation settlement
- The distinct behavior of Mae Moh ultra-soft soil was the delay of excess pore water pressure at the initial stage of consolidation although the settlements had taken place. The higher initial water content resulted in the longer delay of excess pore pressure dissipation. Beyond the delayed time, the excess pore water pressures rapidly decreased with time.
- A significant reduction of water content and increase of undrained shear strength after testing highlighted the successful performance of PVDs on the improvement of the Mae Moh dredged soil. The equation for predicting undrained shear strengths at various vertical effective stress was developed based on SHANSEP's method.

EVALUATION OF THE RELATIONSHIP BETWEEN THE DECREASE IN THE TENSILE LOAD OF GROUND ANCHORS AND GEOLOGICAL CONDITIONS

Mitsuru Yamazaki[1] and Toshinori Sakai[2]
[1] Central Nippon Highway Engineering Nagoya Company Limited, Japan;
[2] Graduate School of Bioresources, Mie University, Japan

ABSTRACT

Ground anchors (hereafter anchors) are structures used to stabilize landslides or cut slopes by transmitting a tensile load to the ground. The tensile load of an anchor is presumed to fall gradually as time passes and varies in the rate at which it declines. The decline of the tensile load of an anchor is expected to be caused by the relaxation of steel or the creep of the ground. This decrease is assumed to be large during the initial period within approximately 30 days after installation and is one index used to evaluate soundness at the maintenance stage. However, the degree to which the tensile load is impacted by specific geological conditions has not been clarified.

Thus, in this study, the relationship between the tensile load 30 days after installation, as obtained by measurements using load cells installed on the anchors, and the rock classification (representing the geological conditions) along the free length of the anchor was investigated. The results demonstrate that poorer geological conditions correspond to a greater decline in the tensile load of the anchor.

Keywords: Ground Anchor, Residual Tensile Load, Geological Condition, Rock Classification, Maintenance

INTRODUCTION

Since ground anchors (hereafter anchors) were first introduced in Japan in 1957, they have been frequently used in landslide and cut-slope stabilization countermeasures. An anchor is a structure consisting in part of a tension member installed in the ground such that one end is embedded in the ground whereas the other end is fixed at the ground surface. With the part between these ends free, the anchor adds a prestressing force (tensile load) to the tension members, stabilizing landslides or cut surfaces by sustaining the tensile load. Most of the anchor is located in the ground.

The tensile load of an anchor generally decreases gradually over time until it converges to a specified value under the action of the creep of the ground or the relaxation of the tension member after the introduction of an initial tensile load during anchoring, as shown in Figure 1 [1]. However, the tensile load of an anchor may not converge to a residual value if, immediately after the ground was excavated by cutting work, an unexpectedly large external force is produced by the geological conditions of the ground where the anchor was installed. Therefore, it is important to maintain anchors while appropriately monitoring their tensile loads.

Figure 2 shows the flow [2] of the tensile load management of anchors on expressways operated by the three Nippon Expressway Company Limited

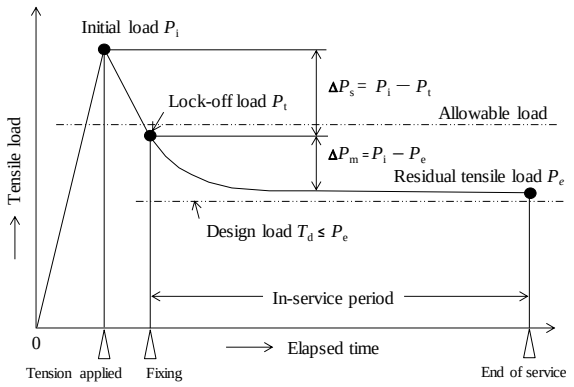

Fig.1 Tensile load acting on an anchor over time [1].

(NEXCO) companies. On such expressways, instruments used to measure the load (hereafter collectively referred to as the load cell) are installed at the construction stage on some of the anchors to monitor changes in the tensile load. At the service stage, measurement by the load cell is continued as required. After the load meters have ceased to function, lift-off tests are conducted as periodical detailed inspections to monitor the tensile load of the anchors (residual tensile load) and evaluate the soundness of the anchor [3].

Table 1 lists the standards [4] for the residual tensile load of an anchor and the corresponding

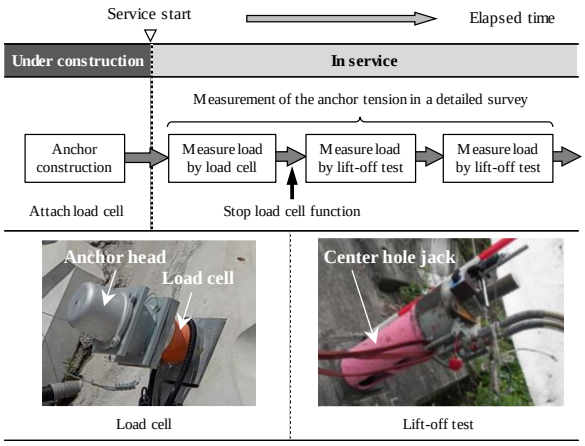

Fig.2 Management of anchor tension [2].

Table 1 Example of standards for the residual tensile load and soundness of an anchor [4]

Range of tensile load	Soundness	State	Example of action to be taken
	E^+	Risk of breakage	Emergency response
$0.9T_{ys}$	D^+	Possible dangerous state	Inplement a countermeasure
$1.1T_a$	C^+	Above allowable load	
T_a	B^+	–	Consider the need for measures by observation
T_d	A^+	Healthy	–
P_t	A^-	Healthy	–
$0.8P_t$	B^-	–	Consider the need for measures by observation
$0.5P_t$	C^-	Greatly reduced functionality	Inplement a countermeasure
$0.1P_t$	D^-	Nonfunctional	

T_{ys} : Yield point load, T_a : Allowable load, T_d : Design load, P_t : Fixed load

anchor soundness, which is generally used to evaluate the anchor function. Management of the residual tensile load of anchors is conducted by clarifying to what extent the tensile load has decreased from the lock-off load P_t when the anchor was constructed. This clarifies the characteristics of the relationship between the design load T_d, allowable load T_a, and yield point load T_{ys} and gives an indication of the appropriate treatment according to the situation. In addition to the measurement of the tensile load, a visual inspection for damage, such as the floating of anchor tops and the protrusion or sinking of tension members, is also conducted as part of anchor maintenance. However, the residual rate of the tensile load is only one index used to evaluate anchor function.

The geological conditions of the slope in which anchors are deployed vary according to the rock type (igneous, sedimentary, or metamorphic); the degree to which it is weathered; and the extent of the development of cracking, joints, and schistosity. Anchors are designed by performing boring surveys at multiple locations to geologically survey the ground where the anchors will be deployed, confirming the state of the geology, and assessing the depth of the slip plane that should be arrested. Moreover, the standards of the anchors and the number required are determined by considering the required arresting force calculated from the target safety factor. The geological conditions of the ground where the anchors are deployed presumably influences the tensile load of the anchors, both initially and in the long term. However, at this time, these factors are not considered during design and maintenance.

Takyu et al. [5] installed load cells on 57 of 1,130 anchors deployed as a large-scale landslide countermeasure and confirmed the tendency of the tensile load of the anchors to decline. They observed that 30 days after execution, the tensile load had decreased greatly at the end of the slope, where loose and weathered ground spread on the surface at the top of a slope that was cut to a shallow depth. The decrease in the tensile load was more than 10% of the lock-off load, and it was impacted by the geological conditions.

Yamazaki and Sakai [6] conducted a geological survey to study the relationship between the rock classification of the bedrock where anchors are installed and the initial decrease in the tensile load. They surveyed eight slopes without deformation for three types of rock: granite, sedimentary rock, and metamorphic rock. The results clearly showed that the reduction in the tensile load 30 days after installation increased as weathering advanced and cracking developed. In the sedimentary rock and metamorphic rock, which were remarkably brittle, the tensile load declined to between 80% and 85% of the lock-off load.

Fujiwara and Sakai [7] performed lift-off tests on all 18 anchors installed on a cut slope as part of an inspection of the tensile load on the anchors 10 years after their installation. The researchers obtained the residual rate of the tensile load, which fell from the center of the slope, where hard bedrock was distributed, toward the slope end, which was softened by the advance of weathering and the distribution of the surface soil. The average declines in the tensile loads in moderately weathered rock, severely weathered rock, and surface soil were 77%, 55%, and 50% respectively, demonstrating that the geological conditions at the installation site of the anchors impact the decline in the tensile load.

As demonstrated by these previous studies, the

tensile load of an anchor is thought to decline naturally under the impact of the geological conditions of the ground where they are installed, even in the absence of any unpredicted external force. However, although the residual rate of the tensile load of an anchor is one index used to evaluate its soundness, it is not clear to what extent the load declines under specific geological conditions. In this study, the relationship between the initial decline of the tensile load in the first 30 days after anchor installation and the geological condition was examined. This relationship was determined using the results of measurements by load cells installed on the anchors at the construction stage and the rock classification obtained by geological evaluation based on a boring survey and slope sketches.

STUDY METHOD

To correlate the decline in the anchor tensile load with the geological conditions, the rock classifications along the free length of the anchors on each of the slopes evaluated in this study were first determined. A detailed geological evaluation based on a boring survey was conducted on the cut slope and during the installation of the anchors. The evaluation of bedrock during a geological survey is typically accomplished using the rock classifications [8],[9] from Tanaka's extended method [10], and records of the evaluation of the borehole core and cut slope during excavation performed by such a method on each object slope were retained. A schematic of the rock classification [11] is shown in Table 2. This rock classification consists of a qualitative evaluation of three elements: the degree of weathering, the hardness of the rock masses, and the state of joints or cracked surfaces. These were compared with a variety of strength and physical constants.

The geological conditions of each slope were defined by broadly categorizing the rock as igneous, sedimentary, or metamorphic based on boring core data and cross sections used for the design and installation of the anchors performed at the construction and in-service stages and slope sketches drawn during excavation. The rock classifications, which were mainly bedrock, that were manifest on the anchor free lengths were divided into eight classes: C_H, C_H–C_M, C_M, C_M–C_L, C_L, C_L–D, D, and D (colluvium), including unconsolidated soil as colluvium.

To determine the tensile load of the anchors, measurement data from the load cells during the 30-day period after installation were used. These were evaluated using the residual rate $R_{pt} = P_e/P_t$ [%], where the residual tensile load P_e and the fixed anchor load P_t were obtained from these data.

Table 3 broadly classifies the slopes used to study the initial decline of the tensile load, the number of measurement data, and the geology. In this study, 30 slopes were examined using load cells installed in 170 locations. Stable slopes were studied where no deformation of the surface level or displacement was seen in dynamic observations. The anchors on each slope showed no damage or anomalies in their heads or pressure-bearing structures and no loss of function. The soundness of the anchors was evaluated based on their external appearance.

Table 2 Schematic of the rock classification [11]

Symbol	Pit wall, outcrop	Boring core	Herdness of rock fragments	Degree of weathering	State of cracked surface	Joint interval
D			Can be crushed with fingers, easily broken	Soil, rock fragments in some places	Argillation, unclear crack	5 cm or less, crushed
C_L			Produces voiced sound with a hammer blow, collapses easily	Weathering until internal, argillation of rock-forming minerals	Argillation, clear crack	5–15 cm, many gravel and rock fragments
C_M			Voiced sound, fragile	Whole browning, noticeable alteration of rock-forming minerals	Many opening cracks, sandwich clay	5–30 cm, many rock fragments, short columnar joints
C_H			Slight metallic sound, unbreakable	Whole slight browning, slight alteration of rock-forming minerals	Contact to slight opening, sandwiched thin clay	15–30 cm, many short columnar joints
B			Metallic sound, unbreakable	Browing alog the crack, no alteration of minerals	Contact to slight opening, no clay	30–50 cm, many short columnar joints and poles
A			Metallic sound, unbreakable	Fresh, unweathered	Contact, no clay	50 cm or more, poles

Table 3 Geology of slopes and amount of data used to evaluate the decrease in the tensile load

Rock classification	Rock type	Geologic time	Number of slopes	Number of load cells
Igneous rock	Ryoke granite	Cretaceous	11	66

DECLINE IN THE TENSILE LOAD DURINGTHE 30-DAY PERIOD AFTER INSTALLATION

To assess the decline in the residual load of the anchors during the first 30 days after installation, the rock was classified as igneous, sedimentary, or metamorphic to discuss the relationship between the residual rate of the tensile load and the rock classification.

Igneous Rock

Figure 3 shows the residual rate R_{pt} [%] of the tensile load 30 days after anchor installation in igneous rock plotted against the rock classification. In cases where there were multiple measurements for a single slope, the plotted data point represents the average value of R_{pt}, and the range bars represent the maximum and minimum measured values. For cases with only one data point for a slope, the single measured R_{pt} is plotted individually. (The same applies below to Figs. 4 and 5.) Table 4 gives the R_{pt} values 30 days after installation and the rock classification of each slope.

In igneous rock in the C_H class, the average R_{pt} 30 days after installation was almost 100%, showing almost no decline in the tensile load. In the C_H–C_M and C_L–D classes, the decline was slightly larger than that for the C_H class; the average R_{pt} was between 96.2% and 99.1% and was consistently 95% or higher. In the case of the D class, the average R_{pt} value was between 92.0% and 97.8%, which was lower than that in bedrock. From C_L to D and D class, R_{pt} was scattered, and it took a minimum value of 85.4% in slope I-12.

Sedimentary Rock

Figure 4 shows the residual rate R_{pt} [%] of the tensile load 30 days after anchor installation in

Table 4 R_{pt} [%] 30 days after installation (igneous rock)

Slope No.	Design load T_d [kN]	Lock-off load P_t [kN]	Free length rock classification	Number of load cells	R_{pt} [%] after 30 days		
					MAX	AV	MIN
I-1	181.4	181.4	C_L-D	2	99.3	98.9	98.6

sedimentary rock plotted against the rock classification. Table 5 gives the value of R_{pt} 30 days after installation along with the corresponding rock classification for each slope.

The results indicate that in sedimentary rock from the C_H–C_M to D and D (colluvium) classes, as the geological conditions worsen, R_{pt} decreases more than in the corresponding case in igneous rock. For rock from slope S-11 from the C_H–C_M class, the average R_{pt} value after 30 days was high at 98.1%, and decreased in the sequence C_M, C_M–C_L, C_L, and C_L–D. On the three slopes with rock from the C_L–D class, the average R_{pt} value ranged from 93.9% to 94.9%, and even the minimum value remained at 90% or more. In the D and D (colluvium) classes, R_{pt} reached the lowest residual rate of between 84.1% and 91.0%, representing a large decline in the tensile load.

Metamorphic Rock

Figure 5 shows the residual rate R_{pt} [%] of the tensile load 30 days after anchor installation in metamorphic rock plotted against the rock classification. Table 6 gives the R_{pt} values 30 days after installation and the corresponding rock classification on each slope.

The results demonstrate that in metamorphic rock of rock classification from the C_H–C_M to D (colluvium) classes, R_{pt} was lower than that in igneous rock and sedimentary rock. In metamorphic rock from the C_H–C_M and C_M classes, the average R_{pt} value was high at 98.1% and 99.1%, but in the C_M–C_L class, it was slightly lower at 94.3% and 98.4%.

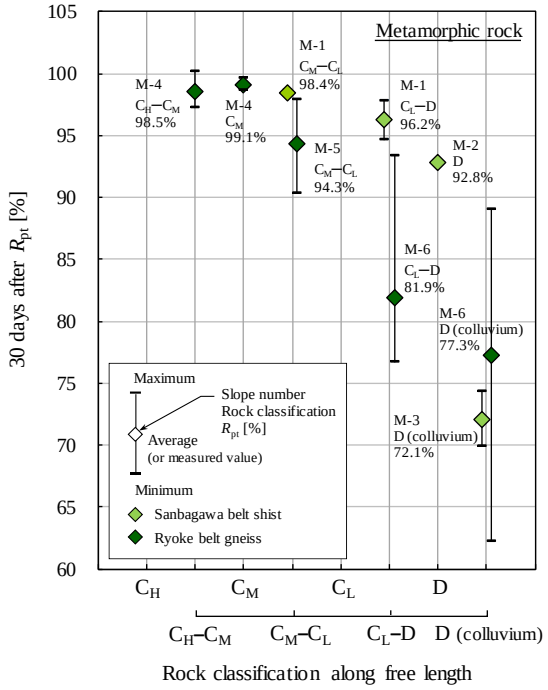

Fig.5 R_{pt} [%] 30 days after installation plotted against rock classification (metamorphic rock).

Table 6 R_{pt} [%] 30 days after installation (metamorphic rock)

Slope No.	Design load T_d [kN]	Lock-off load P_t [kN]	Free length rock classification	Number of load cells	R_{pt} [%] after 30 days		
					MAX	AV	MIN
M-1	639.7	447.8	C_L-D	6	97.8	96.2	94.6
			C_M-C_L	3	98.6	98.4	98.1
M-2	242.7	194.0	D	1	–	92.8	–
M-3	686.4	483.9	D (colluvium)	2	74.3	72.1	69.9
M-4	201.0	201.0	C_M	4	99.6	99.1	98.7
	136.0	136.0	C_H-C_M	5	100.2	98.5	97.3
M-5	872.8	920.4	C_M-C_L	24	97.9	94.3	90.3
M-6	795.4	830.1	C_L-D	6	93.4	81.9	76.7
			D (colluvium)	4	89.0	77.3	62.3

Then, for the C_L–D class, R_{pt} was less than 81.5%. For the D (colluvium) class, which represents colluvium along the free length of the anchor, R_{pt} was even smaller. The average R_{pt} values on slopes M-6 and M-3 were 77.3% and 72.1%, respectively, indicating a large decline in the tensile load.

SUMMARY

The tensile load of an anchor is impacted mainly by the slope on which the anchor is installed and the geological conditions of the slope. The decrease in the tensile load is related to the rock classification

along the free length, which was found to tend to increase with class in the order of C_H, C_M, C_L, and D.

In relatively good geological conditions (C_H, C_H–C_M, and C_M classes) in igneous, sedimentary, and metamorphic rock, R_{pt} 30 days after installation remained at 95% or higher. In particular, R_{pt} in granite of the C_H class was nearly 100%, and almost no decline in the tensile load occurred. In the C_M–C_L and C_L classes in every type of rock, R_{pt} values of less than 95% were observed. In sedimentary and metamorphic bedrock of the C_L–D and D classes that is weathered or cracked, the tensile load fell significantly. In sedimentary rock, anchors with R_{pt} of less than 85% appeared. In metamorphic bedrock of the C_L–D and D classes, the tensile load fell more than in igneous or sedimentary rock, and R_{pt} was lower than 80%. In metamorphic rock of the D (colluvium) class, where there is unconsolidated colluvium along the free length, the tensile load fell even more; R_{pt} 30 days after installation was lower than 80% on average, and anchors with the lowest observed R_{pt} value of less than 65% appeared.

It is thought that a factor represented by a variation in the decrease in the tensile load responded to geological conditions. Regarding the rock classification, three characteristics—the degree of weathering, the hardness of the rock mass, and the state of joints or cracks—were qualitatively evaluated; these characteristics are closely correlated with the decrease in the tensile load. To accurately estimate the decrease in the anchor tensile load, geological information must be incorporated into the model.

CLOSING REMARKS

To maintain anchors, it is necessary to evaluate not only their tensile load but also whether they function and the areal soundness of the entire slope. The results of this study demonstrate that the geological conditions (rock classification) impact the initial decline of the tensile load of an anchor. To maintain anchors, it is necessary to evaluate the decline of the tensile load shortly after installation as well as in the long term, 10, 20, and 30 years after installation. Clarifying the initial decline of the tensile load as performed in this study will permit the prediction of the long-term decline. In the future, methods of evaluating the relationship between the long-term decline in the tensile load and the geological conditions will be investigated, and the functionality of anchors after an extreme decline in the tensile load will be evaluated.

ABSTRACT

Cisumdawu road tunnel is the first on going road tunnel built in Indonesia that located in Sumedang, West Java. The tunnel route lies in mixed soil-rock ground conditions that derived from young volcanic deposits of Tampomas Mountain. Based on the field investigation, tunnel area construction were passing through three soil types, i.e. firm to very firm silty clay (N-SPT values is 4-15), firm to very firm tuff-breccia (N-SPT value is 8-15), hard to very hard tuff-breccia (N-SPT values is 20-60). Boulder sizing from small size of 0.5m until 1.5m were found during excavation, while ground water level identified above the tunnel crown. Face stability and water inflow were main aspects to be considered and control during construction phase. Excavation method "three benches and seven steps" was selected and used in the construction of Cisumdawu road tunnel. Auxiliary methods of forepoling with a double layer scheme and GRF face-bolting as pre-support were applied to increase and maintain tunnel roof and face stability before excavation, while long drainage boring was conducted to lower ground water level and release pore water pressure acting to surrounding area of excavation. The deformation during excavation process was controlled and monitored by measuring the convergence that occur for each cycle and compare to the 3D numerical model using finite element method. The result indicate that the convergence was still under the limit criteria for deformation. The maximum value of convergence that has been measured is 3.3mm. This means that the excavation method and support system applied was sufficient.

INTRODUCTION

Nowadays, the development of infrastructure for roads become one of the main focuses of Indonesian government policy, to support and improve the economy. In this development, the morphological and geological conditions often become the main issues that provoke challenges and constraint in road planning. Currently, tunnel construction began to be considered as an option and a part of road planning, especially in hilly or mountainous area. The application of tunnel construction is expected to provide a more convenient and safe route, as well as shorten the distance and travel time that will not affect and disrupt the condition of the surrounding environment.

Cisumdawu road tunnel becomes the first on going road tunnel that have been built in Indonesia as part of Cisumdawu toll road project (Section II of Tanjungsari - Sumedang) that will connect Cileunyi – Sumedang – Dawuan or connect Padaleunyi toll road with Palimanan-Kanci toll road. This tunnel project is located about 19 km from Cileunyi which is between Sta. 12+600 and Sta. 13+200, as shown in Fig. 1 The length of Cisumdawu road tunnel is about 472 m with diameter of 14 m, and height of 8.5 m and it is a twin tubes or double tubes tunnel that each tunnel consists of 2 lanes.

Fig. 1 Location of Cisumdawu road tunnel.

Geologically, route of Cisumdawu road tunnel lies on Undifferentiated Young Volcanic Product unit (Qyu) that consists of tuffaceous sand, lapilli, lava, agglomerate, as shown in Fig. 2 [1]. The volcanic material that forms the rock units surround Cisumdawu tunnel project is derived from Mt. Tampomas in the northeastern part. This unit forms a flat or low hill area covered by yellowish gray to reddish gray soil in the area between Bandung and Sumedang. Moreover, the older rock units that compose around the Cisumdawu tunnel, i.e.:

- Deep Sediment Deposit (Qol): well bedded tuffaceous clay, sandstones, conglomerate, and breccia. Dark clay contains plant remains and lignite.
- Undifferentiated Old Volcanic Product (Qvu): volcanic breccia, lahar, and lava repeteadly interlayered.
- Old Volcanic Products, Lava (Qvl): lava, showing columnar joints and sheeting. It is basaltic in composition and partly propylitized.
- Old Volcanic Products, Breccia (Qvb): volcanic breccia and lahar. The components consist of igneous rocks between andesite and basalt in composition.

Based on the regional geological map, there are several geologic structures that developed around the Cisumdawu road tunnel area and may affect the ground condition, such as a predicted fault lines directed north to south at west part and Lembang fault with direction of southwest to southeast that located about 3 km away. This tunnel will be construct at depth 14 m (the shallowest) and 52.8 m (deepest) from the ground surface, and the groundwater level will be above the tunnel.

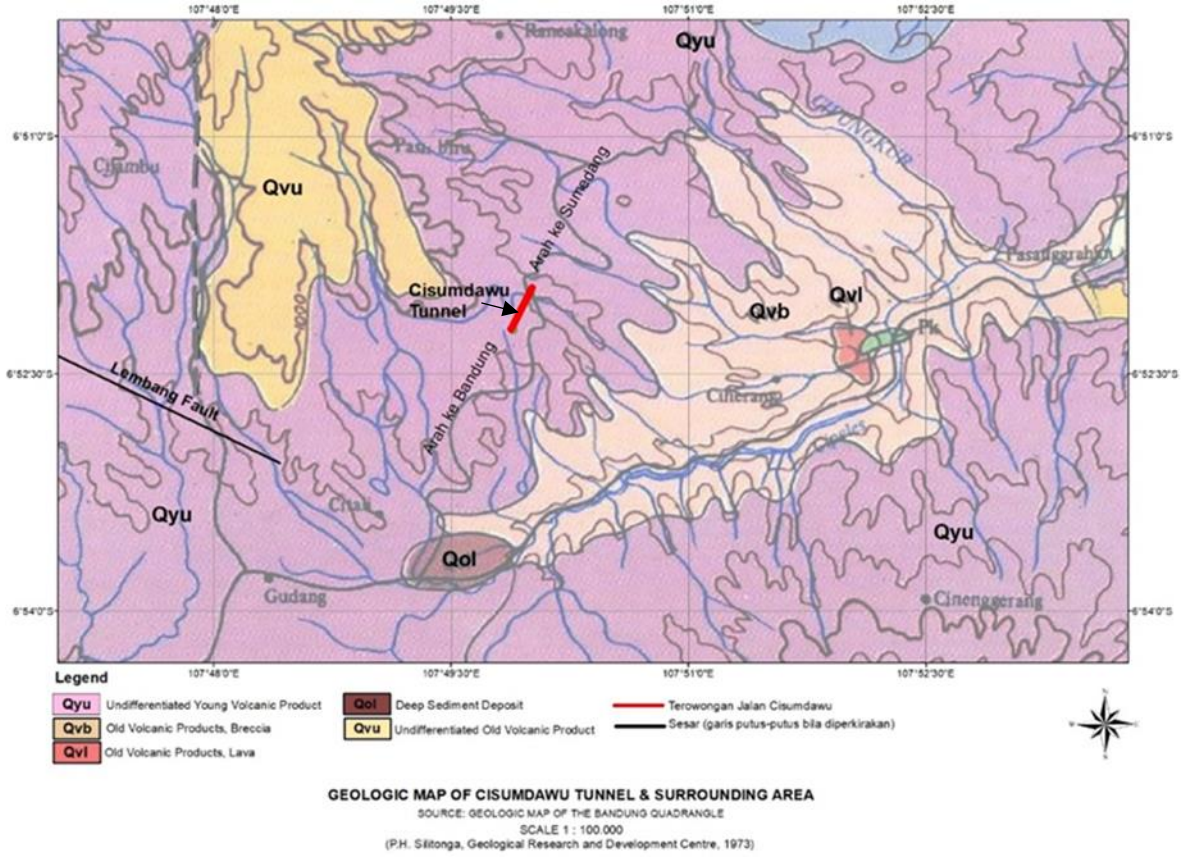

Fig. 2 Geological condition of Cisumdawu road tunnel.

Consequently, the tunnel route may traverse varying or mixed ground conditions. There are some issues that should be considered for tunneling in mixed ground condition, such as short stand up time of ground as well as ground water inflow that can reduce the strength and stability of ground. In order to overcome these problems, the application of an auxiliary method to improve the strength and stability of mixed face ground condition can be utilized. An auxiliary method is a secondary construction method adopted to ensure face stability and tunnel safety also to preserve the environment in cases where either conventional tunnel support or division of heading section do not provide effective solutions or disadvantageous [2]. At Cisumdawu road tunnel project, auxiliary method using fore-poling and face

bolt of GRF type as tunnel pre-support are applied. The excavation is carried out using 3 benches and 7 steps method that divided the tunnel face into 3 section/heading and then excavation is conducted with 7 stages sequentially [3].

To evaluate the performance and effectiveness of auxiliary method that applied in Cisumdawu road tunnel project, an empirical and numerical 3D analysis are carried out that will be discuss as follows.

METHODOLOGY

Field and Laboratory Data

Field investigations and laboratory testing have been carried out by the Cisumdawu Toll Road Project along the tunnel route area. Soil stratification can be identified based on soil consistency as the result of Standard Penetration Test (SPT) that is conducted in the drilling test according to [4] as shows in Table 1. Based on this correlation, the soil condition along Cisumdawu tunnel route was categorized as stiff to very hard soil that comprise of three soil layers (Fig. 3) as follow:

- First layer: soft to stiff clayey silt with N-SPT value between 4 – 15 and depth up to 22m from surface;
- Second layer: hard clayey silt with N-SPT value between 15 – 30 and depth of 5m – 28m beneath the first layer.
- Third layer: tuff with rock fragments sized from gravel to boulder with N-SPT value between 30 – 50 that underlying the second layer.

Table 1 Classification of fine-grained soils from N-SPT value [4]

Characteristics	Value of N-SPT	Category
Extrudes between fingers when squeezed	<2	Very soft
Remolded by light finger pressure	2 – 4	Soft
Remolded by strong finger pressure	4 - 8	Stiff
Indented by thumb	8 – 15	Very stiff
Indented by thumbnail	15 – 30	Hard
Difficult to indent by thumbnail	>30	Very hard

Soil consistency of Cisumdawu tunnel

Soil parameter used for numerical modelling are based on laboratory testing and also empirical correlation according to Standard Penetration Test (SPT) as seen in Table 2.

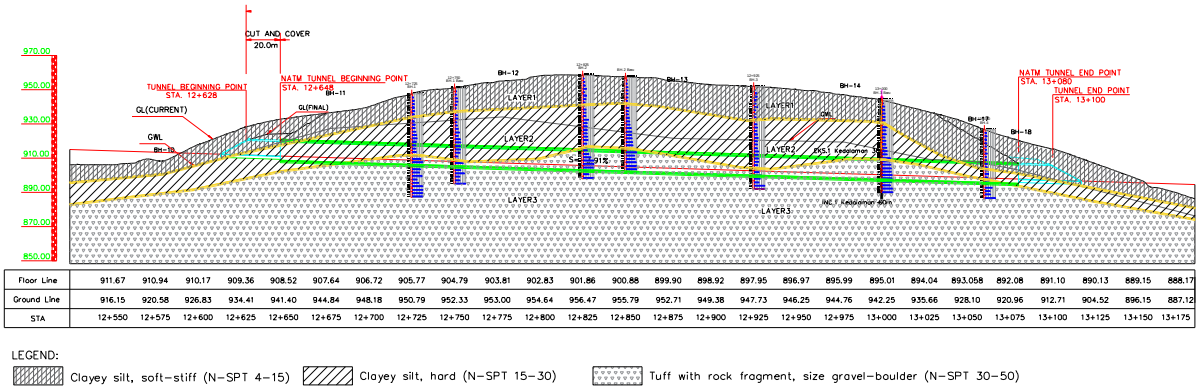

Fig. 3 Stratification of Cisumdawu tunnel route (longitudinal section).

Table 2 Soil parameter for numerical modelling using Mohr-Coulomb material model

Soil Description	N-SPT	γ (kN/m3)	c‘ (kPa)	ϕ’	E (kPa)	ν
Clayey silt, soft-stiff	4-15	16.7	40	26	15000	0.3
Clayey silt, hard	15-30	17	60	26	22000	0.3
Tuff with rock fragment, very hard	30-60	18	80	28	100000	0.3

In addition, the value of shear wave velocity of ground along Cisumdawu tunnel route was obtained from downhole seismic test. The test results show that shear wave velocity of the ground is range between 175m/sec–350m/sec and categorized by means medium soil class (SD) as shown in Table 3.

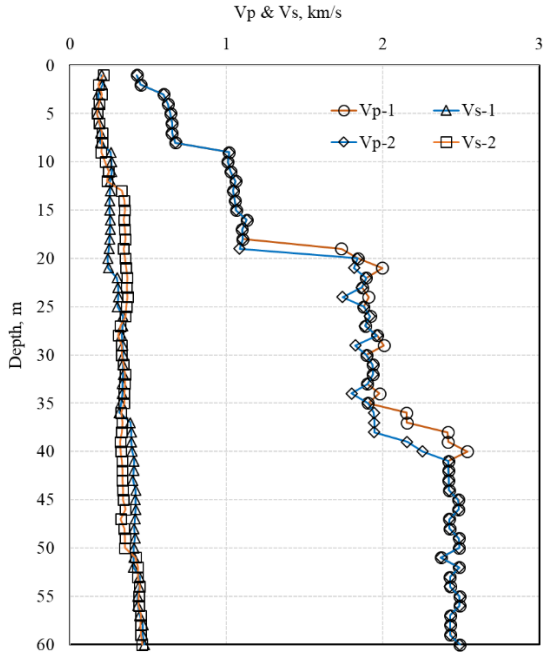
Table 3 Ground classification based on shear wave velocity [5].

Class	Average Shear Wave Velocity, (m/detik)	Average N-SPT Value	Average Undrained Shear Strength, S_u (kPa)
SA (Hard rocks)	> 1500	N/a	N/A
SB (Rocks)	750 - 1500	N/A	N/A
SC (Hard/very dense soils and soft rocks)	350 - 750	>50	≥100
SD (Medium soils)	175 - 350	15 - 50	50 - 100
SE (Soft soils)	< 175	<15	< 50
SF (Specific Soils)	Requires specific geotechnical / geophysical investigations		

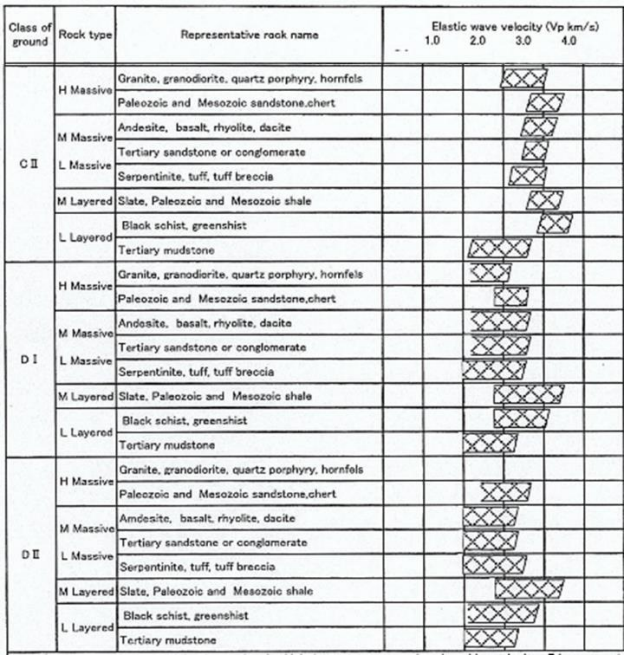
Ground class of Cisumdawu tunnel

Ground Classification

Once the soil stratification of the tunnel route is identified, the next step is to determine the ground class, which in this study refer to [6]. The ground classification used in the technical guideline was adopted from the Japanese classification [2]. The primarily parameter used for determining the ground class were elastic wave velocity that obtained from seismic field test and the competence factor calculated from unconfined compressive strength divided by unit weight multiplied by the thickness of overburden (qu/(γ.H)). Elastic wave velocity of ground in Cisumdawu tunnel route was range between 1.9 km/sec to 2.5 km/sec (Fig. 4a) and the competence factor of 1. Therefore, the ground condition that traversed by Cisumdawu tunnel was considered to ground class of DII as shown in Fig. 4b.



a. Seismic field test profile



b. Ground classification (JSCE, 2007)

Fig. 4 Ground classification of Cisumdawu tunnel.

Excavation Method and Tunnel Support

Further, the excavation method of 3 bench and 7 steps was selected by contractor for constructing Cisumdawu tunnel and for more details it can be seen in Fig. 5. The tunnel face was divided into 3 bench and the excavation conducted on each bench gradually that is starting from the top roof. Besides of its ground condition, this excavation method was selected because it is expected may suitable either for good and bad geological conditions, proper for small as well as large tunnel section, also ensured a continuous and safe excavation works.

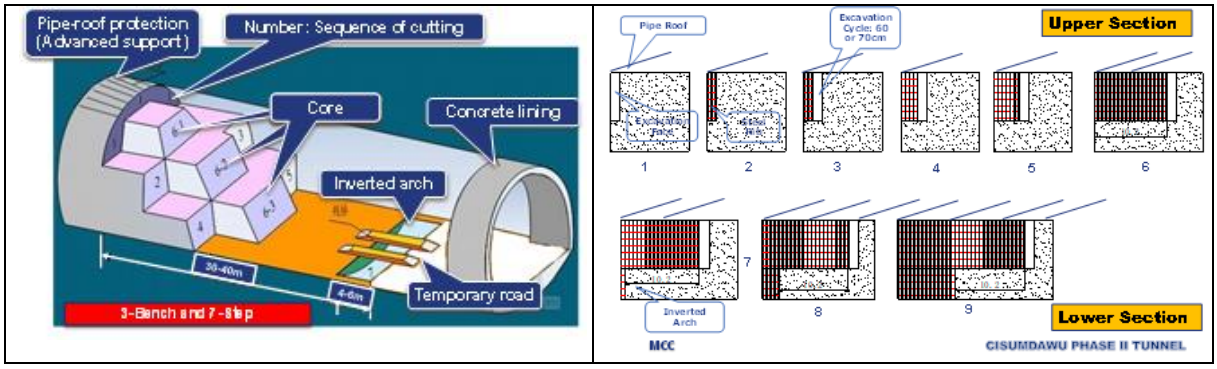


Fig. 5 Excavation stages of 3 bench 7 steps method of Cisumdawu tunnel project [3].

Typical tunnel support system that should be applied for ground class of DII were shotcrete, steel support and invert as shows in Table 4. In addition, auxiliary method was implemented to ensure tunnel face stability during tunnel excavation and the type of auxiliary method selected in Cisumdawu tunnel project were fore-poling, face bolt and drainage boring.

Fore-poling is installed before the excavation to increase the strength and stand-up time of the ground, and in addition face bolt of glass fiber reinforced plastic type was also applied. Drainage drilling or probe drilling was conducted in order to control ground water inflow i.e. 2 at each side of tunnel section and 1 at center of tunnel section. There were 3 type of fore-poling applied in this tunnel project that are varied according to the pipe diameter and its pattern shown in Table 5.

Table 4 Typical support pattern, lining and allowable deformation [2].

Class	Standard Round Length (m)	Rock Bolt			Area of Installation	Steel Support			Thickness of Shotcrete (cm)	Thickness of Lining		The Amount of Allowable Deformation (cm)
		Length (m)	Spacing Circum-ferential Direction (m)	Spacing Longitu-dinal Direction (m)		Top heading	Bench	Spacing (m)		Arch, Side Wall (cm)	Invert (cm)	
B	2.0	4.0	1.5	2.0	Top heading	-	-	-	10	40	-	0

DISCUSSION AND RESULT

To evaluate the appropriateness and performance of excavation method as well as tunnel support system that applied in Cisumdawu tunnel project, a numerical modelling was performed. The excavation method and tunnel support system that applied for constructing Cisumdawu tunnel have been described previously. The allowable deformation for ground class of DII with its typical tunnel support was stated of 10 cm empirically.

The geometry of numerical model for each layer and the tunnel support is shown in Fig. 6. The deformation occurs during the excavation proses is shown in Fig. 7. The excavation scheme is conducted by divided tunnel section into three bench with the core to maintain the tunnel face stability and the excavation performed according to time frame during construction as seen in Fig. 8.

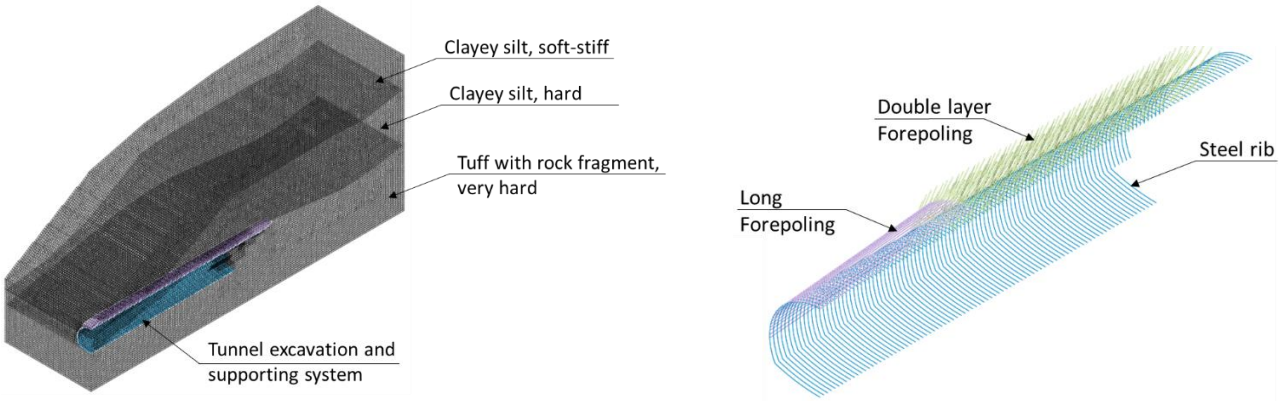

Fig. 6 Geometry of numerical model and tunnel support scheme of Cisumdawu tunnel.

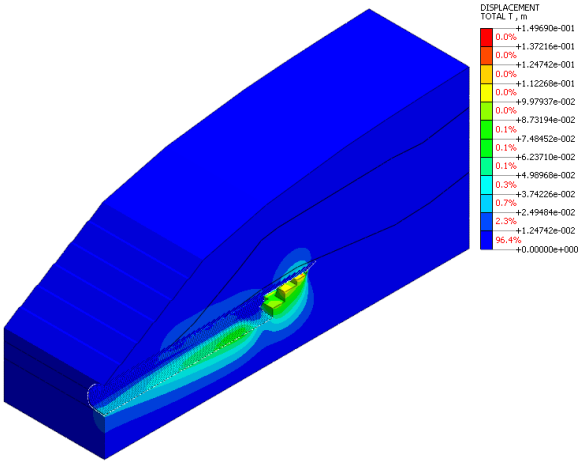

Fig. 7 Deformation caused by tunnel excavation process

In order to identify the appropriateness between the numerical model and the actual condition, the comparison of deformation scale is performed on the reference point of top of tunnel roof or crown as can be seen in Fig. 8. From the actual measurement, maximum value of roof displacement is 3.3 mm, while the deformation of numerical model slightly higher than the actual measurement as shown in Fig. 8. This result show that numerical modeling show a good correlation with actual vertical deformation.

Nevertheless, instrument for deformation measurement are placed after fore-poling, steel support and shotcrete applied for ground reinforcement. This is probably resulting to the small displacement during monitoring due to its elastic deformation and does not represent the actual deformation that occurs (accumulation of ground movement caused by excavation until reinforcement of steel support and shotcrete is installed).

The deformation result indicate that the convergence was still under the limit criteria for deformation which is less than 10 cm. The maximum value of vertical deformation that has been measured is very small. This means that the excavation method and support system applied was sufficient to keep the stability of the tunnel during construction.

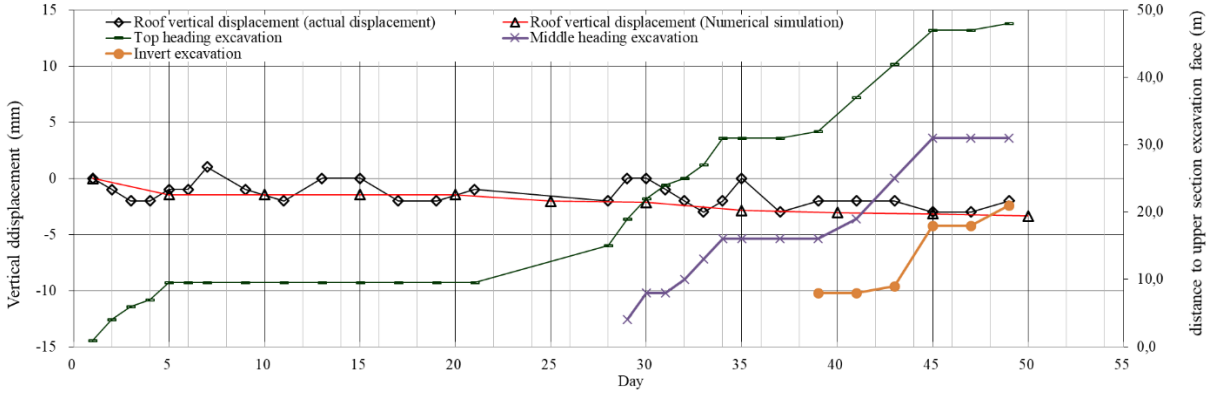

Fig. 8 Comparison of deformation on the tunnel crown.

CONCLUSIONS

The application of auxiliary methods to improve and ensure the stability of tunnel face using fore-poling, face bolt and drainage drilling prior to the excavation show effective performance. The overall evaluation against the performance of excavation methods and tunnel support system by numerical approaches using finite element method show a close result compare to the actual vertical deformation. It seems that Mohr Coloumb models could give a good result when soil parameters are conducted well and stage modelling is simulated according to actual phase of construction.

EVALUATION OF RELATIONSHIP BETWEEN DECREASE IN TENSILE LOAD OF GROUND ANCHORS AND THE GEOLOGICAL CONDITIONS

Mitsuru Yamazaki[1] and Toshinori Sakai[2]
[1] Central Nippon Highway Engineering Nagoya Company Limited, Japan;
[2] Graduate School of Bioresources, Mie University, Japan

ABSTRACT

Ground anchors (hereinafter anchors) are structures used to stabilize landslides or cut slopes by transmitting a tensile load to the ground. The tensile load of an anchor presumably falls gradually as time passes, and varies in the quantity at which it declines. The decline of the tensile load of an anchor is presumably caused by the relaxation of steel or creep of the ground. The decline of the tensile load of an anchor is assumed to be large at the initial period of about 30 days after execution, and is one index used to evaluate soundness at the maintenance stage. However, the degree to which the tensile load falls under specific geological conditions has not been clarified.

Thus, this paper studies the relationship of the tensile load during the 30 days period after execution as obtained by measurements using load cells installed on anchors with the rock classification (geological condition) on the anchor's free length. The results clarified the fact that the poorer the geological condition, the greater the decline of the tensile load of the anchor.

Keywords: Ground Anchor, Residual Tensile Load, Geological Condition, Rock Classification, Maintenance

INTRODUCTION

Since ground anchors (hereinafter anchors) were first introduced in Japan in 1957, they have been used many times in landslide and cut-slope stabilization countermeasure work. An anchor is a structure that fixes the ends of tension members in the ground while the other ends are fixed on the ground surface. With the part between these ends free, the anchor adds prestressing force (tension load) to the tension members to stabilize landslides or cut surfaces by sustaining their tensile loads. Most of each anchor is located in the ground.

The tensile load of an anchor generally falls gradually over time until it converges at a specified value under the action of the creep of the ground or the relaxation of tension members after it has been anchored introducting initial tension load as shown in Figure 1[1]. However, the tensile load of an anchor may not converge at a residual value under the action of an unexpectedly great external force as a result of the impact of the geology of the ground where the anchor was installed immediately after the ground was excavated by cutting work. Therefore, it is important to maintain an anchor while appropriately monitoring its tensile load.

Figure 2 shows the flow[2] of the tensile load management of anchors on expressways operated by the three Nippon Expressway Company Limited (NEXCO) companies. On expressways managed by NEXCO, instruments used to measure the load

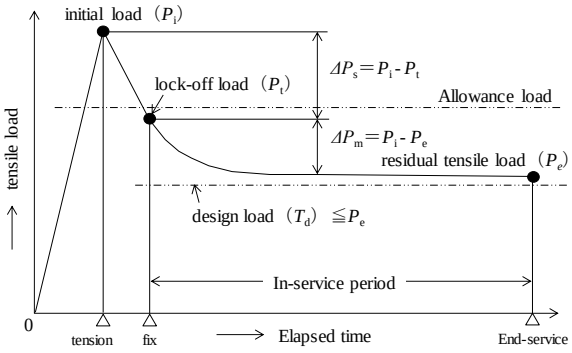

Fig.1 Change with time of tensile load acting on anchor[1].

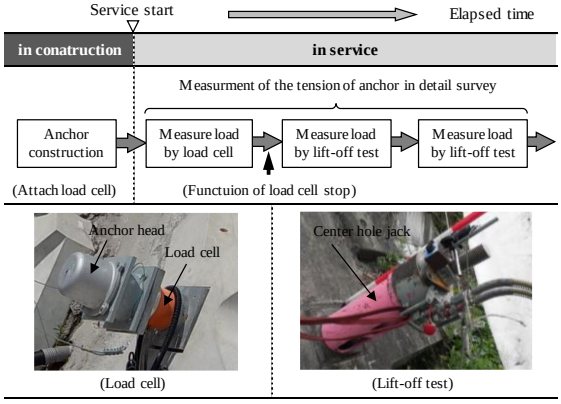

Fig.2 Management of anchor tention[2].

(hereinafter load cell) are installed at the construction stage on some of the anchors to monitor changes in the tensile load. At the service stage, measurement by the load cells is continued as required. After the functions of the load meters have been lost, lift-off tests are conducted as periodical detailed inspections to confirm the tensile load of the anchors (residual tensile load) in order to evaluate the soundness of the anchor functions [3]. Table 1 lists the standards[4] for the residual tensile load (tensile load) of anchors and anchor soundness that are generally used to evaluate anchor functioning. Management of the residual tensile load of anchors is conducted by evaluating the situation by clarifying to what extent the tensile load has declined from the lock-off load (Pt) when the anchor was constructed. This clarifies the characteristics of the relationship between the design load (Td), allowable load (Ta), and yield point load (Tys), and studies the treatment according to the situation. In addition to measuring the tensile load, anchor maintenance is conducted by visually inspecting for damage such as the floating of anchor tops and the protrusion or sinking of tension members. However, the residual rate of the tensile load is only one index used to evaluate anchor function.

Table 1 Standard of residual tensile load and soundness of anchor (example)[4]

Range of tensile load	Soundness	State	Example of deal
	E^+	There is a risk of break	Emergency response
0.9 Tys	D^+	There may be dangerous state	Inplement a countermeasure
1.1 Ta	C^+	It exceeds allowable load	
Ta	B^+	–	Consider the need for measures by observation
Td	A^+	Health	–
Pt	A^-	Health	–
0.8 Pt	B^-	–	Consider the need for measures by observation
0.5Pt	C^-	It has greatly reduced function	Inplement a countermeasure
0.1 Pt	D^-	Nonfunctional	

Tys:Yield Point load, Ta:Allowable load,
Td:Design load, Pt:Fixed load

On the other hand, the geological conditions of the slope where anchors are deployed vary according to whether the rock is igneous, sedimentary, or metamorphic, the degree to which it is weathered, and the extent of the development of cracking, joints, and schistosity. The anchors are designed by performing boring surveys at multiple locations as a geological survey of the ground where the anchors will be deployed, confirming the state of the geology, and assessing the depth of the slip plane that should be arrested. Moreover, the standards of and number of anchors are decided considering the required arresting force calculated by setting the target safety factor. The geological conditions of the ground where the anchors are deployed presumably influence the tension load of the anchors, both initially and in the long term. However, at this time, these factors are not considered during design and maintenance.

Takyu, Shimoda, Kawasaki, and Tamura[5] for installed load cells on 57 of 1,130 anchors executed as large-scale landslide countermeasure works, confirmed the tendency for the tensile load of anchors to decline. As a result, they pointed out that at 30 days after execution, the tensile load had fallen greatly at the end of the slope where loose ground and ground in a weathered state spread on the ground surface on top of a slope that was cut to a shallow depth. This quantity of decline was more than 10% of the lock-off load, and the decline of the tensile load was impacted by the geological conditions. Yamazaki and Sakai[6] conducted a geological survey to study the relationship of the rock classification of bedrock where anchors were installed with the quantity of initial decline of the tensile load on eight slopes without deformation for three types of rock: granite, sedimentary rock, and metamorphic rock. The results clearly showed that the quantity of decline of the tensile load at 30 days after execution increased as weathering advanced and cracking developed. In sedimentary rock and metamorphic rock, which were remarkably embrittled, the tensile load declined to between 85% and 80% of the lock-off load. Fujiwara and Sakai[7] performed lift-off tests of all anchors as part of an inspection of tensile load 10 years after execution on a cut slope where 18 anchors had been executed. The researchers obtained the residual rate of the tensile load, which fell from the center or the slope where hard bedrock was distributed toward the slope end, which was softened by the advance of weathering and the distribution of the surface soil. The average value of the decline in tensile load in moderately weathered rock, severely weathered rock, and surface soil was 77%, 55%, and 50% respectively, and it was pointed out that the geological conditions behind the anchors impacted the decline of the tensile load.

As this shows, the tensile load of anchors is thought to decline naturally under the impacts of the geological conditions of the ground where they are executed in the absence of any unpredicted external force. However, while the residual rate of the tensile load of an anchor is one index used to evaluate its soundness, it is not clear to what extent it declines

under specific geological conditions. This paper reports on a study of the relationship of the initial decline of the tensile load during 30 days after execution of the anchors with geological conditions. The study uses the results of measurements by load cells installed on the anchors at the construction stage and the rock classification obtained by the results of an evaluation of the geology based on a boring survey and slope sketches.

STUDY METHOD

To compare the decline of the anchor tensile load with geological conditions, first, rock classifications of the geology on the free length of the anchors on each of the slopes that were the object of the study were organized. A detailed geological survey based on the boring survey mentioned above was conductedon the cut slope and during the installation of the anchors. The evaluation of bedrock during a geological survey is typically accomplished using the rock classifications [8],[9] from Tanaka's extended method[10], and records of the evaluation of the borehole core and cut slope during excavation performed by such a method on each object slope were retained. The schematic rock classification[11] is shown in Table 2. This rock classification is a qualitative evaluation of three elements: degree of weathering, hardness of rock masses, and state of joints or cracked surface. These were compared with a variety of strength constants and physical constants.

Table 2 Schematic rock classification[11]

Symbol	Pit Wall, Outcrop	Bowring Core	Herdness of Rock Fragments	Degree of Weathering	State of Crack Surface	Joint Interval
D			crushed with fingers, easily broken	soil, rock fragments in some places	argillation, unclear crack	5 cm or less – crushed
C_L			voiced sound with a hammer blow, collapse easily	weathering until internal, argillation of rock-forming minerals	argillation, clear crack	5 to 15 cm, many gravel – rock fragments
C_M			voiced sound, fragile	whole browning, noticeable alteration of rock-forming minerals	many opening cracks, sandwich clay	5 to 30 cm, many rock fragments – short columner
C_H			slight metallic sound, unbreakable	whole slight browning, slight alteration of rock-forming minerals	contact – slight opening, sandwich thin clay	15 to 30 cm, many short columners
B			metallic sound, unbreakable	browing alog the crack, no alteration of minerals	contact – slight opening, no clay	30 to 50 cm, many short columners – pole
A			metallic sound, unbreakable	fresh, unweathered	contact, no clay	50 cm or over, pole

The geological conditions of each slope were defined by broadly categorizing the geology as igneous rock, sedimentary rock, or metamorphic rock using boring core data and cross sections used for the design and installation of the anchors performed at the construction stage and the in-service stage and slope sketches drawn during excavation. Then, the rock classifications that were mainly bedrock manifest on the anchor free lengths were divided into eight classes: C_H, C_H to C_M, C_M, C_M to C_L, C_L, C_L to D, D, and D(colluvium) including unconsolidated soil such as colluvium.

To determine the tensile load (residual tensile load) of the anchors, measurement data from load cells during the 30-day period after execution were used. These were compared with the parameter as the residual rate [Pe/Pt = Rpt (%)] of the tensile load (Pe) under the fixed anchor load (Pt) obtained from these data. As geological conditions, the rock classification of the bedrock distributed on the free length of the anchors classified into eight classes was used as the parameter.

Table 3 broadly classifies the slopes used to study the initial decline of the tensile load, the number of measurement data, and the geology. The study examined 30 slopes using load cells installed at 170 locations. Stable slopes were studied where no deformation of the surface level or displacement were seen in dynamic observations. The anchors on each slope had no damage or anomalies in their heads or pressure-bearing structures and no loss of function. The anchors were evaluated as sound based on their external appearance.

Table 3 Geology of slopes and number of deta used for consideration of decrease

Rock	Rock Type	Geologic Time	slope (number)	load cell (number)
Igneous rock	Ryoke granite	Cretaceous	11	66
	Nohi rhyolite	Cretaceous	2	7
Sedimentary rock	Mino belt sandstone, shale	Jurassic	8	29
	Shimanto group snandstone, shale	Early Cretaceous – Paleogene	2	2
	Yasugawa group sandstone, shale	Jurassic	1	11
Metamorphic rock	Sanbagawa belt schist	Late Cretaceous – Paleogene	3	12
	Ryoke belt gneiss	Cretaceous	3	43
		Total	30	170

DECLINE OF TENSILE LOAD DURING 30 DAYS PERIOD AFTER EXECUTION

Regarding the decline of the residual load of the anchors during the 30 days period after execution, the rock was classified as igneous rock, sedimentary rock, or metamorphic rock to discuss the relationship of the residual rate of the tensile load to the rock classifications.

Ignious Rock

Figure 3 shows the relationship of the residual rate [Rpt (%)] of the tensile load after 30 days in the igneous rock with the rock classification. Rpt in the rock classification of each slope was plotted by (in cases where there were multiple measurement data for one slope) using the average value in the center and the maximum and minimum values plotted above and below by bars linked by vertical lines. When there was only 1 datum, the Rpt of this measured value was plotted individually (the same applies below to the method of representing the relationship of Rpt to the rock classification). Table 4 shows the Rpt at 30 days after execution in the rock classification of each slope.

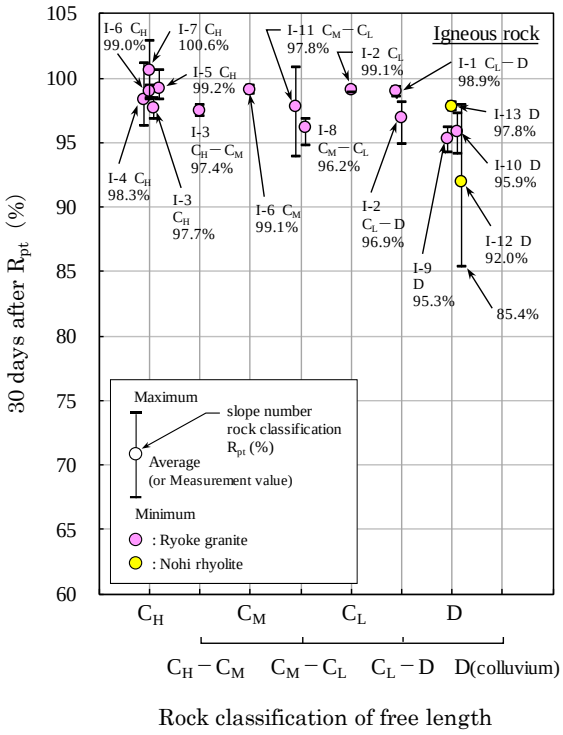

Fig.3 Relationship of R_{pt}(%) of after 30 days and rock classification (Igneous rock).

In the igneous rock, the average of Rpt at 30 days after execution in the C_H class showed almost no decline in the tensile load, and Rpt was almost 100%. In the range between C_H to C_M and C_L to D, the quantity of decline was slightly larger than for C_H, but the average Rpt was between 96.2% and 99.1% and remained at 95% or higher. In the case of rock classification D, the average Rpt was between 92.0% and 97.8%, which was lower than that in bedrock. From C_L to D with D class, Rpt was greatly scattered, and its minimum value was 85.4% in slope I-12.

Table 4 Rpt(%) at 30 days after consturuction (Igneous rock).

slope No.	Design Load Td (kN)	lock-off Load Pt (kN)	Free length Rock classification	load cell (number)	30 days after Rpt(%)		
					MAX	AV	MIN
I-1	181.4	181.4	C_L-D	2	99.3	98.9	98.6

I-13	374.4	374.4	D	4	98.2	97.8	97.4

Sedimentary Rock

Figure 4 shows the relationship of the residual rate [Rpt (%)] of the tensile load after 30 days in sedimentary rock to the rock classification. Table 5 shows Rpt at 30 days after execution in the rock

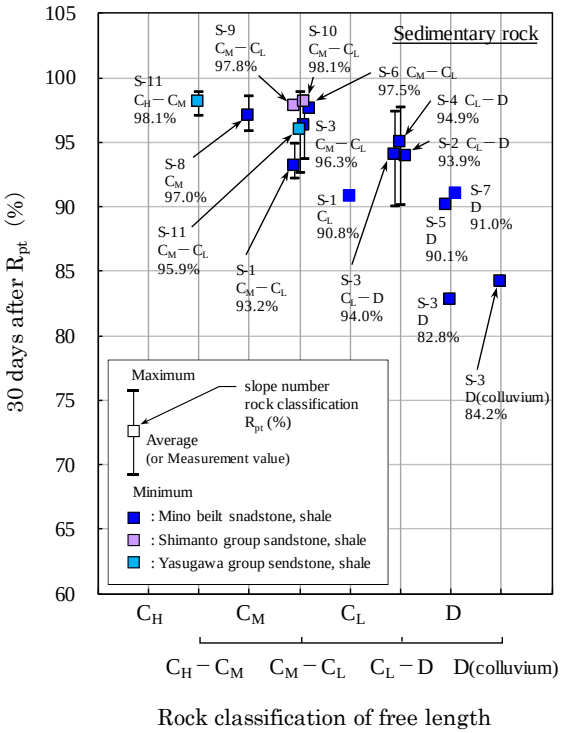

Fig. 4 Relationship of R_{pt}(%) of after 30 days and rock classification (Sedimentary rock).

classification on each slope.

This clearly shows that in sedimentary rock, from the C_H to D class (colluvium), as the geological conditions worsen, Rpt falls more than in igneous rock. On slope S-11 with rock class C_H to C_M, the average Rpt after 30 days was high at 98.1%, and fell in the sequence C_M, C_M to C_L, C_L, and C_L to D. On the three slopes with C_L to D class, the average of Rpt ranged from 93.9% to 94.9%, and even at the minimum value remained at 90% or higher. In D class and D (colluvium), Rpt had its lowest residual rate of between 84.1% and 91.0% (a significant decline in the tensile load).

Table 5 Rpt(%) at 30 days after consturuction (Sedimentary rock).

slope No.	Design Load Td (kN)	lock-off Load Pt (kN)	Free length Rock classification	Load cell (number)	30 days after Rpt(%)

S-10	617.1	615.2	$C_M - C_L$	1	—	98.1	—
S-11	724.0	744.5	$C_M - C_L$	5	98.9	95.9	92.6
	940.0	897.5	$C_H - C_M$	6	98.9	98.1	97.1

Metermorphic Rock

Figure 5 shows the relationship of the residual rate [Rpt (%)] to the rock classification of the tensile load after 30 days in metamorphic rock. Table 6 shows Rpt at 30 days after execution in the rock classification on each slope.

This clearly shows that in metamorphic rock, from rock classification C_H to D (colluvium), Rpt declined in value from its level in igneous rock and sedimentary rock. In metamorphic rock, in the C_H to C_M and C_M classes, the average of Rpt was high at 98.1% and 99.1%; but in the C_M to C_L class, it began to fall slightly, to 94.3% and 98.4%. Then, from the C_L to D class, Rpt was clearly smaller than 81.5%. In D (colluvium), which is colluvium on the free length, Rpt was even smaller. The average of Rpt on slope M-6 was 77.3%, and the average of Rpt on slope M-3 was 72.1%. This indicates a large decline in the tensile load.

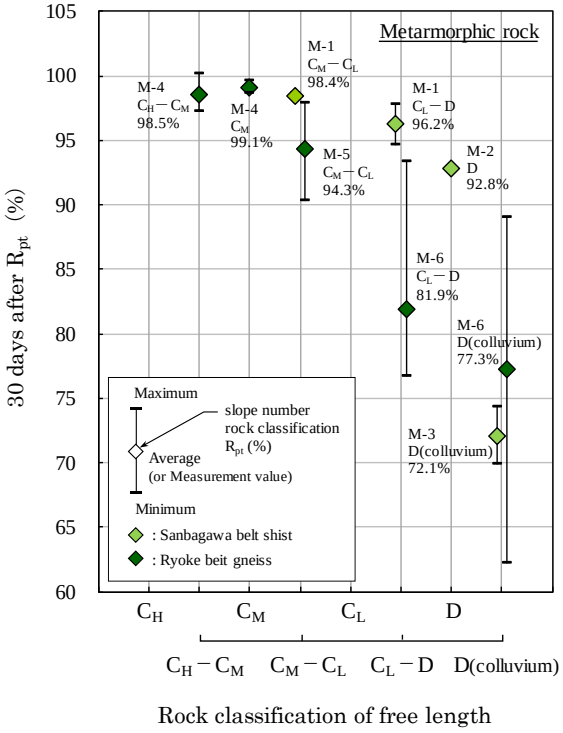

Fig. 5 Relationship of R_{pt}(%) of after 30 days and rock classification (Metamorphic rock).

			D(colluvium)	4	89.0	77.3	62.3

SUMMARY

The tensile load of anchors falls is impacted mainly by the slope on which the anchors are installed and the geological conditions of the slope. The quantity of decline in the tensile load is related to the rock classification at the free length, and this clearly tends to increase in the order of the C_H, C_M,

C_L, and D classes.

In relatively good geological conditions (C_H, C_H to C_M, and C_M classes) in igneous rock, sedimentary rock, and metamorphic rock, Rpt at 30 days after exection remained at 95% or higher. In particular, Rpt in granite of the C_H class was almost 100%, and almost no decline in the tensile load occurred. In the C_M to C_L and C_L classes in every geology, anchors with an Rpt lower than 95% began to appear. In bedrock of the C_L to D class and D class that is weathered or cracked, the tensile load fell significantly in sedimentary rock and metamorphic rock. In sedimentary rock, anchors with an Rpt lower than 85% appeared. In bedrock consisting of the C_L to D class and D class in metamorphic rock, the tensile load fell more than in igneous rock or sedimentary rock, and Rpt was lower than 80%. In the D (colluvium) class of metamorphic rock, where there is unconsolidated colluvium ground on the free length which was classified as D (colluvium) and the tensile load fell even more, Rpt at 30 days after execution was lower than 80% on average, and anchors with a lowest Rpt value of lower than 65% appeared.

It is thought that a factor represented by a variation in the quantity of decline of the tensile load according to geological conditions. As for the rock classification, three elements—degree of weathering, hardness of rock mass, and state of joints or cracks—are qualitatively evaluated, but they are closely correlated with the decline of the tensile load. In order to estimate the quantity of decline of the anchor tensile load, geological information is important.

CLOSING REMARKS

To maintain anchors, it is necessary to evaluate not only their tensile load but also whether they function and the areal soundness of the entire slope. This study showed that geological conditions (rock classification) impact the initial decline of the tensile load of anchors. To maintain the anchors, it is necessary to evaluate the long-term decline of the tensile load after execution and after 10 years, 20 years, and 30 years. Clarifying the initial decline of the tensile load as shown in this paper will permit the prediction of long-term decline. In the future, we wish to study methods of evaluating the relationship of the long-term decline of the tensile load with geological conditions, and the functions of anchors after an extreme decline in tensile loads.

A COMPARATIVE STUDY ON THE PERFORMANCE OF SOIL NAIL AND MICROPILE IN SOIL SLOPE STABILIZATION USING SPENCER'S METHOD

Lee Li Yong[1], Endene Emmanuel[2] and Vivi Anggraini[3]
[1,2,3] School of Engineering, Monash University, Malaysia

ABSTRACT

Reinforcing elements are introduced into steep and unstable slopes to create a stable and reinforced soil section that is able to resist soil mass movements. Soil nail is a commonly used reinforcing element in slope stabilisation owing to its efficiency and cost-effectiveness. Recently, micropile has emerged as an alternative slope reinforcing element to prevent slope failures. Previous studies have demonstrated the efficacy of each of the prementioned reinforcing element in various slope remedial works. However, limited studies can be traced in comparing their effectiveness in soil slope stabilization. Hence, this paper assessed and compared the performance of soil nail and micropile in soil slope stabilization using SLOPE/W software. A parametric study was performed to study the relationship between the geometric properties of the reinforcing elements such as the length, diameter, and inclination angle of the reinforcement bar with the slope Factor of Safety (FoS) based on Spencer's method. The results revealed that the reinforced slope FoS increases with increasing length and inclination angle of the reinforcement bar. However, the FoS was found to decrease as the reinforcement bar attained a certain optimum inclination angle. From the analysis, it is evident that micropile showed a better performance in soil slope stabilization compared to soil nail as micropile achieved a better FoS at a shorter length and smaller inclination angle.

INTRODUCTION

The rapid movement of earth materials down a natural or man-made slope under gravitational stresses is termed as slope failure or landslide. The influence of external stimuli such as earthquake, intense rainfall infiltration, fluctuation of groundwater level, soil erosion, disturbance due to construction activities, among others, can trigger the occurrence of slope failure [1]. In most tropical regions, rainfall-induced landslides commonly occur due to the infiltration of rainwater through the soil, hence the soil suction ability reduces, thus resulting in a decrease in the soil shear strength which eventually lead to slope failure [2]-[3]. The impact of slope failure is often detrimental as it leads to human casualties, severe destruction to existing building and infrastructures as well as disturbance to utilities and transportation networks [4]-[5].

Generally, reinforcing elements such as geosynthetics, soil anchors, soil nails, and micropiles are often introduced into unstable soil slopes to increase the soil shear strength and avoid further soil mass movements along definite rupture surface [6]. Soil nails have been widely employed in soil slope stabilization in comparison to other reinforcing elements owing to their low installation cost and ease of installation [7]-[8]. Likewise, during construction, it causes less environmental impact. Furthermore, the soil-nailed system provides early warning signs prior to failure due to its ductile failure mode [9]. Soil-nailed slope construction is commonly carried out by installing grouted steel bars into the existing slope to create a stable block of soil mass with improved shear strength [10]. The inclusion of steel bars also allows transfer of resisting tensile forces from the steel bar to the soil mass through the mobilization of friction along the nail-soil interface [11]. However, soil nails cannot be employed in a ground condition containing a significant quantity of rock or corestones as they cannot penetrate through such ground conditions [10]. Hence, reinforcing elements with similar properties and advantages to soil nails are extensively being sought. Micropiles serve as great alternative to soil nails as they can overcome the limitation of soil nails. They are capable of transferring the axial and lateral load to a more competent rock layer with side resistance developed along the micropile due to their construction technique [12]. Over recent years, numerous studies have been conducted to assess the efficacy of soil nails and micropiles in soil slope stabilization [7]-[8], [11], [13]-[18]. However, limited studies can be traced in comparing the performance of both reinforcing elements (soil nails and micropiles) in soil slope stabilization employing a limit equilibrium method.

Addressing the aforementioned research gap, this paper aimed at comparing the performance of two reinforcing elements (soil nail and micropile) in soil slope stabilization by employing a commercial SLOPE/W software package based on Spencer's method. The effects of geometric properties of the reinforcing elements such as length, diameter, and inclination angle of the reinforcement bar on the reinforced slope FoS were also explored to provide valuable insight on the relationship between the geometric effects of reinforcing elements and the reinforced slope FoS.

BACKGROUND OF SPENCER'S METHOD

The Spencer's method adopted in this analysis divides the assumed circular failure surface into few vertical slices and performs force equilibrium calculations on each slice. It then determines two safety factors with respect to moment, Fm and horizontal force equilibrium, Ff based on the ratio of interslice side shear to side normal forces. The relationship between the interslice side shear and side normal forces is represented in Eq.(1).

$$X = E\lambda f(x) \quad (1)$$

Where X is interslice side shear force, E is interslice side normal force, λ is the unknown constant to be determined and f(x) is a function.

The Spencer's method assumes a constant function f(x) and this implies that the interslice shear-normal ratio, λ is the same for all slices. Iterative procedures are performed and repeated subsequently until the two safety factors Fm and Ff converge at a constant λ.

METHODOLOGY

SLOPE/W version 2012 software package was employed to assess the safety factors of the natural and reinforced slopes using soil nails and micropiles by developing a 2D model. The geometry of the natural slope considered in the analysis is presented in Fig. 1. The height and width of the slope are 4m and 6m, respectively with an inclination angle of 33.69°. The soil parameters analysed in this study are typical residual soil properties which consist of a combination of silty sand and clayey sand present in natural soil slopes (refer to Table 1). The groundwater level was assumed to be 3m below the ground surface.

The slope stability analysis was conducted based on three stages. First, defining the basic components of the slope such as geometry, soil properties, pore water pressures, and imposed surcharge loading (refer to Fig. 1 and Table 1). This was followed by indicating the location and properties of the reinforcing elements. Three rows of soil nails were placed at a vertical spacing of 1.5m and horizontal spacing of 2m along the slope surface (refer to Fig. 2), while two battered micropiles were located at the middle of the slope with a horizontal spacing of 2m (refer to Fig. 3). The soil nail diameters used in the study were 20mm, 25mm, and 32mm, surrounded by 0.125m diameter of cement mortar. On the other hand, micropiles with diameters of 60.3mm, 73mm, and 88.9mm surrounded by 0.3m cement mortar were considered in the analyses. The analysis was then performed adopting Spencer's method. The geometric properties of the reinforcing elements such as the length and inclination angle varied in this study in order to assess their effects on the performance of reinforced slopes.

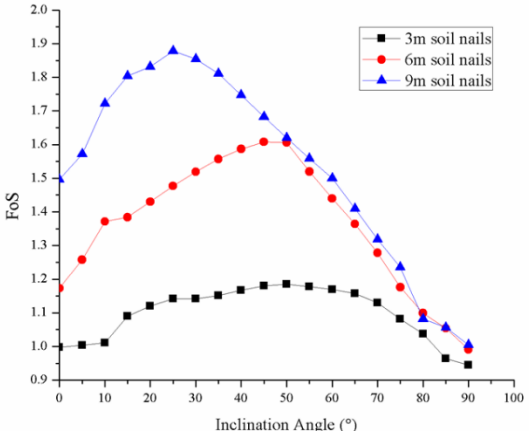
RESULTS AND DISCUSSIONS

Natural Slope

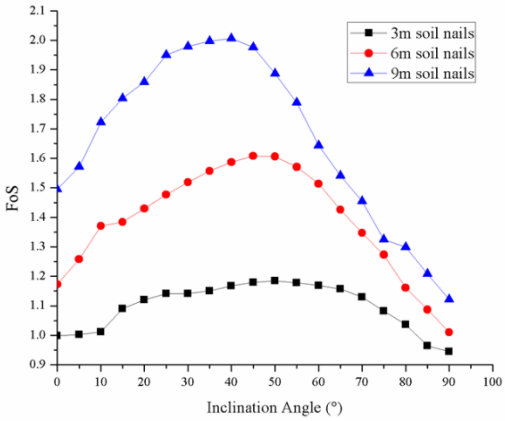
The FoS of the natural slope was found to be 0.846 from the analysis. This did not meet the FoS requirement for natural slope recommended by [19]-[20] of 1.3. Slope reinforcement measures should be applied to the natural slope to enhance its stability, and hence prevent future slope failure.

Soil-nailed Slope

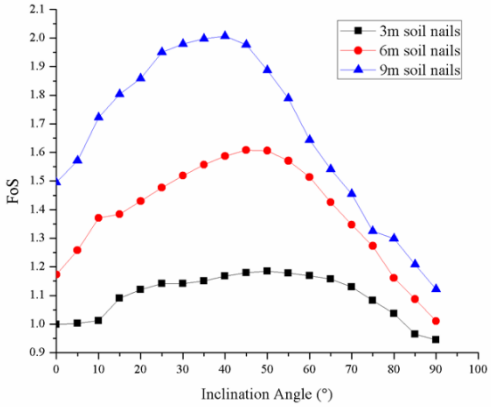
Fig.4 a, b, and c depict the relationship between the FoS and soil nails inclination angle at 3m, 6m, and 9m length for reinforcement bar diameter of 20mm, 25mm, and 32mm, respectively. It can be observed that all three graphs portray a similar trend such that (i) the FoS increases and decreases after the soil nails attained an optimum inclination angle to the vertical and (ii) the FoS increases with increasing length of soil nails. The reinforced slope FoS is closely related to the mobilized tensile forces in individual soil nails. As the nail inclination angle increases, the tensile force of the individual soil nail increases until it reaches a maximum value and further decreases with increasing nail inclinations. These observations are consistent with the results reported by [21]-[22]. Also, the longer anchoring length of the soil nails embedded into a stronger soil strata layer and extended beyond the failure surface as compared to shorter soil nails contributes to a higher FoS. These results are in good agreement with the observations reported by [23]-[24]. However, the differences in the FoS for the three different reinforcement bar diameters (20mm, 25mm, and 32mm) at 3m, 6m, and 9m length appear to be insignificant. These results suggest that the soil nail reinforcement bar diameter does not show a pronounced effect on the reinforced slope FoS compared to its length.



(a) Bar diameter 20mm.



(b) Bar diameter 25mm.

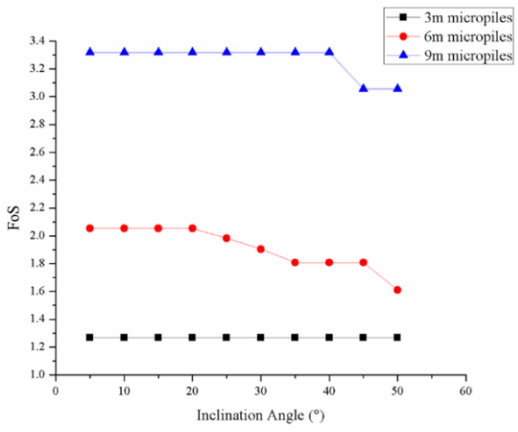


(c) Bar diameter 32mm.

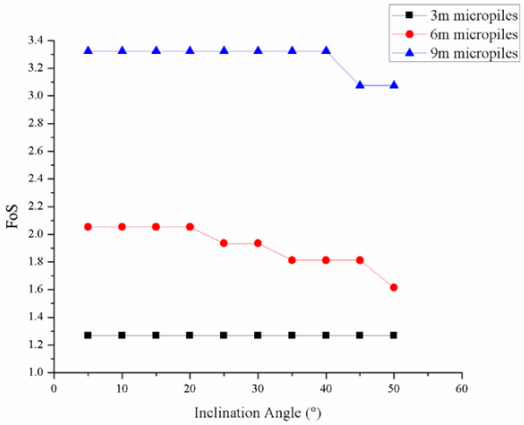
Fig.4 FoS for soil-nailed slope with three different bar diameters at 3m, 6m and 9m length battered from 0 to 90° to the vertical.

Micropiled Slope

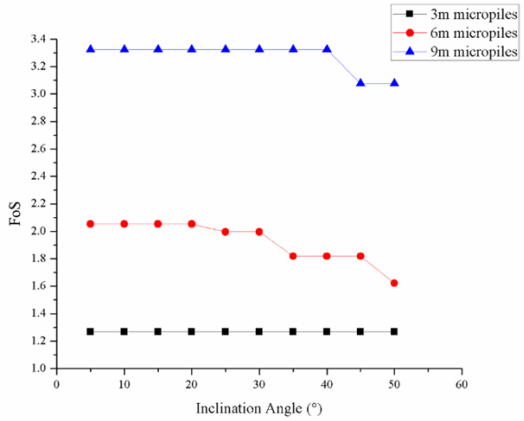
Fig.5 a, b, and c present the relationship between the FoS and micropiles inclination angle at 3m, 6m, and 9m length for reinforcement pipe outer diameter of 60.3mm, 73mm, and 88.9mm, respectively. All three graphs portray a similar trend such that (i) the inclination angle does not affect the FoS for slope reinforced with 3m micropiles (ii) the FoS for slope reinforced with 6m and 9m micropiles remains constant and decreases after attaining an optimum inclination angle and (iii) the FoS increases with increasing length of micropiles. The 3m micropiles with different reinforcement pipe diameter battered at varied inclination angle failed to extend beyond the circular failure surface, and this caused the FoS to remain as 1.267. Unlike soil nails, the shear forces developed along the micropiles also contributes to the FoS of reinforced slope. The mobilization of the two forces namely, shear and tensile forces along the micropiles increases and reduces after achieving an optimum inclination angle. As a result, the micropiles experienced reduced stiffness and consequently led to reduced slope stability [25]. Furthermore, the increment in FoS with increasing length of micropiles is probably due to (i) the longer embedment length of micropile into a more stable layer (layer 2) and (ii) the increased frictional resistance as a result of micropile-soil interactions. These observations are consistent with the results presented by [26]-[27]. Contrarily, the increasing reinforcement pipe diameter does not result in significant variations in the FoS, hence, the length of the micropile governs the reinforced slope FoS compared to the diameter of the reinforcement pipe.



(a) Reinforcement pipe outer diameter 60.3mm.



(b) Reinforcement pipe outer diameter 73mm.



(c) Reinforcement pipe outer diameter 88.9mm.

Fig.5 FoS for micropiled slope with three different bar diameters at 3m, 6m and 9m length battered from 5 to 50° to the vertical.

Comparison between Soil-nailed Slope and Micropiled Slope

In general, micropiled slope achieved a higher FoS compared to soil-nailed slope and this is in line with the observations presented by [28]. The safety factors of micropiled slope satisfied the required reinforced slope FoS which is greater than 1.5 as specified by [19]-[20] at a shorter length (6m and 9m) and smaller optimum inclination angle (20° and 40°) relative to soil-nailed slope. This phenomenon can be attributed to the contribution of bigger grout diameter and reinforcement bar diameter of micropiles that resulted in the mobilization of higher shear and tensile capacity which can enhance the soil stability more effectively. Furthermore, the arrangement of micropiles with two legs affixed to a concrete cap beam at the ground surface (one leg sloping upward and the other leg sloping downwards) enable the micropiles to act in tension (upslope leg) and compression (downslope leg) at the same time [29].

This arrangement provides better resistance against the mobilizing forces developed along the potential failure surface. Moreover, the shear capacity of soil nails is normally ignored in the analysis as the contribution of shear capacity in improving the soil nail resistance is negligible [30]. This factor also constitutes one of the reasons for the lower safety factors of soil-nailed slope.

CONCLUSIONS

This study assessed the effectiveness of two reinforcing elements viz. soil nails and micropiles in soil slope stabilization by conducting slope stability analysis using SLOPE/W software package with reference to Spencer's method. The influence of the geometric properties of the reinforcing elements such as the length, diameter, and inclination angles on the reinforced slope FoS was evaluated accordingly. The following conclusions are established from the analysis:

1. Longer soil nails resulted in higher FoS due to their longer anchoring length that extends beyond the potential circular failure surface. The relationship between the FoS and soil nails inclination angle exhibited a negative parabolic curve such that the slope FoS increases and decreases after achieving an optimum inclination angle. This is attributed to the reduced mobilized tensile capacity of the soil nails. However, the diameter of the soil nails did not cause significant variation in the safety factors of the soil-nailed slope.
2. Micropiled slope showed a higher factor of safety with longer pile length as a result of increased frictional resistance developed along the longer micropiles and increased embedment length of micropiles into more stable soil strata. The 3m micropiles battered at different inclination angle failed to extend beyond the circular slip surface, and this caused the safety factors of the micropiled slope to remain constant at different inclination angles. Furthermore, the reduced mobilization of shearing and tensile forces along the micropiles after attaining an optimum inclination angle led to deterioration of the slope stability for slope reinforced with 6m and 9m micropiles. Similar to the soil-nailed slope, increasing reinforcement pipe diameter exhibited insignificant variations in the FoS of the reinforced slope.
3. Micropiles tend to have higher shear and tensile capacity relative to soil nails. This factor contributes to the higher safety factor of micropiled slope compared to the soil-nailed slope.

From the analysis, it can be concluded that micropiles showed a better performance in improving the stability of slope compared to soil nails.

PORE-STRUCTURAL PARAMETERS OF VOLCANIC ASH SOIL: COMPARISON BETWEEN NON-DESTRUCTIVE AND INDIRECT METHOD

Arjun Baniya[1], Akihiro Matsuno[1] and Ken Kawamoto[1]
[1]Graduate School of Science and Engineering, Saitama University, Japan.

ABSTRACT

Mass transport within porous media is governed by their pore network, which is highly influenced by pore structure parameters such as pore size distribution, porosity, pore tortuosity and pore coordination number. Micro-focus X-ray computed tomography (MFXCT) has emerged as a powerful non-destructive tool for the direct visualization and better understand soil pore geometry. In this study, the soil-pore networks were visualized for volcanic ash soils from Nishi Tokyo, Japan. The study aimed to identify the pore structure parameters using a MFXCT system and compare the indirect pore parameters: equivalent pore diameter and tortuosity-connectivity parameter for gas flow. Both undisturbed and repacked samples were used for characterizing soil pore networking and structure. For repacked soil samples, particle size ($d \leq 2$mm) with field water content were used with different dry bulk densities by hand compaction. Soil samples were scanned by MFXCT system with various scanning resolutions and 3-dimensional models were reconstructed in the regions of interest (ROI). Soil pore-structural parameters effective pore radius, coordination number, and tortuosity were analyzed. Compare to the pore structure parameters of undisturbed samples the repacked samples showed less variation. The pore connectivity-tortuosity factors derived from MFXCT were well correlated with the indirect connectivity and tortuosities from measured soil gas diffusion. However, some variations in pore diameters were observed.

Keywords: Pore Structural Parameters, Microfocus X-ray Computed Tomography (MFXCT), Volcanic Ash soil, Gas Diffusion, Air Permeability

INTRODUCTION

Knowledge and understanding of gas transport processes in porous media are important for the environmental risk assessment and design of remediation methods at the contaminated sites. For examples, estimating emission of greenhouse gases from solid waste landfill site [1], [2], estimating contaminates at polluted sites and estimating aeration rates in agricultural soils [3]. Gas transport in soils occurs through the soil pore network, which is mainly controlled by soil pore structural parameters such as pore size distribution, pore tortuosity and pore coordination number. Nondestructive methods, such as an X-ray computed tomography (CT) has become a powerful technique to identify three-dimensional characterization of soil pore [4]–[6]. Till now, numerous studies have examined pore structural parameters based on the X-ray computed tomography (CT) about porosity [7], pore size distribution [8] and pore network tortuosity [9], [10]. However, there is limited number of studies on visualization and quantification of soil pore network and soil pore networks linked with the indirect pore parameters for gas flow based on measured gas diffusion coefficient and air permeability. [10] measured gas transport parameters (D_p and k_a) for Accusand (Unimin Corp., Ottawa, MN) and Granusil (Unmin Corp., Emmett, ID) and examined the correlations to pore structural parameters from X-ray CT analysis. They suggested that reasonably good agreement in tortuosity values obtained from CT analysis and from gas transport parameters. In this study, the soil-pore networks were visualized for volcanic ash soils using MFXCT system. The gas transport parameters of the soil samples (D_p and k_a) were measured in the laboratory. The objective of this study is to identify the pore structure parameters using a MFXCT system and compare with the indirect pore parameters such as equivalent pore diameter and tortuosity-connectivity parameter for gas flow. Accurate linking of pore structural parameters from MFXCT and gas transport parameters will allow easy and rapid quantification of important soil functional properties.

MATERIALS

For this study, a volcanic ash soil (Andsoils) collected from the grass-covered field at University of Tokyo agricultural site in Nishi-Tokyo, Japan was used. Both undisturbed and repacked soil sampled

from two depths: 5 cm and 50 cm depth below the surface were examined. The soils physical and chemical properties are shown in Table 1. Both undisturbed and repacked samples were used for characterizing soil pore networking. For repacked soil samples, particle size (d ≤ 2mm) with field water content (Samples below the 5 cm depth, w = 76 % and samples below the 50 cm depth w = 124 %) were prepared with various dry bulk densities (5 cm depth samples – 0.55 and 0.80 g cm^{-3} and 50 cm depth samples – 0.49 and 0.55 g cm^{-3}) by hand compaction. The samples were directly packed in an acrylic core of height 4.06 cm and diameter 5.61 cm. Undisturbed samples were used in the intact condition.

METHODOLOGY

Micro-focus X-ray CT Measurements and Analysis

Visualization of the soil pore structures was carried out using a microfocus X-ray CT (MFXCT) system (inspeXio SMX-90CT, Shimadzu Corp., Japan). At first, soil samples were scanned by MFXCT system with different scanning resolution 12, 30 and 50 µm/voxels. The scanned slices were reconstructed as a three-dimensional structure (Exfact VR 2.1, Nihon Visual Science, Inc., Japan) with different region of interest (50×50×50, 100×100×100, 200×200×200 and 300×300×300 voxels) and pore structural parameters such as pore radius, pore tortuosity and pore coordination number with a three-dimensional median axis (3DMA) method [6], [11] (EXFact analysis for porous

particles, Nihon Visual Science, Inc., Japan) were analyzed. The 3DMA package analyzes the CT data using the three steps: image segmentation, image skeletonization (construction of medial axis) and medial axis analysis. The details of the 3DMA package for X-ray CT analysis can be referred in earlier publications [6], [8]–[10]. For image segmentation, predetermined soil air-filled porosity at field water content was used to segment pore and grain spaces. The details of scanning and analysis conditions for the MFXCT system are summarized in Table 2.

Measurements of Gas Transport Parameters

After the MFXCT scanning, the tested same soil samples were reused to measure the gas transport parameters, such as the soil-gas diffusion coefficient, D_p (cm^2 s^{-1}) and air permeability, k_a (μm^2) at the constant room temperature of 20°C. The D_p was measured by using the diffusion chamber method [12]–[14]. Oxygen gas was used as a tracer gas and the change in the oxygen concentration was measured as a function of time in the diffusion chamber. In this study, the gas diffusion coefficient of oxygen in free air (D_0) at 20°C was taken as 0.20 cm^2 s^{-1} [12], [15] was used to calculate soil gas diffusivity. The k_a was measured by an air permeameter from the Darcy's equation [16] based on the pressure differences across the soil sample and viscosity of the air (1.86×10^{-5} Pa s).

The tortuosity-connectivity from gas transport was calculated by using previously developed simple power-law models [17] as equation (1) whereas equivalent pore diameters were predicted by using the relationship between diffusivity (D_p/D_o) and air permeability(k_a) [18] as equation (2) respectively.

$$X_G = log\left(\frac{D_p}{D_0}\right)/log\varepsilon \quad (1)$$

$$d_G = 2\sqrt{8k_a/(D_p/D_o)} \quad (2)$$

Where, X_G and d_G are the pore connectivity-tortuosity factor and equivalent pore diameter from gas flow.

RESULTS AND DISCUSSIONS

Figure 1 exemplifies the Multi-Planner Reconstruction (MPR), and binarized images at 5 cm depth of the undisturbed and repacked volcanic ash samples with different scanning resolution (SR). For each parameter, 3 ROIs were plotted and fitted under either normal or log normal scales. For each scanning conditions, the effective pore radius(r_{eff}) is fitted with log normal distribution curve whereas the pore coordination number and the pore tortuosity in z direction were fitted well by normal distribution curves.

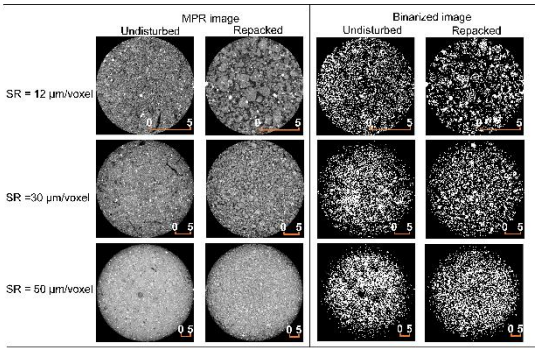

Figure 1. Multiplanar reconstruction image (MPR) and binarized images of undisturbed and repacked volcanic ash samples of dry bulk density 0.80 g cm^{-3}.

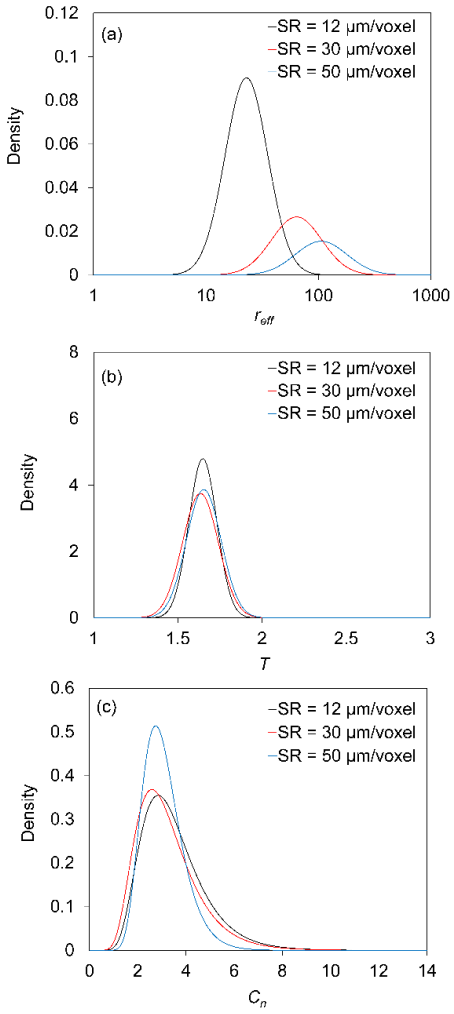

Figure 2. Distribution of pore structure parameters for undisturbed volcanic ash soils of dry bulk density 0.80 g cm^{-3} with different scanning resolution (SR). (a) effective pore radius (r_{eff}) (b) Pore Tortuosity(T) (c) Pore coordination number (C_n). (ROI = 200×200×200 voxels).

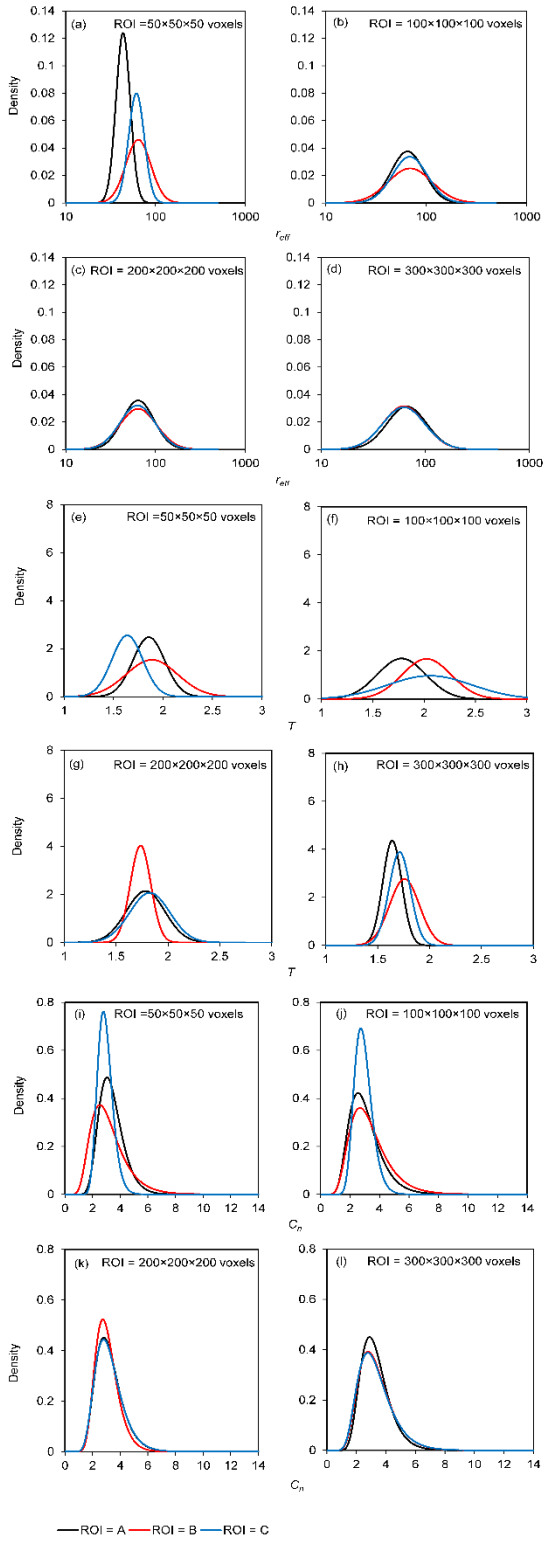

Figure 3. Distribution of pore structure parameters for undisturbed volcanic ash soils of dry bulk density 0.80 g/cm^3 with different region of interest (ROI) (SR 30 µm/voxel) : (a, e, i) ROI = 50×50×50voxels, (b, f, j) ROI = 100×100×100 voxels, (c, g, k) ROI = 200×200×200 voxels, and (d, h, l) ROI = 300×300×300 voxels and (a), (b), (c) and (d) are effective pore radius (r_{eff}), (e), (f), (g) and (h) are pore tortuosity(T), (i), (j), (k) and (l) are distribution of pore coordination number (C_n).

Typical examples of the effects of scanning resolution on the distribution of pore structure parameters are shown in Figure 2. The result shows that the effective pore radius (r_{eff}) is more depended on the SR in the MFXCT scanning compared to the pore tortuosity or the pore coordination number. This verified that lower SR size results in lowering the r_{eff}. All pore structure parameters for undisturbed and repacked samples varied depending on the ROI in the MFXCT scanning (Figure 3). However, such variations decreased with increasing ROI (typically, ROIs ≥ 100×100×100 voxels). For both undisturbed and repacked samples, ROI = 50×50×50 voxels showed high variation due to the limited number of pores in the analysis. The pore structure parameters are generally similar for ROI larger than 200×200×200 voxels. Sometimes, the larger voxels were not used in the analysis due to very large computational complexity for the pore structure analysis software used in the image analysis (EXFact analysis for porous particles, Nihon Visual Science, Inc., Japan). In this study scanning resolution 12 and 30 µm/voxel and ROI = 200 ×200×200 voxels were used for image analysis. Calculated mean (µ) and standard deviation (σ) values of pore structure parameters for undisturbed and repacked samples with different SR are summarized in Table 3. Compare to the undisturbed samples the repacked samples showed less variation of pore structure parameters. The pore tortuosity factors derived from MFXCT (T_{MFXCT}) were well correlated with the indirect connectivity tortuosities (X_G) from measured soil gas diffusion (Fig 4a and Fig 4b). The values that were not detected from the MFXCT analysis and that were not measurable because of low air permeability were not shown in Fig 4. [10] had also reported that reasonably good agreement between the pore characteristic parameter tortuosity determined from MFXCT analysis and from gas transport parameters. However, it was observed that there were some variations between effective pore diameters from MFXCT (d_{MFXCT}) and equivalent pore diameters for gas flow (d_G) estimated by gas transport parameters depending on scanning resolutions (ranging from 1:3 to 2:1 for SR =12µm/voxels and 1:1 to 5:1 for SR = 30µm/voxel) (Fig.4c and Fig. 4d). Similar findings were obtained in a previous study [19] for landfill cover soil (loam). This indicates that further improvements are needed to better correlate the pore diameter derived from MFXCT analysis with the equivalent pore diameter from gas flow measurements. Pores less than SR was not visualized due to limitations of MFXCT system.

CONCLUSIONS

By using microfocus X-ray CT system, soil pore networks of undisturbed and repacked volcanic ash soils with different scanning resolution (voxel) and different ROIs were visualized, and pore-structural parameters were analysed and these parameters were compared with the indirect pore structural parameters

obtained from gas flow methods. The major findings are:

(i) Effective pore radius (r_{eff}) is greatly affected by scanning resolution size compared to pore network tortuosity and coordination number. With the increasing analysis of volume (ROI), less variation of pore structure parameters was observed.

(ii) The pore tortuosity derived from MFXCT was well correlated with the indirect connectivity and tortuosities predicted by using soil gas diffusion. However, some variations in pore diameters were observed.

Measurement of pore network from MFXCT seems highly promising for further understanding of gas transport parameters.

ABSTRACT

Bauxite is a raw material used in the production of alumina and, subsequently, aluminium. Like many metals, world demand for aluminium, and therefore bauxite, has grown substantially over the past 10 years in response to economic growth in emerging Asian economies. Bauxite is a relatively soft ore with a distinctive reddish brown colour. Bauxite ore from Malaysia exported to manufacturing country such as China to be processed into aluminium. Basic properties of bauxite are determined for exporting purpose in which several international specifications need to be followed while handling bauxite in order to ensure those raw materials are passing the standard to be imported. Laboratory test had been done to bauxite samples from Bukit Goh in Kuantan to determine its basic and morphological properties. It is found out that moisture content of raw Bukit Goh bauxite is higher compared to processed bauxite where it has the average of 24.33% over 7.16% only on the processed bauxite sample. For particle distribution, it shows that the processed bauxite has less fine particle compared to raw samples with the average of 16.60% compared to raw with 38.50%. Result from FESEM test proves that the lesser fine particle attached to the processed bauxite ore. Referring to the IMSBC Code, it can be stated that raw bauxite samples from Bukit Goh does not pass the standard. This is due to the presence of bulky fine particles which tend to absorb water more than granular particles that may lead to liquefaction to occur. Liquefaction during cargo transportation is high risk especially when there are strong current at the sea. In order to ensure the bauxite is passing the standard, beneficiation process must take place where it include washing, wet screening and mechanical or manual sorting.

Keywords: International Maritime Solid Bulk Cargoes (IMSBC) Code, Bauxite, Liquefaction

INTRODUCTION

Cargo liquefaction has been an arising issue since it is the major reason for numerous bulk carriers' capsizes. Many solutions have been adopted by researchers and seafarers to avoid these incidents which can be divided into experimental tests and numerical simulations [6] , [1]. The main cause of the problem is excess pore water pressure within the bulk cargo. The presence of unmanageable pore water pressure will weaken the microstructure of the soft soil particles, and it can make the unloading creep damage of soft soil extremely strong and even cause liquefaction [8]. The scenario is similar to liquefaction in solid bulk cargo. The ship's motion and the engine vibration during passage may cause particle rearrangement and compaction [3]. The gaps between the particles become smaller in the process, with the corresponding pore pressure progressively increasing [2]. As a result, the water holding ability of particles and the friction coefficient between cargoes decreases. In particular, the water in the interstellar spaces comes together to form a liquid layer that allows the cargo above to move relative to the cargo below – as if the two layers were part of a liquid and hence the term 'liquefaction'. Such a transition during ocean carriage can cause a sudden loss of stability of the carrying vessel. In the last ten years, more than ten ships capsized and sank due to a loss of hull stability attributed to the cargo liquefaction [4]. In addition, the problem of water pollution was widely reported by mainstream and social media. Bauxite is the major alumina (Al2O3) bearing ore used in the aluminum manufacturing industries. The bauxite containing less than 50% Al2O3 is called low-grade bauxite ore which is commonly used for the alumina-based abrasives and refractories productions. The alumina-silica and alumina-ferrite complexes are the foremost impurities present in the low-grade bauxite [9]. Aluminium is the most abundant metal in the crust of the earth and also can be recycled repeatedly while

maintaining its quality, so it is an environmentally friendly choice for many products. It does not rust, is not magnetic and it conducts both heat and electricity with ease. It is light and more easily shaped than many other metals while still staying remarkably strong [7]. Adaptable and practical, aluminium is often brought to our daily life through the process of aluminium extrusion. Besides smelter and manufacturing its own aluminium, Malaysia also exported the bauxite to China which is Malaysia's largest export destination. Due to strong demand from this country, Malaysia had to double and tripled the production of bauxite in order to meet the demand [10]. Thus, this study is carried out to determine does the bauxite production is achieved the IMSBC Standard or not for exporting where its basic properties; specific gravity, moisture content and particle size distribution is measured.

Percentage of moisture content of the sample does have a relationship with particle size distribution where the presence of fines particles will influence its water-holding properties [2]. Fine particles will increase total void ratio therefore increasing the capacity of the particles to store water. High moisture content as well as high value of specific gravity is not acceptable for solid bulk cargoes because it will be too risky to transport them.

OBJECTIVES OF THE STUDY

In general, this research aims to identify the geotechnical properties of raw and processed Kuantan bauxite by doing a laboratory test on Bukit Goh bauxite samples. In order to achieve the research aim, the following objectives had been established:

I. To determine basic properties of Bukit Goh, Kuantan bauxite
II. To determine morphological characteristics of Bukit Goh, Kuantan bauxite
III. To determine the suitability and quality of Bukit Goh, Kuantan bauxite according to IMSBC code.

SCOPE OF STUDY

The samples of bauxite ore were taken from Bukit Goh, Kuantan, Pahang which is located approximately 25km from Kuantan. A full laboratory scale test is carried out through this research in order to determine the correlation between the basic properties of Kuantan bauxite. The required testing are moisture content test, specific gravity test, sieve analysis test, field emission scanning electron microscope (FESEM) and x-ray fluorescence (XRF).

METHODOLOGY

In this study, to determine basic properties of bauxite sample, there are about five laboratory test and analysis done to 4 samples; 2 samples from Bukit Goh mine (M2L1 and M2L2) and 2 sample from stock pile (PTST1 and PTST2) to list out the required data. Sieving Analysis is done to determine particle size distribution of bauxite samples. Meanwhile, specific gravity of bauxite samples and moisture content determination is carried out to identify the specific gravity and moisture content present in the samples.

Meanwhile, for morphological study, samples is sent for FESEM test to have clear vision about the condition of bauxite particles under certain magnification while XRF test is conducted to identify the composition of elements and oxides of Bukit Goh bauxite

Table 1 Type of Test and Standard of Sample Tested

Soil Sample	Laboratory Tests	Standard
Bauxite (Bukit Goh)	Moisture Content Test	Geospec 3: Part 2; 5 Clause 3.2
	Specific Gravity Test	Geospec 3: Part 2; 7 Clause 3.4
	Particle Size Distribution	Geospec 3: Part 2; 8 Clause 3.5
	X-Ray Fluorescence (XRF)	QUANT-EXPRESS (Full Analysis) by XRF S8 Tiger
	Field Emission Scanning Electron Microscopic (FESEM)	By JSM 7800-F

RESULT AND DISCUSSIONS

Raw data of basic properties of the samples collected from laboratory test were analysed by referring to the formula and method stated in Geospec 3: Model Specification for Soil Testing. There are some standard and regulations that need to be follow by using IMSBC Code. Table 2 below shows the percentage of fine particles between raw and processed Bukit Goh Bauxite for four samples.

Table 2 Percentage of fine particles between raw and processed Bukit Goh Bauxite

Sample	Raw (%)	Processed (%)
M2L1	34	19
M2L2	40	24
PTST1	40	22
PTST2	40	18

Average fine particle	**38.50**	**16.60**

This test was conducted to evaluate the size characteristic of the Bukit Goh bauxite to determine whether it is safe to be exported undisturbed or otherwise. The deposits size that is permitted by IMSBC Code for fine particles content is between 10% to 30%. For bigger lumps; 2.5mm to 500mm, the suitable size for safe transportation is from between 70% to 90%

Referring to IMSBC Code, allowable size for cargo transportation is between 2.5 mm to 500 mm with total percentage of 70% to 90% lumps and only 10% to 30% powder. Based on the result analysis prove that the particle size distribution Bukit Goh bauxite's not in range the requirement size in IMSBC Code. The result proved that raw Bukit Goh bauxite's in average consist more than 30% fine particle and less than 70% coarse particle. Due to this situation, the moisture content of the raw bauxite will increase. Meanwhile, bauxite of the same sample that has been beneficiated has fine particle less than 30% which prove that beneficiation method can reduce the number of fine particles in bauxite.

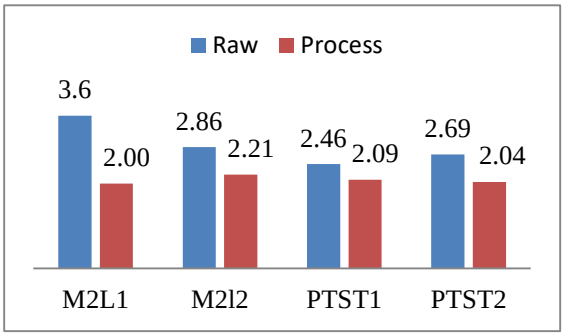

Figure 1 Tabulation of average specific gravity

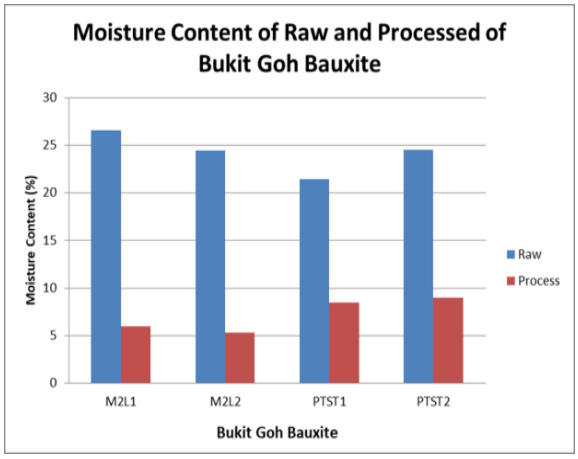
The result from Small Pycnometer Test was collected and tabulated in Figure 1 for PTST1 and PTST2 are almost the same. Meanwhile, there is slightly difference in specific gravity for M2L1 and M2L2. The specific gravity of processed bauxite samples is slightly lower than the raw sample. Specific gravity for bauxite is between 2.0 – 3.0, thus the bauxite samples collected from Bukit Goh mine are still between the range of the study.



`Figure 2 Tabulation of average moisture content

From the comparison in the histogram in Figure 2, it shows that the moisture content of raw Bukit Goh bauxite is higher compared to processed bauxite where it has the average of 24.33% over 7.16% only on the processed bauxite sample. Due to higher moisture content, it clearly demonstrates that raw Bukit Goh bauxite have large amount of fine particle compared to coarse particle. Meanwhile, the moisture content for processed bauxite is within the allowable range in the IMSBC Code; 0%-10% which makes the bauxite safe to be exported [5].

Table 3 Raw and processed Bukit Goh Bauxite elements

Parameters	Unit	Raw	Processed
Iron (FE)	%	31.38	26.49
Aluminium (AL)	%	7.48	7.25
Titanium (Ti)	%	3.96	3.33
Silicon (Si)	%	0.50	0.44
Phosphorus (P)	%	0.40	0.41
Calcium (Ca)	%	0.09	0.11
Sulphur (S)	%	0.09	0.07
Chromium (Cr)	%	0.08	0.09
Manganese (Mn)	%	0.06	0.05
Zirconium (Zr)	%	0.05	0.05
Strontium (Sr)	%	0.02	0.02
Niobium (Nb)	%	0.02	0.02
Zinc (Zn)	%	0.01	0.02
Gallium (Ga)	ppm	69	79
Yttrium (Y)	ppm	35	48

Table 4 Raw and processed Bukit Goh Bauxite oxides

Parameters	Unit	Raw	Processed
Iron (III) Oxide	%	44.86	37.88
Aluminium Oxide	%	14.13	13.69
Titanium Dioxide	%	6.60	5.55
Silicon Dioxide	%	1.07	0.94
Phosphorus Pentoxide	%	0.91	0.93
Sulphur Trioxide	%	0.22	0.18
Calcium Oxide	%	0.13	0.15
Chromium (III) Oxide	%	0.12	0.13
Manganese Oxide	%	0.08	0.06
Zirconium Dioxide	%	0.07	0.06
Niobium Pentoxide	%	0.03	0.02
Strontium Oxide	%	0.02	0.02
Zinc Oxide	%	0.01	0.02

From Table 3, it shows that the quantity of Silicon (Si) is reduced from 0.50% to 0.44% and from Table 4, the amount of Silicon Dioxide (SiO2) or also known as silica is minimized from 1.07% to 0.94% after beneficiation process. Unfortunately, the value of aluminium element also decreases slightly from 7.48% to 7.25% although it has not much effects on the bauxite products. As mentioned before, the core target of washing bauxite is to decrease the amount of silica and improve the amount of aluminium. In addition, along with silica, the insoluble iron and titanium oxides in red mud will also be removed that will abolish lower grade fines and enhance the quality of bauxite

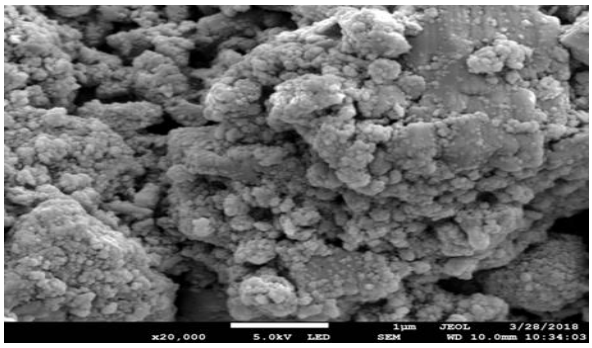


Figure 3 Raw Bauxite Morphology under 20000x magnification

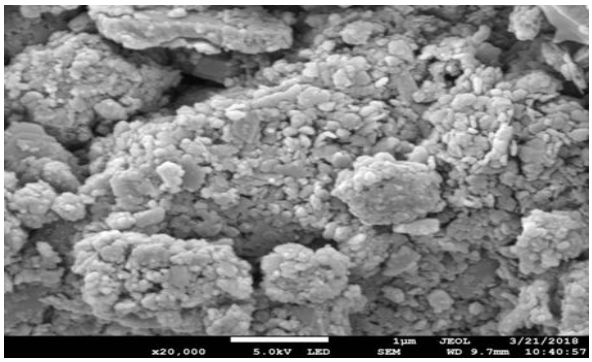

Figure 4 Process Bauxite Morphology under 20000x magnification

Clear image of particles started to be seen under 20000 x magnifications, fine particles attached to the bauxite sample are clearly can be seen for raw samples. This figure explained the main cause of high percentage of moisture content. Large amount of fine particles at the bauxite ore may result liquefaction to take place due to fine particles that have low anti-liquefaction characteristics compared with lump particles and granular particles. Clearly seen that the lesser fine particle attached to the processed bauxite ore. This proved the washing of bauxite can reduce the amount of fine particle in bauxite lump.

CONCLUSIONS

The potential liquefaction of bauxite cargoes has been the subject of a number industry bulletins in recent years. These concerns have been renewed following the recent sinking of the bulk carrier Bulk Jupiter reportedly carrying 46,400 MT of bauxite loaded at Kuantan in Malaysia [10]. Due to series of cargo liquefaction increased while shipping mineral ores, The Maritime Safety Committee of International Maritime Organization (IMO) has adopted the IMSBC Code to facilitate the safety of the cargo while transporting solid bulk. The main purpose of IMSBC Code is to provide a better guidance while handling solid bulk shipping in the cargo in terms of stowage and shipment. Thus, beneficiation process is a good method to reduce the fine particles in bauxite deposits that will minimize the dust pollution when transporting on land by lorries. This process also will decrease the water content of bauxite because there is a lesser fine particle content as well as improving the quality of bauxite that will be extracting into good quality aluminium. This study is focused on three basic properties which are particle size distribution, moisture content and specific gravity. Based on the results and discussion gained from the previous chapter, there are several conclusions that can be finalized as follow:

I. Results from the sieve analysis study concluded that the average fine particle sizes of raw bauxite are 38.50% which is higher than already processed bauxite sample with the average of 16.60%. Thus, by comparing to IMSBC Code, raw Bukit Goh bauxites are not fulfilling the maximum fine particle size passing of 30% requirement in the standard IMSBC Code and therefore it is not suitable to be exported.

II. From the outcome of beneficiation, the Bukit Goh bauxite has lower moisture content percentage with the value of 7.16% compared to raw bauxite with moisture content of 24.33% which exceed the 10% limitation. It is due to the lower content of fine particle in processed bauxite that absorbs less water.

III. The chemical properties of both raw and processed bauxite are tested by X-ray Fluorescence test. The Silicon (Si) element and

silicon dioxide that made up most of the fine particle in bauxite was reduced from 3.81% to 1.53% and 4.61% to 2.32% respectively.

IV. Study on morphological properties of Bukit Goh bauxite displays that the fine particles of raw bauxite is higher than the beneficiated bauxite. Clearly seen that the lesser fine particle attached to the processed bauxite ore resulting in lower absorption of moisture. All these basic properties are lead to lower risks of liquefaction to occur during bauxite cargoes transportation.

V. To be classified as Group C, the moisture content of bauxite must be within the 0% to 10%. For particle size, 70% to 90% for coarse lumps, varying between 2.5 mm and 500 mm and 10% to 30% for powder.

ABSTRACT

Geotextile tubes (geotubes) filled with lightly cement-mixed soil (CMS) are used to construct a containment bund. The proposed containment bund was made of three layers of geotextile tubes, where each of the geotube was infilled to a height of 2m and stacked to form a 6m high containment bund in the shape of a triangular prism. Three geotubes were placed side by side to form the first layer of the containment bund. The shear strength development of the CMS of the first layer containment bund was evaluated using a modified mini Cone Penetration Test (CPT) after the infilling. The results suggested that the shear strength developed in the center geotube is generally lower than the edge geotubes. It was hypothesized that the edge geotubes, which were installed before the center geotube, hindered the dewatering action of the center geotube during its infilling process. Hence, a study on a scaled-down version of the three geotubes arrangement was conducted in the field with instrumentation. The hypothesis mentioned above was examined through the changes in volume and strain mobilised in the geotextile of geotube, the dewatering rate, and the shear strength development of the CMS, pore pressure and total pressure changes during infilling and dewatering phase of the geotubes. The study showed that the construction sequence of the geotubes indeed affects the shear strength development of the CMS.

Keywords: Geotextile tubes, Lightly cemented clay, Containment bund, Dewatering, Shear strength

INTRODUCTION

Sand is conventionally the preferred infill material of geotextile tubes (geotubes) to construct a stable containment bund. However, due to the shortage of sand in Singapore, lightly cement-mixed soil (CMS) is being studied as alternative infilling material for geotubes.

In one of Singapore's land reclamation projects, a containment bund was made up of three layers of geotubes, where each geotube was filled to a height of 2m and stacked to form a 6m high containment bund in the shape of a triangular prism as shown in Fig. 1. The first layer of the containment bund was made up of three geotubes placed side-by-side. After approximately three months since the infilling of the first layer of geotubes with CMS, the shear strength of the infill material was measured using a miniature Cone Penetration Test (CPT) equipment. It was found that the geotube in the center had a lower shear strength as compared to the edge geotubes. This was believed to be related to the construction sequence, where two edge geotubes were installed before the installation of the center geotube. A hypothesis was made that the installed edge geotubes somehow hindered the dewatering action of the center geotube during its infilling process.

In order to verify the proposed hypothesis, a field test with a scaled-down version of the three geotubes arrangement was conducted to simulate the actual large containment bund. These small geotubes were well-instrumented.

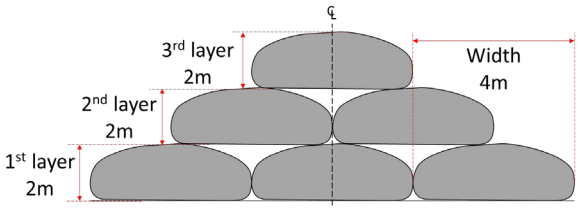

Fig 1 Cross section of geotubes containment bund (schematic).

MATERIALS

This section presents the materials used in this study. The properties of the geotextile, type of soil, cement, and monitoring instruments are elaborated.

Properties of Geotextile Materials

The scaled-down instrumented geotubes have a length of 2m and a circumference of 2.52m. The targeted height of the geotube was approximately 0.6m when fully filled. The geotube was made of Polypropylene (PP) woven geotextile, and the properties of the geotextile are tabulated in Table 1.

Table 1 Properties of geotextile material

Properties	Test Standard	Unit	Values
Tensile strength (MD/CD)	ISO 10319	kN/m	120/120
Elongation at break (MD/CD)	ISO 10319	%	20/15
Seam strength (CD)	ASTM D4884	kN/m	85
CBR puncture resistance	ISO 12236	kN	>14
Water permeability	ISO 11058	l/m^2/s	13
Pore size, O_{90}	ISO 12956	mm	<0.25

Properties of cement-mixed soil (CMS)

The Unified Classification of the soil used to produce the CMS infilling material is Sandy-Clayey SILT. The soil is then mixed with Ordinary Portland Cement (OPC). The cement content used was 7% to the dry unit weight of the soil. The bulk density of the CMS was determined to be 1.25 – 1.35 g/m^3.

Monitoring Instruments

The instrumentation plan for the geotextile tubes is shown in Fig. 2. All three geotubes were each instrumented with six strain gauges to capture the mobilized strains at the locations that were more prone to tearing.

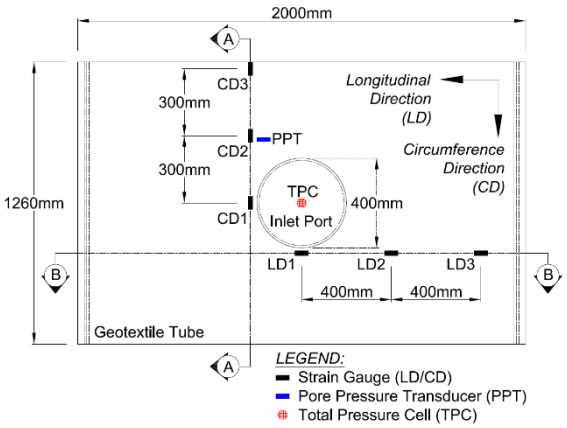

Fig. 2 Monitoring instruments layout on geotube when placed on flat (plan view).

Three strain gauges were attached in the circumferential direction (CD) and the other three were attached in the longitudinal direction (LD) as shown in Fig. 3. The strain gauges installation method proposed by Chew [1] was used in this study. Each geotubes was also fitted with one total pressure cell (TPC) and one pore pressure cell (PPT) near the bottom of inlet port to measure the variation of total pressure and pore water pressure with time, especially during the infilling process. A camera was used to capture the height change of the geotubes during the infilling and dewatering stages.

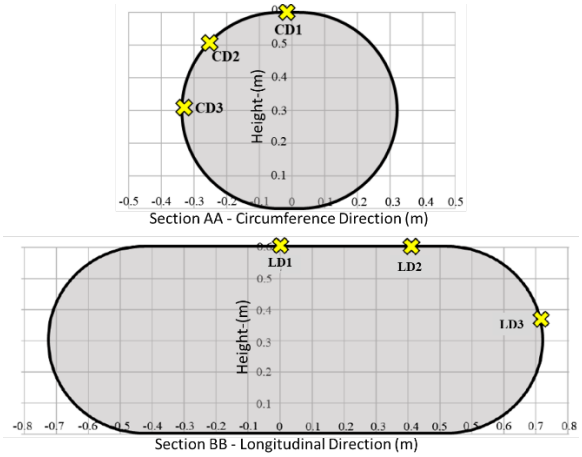

Fig 3 (Section AA & BB from Fig. 2) - Strain gauges location in CD & LD.

FIELD TEST SETUP & TEST PROCEDURE

The field test setup comprises of (a) a mixing pit with pump and pipeline, (b) the infilling and dewatering platform for the geotubes, and (c) a sump pit to collect the "dewatered" water from the geotubes. A layer of geomembrane was laid on the platform before the geotubes were laid on top of it. The geotubes were overlapped by up to 0.4m to simulate the actual construction conditions of the geotube containment bund. In addition, two levelling rods were positioned at both sides of the edge geotubes. The changes in height of the geotubes can then be analysed through the photos recorded by a camera positioned in front of the geotubes. Figure 4 shows the field setup mentioned above.

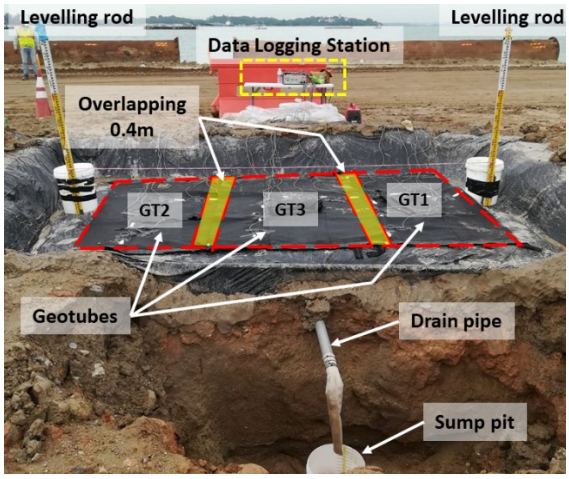

Fig. 4 Field Test Setup.

The field test began with the preparation of the CMS in the mixing pit. The infilling sequence followed with the first geotube on the right (GT1). After the GT1 had attained a height of 0.6m, the geotube on the left (GT2) was immediately infilled. Simultaneously, the water drained out from both of the geotubes during the dewatering process was collected in the sump pit. The volume of water collected was measured.

The infilling process of the center geotube (GT3) started after the dewatering process of the two edge geotubes (GT1 & GT2) ended. Similarly, the volume of water drained from the center geotube was measured. The entire infilling and dewatering process was recorded with a camera, which provides a record of the volume and height change of geotube with time. Fig. 5 illustrates the infilling sequence of geotubes.

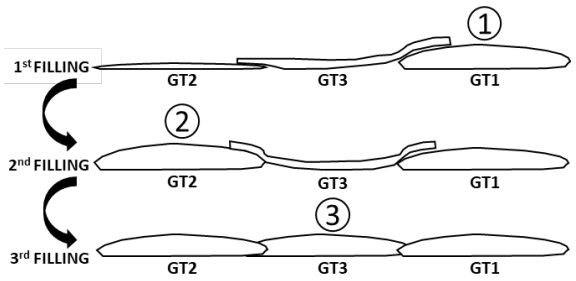

Fig. 5 Filling sequence (front view).

RESULTS & DISCUSSIONS

Changes in Shape, Height & Volume

Figure 6 shows the changes in height and shape of the geotubes with time. This enables the calculation of the change in volume of the geotubes with time by applying Eq. (1) proposed by Yee et al. [2]:

$$V_T = L_T {D_T}^2 \left[\left(\frac{h_T}{D_T}\right)^{0.815} - \left(\frac{h_T}{D_T}\right)^{8.6} \right] \quad (1)$$

where V_T is the volume of the geotube, L_T is the length of the geotube, h_T is the measured height of the geotube, and D_T is the theoretical diameter of the geotube. In this study, L_T = 2m and D_T = 0.802m.

The volume change of each geotube during the dewatering stage with infilling time is presented in Fig. 7. It illustrates that the results for GT1 and GT2 are consistent as they are identical in boundary condition at infilling and dewatering stages. It also clearly shows that the volume reduction of GT3 was much slower than that of GT1 and GT2. This suggests that the dewatering rate of the center geotube, GT3 was lower as compared to the edge geotubes. This suggestion can be further proved from the actual dewatering rate analysis of each geotube that will be presented in the next section.

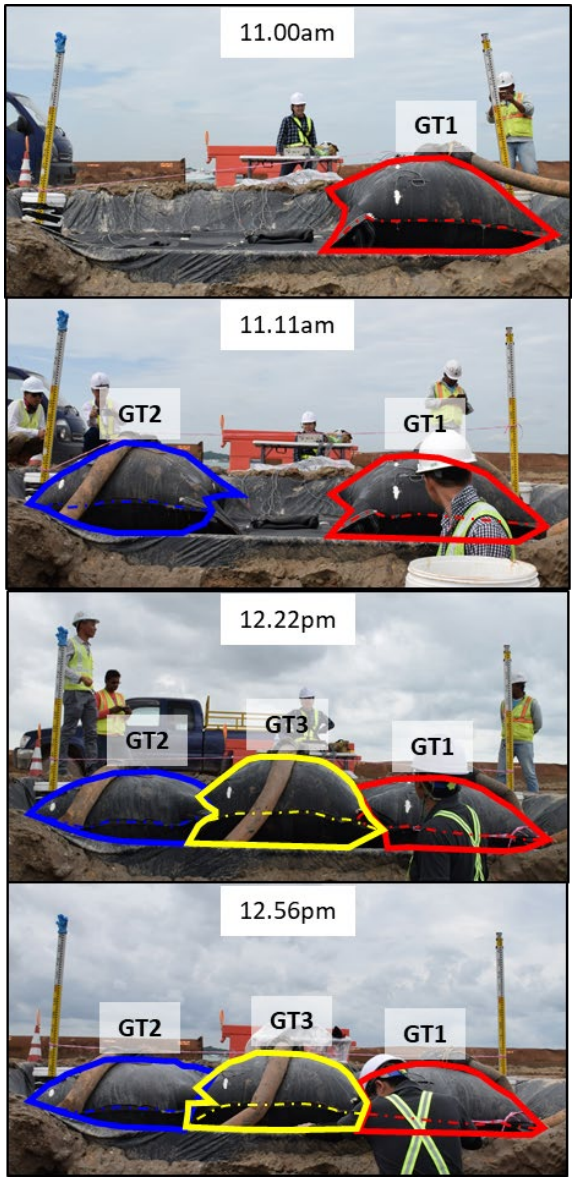

Fig. 6 Shape and height changes of geotubes.

Dewatering Rate

The dewatering rates of each geotube during the dewatering stage are plotted in Fig.8 using the recorded volume of effluent from the geotubes with time. For simplicity of calculation, the edge geotubes (GT1 and GT2) were assumed to have the same dewatering rate in this test. Hence, the volume of effluent collected from the edge geotubes (GT1 & GT2) was aggregated and the average volume was taken to compute the dewatering rate as they took place under the same period of time. From Fig. 8, the center geotube (GT3) showed a lower dewatering rate after 20 minutes as compared to that of the edge geotubes (GT1 & GT2). This matches the hypothesis in the earlier section and leads to the conclusion that the center geotube will be blocked or hindered by the edge geotubes, and thus the dewatering action will be

slowed down during the dewatering stage.

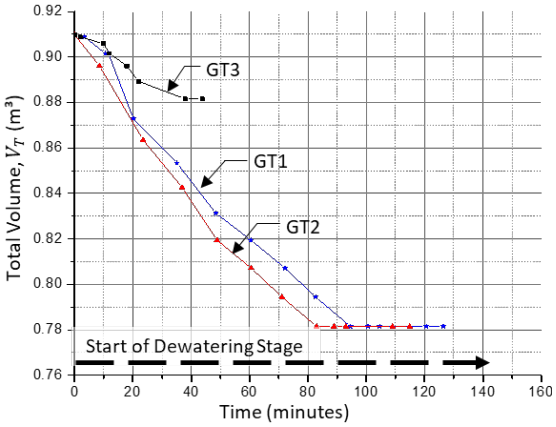

Fig. 7 Volume changes of geotubes over time of infilling.

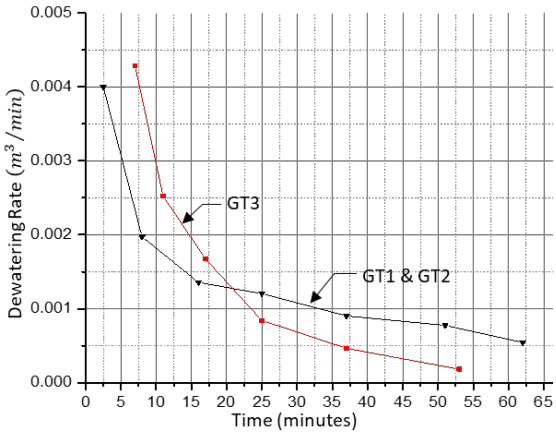

Fig. 8 Dewatering rate of geotubes.

Shear Strength Development

After infilling, the geotubes were left untouched for dewatering action and cementation reaction to take place. A modified mini Cone Penetration Test (CPT) was then conducted on the geotubes after 7 days and 28 days to ascertain the shear strength development of the infilled CMS. At 7 days, only one CPT testing point was conducted at each geotube, while two CPT testing points were conducted for each geotube at 28 days. Fig. 9(a) and Fig. 9(b) show the shear strength development of the CMS in the geotubes at 7 days and 28 days respectively.

The shear strength of the CMS at 7 days was in the range of 5kN/m^2 to 12kN/m^2 and increased to approximately 10kN/m^2 to 20kN/m^2 at 28 days. GT3 consistently had a lower shear strength at 7 days and 28 days than that of GT1 and GT2. This proves that the slow dewatering rate mentioned in the earlier section leads to a slightly lower shear strength development in GT3. It is also interesting to note that the shear strength at 7 days was uniformed with depth, while at 28 days, the CMS seemed to develop a higher shear strength with depth for all 3 geotubes.

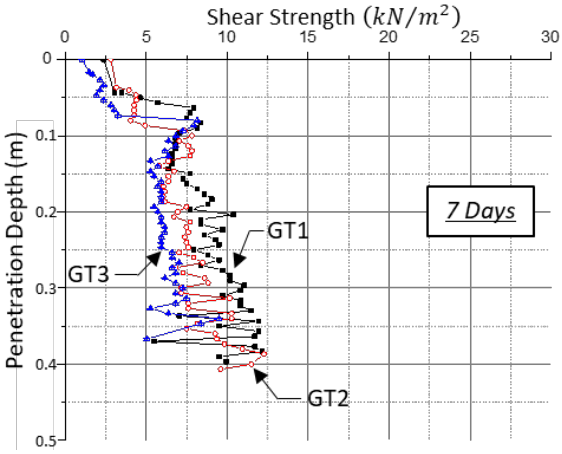

Fig. 9(a) Shear strength of infilling material at 7 days.

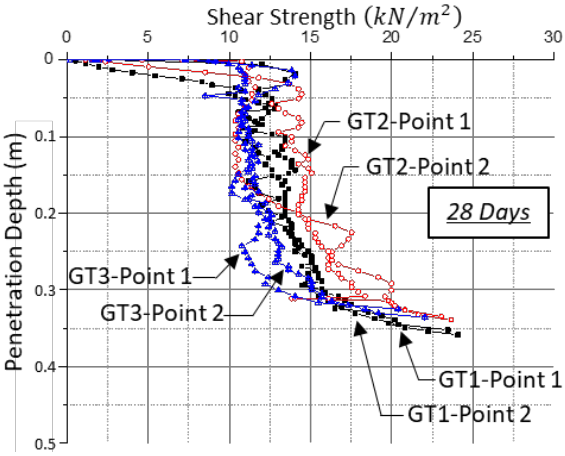

Fig. 9(b) Shear strength of infilling material at 28 days.

Mobilized Local Strain

The mobilized local strains in the circumferential and longitudinal direction on geotextile material of the geotubes are shown in Fig. 10(a) and Fig. 10(b) respectively. The strain data in both directions show that the highest local strain is generally generated at the moment when the maximum infilling height is attained. CD3-GT2 malfunctioned and thus has not been included in the analysis.

CD1-GT1 and LD3-GT1 registered the maximum local strain of 1.7% and 1.5% in circumferential and longitudinal direction respectively. This was because CD1-GT1 was attached nearest to the inlet port and LD3-GT1 was attached at the highest curvature point. Surprisingly, LD2-GT3 also registered the maximum local strain of 1.5% in the longitudinal direction. This could be due to the infilling sequence where the infilling of GT3 commenced immediately after GT1 and GT2 were fully filled. The edge geotubes would

have obstructed the expansion of GT3 in the circumferential direction leading to higher strain developed in the longitudinal direction for GT3 at that moment.

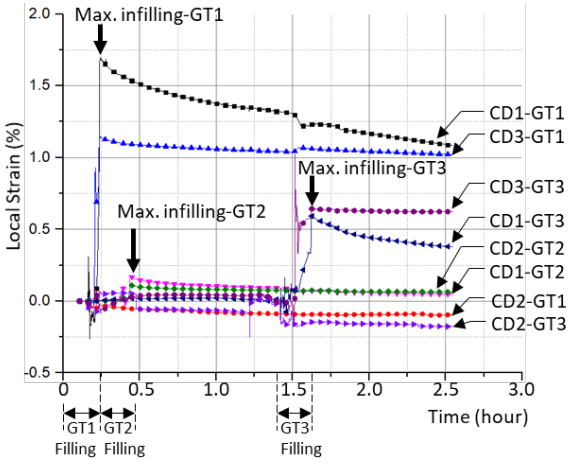

Fig. 10(a) Mobilized strain at CD on geotubes over time. (Refer to Fig. 3 for the location of the strain gauges)

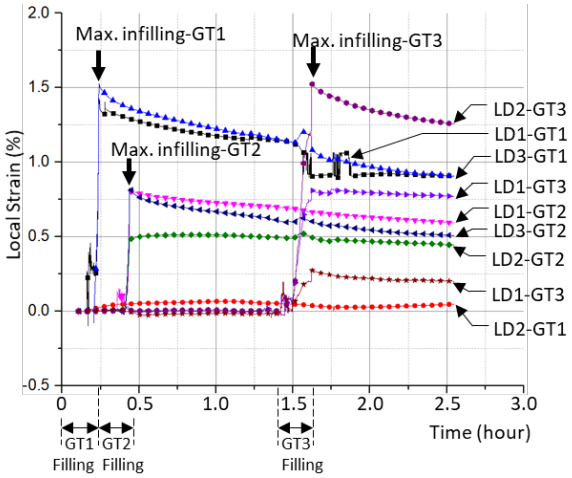

Fig. 10(b) Mobilized strain at LD on geotubes over time. (Refer to Fig. 3 for the location of the strain gauges)

Total Pressure & Pore Pressure

The total pressure in the geotubes during the test are shown in Fig. 11, with the times when the geotubes infilling took place indicated. It is shown that all geotubes registered the maximum total pressure at the end of infilling, and the total pressure subsequently gradually decreased with time.

The pore pressure measured within the geotubes with time is shown in Fig. 12. The maximum pore pressures of GT1 and GT2 were at the end of infilling when the geotubes were pumped to an approximate height of 0.6m. Subsequently, during the dewatering stage, the pore pressures decreased. However, the pore pressure in GT3 increases gradually with time even during the dewatering stage. This might due to a malfunction of the pore pressure transducer in the GT3.

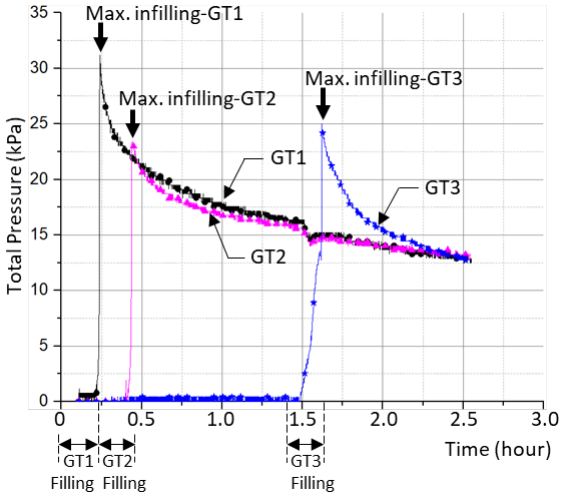

Fig. 11 Total pressure development of geotubes.

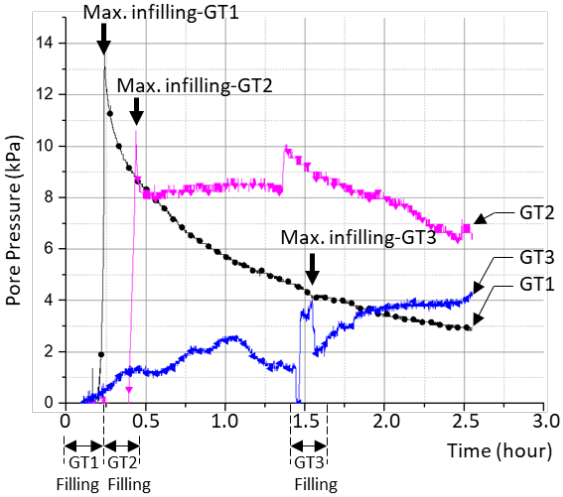

Fig. 12 Pore pressure development of geotubes.

CONCLUSION

A field test with scaled-down size geotubes filled with CMS material was conducted to model the effect of the construction sequence of the first layer of containment bund.

Three geotubes were modelled according to the actual construction sequence, where the two edge geotubes were installed first, followed by the center geotube. It was found that the volume reduction with time of the center geotube is generally slower than the edge geotubes. This is consistent with the observation that the dewatering rate of the center geotube is also the lower than the two edge geotubes.

The shear strength development of the CMS in the

geotubes further supports the finding above, where the center geotube had slightly lower shear strength amongst the three geotubes at 7 days and 28 days. It was also observed that the limited space for center geotube to expand sideways during the infilling stage caused the longitudinal direction of the center geotube to experience slightly higher strain as compared to that in the circumferential direction.

In conclusion, the construction sequence of the geotubes for the first layer in a containment bund would affect the behaviour of the geotubes, particularly the center geotube.

ABSTRACT

Shallow soil mixing (SSM) method with a low dosage of cement can be used to create a sufficiently strong platform for quick access onto grounds that have been recently reclaimed with soft clays. The effectiveness of the SSM method is dependent on the type, dosage and dosing method of cement, the mixing blade design, and the mixing sequence, etc. Hence, a laboratory-scale SSM apparatus was developed to simulate SSM in the field. The early strength development and uniformity of cement mixed soil (CMS) were evaluated by taking into consideration (a) Type of cement: CEM I vs CEM III/A, (b) Dosage of cement: 7% vs 3%, (c) Dosing method: 1-layer vs 2-layer mixing, and (d) Mixing blade design: without overlap between mixing blades vs overlapped mixing blades. Shear strength test results demonstrated that the shear strength development of CMS at an early stage is affected by the type, dosage, and dosing method of cement, while the uniformity of the CMS is affected by the dosage and dosing method of cement and the mixing blade design. From the laboratory test results, it is recommended that CEM III/A cement with 7% cement dosage, 2-layer of dosing method and overlapped mixing blades design parameters be used for SSM in the field to achieve high early strength gain and good uniformity cement soil mix.

Keywords: Shallow soil mixing, Early strength development, Uniformity

INTRODUCTION

In land reclamation, water bodies are usually reclaimed using fill materials such as sandy soils. However, due to the limited sources of sandy soil in Singapore, soft clays are used as the fill material instead. The major problem of using soft soils as the fill material is that it will undergo a substantial amount of settlement when loaded. Hence, ground improvement must be carried out to accelerate the consolidation and reduce post-construction settlement in the soft soil layer for the newly reclaimed land to gain enough strength for future use. However, to carry out ground improvement work on reclaimed land is also a great challenge as the ground improvement works also need a sufficiently strong working platform for machinery access.

One method of constructing the working platform for machinery access is to treat the top layer of the soft clay by mixing it with cement and creating a layer of cement-mixed soil (CMS). Some methods of introducing cement into the soft soils include Shallow Soil Mixing (SSM), jet grouting and Deep Cement Mixing (DCM). SSM and DCM both improve the geotechnical properties of soil by improving their undrained shear strength (Cu) and lowering compressibility [1]. SSM, however, is used to improve a large treatment area to a shallower depths (Fig. 1(a)), while DSM is used to treat soft soil to a greater depths with a smaller treatment area using column-by-column treatment arrangement. Fig. 1 illustrates this difference.

In the application that this study is concerned, since treatment to only the top shallow layer of soft soil is required, the use SSM to create a working platform for machinery access on ground recently reclaimed with soft soils will be discussed.

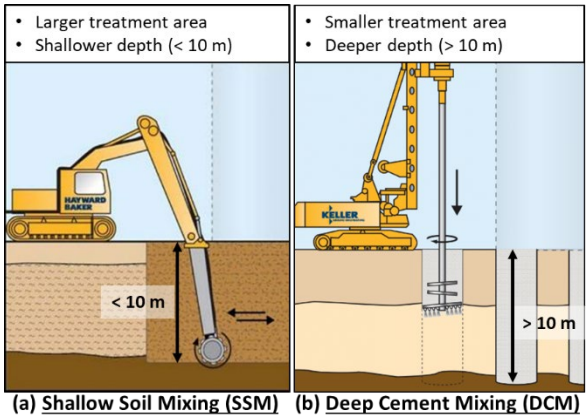

Fig. 1 Schematic illustration for Shallow Soil Mixing (SSM) and Deep Cement Mixing (DCM) [2].

Effectiveness of the SSM

Early strength of the CMS is very important for field implementation, as faster strength gained in the

CMS will allow early machinery access to the site. Existing literature reports that the parameters such as type of cement and dosage of cement affect the early strength development of CMS. Mixing uniformity is another key criteria for successful field implementation. A uniformed CMS will ensure uniformity in strength gained across the treatment area. The cement dosing method and mixing blade design are believed to be the parameters that will affect the uniformity of the CMS.

Hence, this study focuses on investigating the effect of the mentioned parameters on the early strength development and the uniformity of the CMS through a series of laboratory scale-SSM test.

Type of Cement

The two major standards used globally to categorise cement are (a) ASTM International standard, and (b) British Standard European Norm (BS EN). As early strength development is needed for the discussed application (which is the working platform at the shallow depth of soft soils), the type of cement mentioned in the two standards that are related to the early strength gain is as follows.

Referring to ASTM C150/150M, ASTM Type I cement is used for general purposes, while Type III is a rapid hardening cement with relatively high early strength gain. Fig. 2 shows the rate of strength development for various cement types according to ASTM, with higher the Tricalcium Silicate (C_3S) content in the cement composition providing higher early strength gain.

In the BS EN 197-1:2011, cement type is categorized based on the type of additional materials in the cement composition. The type of cement that provides high early strength gain is Portland cement (CEM I) and Silica fume cement (CEM II/A-D) as shown in Fig. 3. CEM I consists of 95-100% clinker, while CEM II/A-D consists of 90-94% of clinker and 6-10% of slica fume.

Blastfurnance cement (CEM III/A and CEM III/B) provides high long term strength development instead of high early strength gain. CEM III/A consists of 35-74% clinker and 36-65% granulated blastfurnance slag (GGBS), while CEM III/B consists of 20-34% of clinker and 66-80% of GGBS.

Cement Dosage

The effect of cement content on the unconfined compressive strength of Singapore Marine Clay is shown in Fig. 4. The strength of cement-treated clay increases with the amount of cement until a "saturated limit", beyond which there is no strength increment observed with additional cement [5]. For the current study, lightly cemented-clay with cement dosage ≤ 10% is adopted.

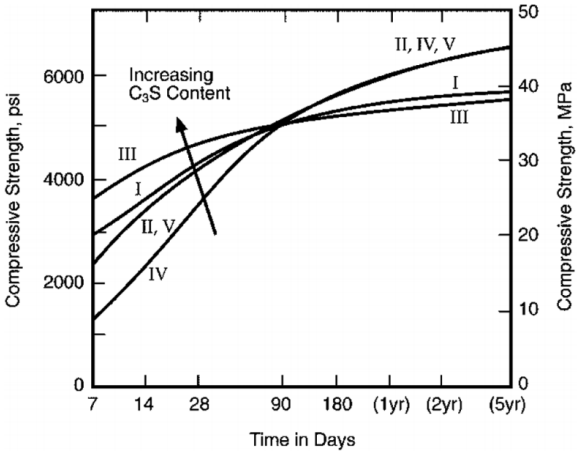

Fig. 2 Rates of strength development for concrete made with cement classified according to ASTM standard [3].

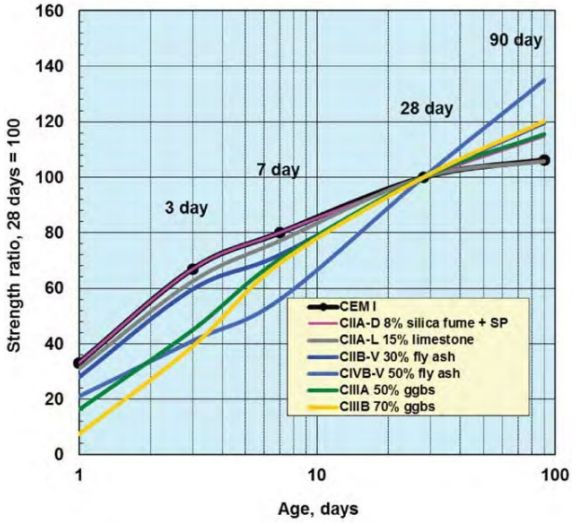

Fig. 3 Rates of strength development for concrete made with cement classified according to BS EN standard [4].

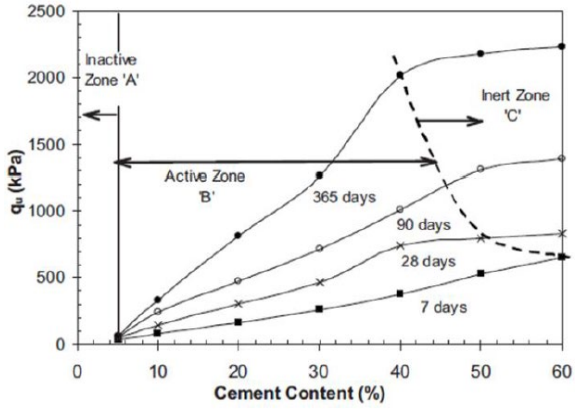

Fig. 4 The effect of cement content on the unconfined compressive strength of Singapore Marine Clay [5].

Cement Dosing Method

The effect of the number of cement layers placed in the soil specimen on the unconfined compressive strength of the CMS was earlier studied [6]. The study reported that the initial cement distribution is one of the dominant factors affecting the uniformity of the soil mix and demonstrated by the distribution of the strength of the CMS.

Mixing Blade Design

Several studies were carried out to investigate the operation techniques (e.g. mixing blade design) on the quality of the CMS [7]. Fig. 5 shows the influence of the number of mixer shafts on the strength of the CMS, where CMS improved by four mixer shafts show similar 7-day strength and higher 28-day strength compared to CMS improved by single mixer shaft.

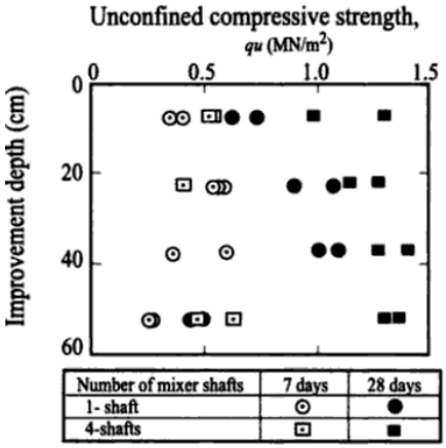

Fig. 5 Unconfined compressive strength achieved using a different number of mixer shafts [7].

MATERIALS & TEST SETUP

The materials and apparatus used in the laboratory-scale SSM test are elaborated in this section.

Properties of Soil

Kaolin Clay and Past Infilled Materials (PIM) were the two types of soils used in this study. PIM refers to excavated soils collected from construction activities that had been temporarily dumped into offshore containment sites and now dredged to be used as an alternative infill material for land reclamation.

The particle size distributions and the soil index properties of the soils used are shown in Fig. 6 and Table 1 respectively. It can be seen that while Kaolin clay is a uniform soil of silt-size, PIM is well-graded sandy-clayey silt.

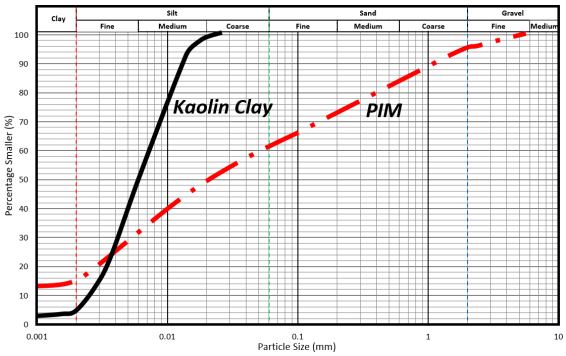

Fig. 6 Particle size distribution of Kaolin Clay and PIM.

Table 1 Soil index properties of Kaolin Clay and PIM

Properties	Kaolin Clay	PIM
Plastic Limit (PL)	40 %	28 %
Liquid Limit (LL)	80 %	67 %
Plasticity Index (PI)	40 %	39 %

Type of Cement

As Singapore adopts the BS EN standard, Cement CEM I and CEM III/A were used in this study. Although it was proven that the CEM I has a higher early strength gain, the use of CEM III/A is more environmentally friendly and cost-effective. There is approximately 11% reduction in the cost of concrete per 1 MPa of strength gained was documented when CEM III/A cement was used instead of CEM I cement [8].

Laboratory Scale SSM Apparatus

A laboratory-scale SSM apparatus was designed to model the SSM in a controlled environment. The SSM apparatus consists of two major components: (1) a 1200mm (length) x 400mm (width) x 400mm (height) rectangular soil container, and (2) motor-powered mixing blades as shown in Fig. 7. Three mixing blades were attached at equal spacing across the width (400mm) of the soil container, and each of the mixing blades had four cutting arms. Fig 8 illustrates two different lengths of the cutting arms (62mm and 75mm) attached on the mixing blades. It was postulated that a longer cutting arm could provide a better overlap between the blades and result in a more uniformed mix.

TEST PROCEDURE

Two dosing methods with slightly different test procedures were studied: 1-layer method and 2-layer method.

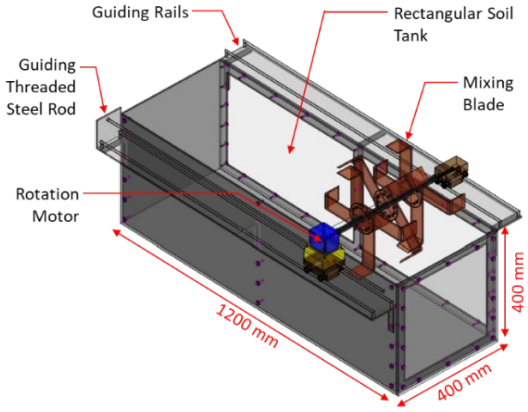

Fig. 7 Schematic diagram of the laboratory-scale SSM apparatus.

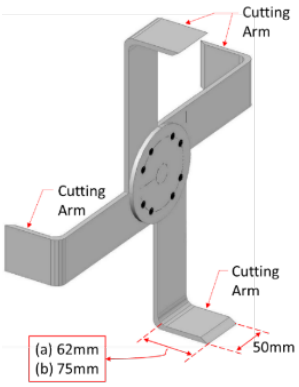

Fig. 8 Different lengths of cutting arm on a mixing blade.

1-layer Method

Soil was prepared to a water content of 1.2x its Liquid Limit (LL) and poured into the soil container. Cement slurry is then sprayed evenly onto the surface of the soil. The motor-powered mixing blades with the rotating cutting arms were subsequently activated to move back and forth the container 8 times.

2-layer Method

The effective treatment depth of 100mm in this study is to be divided into two layers. The first batch of the prepared soil (with a water content of 1.2x its LL) was poured into the soil container until the 50mm mark from the top of the container. The total amount of cement slurry was also divided into two equal portions, and the first portion of cement slurry was sprayed onto the first layer of soil surface.

Subsequently, the remaining batch of prepared soil was added to the top of the container. The second portion of cement slurry was then added onto the top surface of the soil. Finally, the motor-powered mixing blades were used to mix the soil uniformly, similar to the 1-layer method.

TEST PROGRAM

The first test series used Kaolin Clay (KC) with the 62mm cutting arms on the mixing blades. Effect of the dosing method of 1-layer vs 2-layers was studied in this phase. The second test series used PIM with the 75mm cutting arms on the mixing blades. In this phase, the effect of different dosing percentage was studied and evaluated. The parameters used in the first and second test series are listed in Table 2(a) and Table 2(b) respectively.

Table 2(a) First test series (Kaolin Clay and 62mm cutting arm).

Cement	Cement Dosage	Dosing Method	Test no.
CEM I	10%	1-layer	KC-1
		2-layer	KC-2
CEM III/A	10%	1-layer	KC-3

Table 2(b) Second test series (PIM and 75mm cutting arm).

Cement	Cement Dosage	Dosing Method	Test no.
CEM I	7%	1-layer	PIM-1
	3%	1-layer	PIM-2
CEM III/A	7 %	1-layer	PIM-3
	3%	1-layer	PIM-4

RESULTS AND DISCUSSIONS

The performance of the laboratory-scale SSM test is evaluated by the development of the undrained shear strength (Cu) of the CMS over time. Vane Shear Tests (VST) and miniature Cone Penetration Tests (CPT) were used to ascertaining the 3-day and 7-day Cu of the CMS at different locations in the soil container as shown in Fig. 9. The 28-day strength was not included as this study is concerned primarily with the early strength gain of CMS.

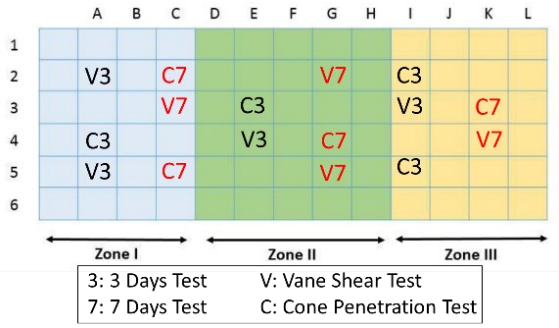

Fig. 9 Plan view for VST and CPT test points in soil container

The undrained shear strength (Cu) obtained for the Kaolin Clay CMS with depth at various locations for each test series are shown in Fig. 10(a) to Fig. 10(c).

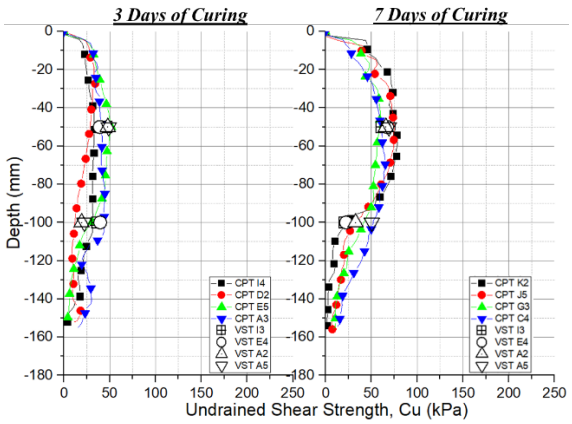

Fig. 10(a) Undrained shear strength, Cu, with depth of CMS for Test KC-1

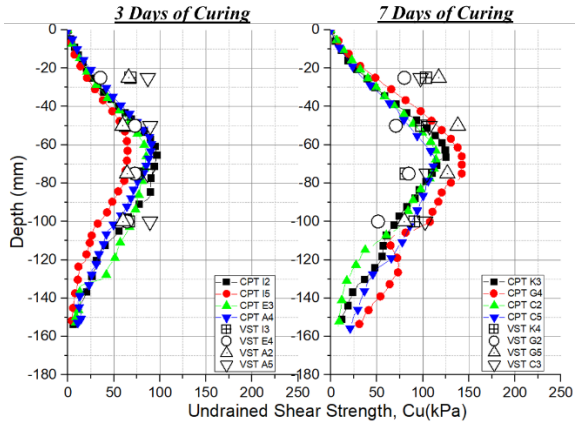

Fig. 10(b) Undrained shear strength, Cu, with depth of CMS for Test KC-2

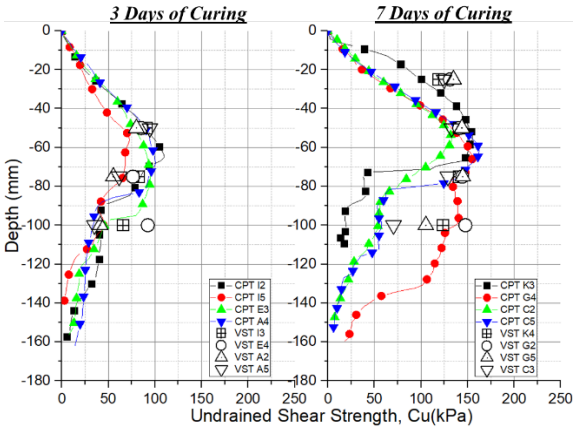

Fig. 10(c) Undrained shear strength, Cu, with depth of CMS for Test KC-3

The undrained shear strength (Cu) obtained for the PIM CMS with depth at various locations of each test series are shown in Fig. 11(a) to Fig. 11(d).

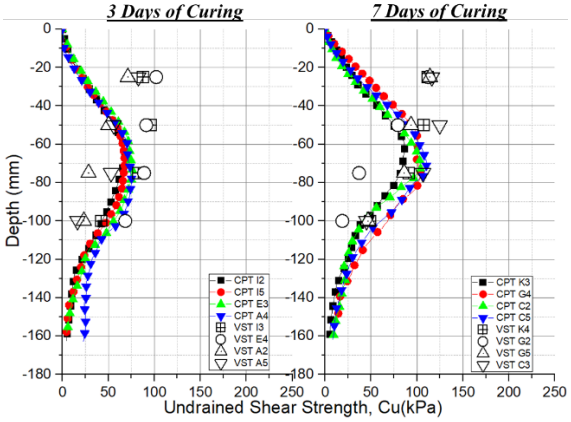

Fig. 11(a) Undrained shear strength, Cu, with depth of CMS for Test PIM-1

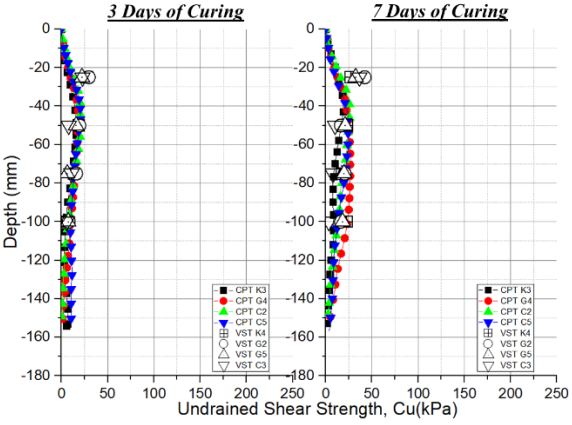

Fig. 11(b) Undrained shear strength, Cu, with depth of CMS for Test PIM-2

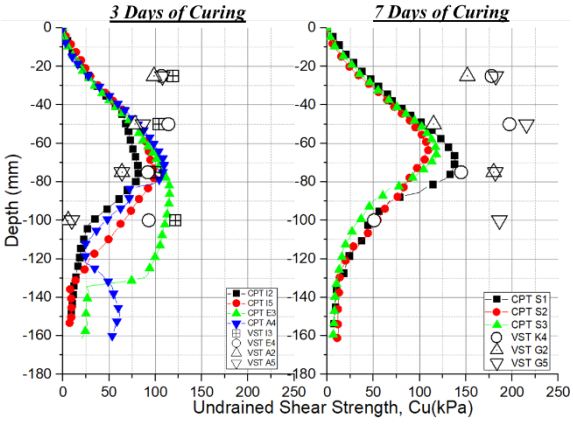

Fig. 11(c) Undrained shear strength, Cu, with depth of CMS for Test PIM-3

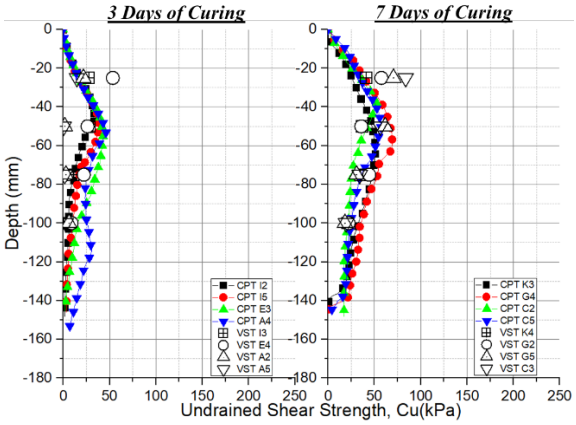

Fig. 11(d) Undrained shear strength, Cu, with depth of CMS for Test PIM-4

Effect of Cement Type

The effect of cement type on strength development can be observed by comparing the Cu distribution with depth in Test KC-1 and KC-3. In general, the 3-day Cu and 7-day Cu distributions of KC-3 are higher than in KC-1. Similar trends are observed in PIM-1 compared with PIM-3, and PIM-2 with PIM-4, where the Cu distribution of CMS with CEM III/A consistently have higher values compared to CEM I.

Effect of Cement Dosage

By comparing the Cu distributions with depth in PIM-1 with PIM-2, and the Cu distributions with depth in PIM-3 with PIM-4, it can be observed that using a higher dosage of cement gives a higher strength gain, which is expected.

Effect of Dosing Method

The results of higher Cu values observed in Test KC-2 as compared to KC-1 indicate that using the 2-layer dosing method provides more uniform strength gained in the CMS.

Effect of Mixing Blade Design

The first test series used 62mm cutting arms, while the second test series used 75mm cutting arms. Apart from differences in the cutting arms, a higher cement dosage was used in Test KC-1 than in PIM-1 is the cement dosage.

Although a higher cement dosage was used in KC-1, PIM-1 unexpectedly obtained higher Cu values at the corresponding location and time than that in KC-1. This proved that the increase in the uniformity of CMS is affected by the blade design such as the amount of overlap of the mixing blades.

CONCLUSION

A series of laboratory-scale SSM test was conducted successfully. In the study, CEM III/A cement shows more rapid strength development in the CMS as compared to CEM I cement, and that a higher cement dosage is an advantage for the development of strength gain. It was also concluded that the dosing method and mixing blade design are important in providing uniformed cement mixed soil. Therefore, for the cost-effectiveness of the SSM method to create a working platform at the top layer of soft soils, the cement dosing method and mixing blade design must be carefully planned as these two parameters impact the uniformity of CMS, which directly increase the overall strength gain across a large treatment area.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the efforts of Mr. Xu T.H. in completing this study.

OPTIMISATION OF SENSOR LOCATIONS FOR RELIABLE AND ECONOMICAL EARLY WARNING OF RAINFALL-INDUCED LANDSLIDES

Abeykoon T[1], Gallage C[2] and Trofimovs J[3]
[1,2,3]Science and Engineering Faculty, Queensland University of Technology, Australia.

ABSTRACT

Rainfall-induced landslide monitoring and early warning is an effective technique for minimising potential landslide risks, especially in circumstances where structural countermeasures are not economically or technically feasible. In this regard, a number of methods have been developed to monitor susceptible slopes and warn against possible slope failures. The majority of real-time slope monitoring systems involve sensor networks that measure slope inclination/displacement, volumetric water content and rainfall, enabling the determination of pre-failure deformation. However, no systematic approach has been made to install such sensors in critical locations to enhance the cost-effectiveness of slope monitoring systems and the accuracy of landslide early warnings. This study has developed guidelines for a systematic approach for the determination of critical sensor installation points using RTK-GPS surface movement measurements, numerical transient seepage and slope stability analysis for the economic and technical optimisation of landslide monitoring and early warning systems.

Keywords: Rainfall-induced landslides, Landslide monitoring, Slope stability, Critical sensor locations

INTRODUCTION

Due to the adverse consequences, prevention and mitigation of rainfall-induced landslides are vital. Even though mechanical countermeasures such as retaining walls, soil hardening techniques and ground anchors are technically adaptable in rainfall-induced slope failure mitigation, practically such methods are commonly not feasible due to high costs, varying slope scales and potential risk factors in mechanical reinforcements. In these situations, continuous monitoring of slope behaviour provides an economical and slope-specific alternative for landslide risk mitigation [1]-[4].

In the context of landslide monitoring and early warning, the majority of early warning criteria are defined on time histories of rainfall intensities and real-time rainfall records (e.g.[5]). These rainfall based early warning techniques enable in advance detection of slope instabilities at a low cost and ease. However, such criteria are defined, assuming uniform rainfall conditions over the area of interest, which is usually in the range of several square kilometres [3]. Additionally, local topographical, geological and hydrological factors are not embedded in producing rainfall based landslide early warnings, which highly correlates with landslide initiation [6]. Therefore, the sole use of rainfall based early warning in evaluating slope instability risks in individual slopes becomes inadequate.

Furthermore, continuous monitoring of displacement or deformation provides a precursor to detect slope instabilities in advance via indices such as cumulative deformation and rate of slope deformation [3]. Hence, the reliability of landslide early warning systems can be improved by incorporating real-time deformation monitoring into the rainfall based landslide early warning systems. In that context, recent developments in multiple factors-based landslide early warning systems heightened the need for low cost, reliable and real-time sensor system.

In order to address the demand, a real-time slope monitoring system equipped with micro electro mechanical systems (MEMS) tilt sensors and volumetric water content (VWC) sensors was proposed by [2] to produce reliable early warnings for rainfall-induced landslides. MEMS technology enables the detection of rotation (or variation of tilt angle) in the unstable surface layers of slopes. Abeykoon [1], Uchimura [3], and Gallage [7] summarised case studies of tilt sensor monitoring systems and the variations of tilting rates during pre-failure and main failure stages, which facilitates the early warning of rain-induced slope failures.

However, in all aforementioned studies, sensors were randomly located, and no previous research to date has aimed to determine the optimum/critical sensor installation locations on the failing slopes. The scarcity of the fore-knowledge on the distinct sensor locations led to the installation of a large number of sensors, many of which were not effectively involved in producing early warnings (e.g. TS-4 and TS-5 sensor units were not detected any slope movement in the study conducted by [1]). Therefore, the optimum economic usage of the sensor system was not exploited.

The current study adopts a real-time monitoring system that consists of five MEMS tilt sensor units that are capable of transmitting real-time collected

data to an online web interface via a combination of wireless and mobile networks to investigate the critical locations of a slope to install sensor units. So that an efficient prediction of possible slope failures can be conducted reducing landslide risks. Further, by optimising the number of sensor units used in a given real-time slope monitoring system, the entire economic capability of the proposed tilt sensor system can be determined. Therefore this study provides novel insights into the low cost, reliable and real-time landslide monitoring and early warning systems.

STUDY AREA

The study area is located in Lake Baroon catchment, Maleny, Queensland, Australia (26.72 ^{0}S 152.87 ^{0}E). Mapleton - Maleny plateau, which has been documented as a highly susceptible area for rainfall-induced slope failures since the mid - 1950s. (e.g. [8]). Slope failures and mass movements of sediment into the waterways within the Lake Baroon catchment are recognised as a significant risk to water quality and the water storage capacity of Lake Baroon, which is used to supply water to South East Queensland. Approximately 170 mass movement landforms have been identified within the Lake Baroon catchment, and the study area is one such high-risk slope. This landslide site hosted a voluminous, single-failure rotational landslide in 2008 following heavy rainfall.

SOIL PROPERTIES

Index Properties

The soil extracted from the monitoring site was subjected to laboratory tests to determine the required soil properties for the numerical analysis. Table 1 summarises the results of the laboratory tests conducted to determine the index properties of the soil according to Australian standards.

Table 1 Soil index properties

Classification Test	Results
Grain size	% finer than 75 μm > 79%
Distribution	Clay % = 41.0 %
Atterburg Limits	LL = 67.2 %
	PI = 28.2 %
Linear Shrinkage	LS = 13.4 %

Strength Properties

Strength properties of the soil were determined by the direct shear test, in which all the samples were prepared to achieve a dry density of 1.25 g/cm^3 to replicate the in-situ dry density of the soil. Direct shear tests were conducted for four different water contents. Figure 1 shows the variation of apparent cohesion with gravimetric water content. However, the soil friction angle did not significantly vary with the gravimetric water content, which was determined as 15.9^0.

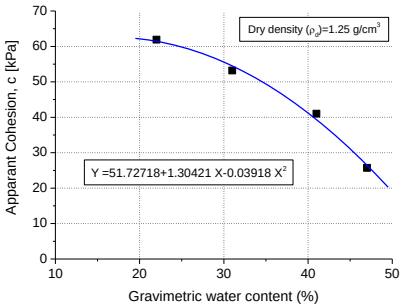

Fig. 1 The variation of apparent cohesion with gravimetric water content

Hydraulic Properties

A genetic-based neural network (GBNN) model was used for the determination of optimal weights of a neural network to predict the soil-water characteristic curve (SWCC) for this study. As defined by [9], five parameters; void ratio, initial water content, clay and silt fraction and the normalised logarithm of suction with respect to air pressure were used as the input neurons while the gravimetric water contents for input suction values are produced as the output neuron. Normalised input parameters were used for each arbitrary suction value. The input-hidden weight and the normalised input vectors were multiplied to obtain the input hidden neuron matrix, on which the sigmoidal activation function was applied to produce the output vector from hidden neurons. Then after the hidden output network weights were applied prior to de-normalising and descaling to obtain the final gravimetric water content. Figure 2 presents the F-X fit SWCC for the soil in the study area, derived from GBNN model [10].

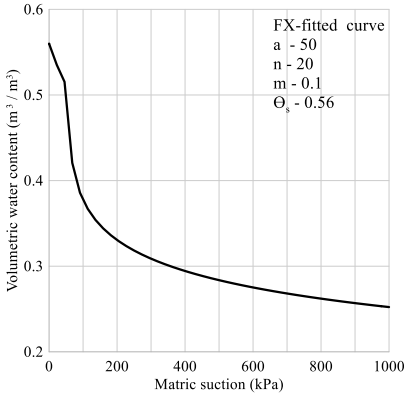

Fig. 2 Soil-water characteristic curve (SWCC) for the soil in the study area

Unsaturated coefficient of permeability function was defined using the SWCC predicted from GBNN model developed by [9] and the saturated permeability. The saturated permeability coefficient was chosen as 1 x 10^{-7} m/s.

METHODOLOGY

In order to determine the critical sensor installation locations for real-time monitoring of rainfall-induced slope failures, initially, the soil properties and sub-surface topography were determined by the laboratory experiments and ground penetrating radar (GPR) survey respectively. Moreover, to determine the predominant slope failure direction for 2-D stability analysis, previous slope failure occurrences along with the recorded RTK-GPS surface movement data were analysed. The obtained soil properties, topographical data were incorporated in the numerical model for stability analysis of 2-D cross-sections parallel to the predominant failure direction within the monitoring site.

Ground Subsurface Survey

A ground surface survey and a sub-surface GPR survey were performed to determine surface topography, and the depth of soil cover to bedrock on the site to evaluate the optimum positions for the monitoring stations using the numerical model. A base GPR transect was mapped downslope from the head of the main scarp to the toe of the site in an attempt to profile the sub-surface in the direction of the original mass movement. After characterising the soil profile by determining the interface between soil and underlying bedrock, four locations were selected to excavate pits for determining the composition of soil layers, soil layer thicknesses and verification of GPR survey results [1].

RTK-GPS Surface Movement and Elevation Monitoring

An array of surface survey points were installed, in order to monitor both horizontal and vertical ground displacement with millimetric accuracy. Less than 10 cm of downslope movement was recorded by individual points using the RTK-GPS system between installation survey points in April 2016 and October 2017. Figure 3 presents the cumulative movement data for these RTK-GPS surveys and summarises the total movement to October 2017. The data is presented as arrow vectors, which point in the direction of measured movement between the two surveys. The size of the arrow is scaled according to the amount of movement, with the larger yellow arrows indicating a larger amount of movement. For scale, the diameter of the orange dots represents a distance of 20 mm in the field, which is the conservative margin of error for measurements recorded by RTK-GPS equipment. Therefore, yellow vector arrows that fit within the 20 mm circle recorded movement within the error of the measuring technique, while arrows that extend outside the circle have recorded a significant movement which is outside the margins of measurement error. As depicted in Fig. 3, there were two main areas of movement during the RTK-GPS surface movement monitoring period.

Fig. 3 RTK-GPS movement map of the monitoring site highlighting the two circled areas with significant recorded movement

Previous Slope Failure Analysis

Several significant mass movements were recorded during the period following October 2017, including a rotational landslide (14th - 21st October 2017), a reactivation of rotational landslide (29th November - 1st December 2017), a debris flow and continued reactivation of landslide (16th February 2018), and a soil creep (9th - 16th March 2018) [1]. These slope instabilities highlighted that the steep upper slope is the most susceptible region for rainfall-induced slope failures. Also, inspections following the rotational landslide at the head scarp showed running and pooling water in the slide cracks. Hence, the sub-surface build-up of this groundwater during, and immediately following, heavy rain was identified as the trigger for landslides. During and immediately after the rainfall events, water infiltrates into the soil profile, largely through the macro-scale surface cracking, and concentrates above the bedrock and water saturated white clay horizon. Consequently, sliding is initiated at this sub-surface slide plane once the soil reaches its liquid limit (~60%) and surpasses the binding strength of the root system. Moreover, the inspection of the new landslide soil profile showed that the grass and tree roots were vertically oriented at the top of the soil profile. However, as tree roots approach the sub-surface slide plane, they were bent towards horizontal due to the shearing associated with the landslide movement. Therefore the observation indicates that the movement occurred at the base of the soil profile, which was acting as a fluid and rafting

slide blocks downslope, which also accounts for the back-rotated orientations of these blocks as soil blocks have come to rest.

The previous slope failure analysis, along with surface movement data, highlighted two areas with significant slope movement at the monitoring site, that includes steep upper slope (which had failed) and northern boundary of the monitoring site as shown in Fig 3. Therefore, a hypothesis was developed that sub-surface (ground) water flow drains from the steep upper slope to down towards the northeast of the monitoring site (Fig. 4A). This is contrary to the surface runoff which has formed a number of erosional gullies to either side of the largely displaced mid-slope that run toward the northeast and east (Fig. 4B).

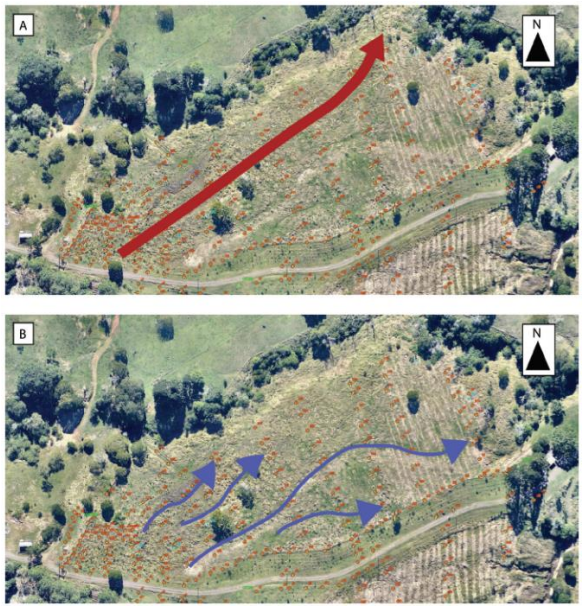

Fig. 4 (A) The hypothesised path of groundwater flow (B) Erosional gullies carved by surface runoff

Numerical Model

Transient seepage analysis and stability analysis were performed in order to determine critical locations of slope instability within the monitoring site. Transient seepage analysis was performed using Seep/W [11] allowing the analysis of wetting front movement and the excess pore-water pressure dissipation. The pore-water pressure profile computed for each time step from seepage analysis was then integrated into the stability analysis using Slope/W [12].

As depicted in Fig. 5, seven cross-sections parallel to predominant failure direction, which was determined through the hydrological (i.e. hypothesised groundwater flow and surface runoff) and previous slope failure analysis, were considered for the slope model. In the finite element modelling using Seep/W, each analysed cross-section consisted of approximately 1500 nodes and 1350 quadrilateral and triangular elements (Fig. 6). On the exposed slope surface, rainfall infiltration was simulated by applying water flux as a time-dependent function with the potential seepage face review. The sandstone bedrock located at approximately 4 m below the ground surface was assumed to be a low permeable layer, which was also justified by the presence of perched groundwater table during and immediately after the rainfall events. Saturated / Unsaturated material model was adopted for both the upper soil layer and the sandstone bedrock, using the hydraulic conductivity function and the water content function [11]. In defining the initial hydrological conditions, the groundwater table was assigned approximately 8 m below the ground surface. Since the initial groundwater table was located within the sandstone bedrock layer, perched groundwater table builds the pore-water pressure in the overlying soil layer in rainfall events, as observed in previous slope failures.

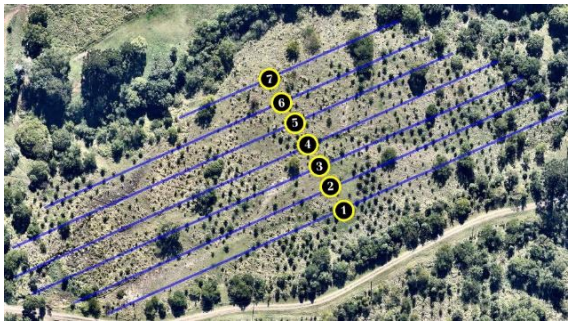

Fig. 5 Cross sections considered for the numerical analysis

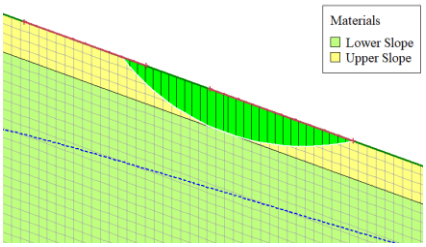

Fig. 6 Finite element mesh and the critical slip surface at the steep upper slope region in the cross section 4

The stability analysis was performed using the pore-water pressure profile developed by transient seepage analysis. Mohr-Coulomb material model was used by employing the laboratory determined shear strength parameters [12]. As shown in Fig. 6, in defining a slip surface for stability analysis, each cross section was analysed multiple times with different positioning of slip surfaces. The position of the critical slip surface with the lowest factor of safety was determined using the entry and exit slip surface condition, in which the entry and exit ranges of the

trial slip surface can be defined. The factor of safety (FS) values were determined using Morgenstern-Price's approach [12].

RESULTS

Validation of the Numerical Model

The developed numerical model was validated using the previous failure and the real-time monitoring data obtained from the real-time monitoring system installed in the study area. The real-time monitoring system is composed of five units of randomly positioned MEMS tilt sensors and VWC sensors, capable of continuously measuring the slope inclination and the soil VWC, respectively [1].

From the previous failure analysis, it was noted the majority of critical failure surfaces were laid within the upper clay layer, due to the low permeability of the sandstone bedrock or in other words shallow failures with a failure depth of 3 - 4 m were observed during the previous slope failures. Therefore, the failure depths, along with the locations of the previous slope failure, were accounted for validating the numerical model. Additionally, the VWC values at all the five sensor locations and the VWC values from the numerical model were compared to validate the developed numerical model. As shown in Fig. 7, the experimental VWC values at the TS-1 sensor location (at the steep upper slope) and simulated VWC values depicted a reasonable agreement, proving the accuracy of the numerical model.

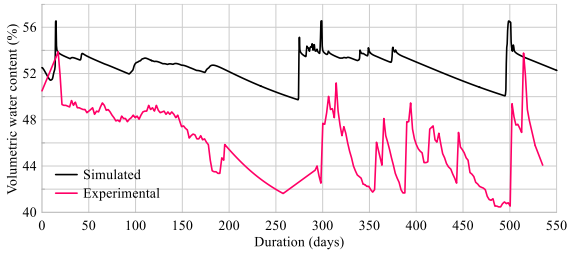

Fig. 7 Experimental and simulated volumetric water content values

Similarly, the VWC values obtained from the remaining sensor locations were also compared to validate the numerical model, which also showed an acceptable agreement. However, as depicted in Fig. 7, a slight lag on experimental VWC values were perceived due to the delay in response of the VWC sensor.

Determination of Critical Failure Locations

The FS value for various positions of entry and exit conditions for each cross section were obtained in order to analyse the critical locations of the study area. The FS variation produced from the numerical analysis showed significantly low values during the time periods with actual slope failures occurred, including October 2017, February 2018 and October 2018 failures, showing a reasonable agreement with the actual results. Figure 8 shows the variation of FS along with the rainfall (water flux) function applied to the exposed slope surface, for the steep upper slope region in the cross-section 4. Figure 9 presents the mean FS values for each location of the study area during the two-years. Therefore, as depicted in the previous failure analysis, the steep upper slope region in the study area has been determined as the most susceptible area for rainfall-induced slope failure.

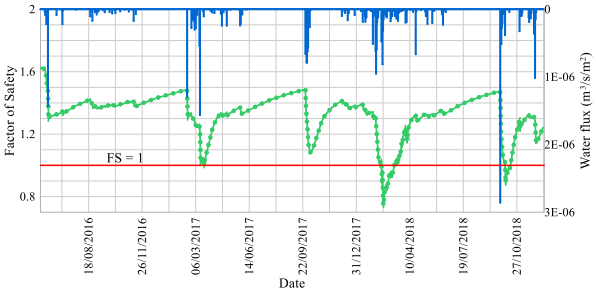

Fig. 8 FS and rainfall (water flux) variation in the steep upper slope section of cross-section 4

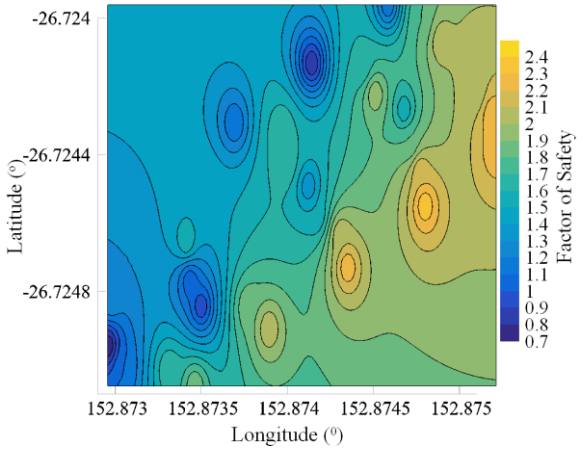

Fig. 9 Mean FS variation in the study area

Moreover, due to the low permeability of the underlying sandstone bedrock, a perched water table was exhibited within lower slope areas. As the rainfall infiltrates into the unsaturated soil zone, flow is moved down the slope creating a perched saturated zone. During the process, water flow moves either downwards into the adjacent unsaturated zone or exits from the exposed slope face, generating atypical pore water pressure conditions. Therefore, analysis of critical slip surfaces encountered intersection of phreatic water surface at multiple locations.

DISCUSSION

Strength and hydraulic properties of the soil become the fundamental requirements in numerical modelling a soil slope for stability. Even though the study adopted experimentally determined soil strength parameters, a GBNN based model was employed in evaluating VWC function, which provides an analytical alternative to obtain SWCC for soils.

Rainfall was applied as a water flux boundary condition to the numerical model in assessing slope stability under rainfall. However, the climatic and vegetation functions were not accounted for in the numerical analysis. Precipitation, air temperature, humidity, wind and solar radiation effects could be considered in developing a more accurate numerical model. Also, it should be noted that even though the study area was not densely vegetated, vegetation plays a vital role in slope stability under rainfall as the root system provides a reinforcement enhancing the slope stability. Therefore incorporating vegetation reinforcement into the numerical model may provide a more realistic evaluation of the critical failure locations.

CONCLUSIONS

The study developed a methodology to determine critical failure locations of a slope in advance so that the real-time slope monitoring instruments can be positioned at the critical locations, enhancing the cost-effectiveness of the monitoring system and reliability early warnings. In that regard, the study proposes a methodology with three steps that include the visual observation for the preliminary characterisation of the steeper regions of the slope, GPS surface movement monitoring to hypothesis the groundwater flow and predominant failure direction along with the susceptible moving areas within the slope and numerical analysis to confirm the critical failure locations. In the context of the current study, installation of sensor units in the regions with lower mean FS values will provide more cost-effective, economical, reliable and accurate landslide early warnings mitigating adverse impacts.

ACKNOWLEDGMENTS

The authors appreciate Seqwater, Australia, for its financial support for this study. Further, gratitude is extended to Mark Amos (Lake Baroon Catchment Care Group) for facilitating the installation of the monitoring system and providing site access at the convenience of QUT researchers. The management of Chuo Kaihatsu Corporation, Japan is greatly acknowledged for providing and installing the monitoring system for the in-kind research support to QUT. The first author acknowledges the scholarship for the doctoral degree received from QUT, Australia.

EVALUATION OF DEBRIS FLOW CONTROL USING SABO FACILITIES BASED ON NUMERICA SIMULATIONS

Naomasa Honda[1]

[1] Faculty of Regional Environment Science, Tokyo University of Agriculture, Japan

ABSTRACT

The present paper describes predicting sediment runoff characteristics and evaluating debris flow control using such sabo facilities as check dams and channel works based on the numerical results of an actual mountain torrent and consider the changes of sediment transport modes. In Ohzedani River, which is a tributary of Sendai River in Tottori Prefecture in Japan, a very active sediment runoff was caused by the second Muroto typhoon in September 1961. A one-dimensional numerical simulation is conducted to investigate the variations of debris flow characteristics through a river reach with sabo facilities. The analytical results show that the debris flow discharge increased several orders of magnitude more than the water, and the sediment transport rate varies with river-bed slope and river width. A check dam is effectively reduced sediment transport when the initial river-bed slope of the deposition area at the dam's upstream was not steeper than the equilibrium slope of the debris flow. The flow path is fixed with channel works, which provide protection against debris flow flooding. The computational condition of the river-bed erosion depth greatly affected the numerical results.

Keywords: Sediment runoff characteristics, Debris flow control, Sabo facilities, Numerical simulation

INTRODUCTION

A large amount of sediment may be produced in areas where earth slides or hillside landslides might occur. Such sediment in steep area is supposed to be eroded and transported as debris flow during severe rains, and various disasters or geomorphic changes are caused by them. Sabo works such as hillside works, channel works and debris flow control dams have been constructed to defend against debris flow hazards.

Generally, sediment runoff modes depend upon such variables as topographical parameters, sediment characteristics, water supply, and so on. Debris flow is formed in the reach where unstable sediment exists and the river-bed slope is steeper than about 15 degrees [1], [2]. The sediment transport mode changes from a debris flow into general contact loads with decrease of river-bed slope [3]. A check dam impacts the sediment runoff, because the channel is wide and the river-bed slope is gentle upstream of the dam [4] [5].

In the present paper, the following problems are discussed: the characteristics of sediment runoff in an actual mountain torrent and such sabo facilities as check dams and channel works on the reductions of sediment runoff as well as on the prevention of debris flow hazards based on the changes of sediment transport modes.

This paper proposes a mathematical method that is composed of mass and momentum conservation equations for debris flow as well as erosion velocity formula on debris from river-beds and conduct a one-dimensional numerical simulation to investigate variations in the debris flow characteristics and the effects of debris flow control using sabo facilities. Such debris flow characteristics as flow depth, flow velocity, flow discharge, and sediment flux concentration can be predicted even if sabo facilities are constructed in a river reach.

This paper also discusses the effects of sabo facilities on sediment load and the mitigation of the hazards of potential debris flow.

METHOD AND PROCEDURE FOR STUDY

Governing Equations for Debris Flow

To analyze sediment transport in a river reach, one-dimensional equations for the flow of a sediment-water mixture developed by Egashira et al. is used [6]. The following are the mass conservation equations for the flow mixture and for sediment alone:

$$\frac{\partial h}{\partial t}+\frac{1}{B}\frac{\partial Bvh}{\partial x}=\frac{E}{c_*} \tag{1}$$

$$\frac{\partial \varepsilon ch}{\partial t}+\frac{1}{B}\frac{\partial \varepsilon cBvh}{\partial x}=E \tag{2}$$

where t is the time, x is the coordinate axis along the flow, h is the flow depth, B is the flow width, v is the flow velocity, E is the erosion velocity (its negative value designates the deposition), c is the sediment concentration by volume, ε is the correction factor

(Egashira et al. [7], $\varepsilon c = c_t$, c_t is the sediment flux concentration), and c_* is the sediment concentration of the river-bed layer. The following is the momentum conservation equation:

$$\frac{\partial v}{\partial t} + v\frac{\partial v}{\partial x} = g\sin\theta - \frac{1}{\rho_m h}\frac{\partial P}{\partial x} - \frac{vE}{c_* h} - \frac{\tau_b}{\rho_m h} \quad (3)$$

$$\rho_m = (\sigma - \rho)c + \rho \quad (4)$$

The second term on the right hand side of Eq. (3) is the pressure gradient and the third is the resistance due to the sediment erosion. g is the gravity acceleration, θ is the river-bed slope, P is the pressure, τ_b is the river-bed shear stress, ρ_m is the mass density of flow mixture defined in Eq. (4), σ is the mass density of gravel, and ρ is the mass density of water. The mass conservation equation of the river-bed sediment takes the following form:

$$\frac{\partial Z_b}{\partial t} = -\frac{E}{c_* \cos\theta} \quad (5)$$

$$\theta = \sin^{-1}\left(-\frac{\partial Z_b}{\partial x}\right) \quad (6)$$

where Z_b is the river-bed elevation, and θ is expressed by Eq. (6). As mentioned above, even though E and τ_b play an important role in the governing equations, no general formulas have been developed for them. The formulas for E [6] and τ_b [8] developed by Egashira et al., are used. Erosion velocity E is as follows:

$$\frac{E}{v} = c_* \tan(\theta - \theta_e) \quad (7)$$

$$\theta_e = \tan^{-1}\left\{\frac{(\sigma/\rho - 1)c}{(\sigma/\rho - 1)c + 1}\tan\phi_s\right\} \quad (8)$$

where θ_e is the equilibrium river-bed slope corresponding to the sediment concentration defined by Eq. (8), which was obtained by Takahashi's formula for the sediment concentration of debris flow [9], ϕ_s is the internal friction angle of the sediment. The following is river-bed shear stress τ_b:

$$\tau_b = \tau_y + \rho f v^2 \quad (9)$$

$$\tau_y = \left(\frac{c}{c_*}\right)^{1/5} \rho(\sigma/\rho - 1)cgh\cos\theta\tan\phi_s \quad (10)$$

$$f = \frac{25}{4}\left\{k_f\frac{(1-c)^{5/3}}{c^{2/3}} + k_g\frac{\sigma}{\rho}(1-e^2)c^{2/3}\right\}\left(\frac{h}{d}\right)^{-2} \quad (11)$$

In Eq. (9), τ_y is the yield stress caused by the particle to particle contacts defined in Eq. (10), and f is the friction factor defined as Eq.(11), where e is the restitution coefficient, d is the reference grain size, and k_f and k_g are coefficients: k_f=0.16, k_g =0.0828.

Outline of Ohzedani River Basin

Ohzedani River is one tributary of Sendai River in Tottori Prefecture in Japan that flows into the Japan Sea (Fig. 1). It has drainage of 3.2 km^2 and a river reach of 4.1 km. Its mean river-bed slope is 10.8 degrees, and its river-width changes irregularly (Figs. 2 and 3).

In this basin, the mountain slope is very steep, and weathering granites, which are susceptible to erosion, are widely distributed on the mountainside, and unstable sediment is liable to be produced in the drainage. Therefore, this torrent is designated as a river's stream that poses debris flow risks.

A very active sediment runoff was caused in September 1961 by the second Muroto typhoon in this basin. Debris flow arrived at the lowest stream reach near Kofune village (Fig. 1). However, the torrent didn't overflow its banks because a check dam and channel works, which were constructed at downstream

reach (Fig. 2), effectively reduced the sediment transport and controlled the debris flow (Photo 1).

Initial and Boundary Conditions of Computation

In this paper, 3,200 m long river reach that is 380 to 990 m above sea level from the point where the river-bed slope changes suddenly to the confluence of Ochiori River, is analyzed. The river-bed and river-width profiles are shown in Figs. 2 and 3.

In this reach, a check dam and channel works are located at the downstream reach (Fig. 2). The effective dam height of the sediment deposition was 5.5 m, and the width of the check storage was 53.0 m before September 1961. The channel works are 308 m long, 6.0 m wide, with a 3.0 m high embankment. In this study, the sediment transport for two cases were computed: 1) the existing stream conditions, and 2) under the investigation of the effect of sabo facilities on sediment transport by eliminating the check dam and the channel works.

There are no hillside landslide data at the upstream reach or river-bed erosion data throughout the reach. Therefore, this study has the following assumptions: the sediment is mainly supplied by the river-bed erosion in this calculation and estimate the critical erosion depth of the river-bed material based on numerical results.

There are no rainfall or runoff data at the reach's upstream end, too. Therefore, the upstream boundary inflow water discharge was estimated, based on the rainfall data of the drainage area. The maximum hourly precipitation was 58.0 mm in the September 1961 debris flow hazard. A rainfall intensity of this value is chosen, which yields 0.50m^3/sec at the reach's upstream end, using the rational formula with a drainage area of 0.05 km^2 and a runoff coefficient of 0.60. Such inflow water discharge is supplied constantly, and then sediment concentration, c_{in} is assumed to be 5 % by volume for convenience.

A finite difference method (the leap-frog scheme shown in Fig. 4) is used. The time and distance were discriminated as Δt= 0.025 seconds and Δx= 5.0 m. The following parameters are required for computation: σ= 2.70 g/cm^3, ρ= 1.17 g/cm^3 (the fine sand concentration into water is 10 % by volume), ϕ_s = 39.0 degrees, d= 5.0 cm and c_*= 0.50.

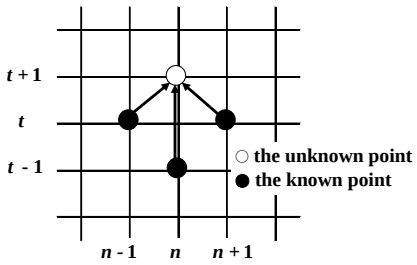

Fig.4 Schematic diagram of leap-frog scheme

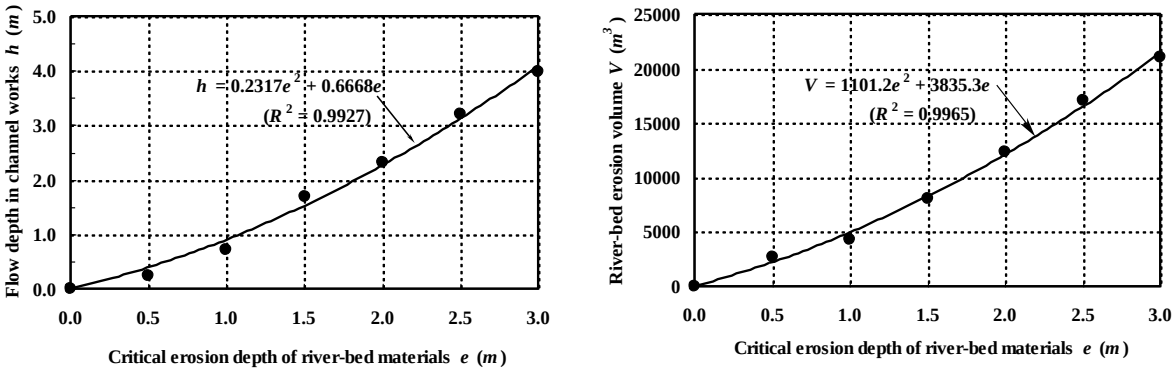
RESULTS AND DISCUSSIONS

Existing Stream Conditions

Figure 5(a) shows the relationship between the critical erosion depth of the river-bed material and the flow depth in the channel works based on the numerical analyses with existing stream conditions. Figure 5(b) shows the relationship between the critical critical erosion depth and the total erosion.



(a) Relationship between critical erosion depth of river-bed material and flow depth in channel works

(b) Relationship between critical erosion depth and total erosion volume

Fig. 5 Estimation of scale of debris flow at Ohzedani River

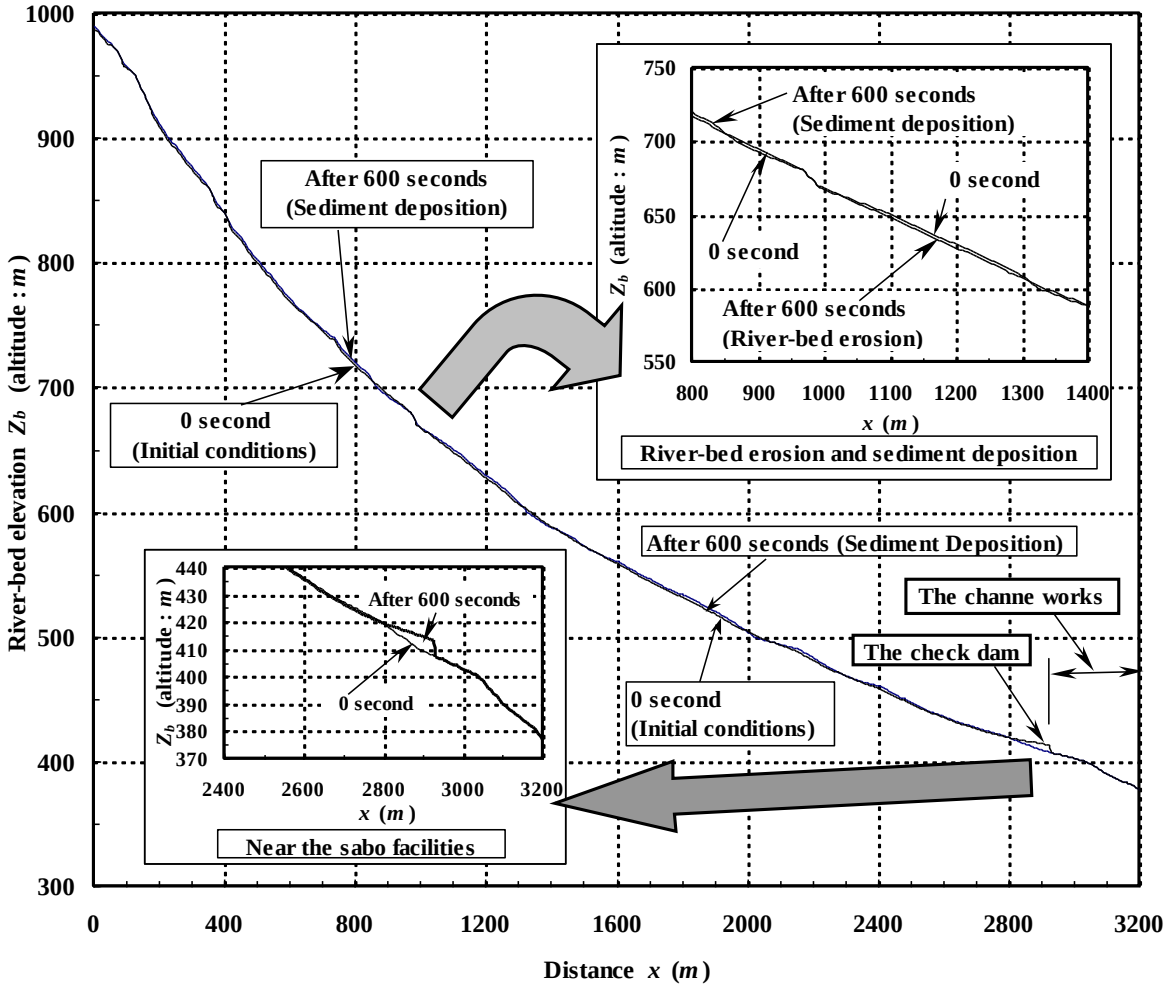


Fig. 6 Comparison of river-bed profiles between initial condition and calculation result after 600 seconds with water supply

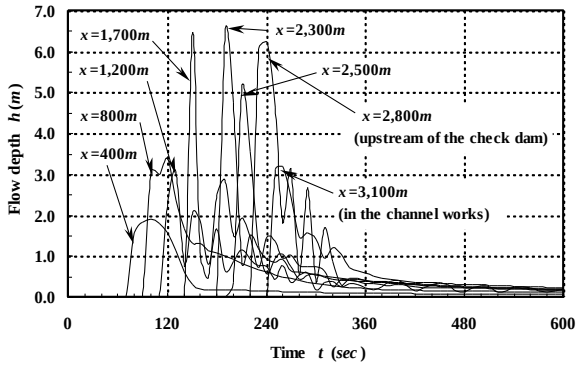
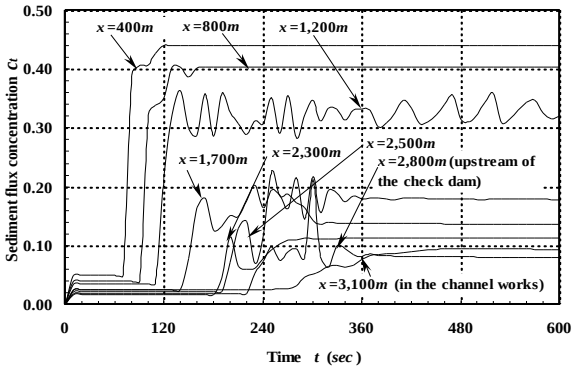
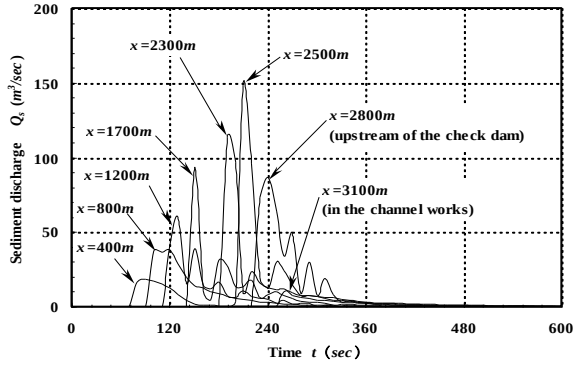


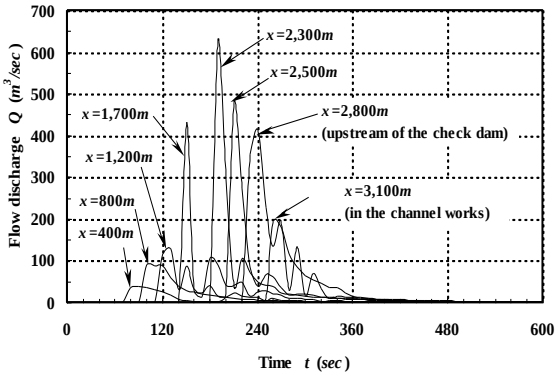
(a) Temporal changes of flow depth



(b) Temporal changes of sediment flux concentration



(c) Temporal changes of sediment discharge



(d) Temporal changes of flow discharge

Fig.7 Temporal changes of debris flow characteristics rates: existing stream conditions

As shown in Fig. 5(a), when the critical erosion depth is shallower than about 2.5 m, the flow depth in the channel works is less than 3.0 m (it equals the embankment height of the channel works). Then the torrent doesn't overflow its banks.

As shown in Fig. 5(b), when the critical erosion depth is 2.5 m, the total erosion volume of the river-bed material is about 17,000 m^3. For the above reason, the scale of the debris flow at Ohzedani River is evaluated (the critical erosion depth and the total erosion volume of river-bed material).

Figure 6 compares the river-bed profiles between the initial condition and the calculation result after 600 seconds with a water supply when the river-bed's critical erosion depth was 2.5 m. Figures 7(a), (b) , (c), and (d) show the temporal changes of the flow depth, the sediment flux concentration, the sediment discharge, and the flow discharge of the sediment-water mixture at the cross-sections; x=400 m, x= 800 m, x=1,200 m, x=1,500 m, x=1,700 m, x=2,300 m, x= 2,500 m, x= 2,800 m (the upstream of the check dam) and x= 3,100 m (the downstream of the check dam and in the channel works).

The debris flow formed quickly after the water supply and the flow discharge increased several orders of magnitude more than the inflow water discharge (x= 400 m in Fig. 7(d)). The debris flow eroded the river-bed from the upstream end to the check dam's upstream (near x= 2,800 m) except the sediment deposition near x=800m (t= 600 seconds in Fig. 6) and the flow depth and discharge increased rapidly by entraining the river-bed material into the debris flow (x=1,700 m and x=2,300 m in Figs. 7(a), (c) and (d)). The sediment flux concentration at the upstream reach is very high, and the flow has debris flow characteristics in this region: x= 400 m, x= 800 m and x=1,200 m in Fig. 7(b)). But they decreased gradually in the midstream reach (x=1,700 m, x=2,300 m and x= 2,500 m in Fig. 7(b)), because the river-bed slope is milder, and the river-width is wider than the upstream reaches.

The debris flow front arrived up stream of the check dam after about 220 seconds with a water supply of x= 2,800 m (Fig. 7(a)), and the sediment began to be deposited on the check storage. The deposition height of the dam height was about 5.0 m,

and the sediment deposition volume on the check storage was about 4,700 m^3 after 600 seconds with a water supply of t= 600 seconds (Fig.6). The debris flow characteristics rate decreased sharply at the cross- section with the check dam due to the change of the transport mode from the debris flow into a conventional water flood with bed-load (x=3,100 m in Figs.7(a)～(d)). The total volume of the sediment-water mixture and the sediment alone, which arrived at the reach's downstream end after 600 seconds with the water supply, was about 10,000 m^3 and 950 m^3, respectively.

Evaluation of Debris Flow Control Using Sabo Facilities

The influence of sabo facilities on sediment transport can be investigated by evaluating the numerical results obtained by varying the initial conditions of the sabo facilities in the river reach. Figures 8(a), (b), (c), and (d) show the temporal changes of the rates of the debris flow characteristics at the cross-sections: x= 2,500 m, x= 2,800 m (upstream of the check dam), and x= 3,100 m (in the channel works) where the check dam and the channel works are eliminated. In these figures, broken lines illustrate the results by the existing stream conditions shown in Figs 7(a), (b), (c), and (d).

Based on these figures, if there is no sabo facility in the reach, the flow depth and flow discharge would amount to about 9.0 m and 360 m^3/sec at x= 3,100 m, respectively. In this calculation, a river-width of x=3,100 m was input as 6.0 m which is the same width of the channel works, and narrower than the local actual condition. Therefore, the torrent will actually overflow its banks near Kofune village. The channel works fix the flow path very well and provide much protection against debris flow flooding. The total volume of the sediment-water mixture and the sediment alone, which arrived at the reach's downstream end after 600 seconds with the water supply, was about 22,000 m^3 and 2,000 m^3, respectively. Therefore, sabo facilities satisfactorily reduced the sediment transport. Sediment deposition reduced the sediment transport, decreased the flow depth and flow discharge, and varies the sediment transport mode.

Fig. 8 Temporal changes of debris flow characteristics rates where sabo facilities are eliminated

CONCLUSIONS

In this paper, the characteristics of sediment runoff and the effects of debris flow control using sabo facilities were discussed, which was based on a numerical simulation and obtained the following interesting results.

1) The scale of debris flow at the Ohzedani River, which was evaluated to be the erosion volume of river-bed material, was about 17,000 m^3. The debris flow discharge increases by several orders of magnitude compared to water, and the sediment transport rate varies with river-bed slope and river width.

2) A check dam is quite effective to reduce sediment transport by depositing sediment on the check storage. The flow path is fixed very well with the channel works that provide much protection against debris flow flooding.

3) The proposed numerical method can reproduce actual sediment runoff processes in a mountain torrent where such sabo facilities as check dams or channel works are constructed. Predicting sediment runoff characteristics is useful and yields valuable results for the evaluation of debris flow control using sabo facilities. Such careful estimates are crucial because the erosion depth of river-beds affects these numerical results.

Faculty of Engineering and Architecture, Rajamangala University of Technology Isan, Thailand

ABSTRACT

Bottom ash (BA) and calcium carbide residue (CCR) are waste by-product form the Mae Moh power plant in Lamphang, and acetylene gas factory in Nakhon Pathom, respectively. This study investigated the possibility of using binder (B) which is a mixture of BA and CCR in order to improve the compressive strength of soft Bangkok clay. The variable used in this study is the SC: B ratios of 90:10, CCR : BA ratio of 70:30, 80:20, 90:10 and 100:0, water content of 1LL, 1.5LL and 2LL (LL is liquid limit of soft clay), and water to binder (W/B) ratio of 1. The 7-day total unit weight and 7-day unconfined compressive strength (UCS) of sample was evaluated. The test results show that the 7-day total unit weight of SC stabilized with CCR and BA samples increases slightly as the BA content increases for all water content because of lower specific gravity of BA. the compressive strength of soft Bangkok clay stabilized with calcium carbide residue and bottom ash tends to increase as the BA content increases because of the pozzolanic reaction resulting in the formation of calcium silicate hydrate (CSH).

Keywords: Soft Bangkok Clay, Calcium Carbide Residue, Bottom Ash, Compressive Strength

INTRODUCTION

The development of infrastructure (road, foundation, and bridges) on soft Bangkok clay has problems. This soil has high water content from 60-130 %, liquid limit is close to the water content which 70-120 % and plastic limit from 20-45 % [5] Ground improvement techniques have been employed to stabilize soft soil over the past three decades such as prefabricated vertical drain (PVD) [20], [6], grouting [21] and deep mixing (DM) [12]-[16]. The DM method has been used worldwide including Thailand, China, Sweden, Japan and Singapore. The cement column has previously been mixed with soft clay and cement. However, the use of conventional Portland cement will result in a large carbon footprint since the production of 1 ton of Portland cement releases about 1 ton of carbon dioxide [9].

Calcium Carbide Residue (CCR) an industrial waste generated from acetylene gas production, has a high calcium hydroxide [Ca(OH)2] content. CCR has been used as a binder to develop green stabilized pavement materials [7-11] and non-bearing masonry units [20]. Phetchuay et al. [21] and Arulrajah et al. [22] have recently used CCR for stabilization of natural soil and Construction and Demolition materials in pavement applications [23].

Bottom ash (BA) is a aluminosilicate-rich materials which is a by-product from electrical manufacturing factory, Mae Moh, Thailand. Chemical compositions of bottom ash is essentially the same as the fly ash which is the main aluminosilicate-rich material [30]. However, the compressive strength of BA was lower than that of fly ash because of larger particle size [31].

This study investigated the possibility of using binder (B) which is a mixture of BA and CCR in order to improve the compressive strength of soft Bangkok clay.The variable used in this study is soft clay:binder, CCR:BA ratio, water content, and water:binder ratio. The 7-day unconfined compressive strength (UCS) of sample was evaluated.

MATERIALS AND METHODS

Materials

Soft clay (SC)

Soft clay was collected at depth of 5-8 m from Khlong Toei, Bangkok, Thailand. Total unit weight (γ_t) = 15.97 kN/m^3, Specific gravity (Gs) = 2.68, Liquid limit (LL) = 63.93%, Plastic limit (PL) = 25.49% and Plasticity index (PI) = 38.44. Soft clay was classified as clay high plastic (CH) according to Unified Soil Classification System (USCS).

Bottom ash (BA)

Bottom ash (BA) is a by-product from electrical manufacturing factory Mae Moh, Lampang, Thailand. The chemical compositions of bottom ash are shown in Table 1. The sum of silica (SiO_2), alumina (Al_2O_3), and ferric oxide (Fe_2O_3) was 65.69% and Calcium

Oxide (CaO) was 21.76%. The BA can be classified as class C according to the standard ASTM C618 [1].

Calcium carbide residue (CCR)

CCR was collected from Sai 5 Gas Product Co., Ltd, Thailand. The CCR was oven-dried at 100 ºC for 24 h and was then passed through a No. 40 sieve (0.425 mm). The specific gravity is 2.32. The chemical composition of CCR is summarized in Table 1, indicating it has a very high CaO content of 75.96%.

Table 1 Chemical composition of BA and CCR

Chemical composition (%)	BA	CCR
SiO_2	36.33	9.81
Al_2O_3	13.71	4.64
Fe_2O_3	15.65	2.03
CaO	21.76	75.96
SO_3	10.15	2.58
K_2O	1.5	N.D.
TiO_2	0.54	1.86
LOI	N.D.	3.12

Mixing proportions

The soft clay was prepared at water content of 1LL, 1.5LL and 2LL (LL is the liquid limit). The SC:binder (CCR and BA) was fixed at 90:10. The water:binder ratio was 1. The CCR:BA ratios were 100:0, 90:10, 80:20, and 70:30 by total weight. Firstly, the CCR, BA, and water were mixed for 2 minutes and then these mixture was added into the SC and mixed for about 3 minutes. Next the homogeneous sample was moved into a cylinder diameter of 36 mm and height 72 mm and cured at room temperature for 24 hours. After that the sample was removed from mold and then wrapped with plastic and store in room temperature. Compressive strength of soft Bangkok clay stabilized with calcium carbide residue and bottom ash at curing 7 day was evaluated by unconfined compressive strength (UCS) according to ASTM D2166 [3]

RESULTS AND DISCUSSION

Total Unit Weight of Soft Bangkok Clay Stabilized with Calcium Carbide Residue and Bottom Ash

Figure 1 shows 7-day total unit weight of SC stabilized with CCR and BA at different LL. The 7-day total unit weight of SC stabilized with CCR and BA samples increases slightly as the BA content increases for all water content because of lower specific gravity of BA. For example, The 7-day total unit weight of SC stabilized with CCR and BA samples at LL=1 was 16.05, 16.43, 16.52 and 16.81 kN/m^3 for BA content of 0, 10, 20 and 30%, respectively. The water content has an effect on the 7-day total unit weight of SC stabilized with CCR and BA samples. The 7-day total unit weight of SC stabilized with CCR and BA samples reduces as water content increases due to high porosity from water.

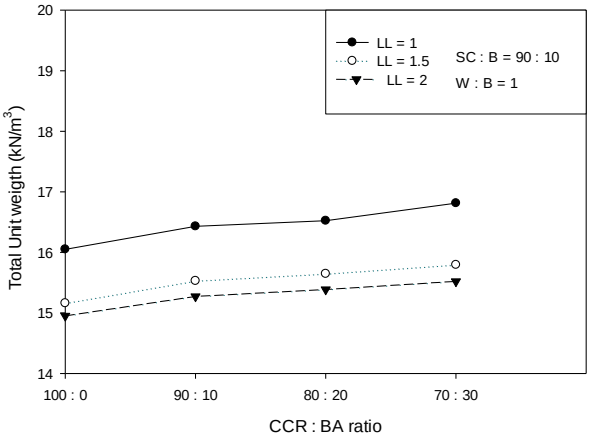

Fig. 1 7-day total unit weight of SC stabilized with CCR and BA at different LL

Compressive Strength of Soft Bangkok Clay Stabilized with Calcium Carbide Residue and Bottom Ash

Figure 2 shows 7-day compressive strength of SC stabilized with CCR and BA at different LL. It was found that the 7-day compressive strength of SC stabilized with CCR and BA increases as BA content increases. This is because Ca (OH_2) from CCR can react with Si and Al form BA, resulting in the formation of calcium silicate hydrate (CSH). The 7-day compressive strength of SC stabilized with CCR and BA decreases as water content increases. For example, The 7-day compressive strength of SC stabilized with CCR and BA samples at CCR:BA of 70:30 was 177.16, 42.97 and 34.76 kN/m^2 for water content of 1LL, 1.5LL and 2.0LL, respectively. The maximum 7-day compressive strength of SC stabilized with CCR and BA samples was found at CCR:BA of 70:30 and water content of 1LL which offers maximum 7-day compressive strength of 177.16 kPa. Table 2 illustrated standard deviation (SD) of SC stabilized with CCR and BA at different LL. The SD of SC stabilized with CCR and BA

ranged from 0.3 to 8 kPa. This low SD values confirmed variation of results.

CONCLUSIONS

The paper investigated the possibility of using a binder material which is a mixture of Bottom Ash (BA) and Calcium Carbide Residue (CCR). The experiments were conducted only for one Soft Clay to Binder ratio, SC:B ratio of 09:10 at various CCR to BA ratios, CCR:BA of 70:30, 80:20, 90:10 and 100:0 at water content of 1LL, 1.5LL and 2LL (LL is liquid limit of soft clay), and water to binder (W/B) ratio of 1. The outcome of the research indicate that the total unit weight of SC stabilized with the binder increases slightly with increasing the water content, the compressive strength increases with increasing the BA content.

EXPERIMENTAL STUDY ON BEHAVIOUR OF VERTICALLY LOADED PILED RAFTS RESTING ON SATURATED CLAYEY GROUND

Lua Hoang[1, 2] and Tatsunori Matsumoto[1]
[1]Faculty of Geosciences and Civil Engineering, Kanazawa University, Japan; [2]Thuyloi University, Vietnam

ABSTRACT

When designing piled raft foundation (PR) on clayey ground, it is necessary to understand time-dependent behaviour of the foundation because stresses and strains in clayey ground will change for a long time after the construction, due to consolidation processes. This paper, therefore, aims to investigate long-term behaviour of PRs through small-scale physical modelling. In the experiments, the model ground was prepared by consolidating a slurry mixture of Kasaoka clay and silica sand. The model foundations consisted of a square raft having a width of 125 mm and 4 or 9 piles having a length of 150 mm. For the loading test of PR, vertical load was increased by multiple steps and each load step was maintained to observe the long-term behaviour. The experimental results show that, the piles effectively suppress the settlement of the foundation for relatively smaller loads. In primary consolidation stage, the pile resistance increases while the raft resistance decreases with elapsed time. This is caused by the dissipation of pore water pressure and the corresponding increase of effective stresses of soils below the raft base. In secondary consolidation stage, the resistances of both the raft and piles are stable while creep settlement continues. In general, the PR with 9 piles reduces settlement significantly, compared to the 4-pile PR.

Keywords: Piled raft, Clayey ground, Experiment, Consolidation, Pore water pressure

INTRODUCTION

In recent years, there has been an increasing need to construct heavy structures, especially in urban areas. To support these structures, piled raft (PR) is a favourable foundation type because of its cost effectiveness and safety, as both raft and piles share the load together.

Behaviours of PRs in clay have been investigated in many researches. In most of these researches, numerical methods were used to solve the behaviour. Physical modelling of PRs in clay subjected to vertical loads were carried out in a few researches ([1], [2] and [4]). These experiments aimed to investigate immediate behaviour of PRs until the end of construction, disregarding long-term behaviour after full construction load was achieved. However, if a PR is located on saturated clayey ground, the foundation will continue to settle for a very long time after the construction, due to primary consolidation process and creep behaviour of the ground.

Hence, one of the main purposes of this research is to study time-dependent behaviour of piled raft foundations in saturated clay through small-scale physical modelling. In this paper, focuses are placed on the settlement of foundation, and on the change of load sharing by the raft and piles with time due to primary and secondary consolidation processes. Two PRs with different numbers of piles were carried out to investigate effect of pile number on long-time load distribution and settlement of PRs.

EXPERIMENT DESCRIPTION

Model Ground

Preparation of the model grounds

Clay ground was prepared in a cylindrical chamber of height 420 mm and diameter 420 mm. The soil used for the model ground was a mixture of Kasaoka clay powder and silica sand #6.

The model ground was prepared as follows: Firstly, Silica sand #3 was poured into the chamber, and compacted in saturated condition until it reached a high relative density, D_r, of 81% and a thickness of 50 mm for a bottom drainage layer. This drainage layer was considered as a stiff layer. Secondly, in a rectangular basin, Kasaoka clay powder and Silica sand #6 were mixed at a dry mass ratio of 1:1 (K50S50). Water was then added to the mixed soil to have a soil slurry with a water content of 1.3 times the liquid limit, *LL*. This soil slurry was poured into the chamber to have an initial thickness of 370 mm. The soil then left to consolidate under its self-weight for two days. After that, a surface layer of silica sand #6 of thickness 10 mm was placed on the clay to provide the top drainage layer, and a rigid circular loading plate was placed on the top. Next, vertical load on the loading plate was increased to consolidate the soil one-dimensionally in several steps, up to a vertical stress of 100 kPa. Each load step was maintained until degree of consolidation reached 90% following the

one-dimensional consolidation theory of Terzaghi. The final load step was kept for an additional week to have higher degrees of consolidation. Finally, the consolidation pressure was removed and the ground was allowed for swelling process in 10 days.

Soil property investigation

T-bar tests, cone penetration tests (CPTs) and unconfined compression tests (UCTs) were carried out immediately after completion of the load test of each model foundation. In each model ground, two T-bar tests (T1 and T2) were conducted at the locations far from the load test area in order to estimate undrained shear strength of the original model ground without effect of loading test of PR. Three T-bar tests (T3, T4 and T5) were carried out at the locations beneath the raft base (loading area) in order to obtain effect of the load test of PR on the ground strength. Three CPTs were also conducted in one experiment. Figure 1(a) shows the locations of the T-bar tests and the CPTs in the two experiments. Undrained shear strength, c_u, was deduced from the average stress acting on T-bar cylinder, $q_{u\ T\text{-}bar}$, or from the cone tip resistance, $q_{u\ cone\ tip}$, using empirical equations [3] indicated in Fig. 1(b).

As for UCTs, soil specimens were sampled from different depths of each model. Locations of the specimens were also selected at, near and far from the loading area (Fig. 1(a)). c_u was estimated from unconfined compression strength, q_u, as $c_u = q_u/2$.

Figure 1(b) shows the distributions of c_u of the model grounds with depth obtained from the three different methods. The c_u varied with depth, and similar results were obtained for both the model grounds. c_u of the original model ground could be expressed approximately by the following equation:

$$c_u\ (\text{kPa}) = 9\ (\text{kPa}) + z\ (\text{mm}) \times 0.04\ (\text{kPa/mm}) \qquad (1)$$

To obtain other properties of the model grounds, laboratory soil tests such as oedometer, Atterberg limits, density and water content tests were conducted, and the results are summarised in Table 1.

Table 1 Properties of the model ground soil

Fig. 1 Distribution of c_u with depth.

Model Foundations

Model piles used in this study were ABS (Acrylonitrile Butadience Stayrene) solid bars (Fig. 2(a)) having a diameter D of 10 mm and a length L of 150 mm. Young's modulus E_p and Poisson's ratio ν of the model piles are 2920 N/mm^2 and 0.406, respectively. In order to measure axial forces along each pile, strain gauges (SGs) were attached on the pile shaft at 4 different levels as shown in Fig. 2(a). Model raft was a square aluminium plate with a thickness of 12 mm and a width of 125 mm (Fig. 2(b)). The raft could be regarded as rigid.

In the experiments, the foundation models included unpiled raft (UR), single pile (SP), 4-pile pile foundation (4P-PF) and 9-pile pile foundation (9P-PF).

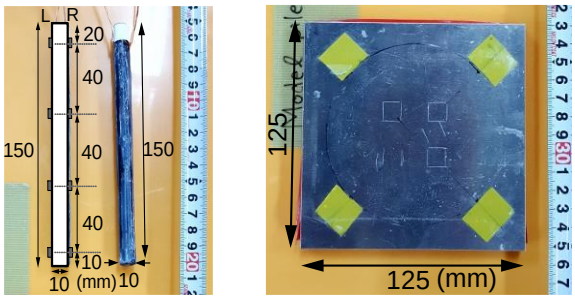
Figure 2(c) and (d) show the dimensions of the pile foundation models. Both the pile foundations (PFs) had the same centre-to-centre pile spacing, s of 3D.

Test Procedure

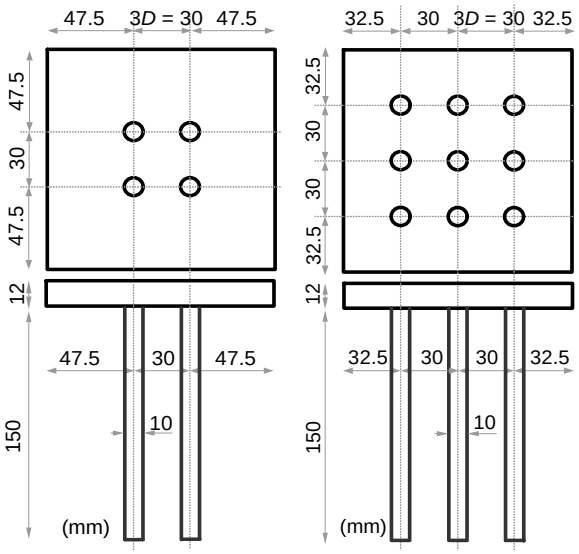
Figure 3 shows the set-up of an experiment. The loading system in the experiment included an air cylinder to apply constant vertical load, a load cell to measure the applied load and 4 dial gauges to measure settlements of the foundation. One pore water pressure transducer and one earth pressure cell were installed at the centre locations of the raft base.

Prior to the load test of PFs, vertical static load tests on single pile and unpiled raft in undrained

condition were carried out to obtain bearing capacity of each element and to determine the magnitude of the vertical load to be applied on the piled rafts.



(a) Model piles and locations of SGs (b) Model raft



(c) 4P-PF (d) 9P-PF

Fig. 2 Model piles, raft and pile foundations.

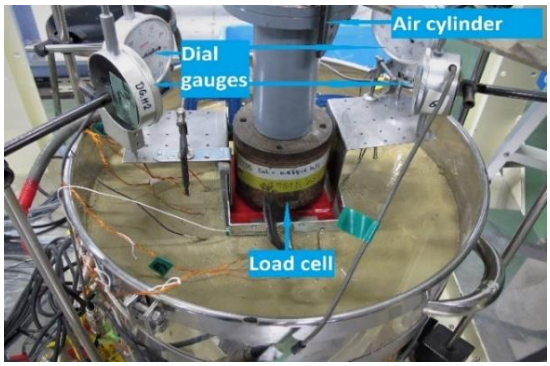


Fig. 3 The set-up of an experiment.

As for the load tests of the pile foundations, the piles were firstly jacked into the ground one by one with a centre-to-centre pile spacing, *s*, equal to 3*D*. Thereafter the raft was placed on the pile heads with a gap of around 5 mm from the raft base to the ground surface, and vertical static loading of the pile group (PG) was conducted in a displacement-controlled manner. The PG changed to piled raft (PR) after the raft base touched the ground surface. In the piled raft condition, vertical load was increased by 4 steps on 4P-PR and 5 steps on 9P-PR in a load-controlled manner. Each load step was maintained for a reasonable time to obtain the long-term behaviour of the foundation.

EXPERIMENTAL RESULTS

Bearing Capacity of Single Pile and Unpiled Raft

Figure 4 shows the results of vertical load tests of the single pile (SP) and the unpiled raft (UR). The bearing capacity of UR and SP were about 2100 N and 100 N, respectively. The sum of bearing capacity of UR and 4 times of a SP or 9 times of a SP was 2500 N or 3000 N, respectively. Based on these results, the load steps applied on the 4P-PR were determined to be 750 N, 1250 N, 2000 N and 2500 N respectively, corresponding to 30% (Factor of safety F_S = 3.3), 50% (F_S = 2), 80% (F_S = 1.25) and 100% (F_S = 1.0) of the predicted total bearing capacity. For 9P-PR, the same 4 load steps were applied in order to compare with 4P-PR. One more final load step, P = 3000 N, corresponding to 100% of the predicted capacity of 9P-PR was additionally applied.

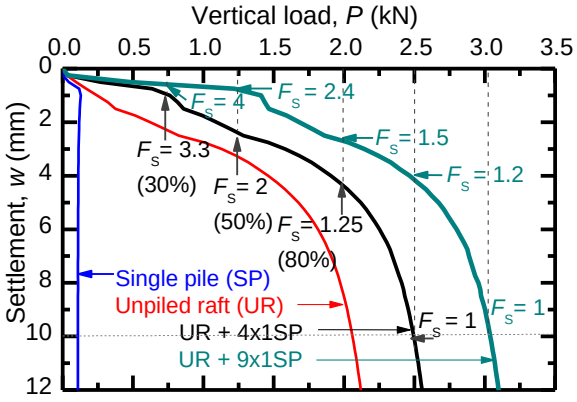

Fig. 4 Load settlement relations of SP and UR.

Settlement and Pile Respond in PR Condition

Immediate behaviour - the time of increasing load

Figure 5(a) shows the relationship between the applied load, *P*, and the settlement, *w*, of the 4P-PR. Figures 5(b), 5(c) and 5(d) are zoom-ins of the periods of increasing load of the first 3 steps of the 4P-PR. Figure 6(a) shows the change of excess pore water pressure (PWP) and settlement with whole experimental duration of the 4P-PR. Figures 6(b), 6(c) and 6(d) are zoom-ins of the periods of increasing applied load of the first 3 steps. Figures 7 and 8 are the corresponding results of the 9P-PR.

It is noticed that the authors do not zoom-in the remained load steps due to the space limitation.

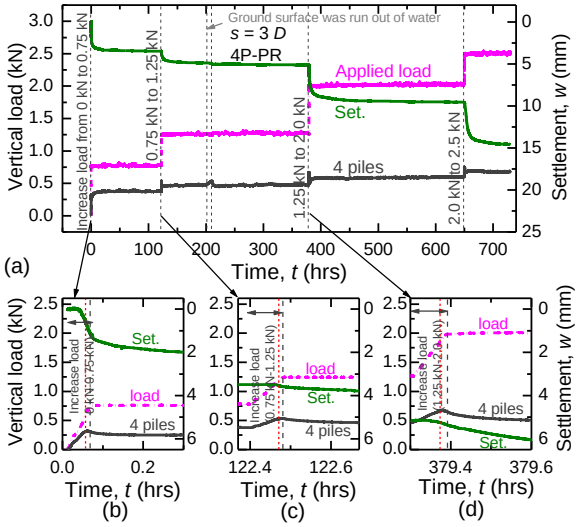

Fig. 5 Changes with time of load and settlement of 4P-PR: (a) full-time of loading test; (b), (c) and (d) zoom-in the duration of increasing the applied load.

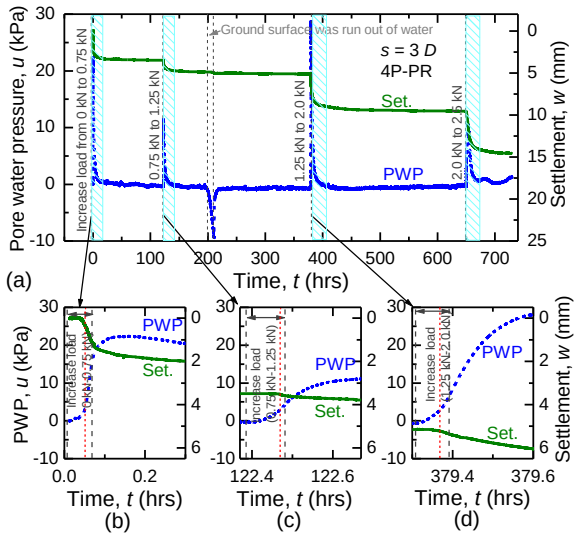

Fig. 6 Changes with time of PWP and settlement of 4P-PR: (a) full-time of loading test; (b), (c) and (d) zoom-in the duration of increasing the applied load.

Let us focus first on the results of the 4P-PF. It should be noted that the bearing capacity of a single pile was around 100 N. The applied load, P = 750 N, in the 1st loading step was less than 9 times of the bearing capacity of a SP, and almost a double of 4 times of the bearing capacity of a SP.

Figure 5(b) shows that, at early stages of increasing load, the increase of the settlement was minor. The reason for this phenomenon is that, when the initial small loads were applied, the resistance of piles increased rapidly to support the load, and the increase of pile resistance was almost equal to the increase of the applied load.

Hence, the piles effectively suppressed the settlement of the foundation in this stage. The foundation then started settling under undrained condition while the pile resistance increased to a peak in this loading stage. After the pile resistance reached the peak, the settlement of the foundation continued rapidly, and pile resistances reduced. The raft load is obtained as the difference of the applied load and the pile resistance.

Let us look at Fig. 6(b). It is clearly seen that PWP started increasing when the undrained settlement started, and PWP increased sharply after the pile resistance reached the peak. The measured results also indicated that when the PWP reached the peak, the pile resistance decreased to a lowest value in this loading stage. Similar trends were measured for the other loading stages (Figs. 5(c), (d) and Figs. 6(c), (d)).

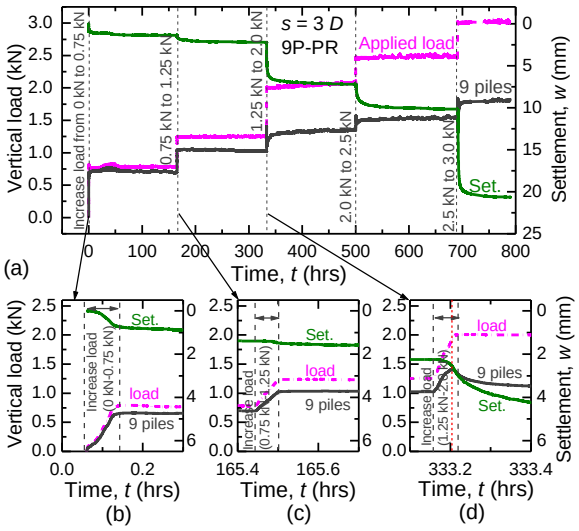

Fig. 7 Changes with time of load and settlement of 9P-PR: (a) full-time of loading test; (b), (c) and (d) zoom-in the duration of increasing the applied load.

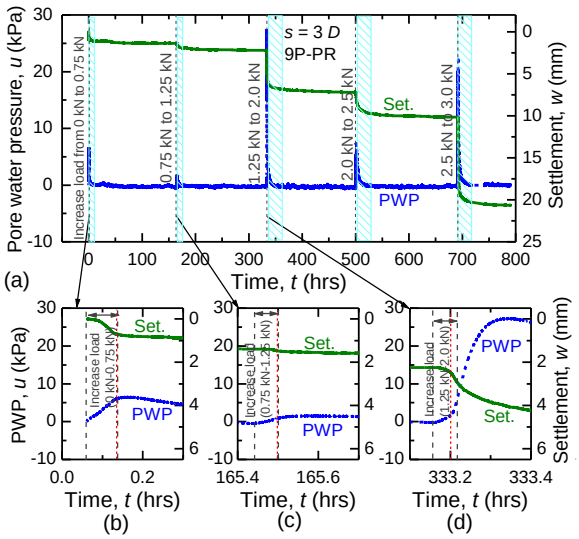

Fig. 8 Changes with time of PWP and settlement of 9P-PR: (a) full-time of loading test; (b), (c) and (d) zoom-in the duration of increasing the applied load.

Let us turn to the results of 9P-PR. Comparing the results of 9P-PR with the results of 4P-PR, in the 1st (Fig. 7(b)) and 2nd (Fig. 7(c)) loading steps, the settlements of 9P-PR were much smaller (about a half of 4P-PR) and the reduction of pile resistance after reaching the peak did not occur. Figures 8(b) and 8(c) also indicate that the increments of PWPs beneath the raft base of 9P-PR were quite small in these stages. The reason for the differences is that the 9P-PR had larger number of piles, therefore the applied loads were mainly carried by the piles in these loading stages.

In the 3rd, 4th and 5th load steps where P was sufficiently large compared with the bearing capacity of 9 times of a SP, the results of the 9P-PR clearly have similar trends to the results of 4P-PR.

It is interesting to notice that in both the foundations, the peak pile resistances increased with increasing the applied loads. For example, the peak pile resistances, in the four load steps of P = 0.75, 1.25, 2.0 and 2.5 kN, were 0.32, 0.53, 0.68 and 0.75 kN for 4P-PF, and 0.66, 1.02, 1.42 and 1.57 kN for 9P-PF, respectively. For 9P-PR, when the applied load increased to 3 kN, the resistance of the 9 piles reached a peak of 1.85 kN which was a double of the resistance of 9 single piles. The increase of the pile resistances with increasing the applied loads is caused by increase of effective stresses in the ground, which will be explained in the next section.

Long-term behaviour - primary consolidation stage

The PWP dissipated after increasing the applied load and returned to the steady state. These time durations could be regarded as primary consolidation stages (highlighted areas on Figs. 6(a) and 8(a)). It is seen from these figures that the settlement rates in the primary consolidation stages were proportional to the dissipation rates of the PWP, and considerable parts of settlements occurred in these stages.

The changes of load sharing with time of 4P-PR and 9P-PR are shown in Fig. 9(a) and Fig. 10(a), respectively. Fig. 9(b) is a zoom-in of the first load step, and Figs. 10(b) and 10(c) are zoom-ins of the first and the third load steps, respectively. Figs. 9(b), 10(b) and 10(c) clearly show that, during the primary consolidation stages, the load supported by the raft decreased while the load supported by the piles increased with the elapsed time. The magnitude of the increment of pile resistance during the primary consolidation stage was roughly proportional to the increment of PWP during the load increasing stages. Hence, this phenomenon is caused by the consolidation process of the ground. The dissipation of the PWP causes the corresponding increase of the effective stress in the ground, resulting in the increase of pile resistances. Similar trends were measured in the other load steps.

Let us look back at Fig. 1(b), in which c_u of the model grounds with and without effect of the loading tests of PRs were presented.

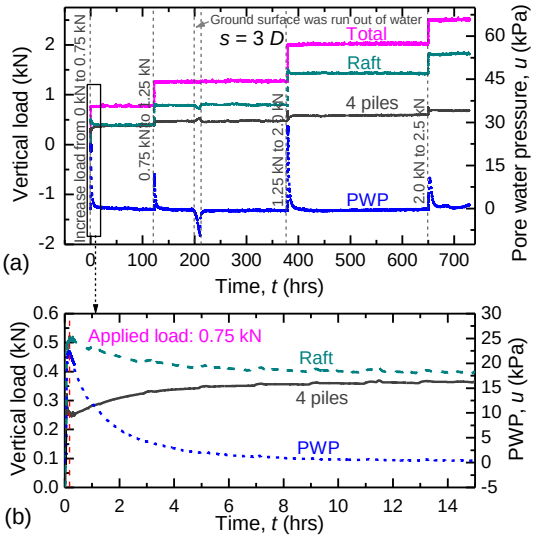

Fig. 9 Load transfer with time of 4P-PR: (a) full-time; (b) zoom-in of the first loading step.

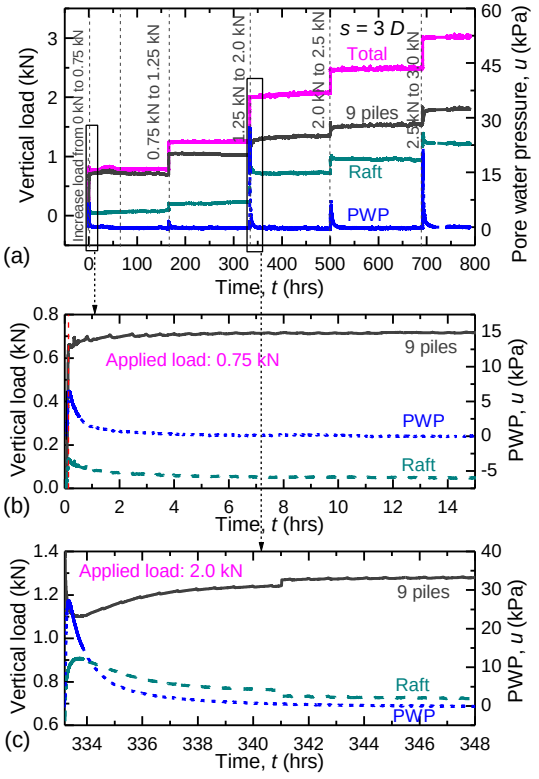

Fig. 10 Load transfer with time of 9P-PR: (a) full-time; (b) and (c) zoom-ins of the first and third loading steps, respectively.

It is clearly seen from the figure that, after the load test of PRs, within a depth of 190 mm from the raft base (≃ 1.5 times of the raft width), c_u was higher at the raft edge areas (T3, T4 and C03) and was highest at the centre area of the raft base (T5), in comparison with the original state (T1 and T2, C01 and C02). Furthermore, c_u beneath the centre of the raft base was much greater than c_u of the original ground within a

depth of 75 mm for the 4P-PR, and of 150 mm for the 9P-PR. For deeper depths, the difference of c_u between the loading area and the original area became smaller with increasing depth. The results indicate that the area affected by loading of 9P-PR was deeper than that of 4P-PR. The results of UCTs also presented similar trends. Therefore, it is clear that the consolidation process increased the ground strength and stiffness.

Long-term behaviour - secondary consolidation stage

After the primary consolidation stages, the foundation continued to settle due to the creep phenomenon of the ground. This phenomenon was seen clearly from Fig. 6(a) for 4P-PR and Fig. 8(a) for 9P-PR. Here let us define the creep settlement index, C_{cs}, as follows where B is the raft width:

$$C_{cs} = \mathrm{d}(w/B)/\mathrm{d}(\log t) \quad (2)$$

In 4P-PR, C_{cs} for the 4 load steps of P = 0.75, 1.25, 2.0 and 2.5 kN were 0.00057, 0.0014, 0.0017 and 0.0165, respectively. The corresponding values for 9P-PR were 0.0005, 0.0021, 0.0118 and 0.0083. For the applied load of 3.0 kN, C_{cs} of 9P-PR was 0.0162. Basically, C_{cs} became larger as larger load was applied.

Load Distribution in Piled Raft Foundations

Figure 11 shows the proportions of loads shared by the raft and the piles with elapsed time in cases of (a) 4P-PR and (b) 9P-PR. Please notice again that the raft resistance includes the uplift force due to PWP.

In both the foundations, the proportion of the load supported by the raft decreased in the primary consolidation stages meanwhile the opposite trend was seen in the proportion of the load carried by the piles. This is due to the dissipation of the PWP at the raft base as described in the previous section. In the all secondary consolidation stages of 4P-PR, the proportions of loads shared by the raft and the piles were stable with time, although the creep settlement of the foundation continued. For the secondary consolidation stages of 9P-PR, the proportion of the load supported by the raft increased slightly in the 1st and 2nd loading stages, in which the applied load was mainly carried by the piles. In the 3rd, 4th and final load steps, the trend of load sharing of 9P-PR became similar to the trend of 4P-PR.

In general, the proportion of the load supported by the raft increased with increasing the applied load, and the raft supported considerable parts of the applied load at relative larger loads.

It is interesting that, at the final stages, the measured results show that, the average load supported by each pile in both the PRs (175N for 4P-PR and 195N for 9P-PR) are much higher than the bearing capacity of a single pile (100N).

(b) 9P-PR

Fig. 11 Load sharing ratio with time in the PRs.

CONCLUDING REMARKS

In this paper, long-term behaviours of PR models in a saturated clay was investigated through a small-scale physical modelling.

Main findings from this study are as follows:

(1) Piles effectively suppressed the settlement of the foundation for relatively smaller loads.
(2) Stresses from the raft base cause consolidation of the ground. Consequently, the effective stresses in the ground increase, resulting in the increase of the pile resistance.
(3) After the primary consolidation stages, the creep settlement continued, the loads supported by both the raft and the piles were stable.
(4) The proportion of the load supported by the raft increased with increasing the total applied load.

COMPRESSIVE STRENGTH OF LATERITIC SOIL IMPROVED WITH BAGASSE ASH AND CALCIUM CARBIDE RESIDUE

Nuttapol Triamcherdtiwong, Cherdsak Suksiripattanapong, Jaksada Thumrongvut and Piyathida Yoosuk
Faculty of Engineering and Architecture, Rajamangala University of Technology Isan, Thailand

ABSTRACT

This research aims to study compressive strength of lateritic soil improved with bagasse ash and calcium carbide residue as a non-bearing interlocking blocks. Binder (B) is the mixture of bagasse ash (BA) and calcium carbide residue (CCR). The Bagasse ash is a waste from sugar industry in Nakhon Ratchasima province. The calcium carbide residue is a by-product from the acetylene gas factory in Nakhon Pathom province. This research studied the influence of laterite soil to binder ratios of 90/10, 80/20, 70/30 and 60/40, the CCR:BA ratios of 100/0, 90/10, 80/20 and 70/30 and curing time of 7 days. The compacted sample was 50 mm in diameter and 100 mm in height under modified Proctor energy. The unconfined compressive strength of laterite soil mixed with bagasse ash and calcium carbide residue increased with increasing in curing time. This research enables bagasse ash and calcium carbide residue as a construction material, which reduces the use of cement.

Keywords: Compressive Strength, Bagasse Ash, Calcium Carbide Residue, Interlocking Block

INTRODUCTION

Interlocking blocks are one of the most popular construction materials. In general, the interlocking block production process uses soil, cement and water. The mixture is extruded with a compression machine. [1]. However, the cement production process requires a large energy. (Burning raw materials at a temperature of around 1450 ºC). This process will result in a large carbon footprint since the production of 1 ton of Portland cement releases about 1 ton of carbon dioxide [2].

Calcium carbide Residue (CCR) is a by-product of the production of acetylene gas used in cutting, welding metal and other industries. For the production of acetylene gas in Thailand, it produces CCR about 21,500 tons per year and is constantly increasing and increasing each year [3]. CCR has been used as a binder to develop green stabilized pavement materials [4-8] and non-bearing masonry units [9]. Phetchuay et al. [10] and Arulrajah et al. [11] have recently used CCR for stabilization of natural soil and Construction and Demolition materials in pavement applications [12].

Bagasse ash (BA) is a waste from the burning of sugarcane for electricity. BA is left from the production process in order to produce approximately 424,700 tons of electricity per year [13]. Particles of bagasse ash are large and high porosity. Bagasse ash has main aluminosilicate-rich material which can be classified as Class N pozzolanic materials according to ASTM C 618.

The objective of this research is to study the possibility of using industrial wastes, CCR and BA, to be used as cementing materials. This research studied the influence of laterite soil to binder ratios of 90/10, 80/20, 70/30 and 60/40, the CCR:BA ratios of 100/0, 90/10, 80/20 and 70/30 and curing time of 7 days. The compacted sample was 50 mm in diameter and 100 mm in height under modified Proctor energy. This research enables bagasse ash and calcium carbide residue as a construction material, which reduces the use of cement.

MATERIALS AND METHODS OF TESTING

Materials

Lateritic soil (LS) was obtained from Sikhio District, Nakhon Ratchasima. The specific gravity of LS is 2.72. the liquid limit and the plastic limit of LS are 32 and 21, respectively. This soil can be classified as clayey sand (SC) according to the Unified Soil Classification System (USCS).

Calcium carbide Residue (CCR) was collected from Sai 5 Gas Product Co., Ltd, Thailand. The CCR was oven-dried at 100 ºC for 24 h and was then passed through a No. 40 sieve (0.425 mm). The specific gravity is 2.24. The chemical composition of CCR is summarized in Table 1, indicating it has a very high CaO content of 75.96%.

Bagasse ash (BA) is a waste from the burning of sugarcane for electricity, the Khonburi sugar factory. The chemical composition of bagasse ash was shown in Table 1. It can be seen that the BA has SiO_2 of 70.91 and Al_2O_3 of 4.28, respectively. BA can classified as type N according to ASTM C 618.

Table 1 Chemical composition of CCR and BA

Chemical composition (%)	CCR	BA
SiO_2	9.81	70.91
Al_2O_3	4.64	4.28
Fe_2O_3	2.03	6.61
CaO	75.96	8.91
SO_3	2.58	0.56
K_2O	N.D.	3.48
TiO_2	1.86	N.D.
LOI	3.12	3.28

Sample preparation

The LS mixed CCR and BA sample is a mixture of LS, CCR, BA, and water. Binder (B) is a mixture of CCR and BA. The LS/B ratios were varied at 90/10, 80/20, 70/30 and 60/40. The CCR:BA ratios were 100/0, 90/10, 80/20 and 70/30. Modified Proctor compaction effort in accordance with ASTM D1557-12 was used to compact the LS mixed CCR and BA sample. Next the LS mixed CCR and BA sample was prepared by static compression with a 50 mm in diameter and a 100 mm in height using a cylindrical split mold. Then, the specimens were wrapped in clear vinyl to prevent moisture loss throughout curing. These specimens were subjected to 7-day unconfined compressive strength (7-day UCS) tests with reference to ASTM D2166 at water content of 0.8OWC, OWC and 1.2OWC (OWC=optimum water content).

TEST RESULT

Compaction of Lateritic soil with calcium carbide residue and bagasse ash

Fig. 1 shows the relationship between dry unit weight and water content of LS mixed with CCR and BA at the LS/B ratios of 90/10, 80/20, 70/30 and 60/40 and the CCR/BA ratios of 100/0, 90/10, 80/20 and 70/30. The test results show that the maximum dry unit weight of the LS mixed with CCR and BA sample was 18.03 kN/m^3 at LS/B ratio of 90/10 and CCR/BA ratio of 80/20. This is because LS has a higher specific gravity than CCR and BA. The minimum dry unit weight of the LS mixed with CCR and BA sample was 13.83 kN/m^3 at LS/B ratio of 60:40 and CCR/BA ratio of 70/30.

–

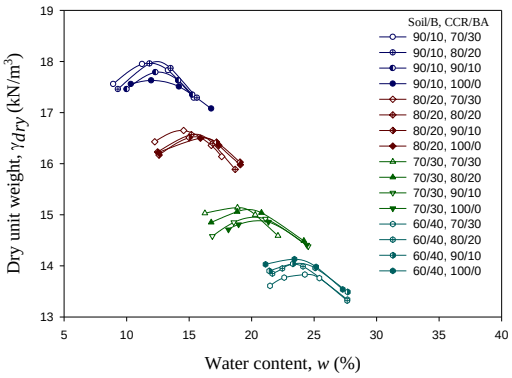

Fig. 1 The relationship dry unit weight and water content of LS mixed with CCR and BA at different LS/B ratios of and the CCR/BA ratios

Compressive strength of lateritic soil mixed with calcium carbide residue and bagasse ash

Fig. 2-5 show the compressive strength of LS mixed with CCR and BA at the LS/B ratios of 90/10, 80/20, 70/30 and 60/40 and the CCR/BA ratios of 100/0, 90/10, 80/20 and 70/30 and water content of 0.8OWC, OWC and 1.2OWC. The test results showed that the compressive strength of LS mixed with CCR and BA at 0.8OWC and 1.2OWC was less than that of LS mixed with CCR and BA at OWC (about 30%). For all LS/B ratios and CCR/BA ratios, the highest 7-day compressive strength of LS mixed with CCR and BA sample was found at LS/B ratio of 90/10, CCR/BA ratio of 70/30 and water content of OWC which offered maximum 7-day UCS of 2.56 MPa.

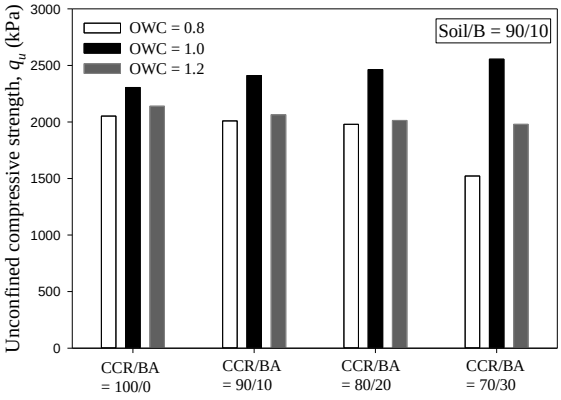

Fig. 2 Compressive strength of lateritic soil mixed with calcium carbide residue and bagasse ash at the Soil/B ratio of 90/10.

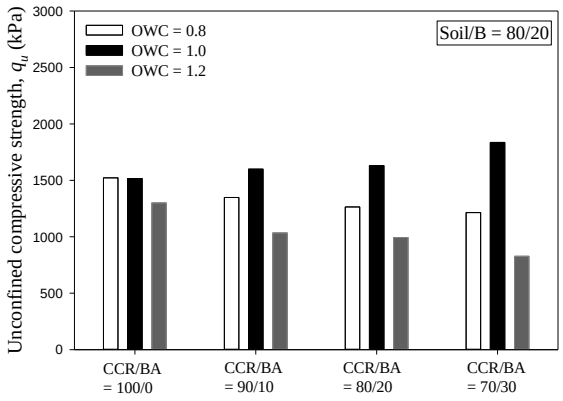

Fig. 3 Compressive strength of lateritic soil mixed with calcium carbide residue and bagasse ash at the Soil/B ratio of 80/20.

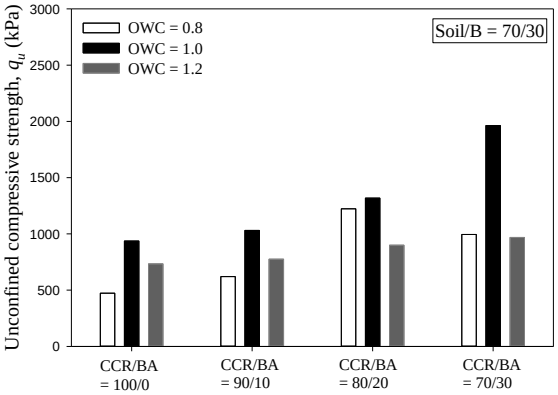

Fig. 4 Compressive strength of lateritic soil mixed with calcium carbide residue and bagasse ash at the Soil/B ratio of 70/30.

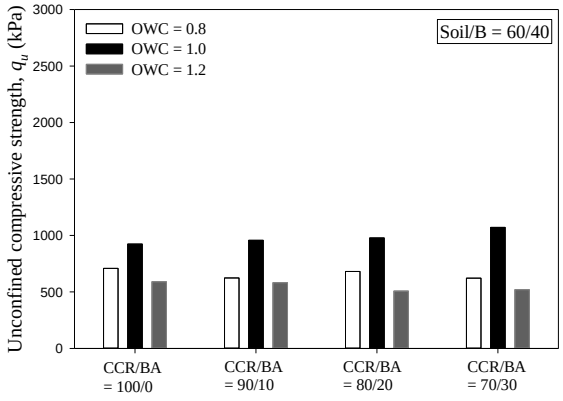

Fig. 5 Compressive strength of lateritic soil mixed with calcium carbide residue and bagasse ash at the Soil/B ratio of 60/40.

CONCLUSIONS

This research evaluated the 7-day compressive strength of lateritic soil mixed with calcium carbide residue and bagasse ash for construction materials. The results of the study can be summarized as follows.

1. The maximum dry unit weight of the LS mixed with CCR and BA sample was 18.03 kN/m^3 at LS/B ratio of 90/10 and CCR/BA ratio of 80/20. This is because LS has a higher specific gravity than CCR and BA.
2. The compressive strength of LS mixed with CCR and BA at 0.8OWC and 1.2OWC was less than that of LS mixed with CCR and BA at OWC (about 30%).
3. The highest 7-day compressive strength of LS mixed with CCR and BA sample was found at LS/B ratio of 90/10, CCR/BA ratio of 70/30 and water content of OWC which offered maximum 7-day UCS of 2.56 MPa and met the TIS 58-2533 standard [11], which specified the compressive strength of more than 2.5 MPa (about 2.4%).

ABSTRACT

Geo-hazards associated with slope failure so far considered to be one of the most devastating natural disasters, responsible for damage to infrastructures and people are buried alive under scratched mass. The extent of slope failure not only limited to the small distance from the source but also extend to several kilometers in the extreme scenario. Rapid urbanization in recent years also increases the fatality and destruction. Numerous researches have been conducted to get the insight of slope failures for rational mitigation of associated hazards. Among several analysis approaches, numerical simulations of the scaled model is a robust way to describe the slope failures realistically. However, large deformation in such geo-disaster problem restricts the use of the traditional grid-based method. Considering the constraints of the mesh-based method, the particle-based method gets the attraction in slope failure analysis owing to its inherent features of capturing large deformation. Smoothed Particle Hydrodynamics (SPH), which was originally developed for astrophysical problems is nowadays used extensively in geo-disaster analysis from small scale model analysis to simulate real disasters. This paper presents a brief review of different numerical modeling in SPH environment for analyzing slope failure, their applications & limitations. The development, validation, application & advantages of SPH method, its numerical errors & treatment procedures, soil constitutive model are also discussed. Findings from various research articles regarding dry & saturated soil, rainfall, earthquake influence on soil mass are also summarized here which supports the SPH method as an appropriate numerical method for analyzing slope instability problem.

Keywords: Slope-stability, Large deformation, Mesh-free method, Smoothed Particle Hydrodynamics, Scaled model

INTRODUCTION

Slope failure associated disasters are considered to be one of the most fatal natural disasters, responsible for the loss of life and property. To be specific, mountainous areas are most vulnerable to this kind of disaster. Among many causes, torrential rainfall and extreme natural hazards like earthquake, volcanic eruptions, and tornados are the prime factors to trigger the failure of slopes. Landslide and debris flows are also the results of slope failures. Extensive research works have been conducted to understand the insight of failures for rational mitigation of such hazards.

Experimental investigation is the traditional way and numerous works have been conducted in the last decade to find the clue behind the slope failure. However, the lack of facilities for large scale experimental investigation is the main drawback of such research methodology and in many cases, difficult to capture the real scenario [1]. Concurrently, development of technological setups, numerical simulations and validation with analytical models have recently become an attractive concern and proven to be useful for most of the analysis of real slope failures and also used to grasp the insight mechanics of slope failures. Application of similarity law also justify the numerical modeling of real instances.

Traditional grid-based numerical tools, especially the Finite Element Method (FEM) is the mostly used numerical framework in geotechnical engineering. The discretization of the entire model into finite elements and simple framework for numerical integration makes it a robust numerical system. However, the distortion of finite elements under large deformation is a serious problem for the convergence of solutions, and to the extreme cases, blow up of the entire system can occur. The large deformation in slope failures, therefore, faces numerical instability by FEM simulation and therefore, an alternative approach is necessary. Pointing this technical difficulties and development of modern computational tools attract the use of mesh-less

numerical methods for large deformation analysis. To date, a number of mesh-less methods have been developed keeping facility to handle large deformation of materials. Hence, the application of particle methods in slope stability analysis is becoming a promising tool in geotechnical engineering. Some notable particle methods are Discrete Element Model (DEM), Discontinuous Deformation Analysis (DDA), Material Point Method (MPM), Smoothed Particle Hydrodynamics (SPH). Among the particle-based methods, SPH is a newly developed numerical framework and extensively used in large deformation analysis. The adaptive and true particle nature with no connectivity between particles make it a robust tool for simulation of large deformation problems. Several frameworks for slope stability analysis with wide variety of material modeling soil water coupling, and continuous development of more sophisticated simulation justify the suitability of SPH in slope stability analysis. Considering the above, a compilation of different aspects of SPH simulation to analyze slope failure is necessary. Therefore, this research paper aims to bring the to-date SPH slope stability simulations in one platform so that further improvement of SPH can be done and also supports this as a prospective tool for future research works. The findings and critical thinking of major approaches are discussed in the subsequent writings.

BACKGROUND OF SPH

SPH was first developed to analyze the astrophysical cases [2], [3] and later extended to the diverse field of engineering, especially free surface simulations [4], [5], viscous analysis [6], [7], heat transfer problems [8] etc. Subsequently, this numerical tool has been applied in the field of geotechnical engineering, more especially, large deformation analysis of geomaterials [9]-[27]. The fundamentals of SPH is written in the following section.

FUNDAMENTALS OF SPH

In the SPH method, the entire computational domain is the summation of discrete points, generally called particles. These particles possess certain volume and mass of the material, having physical properties such as velocity, acceleration, density, stress, etc. The field variables $f(x)$ at any point x of the problem domain are computed by using an interpolation method over its neighboring particles belonging to its influence domain. The basic formulation of SPH is given in the following equation:

$$\boldsymbol{f(x)} = \int_{\Omega} \boldsymbol{f(x')\, W(x - x', h)\, dx'} \tag{1}$$

where, h = smoothing length, W = smoothing or kernel function, x = position vector of particles.

The continuous integral representation shown in Eq. (1) can be further approximated by taking summation over the neighboring particles in the support domain as follows:

$$\boldsymbol{f(x)} = \sum_{j=1}^{N} \frac{\boldsymbol{m_j}}{\boldsymbol{\rho_j}} \boldsymbol{f(x_j)} \mathbf{W}(\boldsymbol{x - x_j, h}) \tag{2}$$

where, $\boldsymbol{j = 1, 2, \ldots, N}$ indicates neighboring particles of the particle at $\boldsymbol{x}$ within the support domain, $\boldsymbol{x}$ = concerning particle, $\boldsymbol{x_j}$ = neighboring particle, $\boldsymbol{m_j}$ = mass of the particle and $\boldsymbol{\rho_j}$ = density of the particle $\boldsymbol{j}$.

The smoothing function $\boldsymbol{W}$ must satisfy unity condition, delta function and compact support condition:

$$\int_{\Omega} \boldsymbol{W(x - x', h)\, dx' = 1} \tag{3}$$

$$\lim_{\boldsymbol{h \to 0}} \boldsymbol{W(x - x', h) = \delta(x - x')} \tag{4}$$

$$\boldsymbol{W(x - x', h) = 0} \text{ when } \boldsymbol{|x - x'| > kh} \tag{5}$$

where, $\boldsymbol{k}$ = constant, $\boldsymbol{kh}$ specifies the non-zero or effective length of the kernel function at point $\boldsymbol{x}$. Interaction between SPH particles takes place when they belong to each other's influence domain. Larger smoothing length generates smoother behavior than smaller smoothing length.

Different types of smoothing kernels are available for implementation into SPH code. These are: Bell-shaped function [2], Gaussian Kernel [3], Cubic Spline function and Super-Gaussian Kernel [28], Quadratic function [29] etc. Cubic spline function, proposed by Monaghan and Lattanzio [28] is the most widely used owing to its convergence nature and the first derivatives of the kernel is also stable and do not cause any unphysical response.

The SPH formulation of the Navier-Stokes equation is written in the following equation:

$$\frac{\boldsymbol{D\rho_i}}{\boldsymbol{Dt}} = \sum_{j=1}^{N} \boldsymbol{m_j}\, (\boldsymbol{v_i^{\alpha} - v_j^{\alpha}}) \frac{\boldsymbol{\partial W_{ij}}}{\boldsymbol{\partial x_i^{\alpha}}} \tag{6}$$

$$\frac{\boldsymbol{Dv_i^{\alpha}}}{\boldsymbol{Dt}} = \sum_{j=1}^{N} \boldsymbol{m_j} \left(\frac{\boldsymbol{\sigma_i^{\alpha\beta}}}{\boldsymbol{\rho_i^2}} + \frac{\boldsymbol{\sigma_j^{\alpha\beta}}}{\boldsymbol{\rho_j^2}} + \boldsymbol{C_{ij}^{\alpha\beta}} \right) \frac{\boldsymbol{\partial W_{ij}}}{\boldsymbol{\partial x_i^{\beta}}} + \boldsymbol{g_i^{\alpha}} \tag{7}$$

Where, σ = total stress tensor, g = acceleration due to gravity, $C_{ij}^{\alpha\beta}$ = stabilization term which is used for removing the tensile instability and stress fluctuation. The expression of total stress tensor can be adopted from an appropriate constitutive model applicable in the SPH framework.

Finally, the governing and constitutive equations are integrated to update the particle positions and their properties. Among several time integration approaches, Leapfrog algorithm is the most efficient one. In this method, the field variables, which include density (ρ), velocity (v), position (x) and stress tensor ($\sigma^{\alpha\beta}$) of a particle are updated by half a time step as follows:

$$\boldsymbol{\rho}_{n+\frac{1}{2}} = \boldsymbol{\rho}_{n-\frac{1}{2}} + \Delta \boldsymbol{t} \left(\frac{\boldsymbol{D\rho}}{\boldsymbol{Dt}}\right)_{\boldsymbol{n}} \quad (8)$$

$$\boldsymbol{v}_{n+\frac{1}{2}} = \boldsymbol{v}_{n-\frac{1}{2}} + \Delta \boldsymbol{t} \left(\frac{\boldsymbol{Dv}}{\boldsymbol{Dt}}\right)_{\boldsymbol{n}} \quad (9)$$

$$\boldsymbol{x}_{n+1} = \boldsymbol{x}_{n} + \Delta \boldsymbol{t} \boldsymbol{v}_{n+\frac{1}{2}} \quad (10)$$

$$\boldsymbol{\sigma}^{\alpha\beta}_{n+\frac{1}{2}} = \boldsymbol{\sigma}^{\alpha\beta}_{n-\frac{1}{2}} + \Delta \boldsymbol{t} \left(\frac{\boldsymbol{D\sigma}^{\alpha\beta}}{\boldsymbol{Dt}}\right)_{\boldsymbol{n}} \quad (11)$$

where, Δt= time step, n defines the present time t, $(n+1)$ defines the onward time $(t+\Delta t)$.

SPH IN LARGE DEFORMATION ANALYSIS

Modeling Dry Granular Flow

A breakthrough in the application of SPH in large deformation geotechnical problem was first developed by Bui, Fukagawa, Sako and Ohno [10] though some works on dealing solid elements were available before this works. Both the cohesionless and cohesive soils were taken into consideration with appropriate constitutive laws. An elasto-plastic Drucker Prager model was chosen to define soil particles and both the non-associated and associated plastic flow rules were implemented in the SPH framework and justified with several applications. The failure of the soil column owing to the instantaneous breakdown of the assembly were simulated and insight of different material types and analysis criteria were evaluated. No significant distortion was found between the experimental and numerical simulation of granular materials; however, instability of simulation was seriously seen for cohesive soils. Therefore, a rational technique was developed to generate additional artificial stress so that clumping and instability of the assembly can be avoided. The results after the treatment were found compatible with experimental results. The works are notable as the detailed discussion of different types of soils and different schemes for keeping numerical stability has been developed and a well-documented reference for the further research works. However, the entire simulation considers dry soil properties and in-situ scenario of saturated soil model is not explicitly discussed. Following the primary development of Bui, Chen and Qiu [13] developed an SPH model in three dimensions to examine the flow of granular materials. The collapse of a 3D soil block was simulated and flow pattern was validated with the conventional flow trace. Besides, granular column collapse of different aspect ratios was simulated and an attempt was made to develop a correlation between aspect ratio and final run-out. Aspect ratio of initial soil mass play an important role in landslide and debris flow dynamics and therefore, the findings on relation between aspect ratio and final run-out length is a notable contribution in large deformation geotechnical simulation. The impact of smoothing length on the outcomes was also critically discussed.

The development of slope stability analysis by SPH has been greatly accelerated with the development of 3D slope simulation of different types of geomaterials [14]. Two 3D slope cases with different geometric configurations are conducted to analyse the final profile, slip surface and distance of soil mass and compared with the 2D cases. Moreover, three slope shapes (concave, common and convex) are taken into consideration. The plastic area of the convex slope is much thicker than the concave one whereas the common slope plastic area takes position between concave and convex. For concave and common slopes, the translational distance of slope toe and the settlement distance of slope top are smaller than the 2D case. An opposite phenomenon is observed for convex slope. The 3D case is found to be more evident for both concave and convex sub-bases. The slip surface of the convex sub-base looks alike down-beating wing with a symmetrical shape whereas it is like a rising wing for concave sub-base. Side slope of concave sub-base and top corner of convex sub-base are subjected to instability and deformation. However, the corner toe of both sub-bases is found safe. This development is worthy to analyse the real landslide and debris flows. However, the effect of constitutive laws and soil-water coupling is not considered in the current paper, which is the major constraints of the practical application of the developed procedure.

Modeling Saturated Soils

However, modelling of slopes considering only dry flow is not realistic all the time. Generally, slope failures are greatly linked with pore water occupied in the void space of soils. Therefore, pore water contribution is a prime requirement for modelling real slope. In the case of slope stability analysis, the Factor of Safety (FoS) of the slope is necessary. Considering this real case, a methodology was developed to simulate slopes with different configurations and FoS was estimated [15]. The unique contribution is that the effective stress concept is applied in the SPH formulation for more realistic modeling. A pore water pressure equation is developed and incorporated in the SPH framework. The simulated FoS was found compatible with the available analytical models for both dry and saturated soils. Not only the

homogenous soils but also the slope with non-homogenous soils were simulated and the entire failure process was captured, which is the main findings of the developed procedure. SPH simulation shows a clear failure surface in the form of a thin layer of plastic strain localization which agrees well with the Bishop's modified method's critical slip surface. Conversely, a little greater slip circle and thicker shear band layer were observed in FEM. FEM simulation was ceased at a definite displacement of soil, while the entire flow process was simulated by the developed model.

Following this work, an improved version of SPH incorporating hydrostatic pore water pressure was developed to simulate an embankment having two sloping sides with a high groundwater table [12]. An investigation was carried out to check the influence of dilatancy angle on the collapse mechanism of the slope. Then, a comparison was made between slip surface outcomes and traditional LEM results (Bishop's modified method). For high dilatancy soils, the new SPH method satisfies somewhat more or less the same slip surface as created by LEM, but for low dilatancy soil, it underestimates the failure zone. It is found that with an increase of dilatancy angle, failure zone and slip surface contracted, and total displacement of the slope increased. The improved model can be applied in general for large deformation as well as post failure simulation and slope stability is considered to be an ideal case to implement the developed idea.

Coupled Analysis

In the earlier works of Bui, Sako and Fukagawa [16], they consider soil and water element separately and the soil-water interaction is given by seepage force following Darcy's law. Erosion of soils owing to the water flow is simulated and a representative solution was found.

Zhang and Maeda [17], [18] conducted a two-phase and three-phase SPH simulation to find out the influence of heavy rainfall on the behaviour and collapse mechanism of slope and levee. The maximum of volume water content was found smaller for drained condition than undrained condition, indicating that undrained condition act as a factor for slope instability. To verify the model test, a simulation process was done in two parts: with and without considering air effect. For the case of no air effect, higher intensity takes less time for saturation than lower intensity which satisfies the model test. Erosion takes place easily on the surface of the slope as the saturation zone starts from the slope model surface. Again, maximum shear strain is found to occur around the center face of the slope. Slip surface is formed for high-intensity rainfall rather than low intensity. Swelling of soil due to pore water pressure is severe for the undrained condition than drainer condition. While considering air effect in simulation, it takes a longer time for saturation than before as air particles slow down the infiltrating process in the soil mass. Again, the concentration of the air bubble is found higher near the slope surface and it rises with time.

Li, Huang, Maeda, Zhang and Saito [19] conducted a two-phase-coupled SPH simulation by using Zhang and Ikariya's proposed constitutive model [20]. Simulation of a dike failure due to water level-up is conducted to evaluate the seepage operation, maximum shear strain distribution, pore water pressure and slip surface. Influence of rainfall intensity using this model is then compared to the model test for 120 min. Soil particle exhibits a very small pressure around the surface, leading to liquefaction. For small intensity (30 and 60 mm/h), dry soil mass is found inside the slope, but soil mass gets nearly fully saturated for high intensity (90 and 120 mm/h). Finally, the proposed model is applied to analyse the failure mechanism of dike due to rainfall with low and high intensities. Simulated infiltrated area and surface infiltration match the model test. The rainfall produces an unsymmetrical shear strain to the symmetric dike. With an increase in rainfall intensity, shear strain enhances. Between the two shear strains, one is developed on the dike surface due to suction reduction. Another one is occurred inside the dike because of seepage force. In the infiltration process, the surface is prone to fail if a shear strain is developed on the surface.

Grabe and Stefanova [21] extended the SPH method to perform a coupled analysis of saturated soils considering deformable soils. An erosional dam break test simulation was performed and a comparison was made with the experimental results of Fraccarollo, Capart and Young [22], [23]. It is observed that sand particles are subjected to sudden hydraulic impact just after the moment of removing a retaining wall, causing the sand particles to get displaced and liquified. The displacement is severe at the dam breakfront. The hydraulic jump and velocity distributions are found consistent with the experimental outcomes.

Earthquake-Induced Slope Failures

A shaking table test was chosen for comparison and verification of the SPH model [24] . The SPH simulation generates horizontal and vertical displacements, velocities, at three defined points like the shaking table test. The displacement, as well as velocity values from the physical test correlate well with numerical results.

Bui, Fukagawa, Sako and Okamura [25] proposed an advanced SPH method in conjunction to conduct the progressive failure of a slope subjected to seismic loading. Laboratory experiments were also conducted for verification of numerical performance. In the experiment, the slope model experiences horizontal seismic shaking by a vibration generation machine. In

simulation, this seismic condition is created by applying seismic acceleration directly to the horizontal of each SPH particle as the external load, rather than shaking. SPH can predict the final slope configuration fairly well with the experimental test. Slope failure in the experiment produced four sliding surface and rotational blocks whereas SPH simulation resulted in one sliding surface and rotational block. Again, the failure surface of the last failure mode of the experiment is found to be a straight line, while the failure surface is almost circular in case of simulation. From the horizontal and vertical displacements of the sliding mass at the center of the slope, it is seen that the experimental results underestimated the simulation performance. Furthermore, the slope failure in the experiment started at about 1s later than that in simulation. Ono [26] conducted a simulation using a Corrective SPH (CSPH) method to investigate the large and discontinuous failure of slope initiated by an earthquake. The vertical stress distribution for three different types of particle spacing (0.5 m, 1.0 m and 2.0 m) is obtained properly. Failure lines emerged at the same place whereas the width of the slip line and displacement of sliding soil mass are different for all cases. The larger the particle spacing, the greater the kernel smoothing length. Larger particle spacing reduces the spatial resolution of the SPH simulation.

CONSTITUTIVE MODELS

In any numerical approach, the most difficult part is to characterize its materials. Even in SPH analysis, a proper constitutive relation is necessary to solve the momentum equation. Mixture of wide range particles, varity of packing's, geological formation, weathering etc. are the main factors which makes soil as most complicated one to model in any numerical scheme. Besides, its behavior under different loading conditions and presence of water in pore space are responsible for complicated behavior of soils. Therefore, actual modeling of soil is practically impossible. Keeping this critical point, researcher developed some simplified model to account for soil particles. A very simple way to consider soils as purely elastic solid models. Based on the experimental results, it is more rational to consider an elastic perfectly plastic model for geomaterials. From this perspective, elasto-plastic Drucker Prager model is one of the widely used rheological models that used in many SPH simulations. The traditional Mohr-Coulomb failure law is also used for some soil modeling. However, the concept of finite strain sometimes restrains the use of those elastic and/or elasto-plastic models. Likewise, real slope failures are mostly saturated flows and contain many other substances with the soil. Defining those complicated scenarios can be done by considering viscous flow model. For rapid flow model, either Newtonian or Dilatant Fluid model is proven to be an effective option. In addition, Bingham model or Hershel-Bulkey model are also used in SPH simulations. Recently, some other models like viscoplastic model, Hyperbolic model, mixture model have gained attraction and implemented in SPH code.

Application of SPH In Real Simulation

Dai, Wang, Huang, Song and Iio [27] conducted a three-dimensional SPH simulation to investigate the post-failure features of two typical landslides in Kyushu Region, Japan induced by the Kumamoto earthquake in 2016. For landslide near the Aso Bridge, the simulated run-out distance (364.5 m) agrees fairly well with the field data (395 m). Again, for landslide in the northeast of the Aso Volcanological Laboratory of Kyoto University, the run-out distance from simulation (70.3 m) was found in good agreement with the surveyed field data (65 m).

Huang, Zhang, Dai and Xu [11] conducted a physical model test along with a soil–water-coupled numerical simulation to analyse flow processes in liquefied soils. Displacements and velocity data matched well for both cases. Finally, a practical example of liquefaction occurred in northern Sweden causing an embankment failure was taken for simulating the actual flow caused by liquefaction. Proposed SPH method closely agrees with the actual field flow mode and distance triggered by liquefaction.

CONCLUSIONS

The success of the SPH method in diversified fields has been witnessed by the world yet many challenges are remaining. This paper summarizes the SPH method for slope stability analysis and it's so-far development and applications in short. Some remarkable works related to the slope failure simulations were discussed critically. However, the scope of this paper limits the detailed discussion of SPH.

ABSTRACT

The rapid urbanization and industrial evolution of the developing cities is commonly seen all over the world. This development results construction of new infrastructures and industries are always in a hurry to build structures at the earliest time. However, lack of proper geotechnical data makes it always cumbersome to get the idea of the sub-surface condition which is a prime importance for the construction of new structures. Considering the current burning scenario, this research work aims to develop a comprehensive procedure for the preparation of soil zonation map by using geostatistical tools. Therefore, the spatial distribution of geotechnical sub soil characterization of chattogram city which is 2nd largest and the major port city of Bangladesh located between 22.13º and 22.28ºN latitude and between 91.45º and 91.54ºE longitude with 168.1 square kilometer divided into 41 wards are presented and soil zonation map at depth 3m to 9m is developed using spatial analyst tools with corresponding SPT -N values. The prepared zonation map is afterward validated with the second data set to implicitly justify the suitability of the proposed approach. Based on the comparison between the predicted and real values, the proposed method provides a better agreement and can be a plausible option for the development of soil zonation map.

Keywords: SPT, soil zonation map, Chattogram, IDW, geostatistical analysis

INTRODUCTION

Before the construction of any structure, the soil condition of the proposed area must be known. Actual geotechnical data, which is an important parameter to develop any kind of civil engineering construction is not only easily available but also expensive due to costly boring technique. Sub-surface investigation, which is to date the sophisticated exploration system, consists of determining the profile of the natural soil deposits at the site, and determining properties of the soils by laboratory analysis [1] . A soil profile and soil zonation maps can be a useful means to understanding and evaluating the suitability and sustainability of the proposed structure because it provides information about soil suitability, soil behaviour for current and future use, basis for monitoring and formulating land use strategies. The soil profile modelling is a useful option to mitigate geotechnical hazards. Having a proper soil profile of a certain location, the geological condition of that location can be known. However, for getting preliminary idea of a proposed site, it is not economical to conduct geotechnical investigation all the time. Rather, an alternative approach needs to be developed to qualitatively justify the geotechnical condition of sub-surface [2]. Experimental and numerical simulation is not justified here to get such rational information's. Besides, statistical formulation based on random data sets can be a good option to prepare spatial distribution of any quantity [3]. For soil profile, SPT, N is a critical parameter and implicitly used to determine the necessary parameters for determination of bearing capacity of soils. Therefore, feeling the necessity of the current situation, an attempt is made to prepare spatial distribution of soil profile by using SPT, N values. Afterward, the prepared map is validated with the field data set. The subsequent sections describe the detailed procedure of the developed methodology.

BACKGROUND AND STUDY AREA

Chattogram, the second largest city and the major commercial hub of a geographically important country named Bangladesh. The Government of Bangladesh is going ahead taking many development projects and some mega projects such as Elevated Express Road, Outer Ring Road, Expansion of Port, and Deep Seaport in Sonadia Island, Chattogram -

Cox's Bazar Railway etc.. Moreover, the city is growing day by day. Based on these developments and extension of the city, a number of infrastructure, buildings and associated structure will be required in coming days. All these leads to our comment that Chattogram is destined to grow and became more populous in the coming days. These will create demand for more housing and utility of infrastructure. To fulfil these needs an important task is geological and geotechnical investigation. Therefore, GIS based SPT-N zonation maps can be useful tools in the subsurface exploration system.

The geographical location of Chattogram Metropolitan Area (CMA) is between 22.13º and 22.28ºN latitude and between 91.45º and 91.54ºE longitude. It has an area about 168.1 square kilometers and divided into 41 wards. The city is located on the bank of Karnaphuli River. The Bay of Bengal is on western side and hilly terrain on the north side adds to its beauty. Much of Chattogram Division is located within the ecological Indo-Burma zone on the boundary of the India plate and Burma Plate. The current population of the city is 8.6 million as per census 2017. The natural harbor of Chattogram has been a gateway to the historic region of Bengal for centuries. It is a prominent trading center and the oldest living city of Bangladesh. In the current research, about 450 soil investigation reports, related to the already constructed/proposed buildings and other engineering structures, were used as the sources from which the geotechnical properties of the soil, for the region of study area (CMA) were extracted. The location of the study area is shown in the Fig.1.

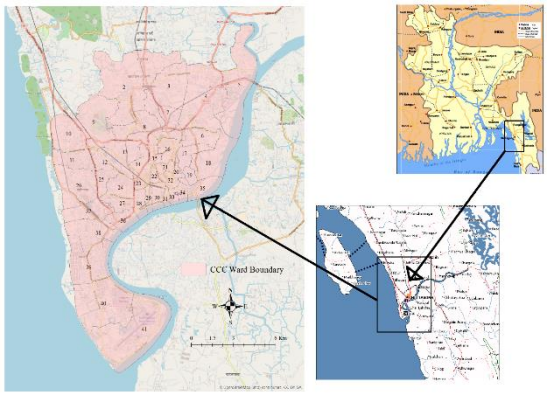

Fig. 1 Study Area.

METHODOLOGY

The data extraction process used in the current study involved in two approaches. The first approach was achieved using the arduous manual extraction of the data from the soil reports available in many different forms and locations. Afterward, statistical model was developed to prepare the spatial distribution of the selected locations.

Several types of interpolation techniques exist for geo-statistical and spatial analysis. Inverse Distance Weighting (IDW) is a interpolation technique, which was used to characterized the Standard Penetration Test SPT-N value to produce the soil zonation maps .The Spatial Analyst Inverse Distance Weighting(IDW) technique was deemed the most suitable method to represent the SPT-N value data in the study area. The mandatory fields in the process include the input point features, the z value (SPT-N) and the output raster name. Therefore, the IDW interpolation method was used to spatially analyze the produced SPT-N value zonation maps. It determines the cell values by using a linear-weighted combination of set of sampled points. The IDW method is a deterministic interpolation technique which creates maps or interpolated surface, based on mathematical formulas and measured points. The interpolation, in turns, predicted the values of the cells at the specific locations that lacked sampled points and also predict unknown attributes at particular location. The main aim of this process was to provide new geotechnical properties in locations where there were no geotechnical data existed.

The GIS methodology, using ArcMap 10.5 formed the second complementary part of the main methodology. This technique can produce zonation maps which can categories the properties of soil in the study area. Standard Penetration Test SPT-N values were used as the key data for the production of the GIS-based soil zonation maps. This procedure enables the interpolation (generation) of the new SPT-N values in the areas that lacked sampled SPT-N data. Such Interpolation is important in any attempt to solve problems or, at a very least reducing the escalating of for soil investigation.

To prepare such soil profile map, a total of 450 sub-soil reports were collected and N values were updated with locations. For current research, the soil profiles at 3m, 6m, and 9m were chosen and N values at those depths were separated and synchronized in GIS environment. Later, IDW technique was employed to prepare spatial distribution of the quantity over the CMA. The location of the collected sampling points are shown in Fig.2.

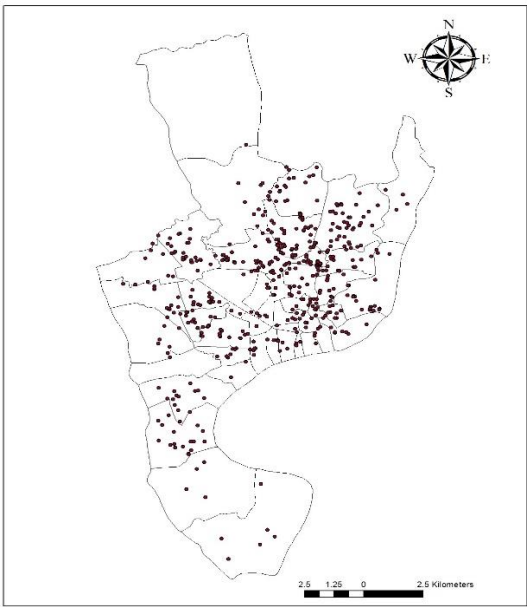

Fig. 2 Distribution of borehole over the city.

RESULTS AND DISCUSSIONS

SPT, N values were represented on the Geographic Information System (GIS) and IDW analysis was conducted to develop the GIS based soil zonation maps. This zonation maps characterized the soil of the CMA area using the interpolation techniques in the spatial analyst in GIS. GIS based SPT-N values zonation maps were obtained for three different depths are 3m, 6m, and 9m.

Zonation map at different depths

Fig 3 depicts Zonation map at 3m depth from existing ground surface. The maximum area covered pink color for which the dominant SPT-N value range is 4 – 10. This range of SPT-N represent very loose to loose type soil and very soft to stiff type soil. The minimum area covered green color for which the SPT-N range is 30 -50 .This range of SPT-N represent dense type soil. The maximum area of Ward No 2,5,10,21,26,30,33,38,39,40 fall in the range of SPT-N ,4 – 10 . This map suggest that at shallow depth the soil are very loose and soft types.

In Fig.4, it is represented the soil zonation map at 6m depth from existing ground surface. The maximum area covered pink and also yellow color. The SPT-N range for pink color 4- 10 for which the soil is very loose to loose, very soft to stiff type soil. Maximum area of ward No 10, 35, 36, 37, 38, 39, 40, 41 fall in this range. The area covered yellow color also remarkable for which the SPT-N range is 10-30, 10 to 30 SPT-N range indicates medium dense, very stiff type soil. This map suggest that from the low N value in the shallow depths towards higher value of N in the deeper depth. The soil is transition from loose to medium dense, soft to stiff type soil.

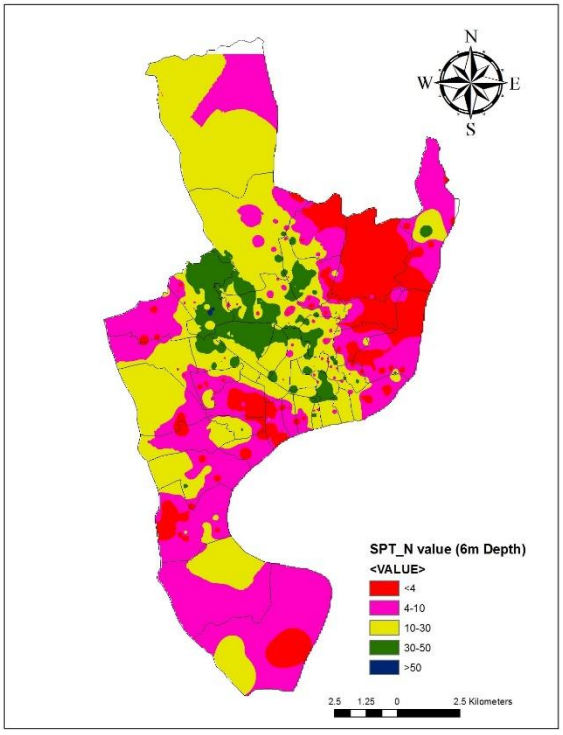

Fig. 4 Soil zonation at 6m depth.

In Fig.5, it is represented the soil zonation map at 9m depth from existing ground surface. The maximum area covered by yellow color. The SPT-N range for yellow color is 10 – 30 for which the soil is medium dense, very stiff type soil. Maximum area of ward No 1,2,26,27,28,29,30,36,38,40 fall in this

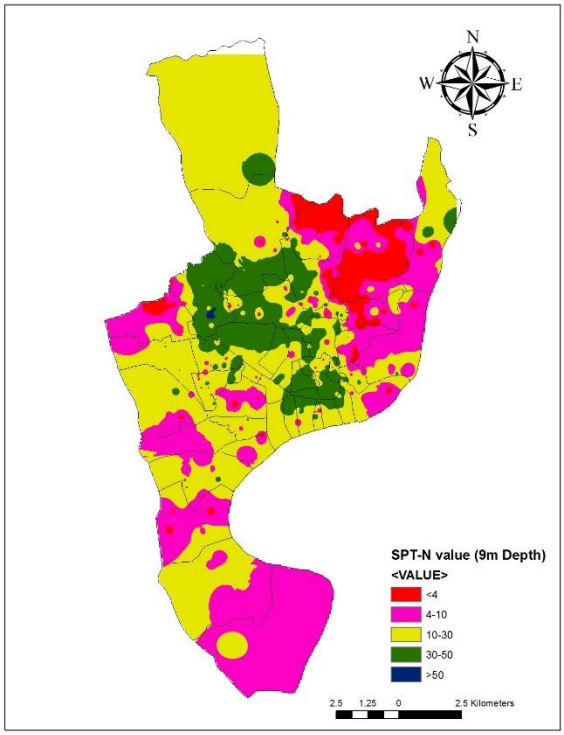

Fig. 5 Soil zonation at 9m depth.

range. The area covered by green for which SPT-N range 30 -50 large then above shallower depth. This map suggest that from the low N value in the shallow depths towards higher value of N in the deeper depth. The soil is transition from loose to dense, soft to very stiff type soil.

Cross-validation Validation curve for zonation map of 3m depth is plotted in Fig.6 between predicted N value and actual N value. The R-squared value of best fit line is 0.827 and considered to be satisfactory for such highly non-linear datasets.

The validation curves for 6m and 9m depths were also plotted in Fig. 7 and Fig.8 , respectively. In all cases, the R-squared value was found nearly 0.8, which portrays quite good match between actual and predicted values.

CONCLUSIONS

Due to scarcity of sufficient borehole location and lack of additional information and also soil variation from place to place, it is difficult to analyze soil profile of Chattogram City Corporation area of 41 wards. The data for the current study were collected from reliable sources related to the already erected building and others engineering structure. The study has two scope, first scope represented soil type, properties of soil, depth and the second scope represented Geographic Information System (GIS), which was conducted to develop GIS-based SPT-N value soil zonation maps. These zonation maps characterized the soil in Chattogram City using the interpolation techniques in the Spatial Analyst in GIS. The soil profile of Chattogram City consists of very loose to loose type soil at shallow depth with lower SPT-N value. A layer of medium dense type soil occurs beneath the loose layer with a higher SPT-N value. Very dense type soil is located underneath this layer with SPT-N value 50 or greater than 50.

The overall result of the study will help in future expansion and development process, construction of infrastructure,general planning, sustainable land use and management. The analyze of the soil beside Karnaphuli river which is the most important river of the city and Bay of Bengal would be helpful for the construction of hydraulic structure or other structure and further development of river and sea shore. The identified hotspot location will help to future development of any civil engineering structure on specified location.

ABSTRACT

Many urban areas in Japan are located on soft ground and there are many buildings with pile foundations. Therefore, when dismantling a building, it is necessary to remove the pile (existing pile) designated as industrial waste remaining in the ground. There is a method of crushing and removing the pile as a method of removing the existing pile, but there is a problem of vibration and noise. Therefore, in many existing pile drawing methods, the outer circumference of the pile is drilled by the steel casing, and the existing pile is pulled out by cutting the boundary between the pile and the surrounding ground. Among them, when pulling out the existing pile that exists diagonally due to the pressure in the soil or the construction failure, it is confirmed that the steel casing follows the sloped pile when inserted into the ground. However, the dynamic mechanism of this phenomenon is unknown because the situation in the ground cannot be observed visually. Therefore, in this study, we will use MPS-CAE simulation to clarify visually and quantitatively the dynamic mechanism along the existing pile in which the steel casing is inclined when inserted into the ground, which occurs in the realization site.

INTRODUCTION

In Japan, with the rapid economic growth, demand for offices and commercial facilities increased rapidly, and construction of high-rise buildings that could effectively utilize narrow land proceeded. However, it is thought that the aging of those structures built in the same period will be concentrated, and that rebuilding demand will increase. In addition, the disaster prevention awareness of the people has been raised by the topic of the Tohoku region Pacific offshore earthquake that occurred on March 11, 2011, and by the Tokyo metropolitan area earthquake, the Tokai earthquake, the Tonankai earthquake, and the Nankai earthquake that are said to have a high probability of occurrence. It is thought that it is increasing the demand for rebuilding of aging structures. Furthermore, it is thought that not only because of deterioration but also because facilities are being reduced due to obsolescence and population decline are factors that accelerate the increase in demand for rebuilding structures.

Many urban areas in Japan are located on soft ground and there are many structures using pile foundations. Therefore, it is necessary to remove not only the existing structure but also the existing piles supporting the structure, in order to newly utilize the land where the existing structure exists. In addition, because existing piles are treated as industrial wastes that are generated as a result of business activities and defined by the Waste Disposal Act, it is a problem to leave them in the ground [1]-[3]. Furthermore, in the land sale transaction and so on, a problem has actually occurred as a “hidden trap”. Therefore, it can be said that removal of existing piles is essential [1]-[3].

As methods of removing the existing pile, there are the method of crushing and removing the pile with a rock auger and the method of cutting out the friction between the pile and surrounding ground by a cylindrical steel casing [1]-[3]. However, in these methods, vibration and noise generated during construction works often become a big problem. Furthermore, in these methods, there are cases where the pencil part and flange at the tip of the pile cannot be removed, which means that industrial waste is left in the ground, so it can be said that these methods also have problems with the environment.

Therefore, pulling out of piles is now being adopted at many sites. At the beginning of the work for pulling out the pile, the outer periphery of the pile is drilled with the steel casing, but at this time the situation in the ground cannot be visually checked, so various examinations have to be carried out to check the inside situation. However, because many on-site surveys cannot be performed in terms of time and money, computer-based simulations can provide a visual and efficient evaluation.

In this study, the authors will clarify the mechanism of the behavior that occurs in the

realization site that the steel casing follows the existing pile when the steel casing is inserted into the ground by verifying the behavior of the ground and the pressure distribution using MPS-CAE [4]-[5].

ANALYSIS CONDITIONS IN MPS-CAE

Outline of MPS-CAE of steel casing drilling

In the case of removing an existing pile work, the inside of the steel casing and its surroundings are filled with muddy water because the water is discharged from the lower part of the steel casing while penetrating the steel casing (see Fig. 1).

In this analysis, the authors set the state that the existing pile area up to the depth of 15,000 mm was filled with muddy water particles, and carried out the analysis to make rotational penetration of the steel casing to the depth of 10,000 mm. In addition, the existing pile in this analysis has a foot protection part at the depth of 16,100 mm or deeper, and the steel casing is not penetrated to the foot protection part at the lower end of the existing pile. The authors will analyze two patterns in which the inclination angle of the existing pile is inclined 0° and 2° from the vertical direction.

Parameter setting for muddy water particles

Table 1 shows the material parameters for the mud water in MPS-CAE. The parameter setting was performed with the mud water to be analyzed as the Bingham fluid. Regarding the density and plastic viscosity, the authors measured the density of the mud collected from the hole of the existing pile at the site of the removing work of the existing pile, and set the plastic viscosity by measurement using a Brookfield's B-type viscometer. In addition, the yield value gives the measurement result 10 Pa of the yield value of drilling mud obtained by measurement with a double cylinder type rotational viscometer from previous researches [1]-[3].

Modeling method of existing pile and steel casing

The existing piles and steel casings were created according to the actual dimensions using 3D-CAD based on the shape of the steel casing used at a certain field site and the removed existing piles. From Figs. 2 and 3, the existing piles in this analysis are existing piles with a foot protection part, and the steel casing is cylindrical. In addition, the steel casing was set as the wall boundary, and the characteristics were determined not by the material parameters but by the contact angle between the liquid and the wall boundary. According to previous researches, the contact angle between water and stainless steel is 45° to 58°, and the analysis results when the contact angle is set to 45° and 58° did not show a large difference.

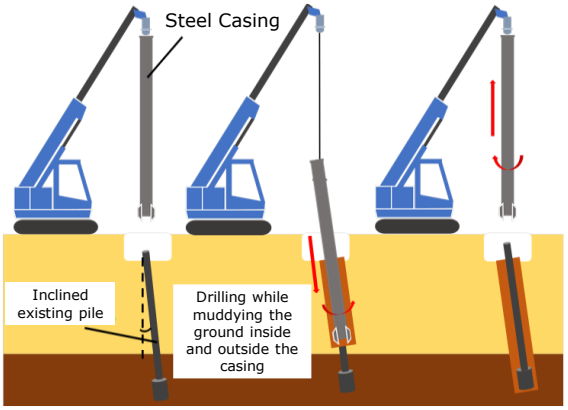

Fig. 1 State of muddy water on the ground

Table 1 Material parameters of muddy water particles

	Density (kg/m³)	Plastic viscosity (Pa·s)	Yield value (Pa)
Muddy water	1200	6.92	10

The authors reproduced steel casing as 50° [6]-[7]. Table 2 shows the penetration speed and rotational speed of the steel casing.

MPS-CAE SIMULATION FOR STEEL CASING DRILLING

Velocity of muddy water particles according to drilling depth

The cross section color-coded by the vertical velocity at the depth of 5 and 8 m is shown in Fig. 4. Particles close to red have velocity components in the vertical upward direction, and particles close to blue have velocity components in the vertical downward direction. From Fig. 4 (a) and (c), in the case of an inclination angle of 0°, particles with similar velocity components are evenly distributed, but from Fig. 4 (b) and (d), in the case of an inclination angle of 2°, the distribution of velocity of muddy water in the vertical direction was confirmed on both sides of the existing pile.

Pressure gradient acting between muddy water particles according to drilling depth

The cross section color-coded by the pressure acting at the depth of 5 and 8 m is shown in Fig. 5. From Fig. 5 (a) and (c), when the inclination angle is 0°, almost the same pressure is received as a whole, and no pressure gradient is generated. However, according to Fig. 5 (b) and (d), when the steel casing is inserted into the existing sloped pile, the pressure increases in the process of narrowing the gap between

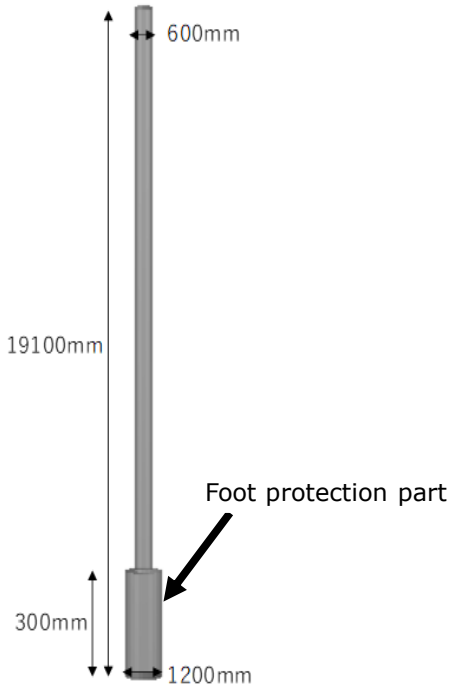

Figure 2 Existing pile

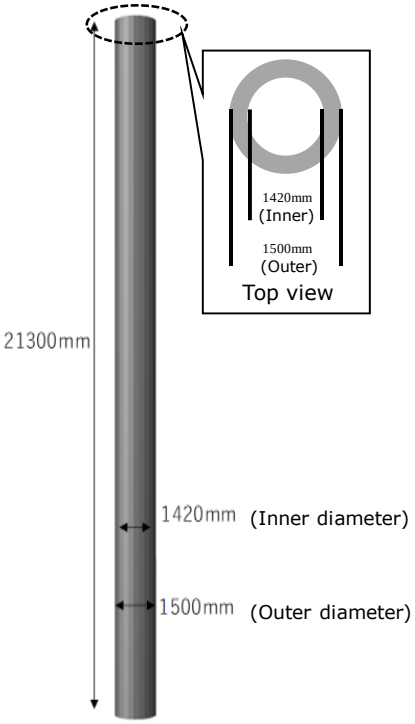

Fig.3 Steel casing

Table 2-Parameters of MPS-CAE steel casing

	Rotational speed (rpm)	Penetration speed (m/min)
Steel casing	15	0.5

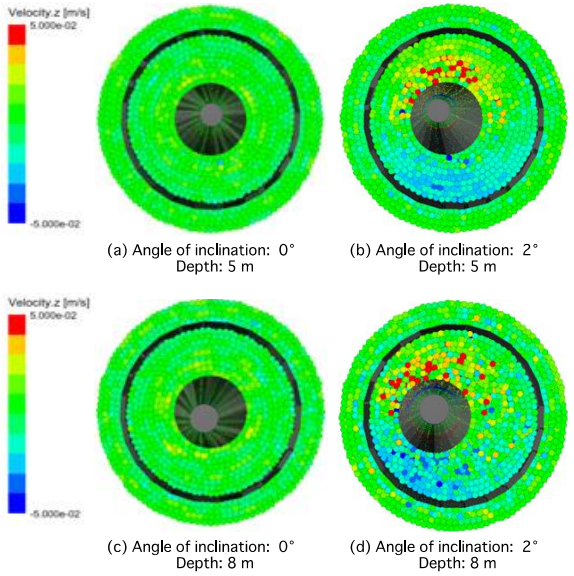

Fig. 4 Velocity of muddy water particles (vertical direction)

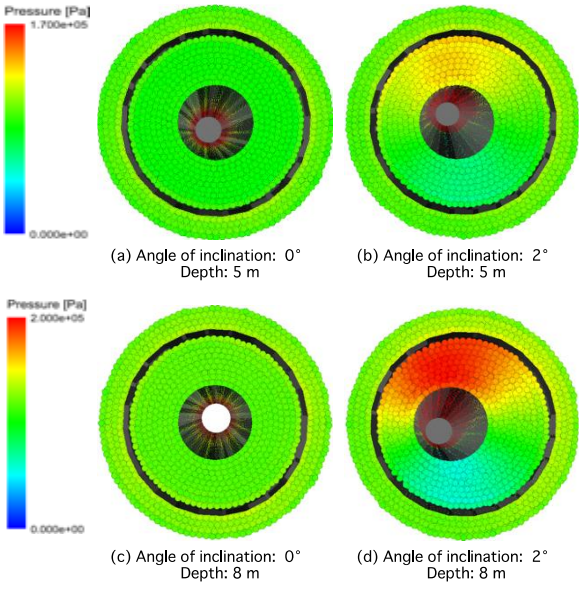

Fig. 5 Pressure gradient of muddy water particles

the pile and the steel casing, and the pressure decreases in the process of widening the gap There is a pressure gradient. It is considered that this is caused by the mud water rotating together under the influence of the rotation of the steel casing.

A co-rotation is a phenomenon in which they (this case is both steel casing and muddy water) move together due to the frictional force generated between the steel casing and the muddy water. From Figs. 4 and 5, when the existing pile is inclined, muddy water particles inside the steel casing show different behavior compared to the case of 0°. It has been

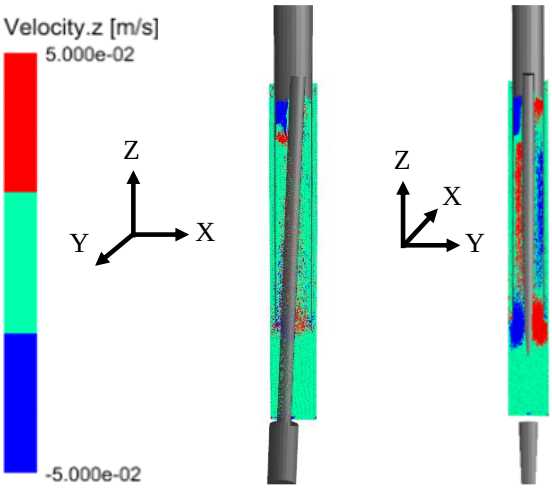

Fig. 6 Vertical velocity of muddy water particles (vertical cross section)

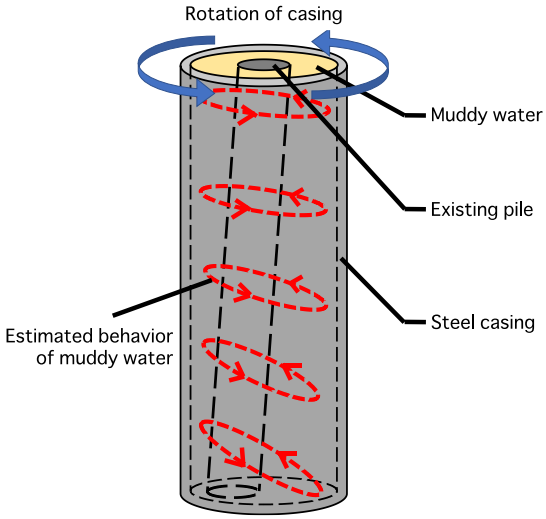

Fig. 7 Estimated behavior of muddy water particles

confirmed that the muddy water particles have a vertical upward velocity at high pressure and a vertically downward velocity at low pressure, in addition to co-rotation by the rotational force of the steel casing. This is due to the fact that the muddy water particles subjected to high pressure try to move in a spiral trajectory toward the released ground surface (upward direction) so that the pressure gradient disappears.

MECHANISM OF STEEL CASING FOLLOWING INCLINED EXISTING PILE

The vertical cross section obtained by cutting the analysis target in the X-Z plane is shown in Fig. 6 (a), and the vertical cross section obtained by cutting in the YZ plane is shown in Fig. 6 (b). Red particles have vertically upward velocity components, and blue particles have vertically downward velocity components. From Fig. 6 (b), it can be understood that the vertical velocity of the muddy water is different on both sides of the existing pile. First, due to the rotation of the steel casing, the muddy water inside rotates together. When the existing pile is inclined, the gap between the steel casing and the pile becomes different as the penetration depth of the steel casing gets deeper, and a pressure gradient as shown in Fig. 5 (b) and (d) occurs. That is, in addition to the rotational speed of the steel casing due to the co-rotation of the steel casing, it has a vertically upward velocity at high pressure and a vertically downward velocity at low pressure, resulting in the pressure gradient of the mud in the steel casing as shown in the figure. As shown in Fig. 7, spiral co-rotation occurs. In addition, the steel casing is considered to be along an inclined pile so that the pressure gradient produced is eliminated.

CONCLUSIONS

In this study, the authors aimed to clarify the mechanism of the behavior of a steel casing along the existing inclined pile confirmed in the field by performing the MPS-CAE analysis. An MPS-CAE analysis was performed by inserting a steel casing into the ground to an inclined existing pile, and the behavior and pressure gradient of muddy water mainly in the casing were visually represented. It was possible to deduce the mechanism of behavior of the casing along the sloped existing pile, which has not been elucidated yet by separating and examining the behavior of the mud particles and the pressure gradient for each depth.

Until now, the co-rotation phenomenon of muddy water has not been captured in a positive image. There are many cases where the existing piles remain in the unhealthy condition as shown in Figure 2.1. If cracks and joints are not properly joined, penetration may occur while rotating the casing, which may further damage the pile. That is, at the time of casing penetration, the lower part of the existing pile is not yet cut off and fixed to the surrounding ground, but the upper part is forced by the rotation of the casing due to the co-rotation of muddy water, resulting in the existing pile Is considered to be in a twisted condition and to be broken. However, in this research, it is concluded that the phenomenon that the casing follows the sloped existing pile cannot occur because the pressure gradient does not occur if the muddy water does not rotate together and the muddy water does not move vertically due to it.

(1) By using MPS-CAE to visually represent the behavior and pressure gradient of muddy water particles in the steel casing, it is possible to simulate steel casing drilling in existing pile drawing-out work.

(2) The phenomenon along the existing pile in which the steel casing is inclined causes spiral co-rotation due to the influence of the pressure gradient of the muddy water in the steel casing, and the steel casing is gradually inclined along the pile in which the pressure gradient disappears.

A STUDY OF THE COMPACTED KHON KAEN LOESS PARAMETER FOR THE DESIGN OF GRAVITY WALL

W. Phimonnok[1], R. Nuntasarn[2] and S. Tirapat[3]
[1,2,3] Faculty of Civil Engineer, Khon Kaen University, Thailand

ABSTRACT

This paper presents the testing of retaining walls on the compacted Khon Kaen Loess by using the physical models. The specification of this research is to compact Khon Kaen Loess in the box size 100x100x100 cm to achieve the dry density of 1.91 t/cu.m, which is the 90% of the maximum dry density by the modified method. Moreover, the moisture content of this compacted Khon Kaen loess was 11.85%. The effective friction angle (ϕ′) and effective cohesion (c′) of this compacted Khon Kaen loess at saturated condition was 29 degree and 12 kPa, respectively. The soil sample was compacted in five layers in the box, and the thickness of each layer was 45 cm. The dry density of each layer was examined by the sand cone method. The retaining the wall, a gravity wall, wherein the size of the 15x30x50 cm, was installed in the box to determine the stability of the retaining wall. The horizontal force was applied by using the pneumatic jack. The weight plate was applied to the top of the retaining wall as a vertical force. The horizontal and vertical movement was measured by using LDVT. The soil- concrete interaction was determined from the relationship between the horizontal pressure and the vertical pressure.

Keywords: Retaining Walls, Compacted Khon Kaen Loess, Physical Models, Soil- Concrete interaction

INTRODUCTION

The structure of Khon Kaen Loess is loose like a honeycomb as classified as silty sand (SM) or clayey sand (SC). The sand grains may be bonded by clay silt or iron oxide (Fe2O3). As a moisture content increases, the bonding between sand grain was destroyed, which causes to loss of the shear strength and collapses suddenly.

Barden et al. [1] studied loess structure by collecting soil samples from around the world. The predominant of loess is sand, whereas clay particles or silt particles or chemical cementing agents like calcium carbonate or iron oxide is the bonding. The cause of collapsing loess can be classified as 3 characteristics.

1. The structure is unsaturated and unstable. Easily to destroyed.
2. Excessive applied stresses destroy the soil structure, which causing subsidence.
3. The increasing of moisture content dissolves the bonding and making void ratio decrease. As a consequence of compact soil.

Collapsible soil always found in arid areas and semi-arid areas. The soil in this climate is mostly unsaturated by deep groundwater level. The moisture content of the soil in the summer season is about 3-5% and in the rainy season is about 10-12%.

Udomchoke [2] found that Khon Kaen loess is collapsible soil with a very severe degree of collapse. Moreover, the shear strength parameters of Khon Kaen loess are decreased when the moisture content is increased.

Gasaluck [3] found that loess is cover in many areas of northeastern Thailand. This loess has a relatively high permeability, which soil moisture content is easily increasing.

Muktabhant [4] present that the color of the soil in Khon Kaen province, especially in Khon Kaen University, is red. With a mixture of fine sandy loam, silt and clay are the caused of windblown as known as loess. The thickness of the soil layer is about 4 - 8 meters. According to USCS, Khon Kaen loess was classified as SM, SC or SM-SC with 13 - 19% of LL, 11 - 14% of PL, 0 - 5% of PI and specific of gravity between 2.60-2.72.

The purpose of retaining wall construction is to prevent lateral movement of soil. Application of retaining walls is in engineering works, such as embankment, excavation work, bridges, and waterproof structures. Das [5] suggested the smallest dimension of the retaining wall as shown in Fig.1.

The failure mode of a retaining wall can be classified into 4 categories, which is overturning, sliding, bearing capacity failure, and deep-seated shear failure, as shown in Figure 2. As the acting force on the retaining wall as shown in Fig. 3, safety factor against overturning about the toe, sliding and the bearing capacity as present in equation (1), (2) and (3), respectively. The minimum factor of safety against overturning, sliding and the bearing capacity is 2, 1.5 and 3, respectively

$$FS_{(overtruning)} = \frac{\sum M_R}{\sum M_O} \quad (1)$$

Where;

$\sum M_R$ = sum of the moments resist overturn about point C

$\sum M_O$ = sum of the moments overturn about point C

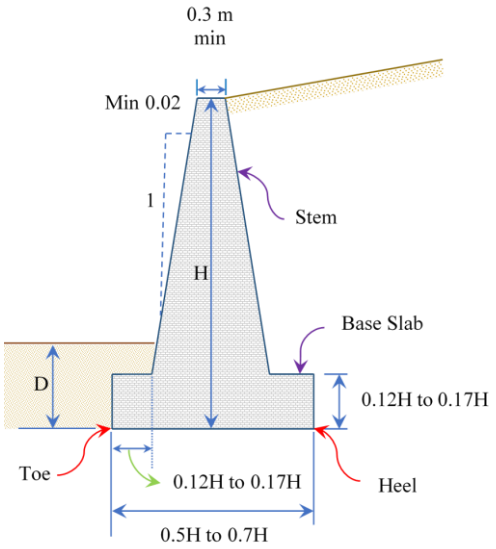

Fig. 1 Smallest dimensions of gravity retaining wall.

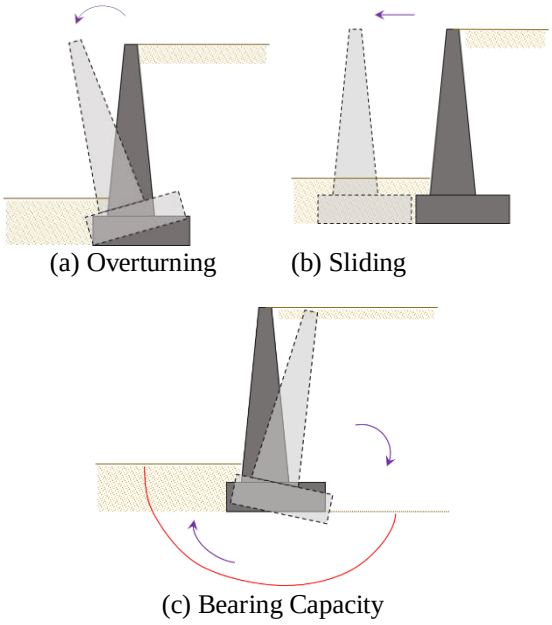

Fig. 2 Failure ode of retaining wall.

$$FS_{(sliding)} = \frac{\sum F_{R'}}{\sum F_d} \quad (2)$$

Where;

$\sum F_{R'}$ = sum of the horizontal resisting forces.

$\sum F_d$ = sum of the horizontal driving forces.

$$FS_{(\text{bearing capacity})} = \frac{q_u}{q_{\max}} \quad (3)$$

Where;

q_u = ultimate bearing capacity

q_{max} = maximum pressures

At present, many projects are using Khon Kaen loess as backfill. Therefore, this study investigates the physical modeling of retaining wall on compacted Khon Kaen loess. The Khon Kaen loess was compacted to 90% of the maximum dry density by the modified method on the wet side. Moreover, the gravity retaining wall is precast concrete.

APPARATUS

Modeling gravity retaining wall was 0.15 m wide, 0.50 m long and 0.30 m high as illustrated in Fig.4. The tank size is 1.0x1.0x1.0 m in width, length, and depth, respectively.

Fig. 4 Model gravity retaining wall.

The loading equipment as shown in Fig. 5 consists of

(1) A pneumatic system controls the horizontal load by using speed as 1 mm/min.

(2) A proving ring was used to measure the horizontal load.

(3) The 4 LDVTs were used to determine the vertical and horizontal displacement

(4) Weight plates were used as vertical loading.

(5) Two soil pressure transducers were used to measure the passive pressure

METHODOLOGY

Khon Kaen loess was determined the basic properties to classify according to [6]. Moreover, the soil-water characteristic curve (SWCC) was examined from the pressure plate. The soil structure and chemical

analysis were determined from scanning electron microscope (SEM) and EDX, respectively. Besides the undrained shear strength of compacted soil was investigated from the direct shear test. The samples to do SEM, EDX, direct shear test and modeling were prepared to compaction 90% wet side of maximum dry density by modified compaction.

(a) soil pressure transducers (b) LVDT

(c) Weight plates

Fig. 5 Apparatus

.

Three vertical loaded were examined to physical retaining wall modeling, which is 100, 200, and 400 kg.

Step I: Khon Kaen loess was compacted 90% of maximum dry density at the wet side in the tank. A soil sample was compacted in 5 layers 9 cm thickness for each layer. Then the dry density was checked by the sand cone method.

Fig. 6 This is preparation of Soil sample

Step II The speed of pneumatic was adjusted to be 1 mm./min.

Step III Two earth pressure cells, the modeling gravity retaining wall, four LDVTs were installed in the tank. The vertical loads applied at the top of the modeling. Then the test was started immediately.

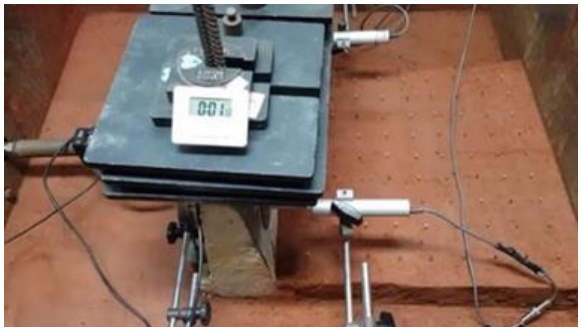

Fig. 8 Test running

RESULTS AND DISCUSSION

The sieve analysis and hydrometer analysis present that the predominant of Khon Kaen loess is sand, whereas silt and clay are the binders, as shown in Table 1. Moreover, the EDX's result, as present in Table 2 showed the high percentage of iron. Therefore, the iron oxide is also the binder. Khon Kaen loess was classified as silty sand (SM) according to [6]. The comparison between disturbed and undisturbed Khon Kan loess was shown in Fig. 9. There are various sizes of the void in both samples. But there is numerous void in an undisturbed sample rather than a disturbed sample. Besides, the structure of the undisturbed sample is flocculated, while the structure of the disturbed sample is dispersed. The test result of the soil water characteristic curve (SWCC) was shown in Fig. 10. there are two air-entry values and two residual points. The first and second air-entry values are 3 and 450 kPa, respectively. Moreover, the first and second residual degrees of saturation are 42% and 16%, respectively.

Direct Shear Test (UU test)

According to the direct shear test as shown in Fig. 11. The total cohesion and the total friction value is 27 deg and 12 kPa, respectively.

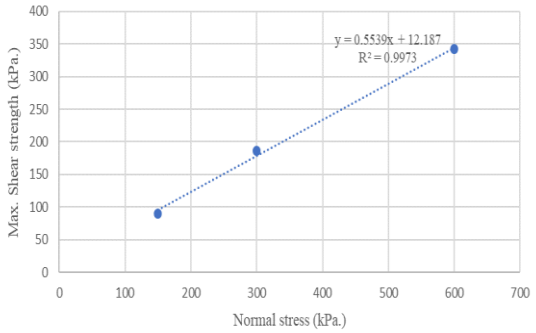

Fig. 11 This is result of direct shear.

Physical Model Test

The relationship between the different active and passive pressure (P_a-P_p) and the vertical displacement, as shown in Fig.12 showed that the retaining wall was uplift and going to overturning. The data of pressure of uplifting were provided in Table3. The retaining wall was going to overturning due to the soil in front of retaining wall cannot be moved anymore. Because of the soil reached passive pressure (the failure). The passive pressure at the uplift point, which read out from earth cell pressure, was quite constant at 2.6 kPa, as shown in Table 3. Therefore, the Rankine passive earth pressure coefficient, K_p, equal to 3.5888. Due to the soil thickness in front of the retaining wall was 7 cm, and the total density was 2.11 t/m^2. Due to the effective vertical stress was 0.72 kPa. The retaining wall was sliding due to the driving pressure (P_d) equal to the active pressure (P_a) minus passive pressure (P_p) and kinetic friction between the base of retaining wall and soil (F_k) as shown in equation (4).

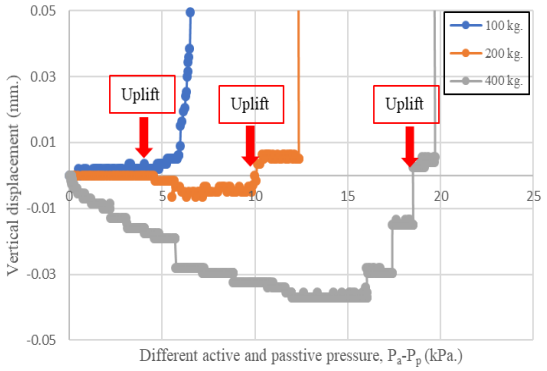

Fig. 12 The relationship between the different active and passive pressure (P_a-P_p) and the vertical displacement.

Table 3 Lateral pressure on the retaining wall at uplift point

σ_v		P_a	P_p	T	FS
kg.	kPa.	kPa.	kPa.	kPa.	
100	13.08	7.92	2.72	5.20	1.26
200	26.16	13.16	2.54	10.63	1.93
400	52.32	18.53	2.53	16.00	2.12

$$P_d = P_a - P_p - F_k \quad (4)$$

Where
P_d = the driving pressure
P_a = the acting pressure
P_p = the passing pressure
F_k = the kinetic friction between the base of retaining wall and soil

Given
T = different pressure between active and passive pressure

Therefore

$$P_d = T - F_k \quad (5)$$

$$T = P_d + F_k \quad (6)$$

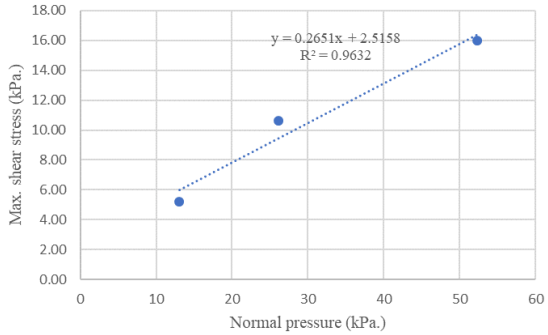

Fig. 13 The relationship between normal pressure (N) and T

The plot between the normal pressure (N) and T as shown in Fig. 13 give a good linear relationship as present in equation (7).

$$T = 2.5158 + 0.2651N \quad (7)$$

Where
N = the normal pressure

Equation (6) equal to (7) therefore

P_d = 2.5158 kPa

And
F_k = 0.2651N kPa
Where $F_k = \mu_k.N$
Hence $\mu_k = \tan(\delta'_k) = 0.2651$
Sine δ'_k = 14.85 deg.

According to the direct shear result, the friction angle (ϕ) equal to 29 deg. Therefore, the ratio between δ_k:ϕ of compacted Khon Kaen loess equal to 0.5.

The passive failure plane, as shown in Fig. 14, presents the failure angle (θ) equal to 31 deg. According to [7], the passive failure planes is (45-ϕ/2). Therefore, the friction angle (ϕ), which was back-calculate from the passive failure plane, is similar to the result of the direct shear test. Moreover, the maximum horizontal movement was 0.07 m or 15.9%strain at failure, as shown in Fig. 15.

All test series was terminated because of overturning. The lateral pressure at the failure shown in Table 4. The maximum factor safety against the overturning was 1.65. According to Table 3, the maximum factor safety against overturning at the uplift point was 2.12, which is over the specification.

Fig. 15 Horizontal movement

Table 4 This is Lateral pressure on the retaining wall at failure.

	σ_v	P_a	P_p	FS
kg.	kPa.	kPa.	kPa.	
100	13.08	12.13	2.72	0.81
200	26.16	15.03	2.90	1.30
400	52.32	23.75	3.26	1.65

CONCLUSIONS

The predominant of Khon Kaen loess is sand, whereas silt, clay, and iron oxide are the binders. The structure of the undisturbed sample is flocculated, while the structure of the disturbed sample is dispersed. The total cohesion and the total friction value is 27 deg and 12 kPa, respectively. According to the physical modeling found that the ratio between δ angle and ϕ angle equal to 0.5.

A STUDY OF THE TENSILE STRENGTH OF VEINS AND ITS INFLUENCE ON ROCK MASS STRENGTH

Nikhil Tukaram Urmale and John Victor Smith
School of Engineering, RMIT University, Australia

ABSTRACT

Rock mass strength models include open discontinuities but typically do not include discontinuities that have been sealed by precipitation of minerals. These veins can represent significant weaknesses in a rock mass yet are not accounted for in most rock mass models. The Warramboo magnetite deposit in South Australia is hosted by a strong gneiss rock mass with a low level of open joints. Veins are relatively abundant throughout the rock mass. The distribution of veins has been analysed from the database of core drilled at the project site. Samples of veins of various mineral types have been collected and tested for tensile strength. Sample strength was measured by direct tension in a Shimadzu 50 kN loading machine. Initial results indicate that the veins do not contribute a significant weakening effect to the rock mass. The test result showed that the veins have a significant tensile strength which varies between 3 MPa to 9 MPa. But the majority of the samples failed in rock rather than on the vein itself. The observed tensile strength values for the veins are not significantly less than the tensile strength of the host rock gneiss.

INTRODUCTION

Deformation of rock commonly creates fractures. The aperture of the fracture can be closed by the precipitation of minerals to form a vein [1]. The influence of open fractures, known as discontinuities, on rock mass strength is well known [1]. Some of the open discontinuities may actually be veins which have become open due to the weakness of the mineral fillings. However, the impact of sealed discontinuities, such as veins, on the strength of a rock mass is usually neglected.

An investigation into the significance of veins and vein-parallel open discontinuities is needed to improve methods of rock-mass strength determination. Veins are common in mineralized systems and have the portiential to create weakness in the rock mass that could affect the stability of excavated slopes and affect the selection of blasting methods. Various studies have been done on the characteristics of vein systems but their effect on the strength of rock masses has not generally been considered. This study will investigate the topic using an extensive drill hole database from the feasibility studies of a major proposed mine in South Australia.

A previous study by one of the authors investigated the role of foliation in the gneiss in forming discontinuities in the rock mass of this deposit [2]. The purpose of the present study is to investigate the potential for veins in the rock mass to represent a weakness that could affect stability of the large slopes of the proposed mine open pits (Fig. 1). For this research, rock core samples were collected from the proposed Warramboo magnetite iron ore mine on the Eyre Peninsula of South Australia. Samples containing sealed veins were tested in the RMIT University laboratory to determine the tensile strength of rock samples with an intact vein. This was done by performing a direct tensile test on all the samples by keeping the orientation of the vein at 90° following methods developed in previous studies [3].

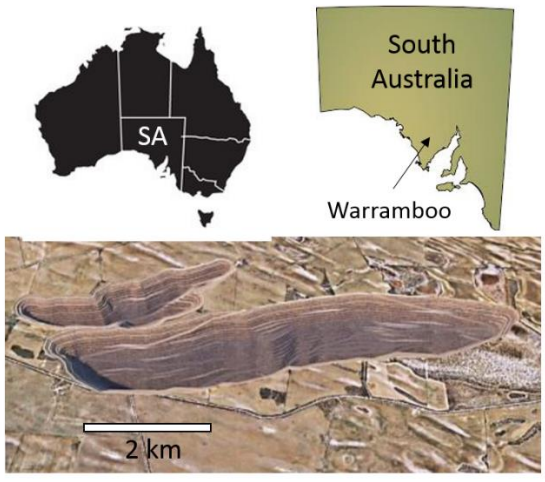

Fig. 1 Location of the Warramboo Iron Project and proposed final pits (Iron Road Limited).

VEINS IN ROCK MASS

The influence of veins and vein-parallel open discontinuities on rock mass strength has been

generally overlooked while significance is predominantly given to open discontinuities such as joints and faults [4]. Most well-known rock mass classification schemes do not recognize veins and vein-parallel open discontinuities as important characteristics influencing the mechanical behavior of a rock mass. The Rock Mass Rating (RMR) system only briefly considers the surface coating of open discontinuities that may be related to the mineralogy of the veins [5]. Similarly, in the GSI and Q rock mass classification systems, only minor attention is given to the texture of vein infilling material and surface characteristics of the discontinuity [6,7]. Although these rock mass classification schemes do consider some aspects of veins in the form of the surface characteristics of open discontinuities, the tensile strength of the mineral infilling in sealed veins is not considered.

VEINS

Veins have been studied in detail for their geological origins and implications for fluid flow through fractured rock. For example, synkinematic quartz veins formed from dissolved minerals transported to growth sites in fractures by the transient pathway created by intragranular, trans-granular and intergranular dilation [8]. Many different vein mineralogies occur and each vein system differs in its formation and therefore each vein may have different mechanical behaviour.

Many experiments have been carried out on veins using techniques such as X-ray diffraction to identify vein minerals and investigate the mechanical behaviour of veins [9]. In another study, triaxial compression stress result showed that an intact veined rock sample behaved differently from the intact rock without veins [4]. It was also observed that the infilling material may have intermediate or even high tensile strength, sometimes higher than the parent rock [10]. If the strength of infilling material is greater than parent rock, then it does not pose a great threat to the stability but when the infill is weaker then it has potential to be a weakness in the rock structure.

Studies have been carried out to find out the relationship between the rock strength anisotropy and vein emplacement. The results showed that the rock mass has greater rock strength in the direction perpendicular to weaknesses such as foliation than parallel to it [11]. The most important study done very recently about veins and vein-parallel open discontinuities significance in the rock mass stability [12]. That study investigated vein characteristics, discrete vein networks, vein thickness, orientation, and mineralogy prior to the triaxial compression testing. It was observed that the vein orientation with respect to the direction of loading was the most important factor for a vein to take part in the fracturing of the rock specimen [12] That study did not explain the characteristics of different vein types and was unable to demonstrate the relation between vein mineralogy, vein thickness, and strength of rock specimens.

Numerous studies have been done to determine the significance of joints and other open discontinuities for rock mass strength but very less research is done to determine the role of veins and vein-parallel open discontinuities in rock mass strength. The role played by veins and vein-parallel open discontinuities in slope stability and underground excavation require further investigation. For this, the tensile strength of veins may play an important role in the strength of the rock mass and, if the tensile strength of the veins is low, may downgrade the overall strength of the rock mass.

VEINS IN THE WARRAMBOO DEPOSIT

In the preliminary stage of this research, an extensive drill hole database from the feasibility studies of a major proposed iron ore mine in South Australia was analyzed. In total, a database of 63 drill holes was studied. Each drill hole ranged from 180m to 700m in length. A detailed study of the core log record database was made. All the discontinuities were recorded alongside comparing them with the photographs of all the core boxes.

Also, a detailed study was done on veins, considering its mineral classification, thickness, and their characteristics whether they are open or sealed. It was observed that there are 21379 discontinuities present in the complete database of which 4307 are veins, which comprises of more than 20% of all the discontinuities observed (Fig. 2).

Chlorite, carbonate, sericite, and quartz were the major infill minerals observed in the veins at 43%, 30%, 12%, and 5%, respectively. Epidote, gypsum, pyrite, hematite, clay, feldspar and limonite were the other minerals observed.

Carbonate and chlorite are most abundant veins and more than 80% of these veins were recorded as open, whereas quartz infill had less than 17% open (Table 1). The open conditions of the rock mass at vein may act as an indicator of strength for the rock mass. So, from the data, it was observed that veins

may represent additional weakness to rock structure stability and need to be considered while determining the stability of rock structure.

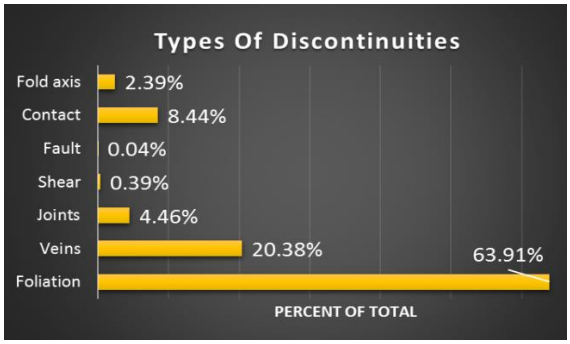

Fig. 2 Relative proportions of discontinuity types in the rock mass at Warramboo Iron Project.

Table 1 Vein mineralogy types and proportions.

Minerals	Total mineral veins	Mineral veins (%)	Open veins (%)	Sealed veins (%)
carbonate	1310	30.4%	81.4%	18.6%
chlorite	1851	43.0%	88.9%	11.1%
sericite	504	11.7%	82.1%	17.9%
quartz	195	4.5%	16.9%	83.1%
clay	148	3.4%	98.0%	2.0%
epidote	98	2.3%	30.6%	69.4%
gypsum	117	2.7%	76.9%	23.1%
pyrite	53	1.2%	56.6%	43.4%
hematite	22	0.51%	77.3%	22.7%
feldspar	3	0.07%	0.0%	100.0%
limonite	6	0.14%	83.3%	16.7%

METHODOLOGY

Sample Selection

The specimens for the research were collected from the drill core repository of the Warramboo iron ore project on Eyre Peninsula South Australia. The deposit is hosted by high-grade metamorphic rock, mainly gneiss [2]. Gneiss is a coarse-grained rock comprising mainly quartz and feldspar and generally of high strength.

The selection of the specimens was done from the extensive drill hole collection from the feasibility study of the proposed mine. The total length of core studied for the research is approximately equal to 25.6 km. The specimens with intact veins were selected after comparing the database and the photographs of the core boxes.

Sample Preparation

Specimens for the tensile test were prepared from the 60mm diameter original core specimens in the following steps:

Drilling

30mm diameter pedestal-mounted diamond drill was used to drill the specimen from the main sample in such a way that the vein plane is perpendicular to the direction of the drilling (Fig. 3A). The tensile strength of a discontinuity tends to decrease with the increase in the relative orientation of the discontinuity relative to the direction of the load applied [3].

Cutting

The cylindrical specimens were made flat at each end using a rock cutting diamond blade saw. The specimens were then kept in the oven for 24 hours at 100°C to dry.

Sandblasting

The end caps were prepared from 4 cm wide T-Bar. The long bar was cut at the 4 cm interval and then the cementing surface was sandblasted to remove any oil or grease present on the surface. This process is important for the strong adhesion of the specimen with the end caps.

Cementing

The specimens were cemented to the end caps using the Araldite 420 adhesive. The specimens were clamped on both the ends and kept for curing for 1 week after the application of the adhesive.

Although samples of a range of sizes were produced, a previous study of direct tensile testing methods found that there was no significant difference in the tensile strength of samples with different sizes [13].

Test Method

To gain a deeper insight into the vein strength and its influence on the overall rock strength, it was important to know the strength and behavior of the

vein in tension. In order to find the tensile strength of veins the direct tensile strength testing method was selected as it has the ability to provide the most valid results [14].

In direct tensile testing, the failure occurs in tension at the weakest link of the rock sample and is not affected by any other factors if the test is done properly. Whereas, for indirect tensile tests such as the Brazilian test, the compression force must overcome the frictional forces at grain boundaries in order to initiate tensile force. Due to this reason, the Brazilian test tends to yield higher strength values than the direct tensile strength [15].

Specimens were prepared from 60mm diameter core specimen, so the new specimen size is smaller than the original specimen, which makes it difficult to perform Brazilian or the point load test on the specimen.

Laboratory investigation of rock sample containing intact veins has been carried out using SHIMADZU universal testing equipment, which has the maximum capacity of 50 kN and was used for the tensile testing of 9 specimens.

Some specimens were loaded at the rate of 1 mm/min and others were loaded at 0.05mm/min rate. The specimens were tested with different arrangements at various stages of the research. Following are the ways in which specimens were tested:

Direct clamping

Only one sample was tested in this arrangement (Fig. 3B). The specimen was not perfect cylinder, the ends of the sample were not parallel because of which there was stress concentration at the edges of the specimen and the sample failed at one of the edges. So, in order to solve the issue of stress concentration a small chain system was used.

Small chain assembly

Small chain arrangement used 2 D-shackles on both the ends of the sample caps which were clamped to the testing machine (Fig. 3C). With this arrangement, two samples failed on the vein but the other six samples failed in rock, which may have been partly due to stress concentrations [16].

Long chain assembly

In order to stress alignment, samples which had failed in rock were re-glued and again tested with long chain arrangement (Fig. 3D). This arrangement is intended to ensure the center of mass of the specimen is in line with the tension of the testing machine.

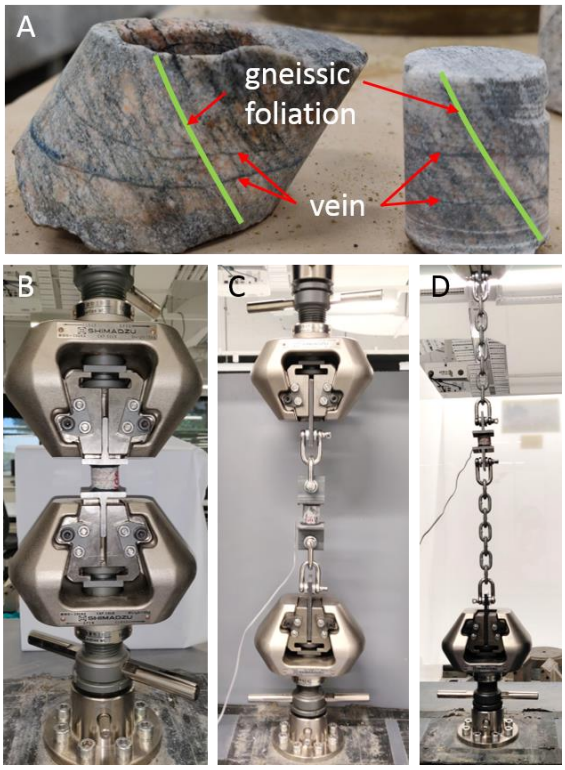

Fig. 3 A) Core sample of foliated gneiss which has been re-cored perpendicular to veins. Method of direct tensile strength experiment (Shimadzu 50 kN). B) Direct clamping, C) short chain assembly and D) long chain assembly.

Trimming of samples in dog bone shape

The cylindrical specimen can fail near the ends due to stress concentration. Fairhurst [17] observed that the stress concentration can be reduced if the end caps have sample dimensions that of the specimen. But due to the very small size of the present samples with a radius of around 25mm, it was very difficult to prepare a cap of at a smaller dimension

It was observed that the dog bone shape of sample reduces the stress concentration at the edges so three samples were trimmed around the vein to form a dog bone shape and tested with the previous long chain arrangement.

RESULTS

Most samples failed in rock at the end of the sample rather than in the vein (Fig. 4). These failures were observed to have relatively high tensile strength value. The highest tensile strength was observed was 14.25 MPa. Other samples failed between 3 MPa to 10 MPa range. Considering the magnitude of force at which the samples failed, the veins are inferred to have significant strength.

Even in the four samples which failed on the vein, the failure was observed at reasonably high tensile stress. These veins have significant tensile strength ranging from 3 to 9 MPa. They are not very weak and have considerable strength in tension.

Table 2 Direct tensile test results.

Sample ID	Vein Mineral	Test Number	Set-up*	Tensile strength (MPa)	R/V *
4	Sericite	1	S	7.07	R
		2	L	6.22	R
19B	Carbonate	1	S	14.25	R
		2	L	8.96	V
92	Carbonate	1	S	9.03	R
		2	L	3.45	R
106A	Epidote	1	S	9.62	R
106B-I	Chlorite	1	D	7.69	R
		2	L	9.00	R
106B-II	Chlorite	1	S	7.12	R
		2	L	7.29	R
107	Chlorite	1	S	3.12	V
110-I	Chlorite	1	S	4.52	V

		2	L	5.04	V

* D=direct clamping, S=short chain assembly, L=long chain assembly. R=failure in rock, V= failure on vein.

DISCUSSION

Typically, the tensile strength of rock mass can be estimated as about 1/10th it's UCS value [18]. The Warramboo gneisses have been reported to have UCS strength ranging from 56 to 187 MPa [2]. This would correspond approximately to a range of 6 to 19 MPa of tensile strength. This is similar to the range of tensile strength for gneiss given in reference sources as 5 to 20 MPa [19]. The tensile strength for all the specimens tested falls close to this range.

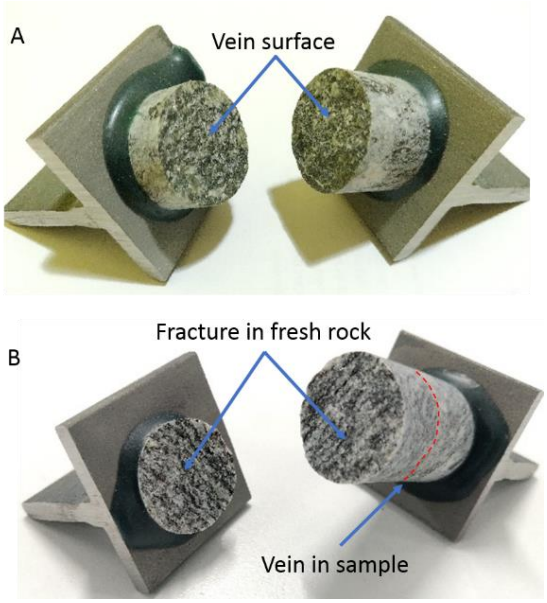

Fig. 4 Completed direct tensile tests. A) Failure on the vein. B) Failure in the rock.

In cases where the specimen failed in rock rather than on the vein the specimens were re-tested with a long chain assembly. In two cases this led to specimen failure on the vein which is attributed to the benefit of improved force alignment in the long chain assembly.

The eleven samples that failed in rock rather than on the vein had an average tensile strength of 8 MPa. This value is at the low end of the expected range of tensile strength of gneiss. The four samples that failed on the vein had an average tensile strength of 5 MPa. This value is at the low end of the range of tensile strength expected for gneiss. So, the vein samples behaved similarly to the parent rock in tension.

CONCLUSIONS

In this research, a study of core samples obtained from a proposed iron ore mine in Eyre Peninsula South Australia was conducted. For this research, all the samples tested for tensile strength have been gneisses with a range of vein mineral fillings.

From the laboratory testing, it was observed that the veins have shown significant tensile strength. The tensile strength of veins observed from the tests is generally comparable to the typical tensile strength of a gneiss. Also, the samples which failed in rock rather than on the veins imply that the veins were not excessively weak in those cases. Failure of the

specimens in rock at the ends of the samples may be due to stress concentrations which will be investigated in future work. The vein tensile strength measurements and the tendency of some samples to fail on rock rather than on the vein indicates that the veins are not highly significant weaknesses in the rock.

BEARING CAPACITY ANALYSIS OF EMBEDDED SPREAD FOUNDATION USING RIGID PLASTIC FINITE ELEMENT ANALYSIS WITH NONLINEAR CONSTITUTIVE EQUATION

Kazuhiro KANEDA[1], Masamichi AOKI[1]
[1]Reseacher, Takenaka Corporation, Japan

ABSTRACT

The Architectural Institute of Japan's guidelines for building foundation design provide a formula for calculating the ultimate vertical bearing capacity. With a wider footing, the ultimate bearing capacity becomes smaller than that obtained using Terzaghi's formula for sandy grounds owing to the decrease in the inertial friction angle or progressive failure. Furthermore, the ultimate bearing capacity of embedded and inclined loads have not been clarified. In this study, the rigid plastic finite element method is used to calculate the ultimate bearing capacity of a large foundation against inclined and embedded loads.

Keywords: Embedded spread foundation, Ultimate bearing capacity, Rigid plastic finite element method, Inclined load

INTRODUCTION

The calculation of the ultimate bearing capacity of soil is important when designing a building [1]. The formula for calculating the ultimate bearing capacity of building foundations is specified in the guideline published by the Architectural Institute of Japan (AIJ) [2]. These formulae are based on both experimental and theoretical considerations of risk avoidance. Researchers have applied the rigid plastic finite element method (RPFEM) to this problem. For example, the bearing capacity under squeeze breakdown of clayey soils was last discussed at Geomate2017 [3]. Further, the bearing capacity of footing in a two-layered clayey soil system was discussed at Geomate2018 [4]. The inclined bearing capacity was also investigated in some specific cases.

The calculation for the bearing capacity of a spread foundation uses the coefficients of bearing capacity N_c, N_γ, and N_q. In equation (1), which is proposed by the AIJ, the size effect is considered using the parameter η that reflects the effect of the constraint stress of the inertial friction angle for only N_γ and not for N_c and N_q.

$$q_u = i_c \alpha c N_c + i_\gamma \beta \gamma_1 B \eta N_\gamma + i_q \gamma_2 D_f N_q \quad (1)$$

where q_u (kN/m^2) is the beating capacity; $\eta = (B/B_0)^{-1/3}$, where B is the foundation width and B_0 = 1 m; $i_c = i_q = (1\text{-}\theta/90)^2$; $i_\gamma = (1\text{-}\theta/\varphi)^2$; θ = tan(H/V) is the inclined angle (°), where H and V are respectively the horizontal and vertical load; D_f (m) is the embedded height; and γ_1 and γ_2 (kN/m^3) are unit weights.

Furthermore complicated loads that could occur during an earthquake (e.g., vertical or horizontal moment and eccentric load) should be considered when calculating the bearing capacity. In the present study, RPFEM is used to calculate the ultimate bearing capacity of a large foundation against embedded and inclined loads using a high-order function.

ANALYSIS CONDITIONS

In this study, the effect of an embedded load is assumed for the overload of surrounding soils. Figure 1 shows the analysis mesh for B = 1 m. The mesh size is changed according to the foundation width. For the plane strain condition, a rigid footing is modeled. A increasing vertical load was applied to the footing to calculate a ultimate vertical bearing capacity. The soil strength is φ = 30° and 40°, soil density is γ = 18 kN/m^3, footing strength is c = 100 MPa, and embedded height is D_f = 1–5 m. Table 1 lists the analysis conditions. A high-order function is used in the soil constitutive model [5] to evaluate φ reduction under high constraint stress as follows.

$$f(\boldsymbol{\sigma}) = aI_1 + (J_2)^n - b = 0 \quad (2)$$

where I_1 and I_2 are stress invariants and a and n are material parameters.

In a previous study, the material parameters for φ = 30° and 40° were respectively a = 0.175, b = 1.5, and n = 0.52 and a = 0.237, b = 1.5, and n = 0.52 [6]. These values are determined to fit the bearing capacity of various foundation widths calculated using the AIJ's formula. The bearing capacity of an inclined load (θ = tan^{-1}(H/V), where H and V are respectively the horizontal and vertical load) was also simulated.

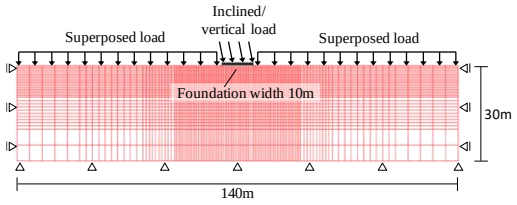

Fig. 1 Analysis model (B = 10 m).

Table 1 Analysis conditions

Foundation width (m)	1, 3, 10, 30
Embedded length (m)	0, 1, 2, 5
Inclined load (°)	0, 10, 20

ANALYSIS RESULTS

Figure 2 shows the relationship between the bearing capacity value and the foundation width for θ = 0. The figure indicates that equation (1) can be well reproduced by RPFEM using a higher-order function between 1 and 30 m for the foundation width. Figure 3 shows the shear strain contours at failure for B = 10 m, D_f = (a) 0 m and (b) 5 m. When the surcharge load on the top of the soil surrounding the footing was applied as the embedded load, the shear strain at the footing edge at failure with the embedded load is smaller than that in the case without an embedded load and the distribution area of slip failure tends to become slightly larger. The effect of N_q was discussed using q_uD_f (results with embedded load) - q_{u0} (results for D_f = 0). Figure 4 shows the relationship between q_uD_f - q_{u0} and embedded length for both φ = 30° and 40° using the AIJ's and the Japan Road Association's guidelines [7]. The effect of increased bearing capacity of D_f is smaller than that in the case of the AIJ's guideline. However, the effect of increased bearing capacity of D_f is almost the same in the case of the Japan Road Association's guideline for both φ = 30° and 40°. The modification coefficient S_q = $(q/q_0)^{-1/3}$ = $(\gamma D_f/10)^{-1/3}$ for N_q was adopted in the Japan Road Association's guideline. Figure 4 shows the relationship between H/V_m and V/V_m (where V_m is the ultimate vertical bearing capacity for H = M = 0) for both φ = 30° and 40° for the AIJ's guideline and Nova's equation with M = 0, μ = 0.5, and β = 1.0 (3) [8].

$$\left(\frac{H}{\mu Vm}\right)^2+\left(\frac{M/B}{\phi Vm}\right)^2=\left(\frac{V}{Vm}\right)^2\left(1-\frac{V}{Vm}\right)^{2\beta} \quad (3)$$

$$\left(\frac{H}{0.5Vm}\right)=\left(\frac{V}{Vm}\right)\left(1-\frac{V}{Vm}\right) \quad (4)$$

i_q obtained using the AIJ's guideline (black line) is much larger than that obtained in the RPFEM results. When the foundation width B is small and D_f is large, the results approached those obtained using Nova's equation.

REMARKS

Numerical simulations of the vertical and inclined bearing capacity of an embedded footing were conducted using RPFEM considering the size effect. When using a high-order function for the size effect, the obtained vertical bearing capacity is smaller than that obtained using the Drucker Prager model with increasing foundation width. Although the size effect for an embedded foundation is not considered in the current AIJ guideline, the results obtained in this study clearly indicate that the size effect should be considered.

ABSTRACT

Large soil deformation can occurs allowing the structure to settle and tilt when the soil supporting a building or other structures liquefies and loses strength. The presence of excess pore water pressure below ground surface indicates that upward flow is taking place and liquefaction occurs. Dissipation of excess pore water pressure will be accompanied by densification of the soil and settlement of the surface. Liquefaction first developed in a sand layer several meters below ground and then propagated upward flow water through overlaying sand layer. In this paper, the effect of upward flow of water will be discussed based on laboratory experiment results. The soil samples used are varies from coarse sands, medium sands and fine sands according to United Soil Classification System. The results of study show that the size of sand particles greatly affects the stability of the foundation due to upwards flow of water. The shallow foundations on fine sand are more susceptible to settlement and tilt compared to foundations on coarse sand at the same seepage velocity.

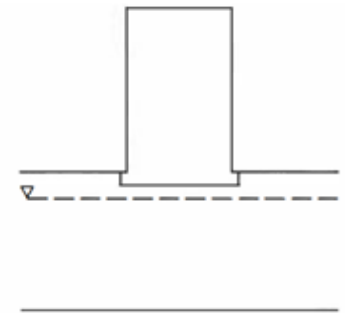
Keywords: Upward flow, Tilt, Settlement, Shallow foundation

INTRODUCTION

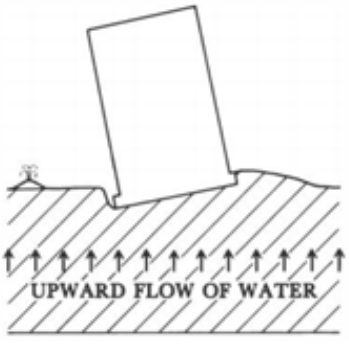
Upward flow of water is formed when excess pore water pressure develops at some depth. If the upward gradient is large enough, flowing water will lift up soil particles, with homogeneous soil. This can produce extensive quicksand conditions. However, it is likely that the flow will break through to the surface in places where the top layer is very thin or where there are cracks or other weaknesses in superficial soil. Soil particles are brought up with water in these locations and will be left on the surface when the sand boils. Sand boils indicates that liquefaction has occurred.

The liquefaction in Padang city due to the last 7.6 SR earthquakes of 30 September 2009 was identified by numerous sand boils [1] and [2]. Based on field observations and laboratory testing conducted on soil samples in Padang city is found that the fine sand grains of the sites are more than 65%, where this types of soils susceptible to liquefaction criteria [3]. One of the studies conducted to evaluate the potential of liquefaction in Padang city was carried out at the Nurul Haq Shelter. Based on N-SPT data, the soil condition at the Nurul Haq Shelter between the depths of 11.55 m and 29.55 m has a high potential of liquefaction [4].

When soil that supports buildings or other structures liquefies and loses strength, large soil deformations can occur, allowing the structure to settle and tilt (Fig. 1).



a. Without upward flow of water



b. Upward flow of water

Fig. 1 Tilt of building with shallow foundation (Youd, 1984b in [7])

Based on the available geotechnical data and information from the site observations following the 2009 Padang earthquake, the ground settlement and sand boiling generally occurred in the populated areas up to 5 km from coastal line, with a significant damage to the city infrastructures. Many buildings, located near the river front experienced foundation movement due to ground settlement [3]. For this reasons of sand soil near the beach and on the riverbank of the Padang city area need to be examined from the effect of upward flow.

The objective of this investigation is to study the effect of the particle size distribution and dry density on the critical hydraulic gradient due to upward flow are then explained the effect on tilting and settlement of shallow foundation. It is known that have different sizes, and these characteristics also have a significant effect on its engineering behavior.

LITERATURE REVIEW

The key parameters affecting liquefaction induced settlement and tilting of shallow foundation, namely (a) increase contact pressure, decreasing ground water table depth and thickness of the non liquefied; (b) increase eccentric mass and distance ratio due to the tilt angel of the building; and (c) the safety factors against vertical load and dynamic overturning moment [6].

According to previous studies, there are three variables that cause strength reduction of Non Cohesive soil, namely the fine content, relative density of the soil and hydraulic gradient on the soil sample. Soil with a fine fraction and coarse fraction are vulnerable to increase in hydraulic conductivity that resulting decrease in the soil strength from its initial value [5]. Non Cohesive soil and relatively permeable soil overlaying the liquefied material causes a general settlement of the ground, with uniformity of the settlement depending on the degree of homogeneity of the material [7].

If water is seeping, the effective stress at any point in a soil mass will differ from that in static case. The effective stress will decrease due to upward flow of water. The effective stress at a point located at a depth z measured from the surface of a soil layer is reduced by an amount $iz\gamma_w$ because of upward flow of water. If the rate of seepage and thereby the hydraulic gradient gradually are increase, a limiting condition will be reached, at the point the effective stress will be zero. Where critical hydraulic gradient for zero effective stress. Under such situation, soil stability is lost. This situation is referred to as boiling or a quick condition.

RESEARCH MEHODOLOGY

The research was carried out with a series of simple model test at the Soil Mechanics Laboratory, Department of Civil Engineering Andalas University of Padang. Soil used for the test was collected in Muaro Baru area is located close to the coastline of Padang city (Fig. 2), and in riverbank area of Gurun Laweh Naggalo with a distance of ± 5 km towards the coastline of Padang city (Fig. 3). Soil sample used in this investigation is a disturbed sample, taken at a depth 30 cm from soil surface in Muaro Baru area and on the riverbank of the Gurun Laweh Nanggalo area.

The sieve analysis test was carried out in both locations of soil sampling. In this study a Unified Soil Classification System (USCS) used are to determine group symbol and group name. The sample of sand soil used was soil fraction or component for sand according Table 1. The dry unit weights test of granular soil also carried out for each soil fraction according Unified Soil Classification System (USCS).

Fig. 2 Location of soil sampling in the Muaro Baru area of Padang city

Fig. 3 Location of soil sampling in the Gurun Laweh Naggalo area of Padang city

Table 1 Soil fraction according Unified Soil Classification System (USCS)

Soil Fraction	Size range
Coarse Sand (CS)	No. 4 (4.75 mm) to No. 10 (2 mm)
Medium Sand (MS)	No. 10 (2 mm) to No. 40 (0.425 mm)
Fine Sand (FS)	No. 40 (0.425 mm) to No. 200 (0.075 mm)

Schematic diagram of experiment system can be seen in Fig 4. The experiment do not attempt to simulate an earthquake but to examine the effect of upward flow to settlement. All dimensions in millimeters and small prototypes.

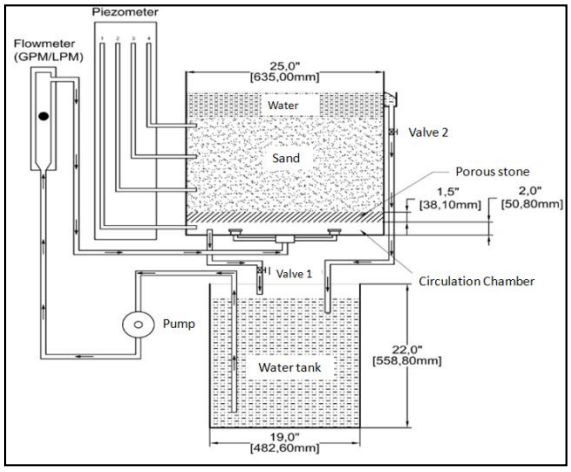


Fig. 4 Schematic diagram of experiment system

RESULT AND DISCUSSION

The grain size characteristics of a soil are given on the Table 2 and the grain-size distribution curve is show in Fig. 5.

Table 2 Sieve analysis

Sieve size	Sieve opening	% Finer			
		Original sand MB	Oroginal sand GLN	FS-MB	FS-GLN
	10	100	100	100	100
4	4.75	100	100	100	100
10	2	100	80.5	100	100
20	0.841	99	46.3	95.9	43.1
40	0.42	95.8	28.4	0	0
100	0.149	5.1	4	0	0
200	0.075	1.4	2.9	0	0

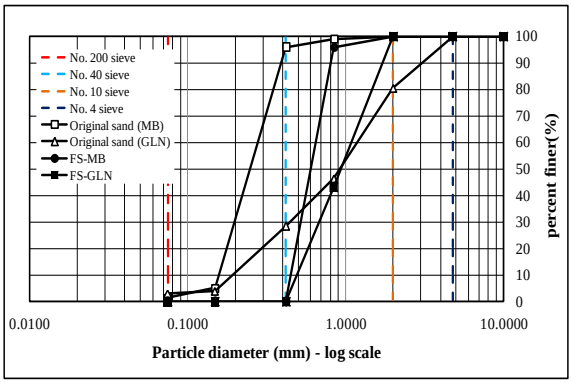

Fig. 5 Grain size distribution of sands in Muaro Baru beach and sands in riverbank area of the Gurun Laweh Naggalo.

A particle-size distribution curve can be used to determine the parameters following.

The coefficient of uniformity (C_u) is

$$C_u = \frac{D_{60}}{D_{10}} \quad (1)$$

The coefficient of gradation (C_c) is

$$C_c = \frac{D_{30}^2}{D_{60} \times D_{10}} \quad (2)$$

Where

D_{10} = Grain diameter (in mm) corresponding to 10% passing
D_{60} = Grain diameter (in mm) corresponding to 60% passing.
D_{30} = Grain diameter (in mm) corresponding to 30% passing.

Based on results of the particle-size analysis then the soil in Muaro Baru and Gurun Laweh Naggalo can be classified as on the Table 3 below :

Table 3 Classify the soil by USCS

Parameters	Muaro Baru (MB)	Gurun Laweh Naggalo (GLN)
% passing No. 200 sieve	1.4	2.9
% retained on No. 4 sieve	0	0
D_{10} (mm)	0.16	0.18
D_{30} (mm)	0.19	0.44
D_{60} (mm)	0.27	1.3
C_u	1.7	7.2
C_c	0.84	0.82
Group symbol	SP (Poorly Graded Sand), C_u<6 and/or 1 > C_c > 3	SP (Poorly Graded Sand), C_u<6 and/or 1 > C_c > 3

The classification results according to USCS show that the sand in the Muaro Baru area and Gurun Laweh Naggalo are both Poorly Graded sand (SP). Fig. 6 and Fig. 7 show photograps of sand soil fraction samples

(a) (b)

The dry unit weight (γ_{dry}) and saturated unit weight (γ_{sat}) of sand fraction in the Muaro Baru and Gurun Laweh Naggalo area shown in Table 4 below.

Table 4 Dry unit weight and saturated unit weight in Muaro Baru and Gurun Laweh Area.

Area	Sand fraction	Dry unit weight, γ_{dry} (gr/cm^3)	Saturated Unit Weight, γ_{sat} (gr/cm^3)
Muaro baru (MB)	Medium Sand	1.13	-
	Fine Sand	1.15	1.76
Gurun Laweh Naggalo (GLN)	Coarse Sand	1.36	1.41
	Medium Sand	1.35	1.60
	Fine Sand	1.32	-

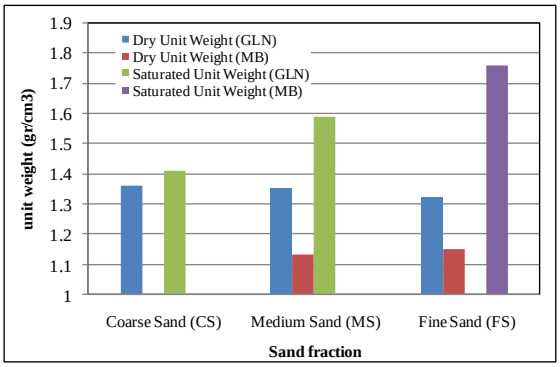

Fig. 8 The unit weight versus sand fraction

From Figure 8 it can be concluded that the size of the sand fraction does not affect the value of dry unit weight and value of the dry unit weight of river sand greater than the dry unit weight of the beach sand. The saturated unit weight value of fine sand is greater than medium sand and coarse sand.

For the model test, the first condition of the material used is fine sand from the Muaro Baru area (Fig. 9 and Fig. 10), while for the second condition the material used was a combination of medium sand with coarse sand from the Gurun Laweh Nanggalo (Fig 11 and Fig. 12). A square foundation measuring 15 cm x 15 cm with a weight of 3080 kg located at ground level. The following are pictures that show the initial conditions and the final conditions of the test.

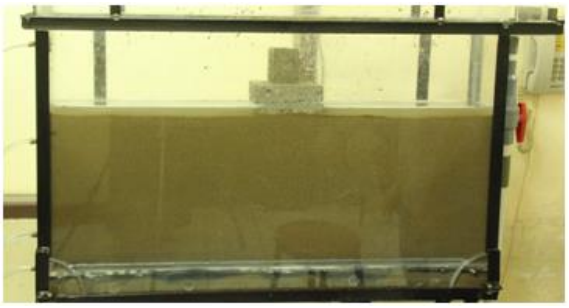

Fig. 9 Initial condition model test for fine sand

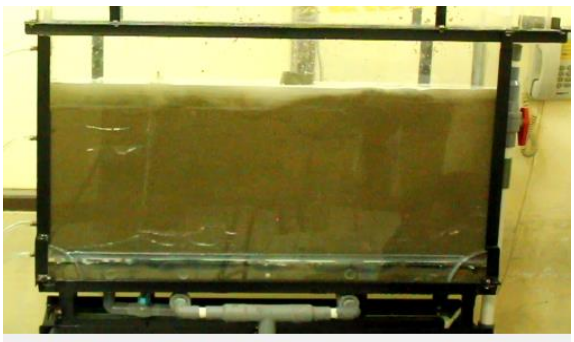

Fig. 10 Final condition model test for fine sand

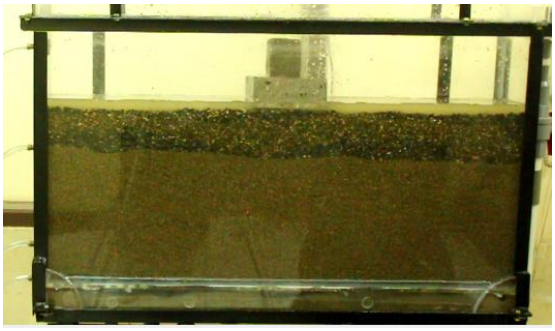

Fig. 11 Initial condition model test for combination of the coarse sand with medium sand

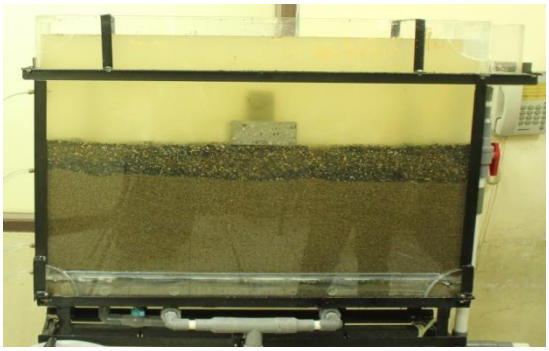

Fig. 12 Final condition model test for combination of the coarse sand with medium sand

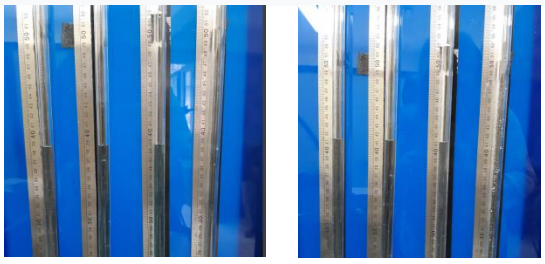
In Figure 9, the initial water level is at elevation 38.8 cm (Fig 13a), the ground level is at an elevation of 36.8 cm and the thickness of the soil is 33.8 cm. In the Figure 11, the initial water level is at elevation 41 cm (Fig 13b), the ground level is at an elevation of 39 cm and the total thickness of the soil is 36 cm where the thickness of coarse sand and medium sand respectively 8 cm and 28 cm.



a b

Fig. 13 Initial condition water level

From the results of observations of the two conditions there is a significant difference between in the final condition in Figure 10 and final condition in the Figure 12. In the first conditions where the material is fine sand there is a settlement and tilt on the foundation. whereas in the second condition where the material is coarse sand and sand, there is no settlement and tilt at all.

CONCLUSIONS

From the results of the study it can be concluded that :

- The sand fraction in the coastal area is dominated by fine sand and medium sand while in the river area the sand fraction is dominated by medium sand and coarse sand while fine sand is less.
- The dry unit weight of the sand in the coastal area is smaller than the dry unit weight of sand in the river bank.
- The size of sand particles greatly affects the stability of the foundation due to upwards flow of water, where the foundation which is on fine sand is more susceptible to settlement and tilt.

STABILIZATION OF RIMBO PANJANG PEAT SOIL USING LIGHTWEIGHT MATERIALS MIXED WITH CEMENT AS SUBGRADE FOR ROAD PAVEMENT

*Elsa Eka Putri[1], Rina Yuliet[2], Lusia Elfina Harris[3] and Jodin Makinda[4]

[1,2]Faculty of Engineering, University of Andalas, Indonesia; [3]Public Works Agency and Spatial Planning, Riau, Indonesia; [3]Faculty of Engineering, Universiti Malaysia Sabah, Malaysia

ABSTRACT

Most of the road constructions in Riau Province are built on problematic and poor peat soil. This is one of the reasons why roads in this province do not last long according to their design. The aim of this research is to improve the engineering properties of the peat soil obtained from Rimbo Panjang, by using lightweight materials such as Bagasse and Sawdust Ash mixed with Portland Cement so that they meet the conditions stipulated as subgrade for road pavement layer. The tests conducted include determination of the physical properties of the peat soil such as Water Content, Organic Content, Ash Content, Unit Weight, Specific Gravity, Atterberg Limit and Dry Density, and engineering properties such as CBR and Unconfined Compressive Strength. A total of 18 CBR and 24 Unconfined Compressive Strength samples were prepared and tested. Results obtained showed the increases the Dry Density, CBR value and Unconfined Compressive Strength. The highest increment is observed on peat soils that mixed with 15% Cement with Unconfined Compressive Strength of 92 kN/m^2, Dry Density of 0.53 gr/cm^3 and CBR value of 4.67 %. It is followed by peat soils that mixed with 15% Cement and 20% Bagasse Ash with Unconfined Compressive Strength of 82 kN/m^2, Dry Density of 0.5 gr/cm^3 and CBR value of 4.56%. By comparison, Bagasse Ash shows a better result than Sawdust Ash in stabilizing Rimbo Panjang peat soils.

Keywords: Stabilization, Bagasse Ash, Sawdust Ash, Cement, CBR, Unconfined Compressive Strength

INTRODUCTION

Peat soil is soft soil with an organic content of >75% (Department of Settlement and Regional Infrastructure, 2004). Peat soil has low bearing capacity, high compressibility and low shear strength [1].

Most of the road constructions in the Riau Province area are built on peat soil. This is one of the reasons why roads in the Riau Province do not last long according to their design. During rainy season, peat soil will be saturated with water, while in the dry season, peat soil will compress due to the loss of water from the pores. This causes damage to the road construction due to the expansion and shrinkage of the soil surface. Typical illustration of peat soil can be seen in fig. 1 below.

Fig.1 Peat Soil at Rimbo Panjang, Riau Province

For this reason, peat soils found in the Riau Province, especially in the Rimbo Panjang area need to be stabilized and improved so that they are in accordance with the conditions stipulated as subgrade for pavement layers. One of the stabilizing methods is by using lightweight materials. Bagasse ash and sawdust ash as lightweight materials mixed with Portland cement were chosen to be investigated in this research. Mixing the peat soil with lightweight materials were not expected to add the weight of the peat soil itself. Moreover, the purpose of adding cement to the mixes is to increase the binder properties of the peat soil mixtures.

The objective of this investigation is to study the properties of stabilizing peat soils with lightweight materials namely bagasse ash (BA) and sawdust ash (SA) mixed with Portland cement (PC). In addition, the study aims to determine to what extent can these new mixtures improve the engineering properties, i.e. California Bearing Ratio (CBR) and unconfined compressive strength (UCS), as subgrade for pavement layers.

LITERATURE REVIEW

Department of Settlement and Regional Infrastructure defines peat as a part of soft soil consisting of inorganic clay and organic clay [2], forms mainly of plant debris in various levels of decomposition [3], and has a density ranges from 1.4 to 1.5 [2]. Peat also has a dark brown to black colour, distinctively scented with decaying plants, hollow consistency without showing obvious plasticity and fibrous to the amorphous texture [3].

Weathering of organic materials is the main process that forms this soil [4]. Due to this, the content of organic matter in peat soil is higher than 75%, consisting of fibrous material produced by the accumulation of half decaying plant debris in an environment with low oxygen level [1]. This type of soil has a field CBR value of less than 2% [5].

Higher groundwater level resulting in higher water content of the peat soil. It can be visualized, identified and observed by their dark brown colour [6].

Sawdust used in this research was obtained from a factory that manufactures frames, doors and windows. Sawdust ash is a lightweight material thus it is expected not to overburden the load on peat soil. A study by Munthe (2012) found that the use of sawdust ash increases the value of the UCS and cohesion of clay soil, moreover, the addition of 12% SA reduces the permeability and the plasticity index and increases the shear strength and the maximum dry density [7]. SA used in this study can be seen in Figure 2.

Fig. 2 Sawdust Ash (SA)

Bagasse ash (BA) used in this research was obtained from sugar cane drinks seller at a local market. The use of BA produced from the remnants of sugar cane helps in reducing the environmental impact caused by garbage dumping on the street and open areas. Similar to SA, BA is also a lightweight material that might not increase the load on peat soil.

A previous study by Yuliet et al. (2006) on the use of BA and cement as stabilization material for clay soils proven to reduce soil expansion and increase the CBR value [9]. Whereas Rezki and Roesyanto (2014) concluded that a mixture of BA and cement increases the compressive strength and maximum dry weight of clay soil. BA used in this study can be seen in Figure 3 [10].

Fig. 3 Bagasse Ash

Soil which in its original state is poor can be changed through compaction, adding aggregates or other materials so that it can be used as subgrade for pavement. Soil stabilization is one of the common methods used to improve the properties of existing soil to meet the technical demands [11]. According to the Department of Settlements and Regional Infrastructure (2002d), there are five methods to improve the subgrade properties that have been accepted and applied in Indonesia. Such as a material replacement, counter berms, surcharging, for stage construction and the use of lightweight material [12].

RESEARCH METHODOLOGY

The research was carried out at the Material Testing Technical Implementation Unit of the Public Works and Spatial Planning of Riau Province. BA, SA and Cement are varied to be mixed with peat soil in order to achieve higher CBR value and unconfined compressive strength (q_u) values for pavement subgrade.

Peat soil was collected from Km. 18. Pekanbaru-Bangkinang road, Riau Province which is ± 100 m from the main road. Peat soil used in this investigation is in a disturbed condition, taken at a depth of 40 cm to 60 cm. Peat soil is dried for four weeks, the roots are removed then filtered with sieve no. 4.

Bagasse ash used in this investigation was derived from the surrounding waste. Bagasse ash was air dried then burnt in the drum. The ash derived is then ground with 12 kg grinder for 10 minutes. The use of bagasse ash as additional material to stabilize the peat soil was then implemented according to the Guidelines issued by the Department of Settlements and Regional Infrastructure No: Pt T-10-2002-B regarding Geotechnical Guidelines 4 Road Construction Design and Construction in Soft Soil [2].

The sawdust powder was derived from the wood cutting process from the sawmilling process. The use of sawdust ash to stabilize the peat soils

was implemented according to the Guidelines issued by the Department of Settlements and Regional Infrastructure using the same aforementioned guideline. As with bagasse ash, sawdust ash was also through the process of burning and grinding.

Cement used in this investigation was Type 1 Portland Cement from Padang Cement Factory based on the Procedure of Land Stabilization with Portland Cement for Roads and Base Coarse Manual, Road Book no. 6 Department of Public Works Directorate General of Highways No: 002-06/BM/2006.

Peat soil was mixed with various materials such as bagasse ash, sawdust ash and cement in different percentage variations as seen in Table 1.

Table 1: Variation of materials studied

SAMPLES	Portland Cement (PC) in Peat	Baggage Ash (BA) in Peat	Sawdust Ash (SA) in Peat
P	-	-	-
P15BA	-	15%	
P15PC	15%	-	
P15PC10BA	15%	10%	
P15PC20BA	15%	20%	
P15PC30BA	15%	30%	
P15SA	-	-	15%
P15PC10SA	15%		10%

RESULTS AND DISCUSSION

The physical and mechanical properties of the peat can be seen in Table 2.

Table 2. Properties of Rimbo Panjang Peat Soil

Parameter	**Value**
CBR Lab, (%)	4.50
UCS, q_u (kN/m^2)	52
Undrained Shear Strength, S_u (kN/m^2)	26
Maximum Dry Density, ρ_d (gr/cm^3)	0.48
Optimum Water Content, w (%)	106.50
Liquid Limit	131.10
Plastic Limit	101.24
Plasticity Index	29.86
Natural Water Content (%)	324.66
Dry Air Water Content (%)	21.50
Ash Content (%)	66.34
Organic Content (%)	33.66
Specific Gravity	1.5
Weight/Volume (gr/cm^3)	0.4

Based on the results, Rimbo Panjang peat soils can be categorized as 'high ash' due to the ash content of >15%. Moreover, from the previous report by the Department of Settlements and Regional Infrastructure (2004) [5], it classifies the Rimbo Panjang peat soil as organic clay because of the organic content was in the range of 25% -75%.

Dry Density vs. Moisture Content

Figure 4 shows the relationship between the moisture content against the dry density for various variations of peat soils stabilized with bagasse ash and Portland cement.

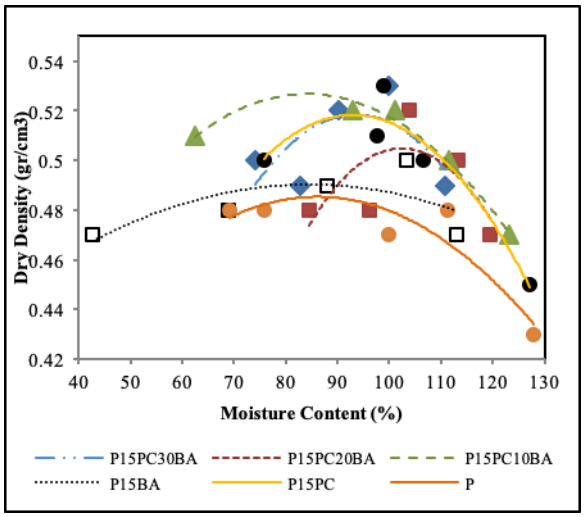

Fig. 4 Dry Density vs. Moisture Content of Peat Stabilized with BA and PC

It can be seen from Figure 4 that the maximum dry density increases in all mixes compared to the control sample. The highest increment is observed in peat soil + 15% PC + 10% BA, where the value increases from 0.480 gr/ cm^3 to 0.528 gr /cm^3, obtained at optimum water content (w) of 84%.

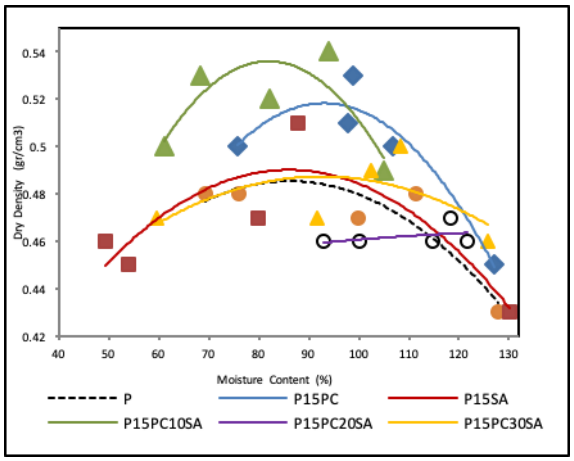

Fig. 5. Dry Density vs. Moisture Content of Peat Soil Stabilized with SA and PC

Figure 5 shows the relationship between the moisture content against the dry density for

various variations of peat soils stabilized with SA and PC from the compaction test.

It can be seen that the maximum dry density increases in all mixes. The highest increment is observed in peat soil + 15% PC + 10% SA, where the value increases from 0.480 gr/ cm^3 to 11.67 gr /cm^3, obtained at optimum water content (w) of 81%.

Relationship Between CBR Value (%) and Dry Density (gr/cm^3)

Figure 6 shows the relationship between CBR value and dry density. It can be observed that the CBR value and dry density increase in all mixes. The highest increment is observed in peat soil + 15% BA (P15BA), where the CBR value rises by 1.49% from 4.50% to 5.99% and the maximum dry density increases by 4.17 % from 0.48 gr/cm^3 to 0.50 gr/cm^3.

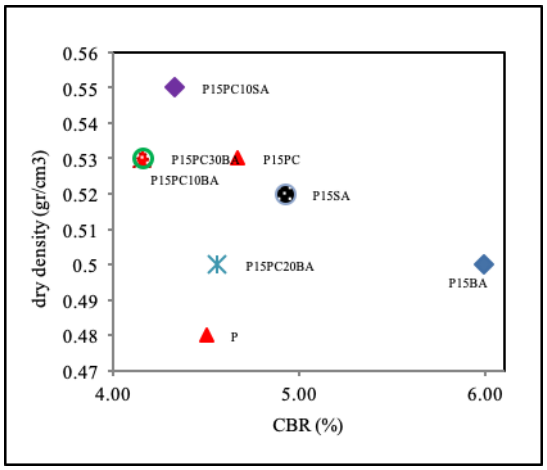

Figure 6. Relationship Between CBR Value and Dry Density of Peat Soil Stabilized with BA and PC

Meanwhile, Peat soil stabilizes with 15%PC and 10%SA achieved the highest density at 4.3%CBR value which is above the minimum value of CBR subgrade i.e 3%.

Relationship between UCS, q (kN/m^2) value and Dry Density (gr/cm^3)

Figure 7 shows the relationship between dry density and UCS. It can be seen that the UCS and the dry density increases in all mixes. The highest value of the UCS is 92 kN /m^2 observed in a mixture of peat soil + 15% PC. This a 76% increment compared to the UCS of Peat soil at 52 kN/m^2. Moreover, the highest value of the maximum dry density is 0.55gr/cm^3 occurs in a mixture of peat soil + 15% PC + 10% SA, increasing by 15 gr/cm^3.

Thus, it can be concluded that the variation with the highest dry density and UCS achieved at Peat soil stabilize with 15%PC+10%SA.

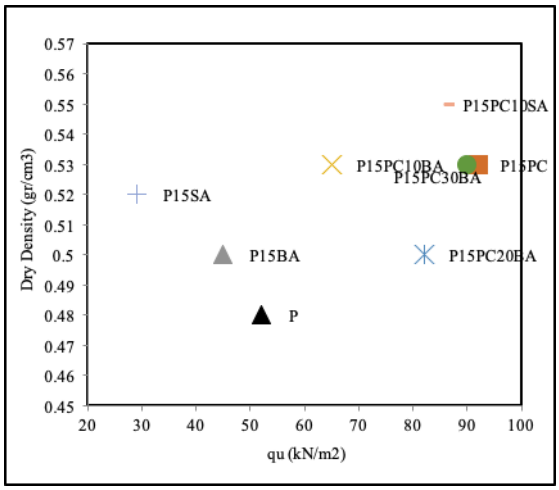

Fig. 7 Relationship Between UCS and Dry Density of Peat Soil Stabilized With BA, SA and PC

Relationship Between CBR Value (%) and UCS, q_u (kN/m^2)

Figure 8 shows the relationship between CBR and UCS.

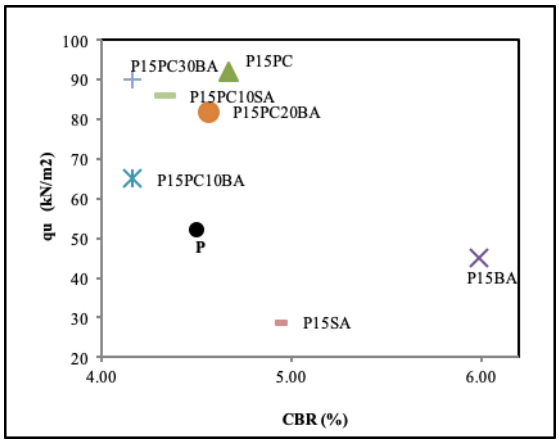

Fig. 8 Relationship Between CBR Value and UCS for Peat Soil Stabilized With BA, SA and PC

It can be seen from Fig.8 that the UCS and the CBR value increase in all stabilize variation mixes. The highest value of UCS observed is 92 kN/m^2 occurs in a mixture of peat+15%PC, which is increased by 40 kN/m^2. Meanwhile, the highest increase in CBR value occurred in a mixture of peat soil + 15%BA where the CBR value increased by 1.49% from 4.50% to 5.99%.

Referring to Fig. 7, peat soil stabilizes with 15%PC+10SA (P15PC10SA) achieved the highest dry density and as shown in Fig.8, the same sample achieved CBR value of 4.33%, which is above the minimum value of CBR design for pavement thickness.

Stress and Strain RELATIONSHIP

The relationships between stress and strain for various variations of the mixture of peat and cement were presented in Figure 9 where the increase in UCS is observed in all mixtures. The highest increment is observed on peat soil+15% PC at 96 kN/m^2, an increase of 125% compared to the lowest strength of Peat soil itself with a value of 48 kN /m^2.

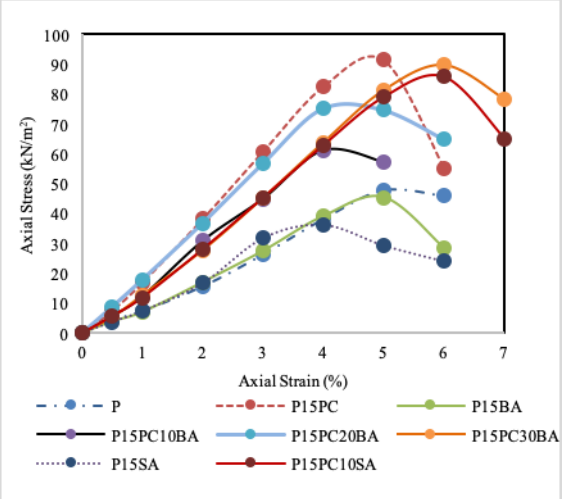

Figure 9. Stress and Strain Relationship for Peat Soils Stabilized with PC, BA and SA.

The highest increment is observed on peat soil+15% PC+ 10% SA at 96 kN/m^2, an increase of 147% compared to the an increase of 121% compared to the peat soil without stabilized materials. Then it was followed by peat soil + 15% PC + 30% BA at 94 kN/m^2, an increase of 121% compared to the peat soil without stabilized materials.

Cross-Examination of the Values of UCS, Dry Density and CBR.

In this study, a cross-examination was carried out to determine which of the mix variations could be implemented in the field as summarized in Table 4. For comparison purpose, the control sample is also included.

It can be observed that the optimum mixture is peat soil + 15% PC with unconfined compressive strength of 92 kN/m^2, dry density of 0.53 gr /cm^3 and CBR value of 4.67 %, followed by the peat soil + 15% PC + 20% BA with unconfined compressive strength of 82 kN/m^2, dry density of 0.5 gr /cm^3 and CBR value of 4.56 %.

Table 4. Cross-examination of the Values of UCS (q_u), Dry Density and CBR

No	Mix Variation	q_u (kN/m^2)	C_u	Dry Density (gr/cm^3)	CBR (%)
1	Peat Soil	52	26	0.48	4.50
2	Peat Soil + 15%PC	92	46	0.53	4.67
3	Peat Soil + 15% BA	45	22.5	0.5	5.99
4	Peat Soil + 15%PC+10% BA	65	32.5	0.53	4.16
5	Peat Soil + 15%PC+20% BA	82	41	0.5	4.56
6	Peat Soil + 15%PC+30% BA	90	45	0.53	4.16
7	Peat Soil + 15% SA	28	14	0.52	4.92
8	Peat Soil + 15%PC+10% SA	86	43	0.55	4.33

From the mixed variations, the selection of which mix should be implemented in the field should be based on; i) CBR value; higher CBR value of the subgrade is considered better and more economical because of its larger bearing capacity thus reduces the need of thicker pavement layer above it. Of the two mixed variations, the highest CBR value was a mixture of peat soil + 15% PC with a CBR value of 4.67%., ii) Ease in workmanship ; as it determines the success of a job in the field as the suitable mix could avoid constant technical and non-technical disruption to the construction works and iii) Human Resources or skilled workers whom are capable to carry out the job in the field.

CONCLUSIONS

From the results of research and discussion, some conclusions can be drawn;

- An increase in observed in the value of dry density, CBR value and unconfined compressive strength of the peat soil for all mixes.
- The most optimum mixture is peat soil + 15% PC with unconfined compressive strength of 92 kN/m^2, dry density of 0.53 gr /cm^3 and CBR value of 4.67 %, followed by peat soil + 15% PC + 20% BA with unconfined compressive strength of 82 kN/m^2, dry

density of 0.5 gr /cm^3 and CBR value of 4.56 %.

- Addition of bagasse ash gives better results than sawdust ash in stabilizing peat soil.
- Because bagasse ash used was not filtered with a 200 sieve, they lack the binding capacity, thus they only function as filler.

Abstract

Unmanned autonomous robots will be widely used very soon for land use, treatment, and monitoring. Our and the other groups already described technologies, that can be used for such robots (Kupervasser et al., International Journal of GEOMATE, May, 2018 Vol.14, Issue 45, pp.10-16; Djaja et al., International Journal of GEOMATE, Aug, 2017, Vol.13, Issue 36, pp.31-34). We continue developing these technologies and present here new patented technology of airborne vision-based control of ground robots. The main idea is that robot's "eyes" is not located on robot, but are independent autonomous system. As a result, the "eyes" can go up and observe the robot from above. We present in this paper algorithms used for two real physical prototypes of a such system.

Keywords—visual navigation; ground robots; tethered platform; airborne control; prototype; vision-based navigation

INTRODUCTION

Unmanned autonomous robots will be widely used very soon for land use, treatment, and monitoring. Our and the other groups already described technologies, that can be used for such robots [1,2].

The most popular outdoor robots are currently robot-lawnmowers. Current robot-lawnmowers need for staked border wires. They have random navigation methodologies. They are inconvenient, static, expensive technology.

You can see the following citation from "THE ROBOT REPORT: TRACKING THE BUSINESS OF ROBOTICS" [3]:

"... Too expensive for most home use, not professional enough for industrial use, robotic lawnmowers have yet to become as commonplace as Roombas, But a new crop of consumer manufacturers is quietly making inroads by providing more bang for the buck."

".., Friendly Robotics and their line of Robomowers, $2,000, and Husqvarna and their Automower line, $2,200, have been around for a few years but never hit consumer traction outside of Europe (Husqvarna has sold over 100,000 of their Automowers), partly because of their high price, mulching clumps, inability to handle high grass, need for staked border wires, and their random navigation methodologies."

The solution of the problem is vision-based navigation [4-6]. Vision-based navigation of robots is similar to human navigation by the help of eyes vision. However, we do not eyes on the robot. We put eyes on a top and from the top robot can see itself and its motion. We use airborne terrestrial robots control (Figure 1).

We continue developing these technologies and present here new patented technology of airborne vision-based control of ground robots [7-10]. It is planned to develop a software package including approaches for comprehensive video navigation solution of ground robot from top position (tethered drone, balloon, tower, antenna on the ground robot) and a physical prototype (camera on the top position, ground robot, ground station with computer) controlled by this software.

The system relates to the control systems of automated devices and may be used for the coordination of the ground movable automated devices (automated transport, automated agricultural machines, municipal and aerodrome vehicles, garden lawnmowers and so on), hereinafter referred to as the robots.

The invention essence is the system of navigation [1-10] and intercoordination of one or more roots located on the controlled area including one or more robot tracing devices on the suspended platforms, natural or artificial markings, central module for robot coordination and orientation detection to which the information is transferred from all the tracing devices, charger and the system is equipped with the central calculation module located on the suspended platform, on the ground, on the charger or on the robot designed with the possibility to detect the coordinates, to orient the system and to form the control commands based on the information received from all the above described devices.

The technical result is the development of the robot efficient coordination using the devices located on the towers or the aerial apparatuses tracing the robots on the controlled area and supervising their environment including natural and artificial markings. One of the developments is to take into account delays in the control system. The technical result coincides with the engineering challenge.

This visual system can also be used for preventing collision of ground robot with children or animals. Also we can use this visual system for security purposes.

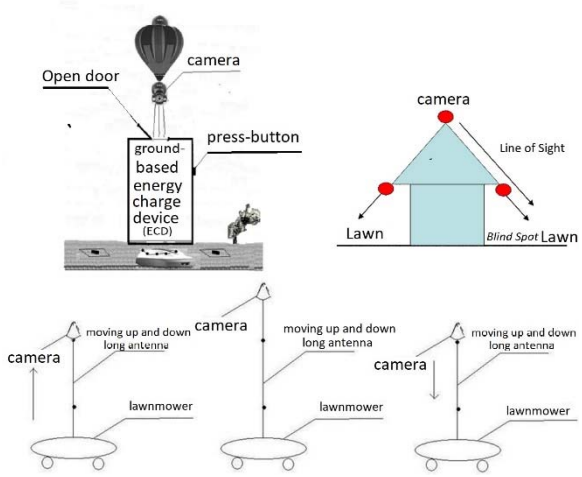

Fig. 1. Airborne terrestrial robots control, some possible camera dispositions

The system (the proof of concept) was defined to work as follow:

1. A toy car will simulate the lawnmower.
2. The car will be controlled by a software that will connect to a webcam that watch all the area.
3. There will be two options to drive the car:
    a. A random movement
    b. A user predefined route
4. For random route, the user will define on the live video:
    a. The edges of the area (practically close to the edge of the frame).
    b. Using lines and squares, areas in the frame that the car can't go to.
5. For predefine route, the user will define on the live video:
    a. Continues and close route that is starting at the location of the car and end about the same location.
    b. The user will use lines to draw the route.
6. The software will receive the life video from the webcam
7. The software will analyze the location and orientation of the car.
8. The software will instruct the car what to do next according to its analyzing and the user definition.

The paper is constructed as following:

Section 1 is the introduction and includes a description of the system.

Section 2 provides a system overview.

Section 3 describe the software.

Section 4 describes the algorithms in use.

SYSTEM OVERVIEW

System Components

The following figure describe the system components (Figure 2):

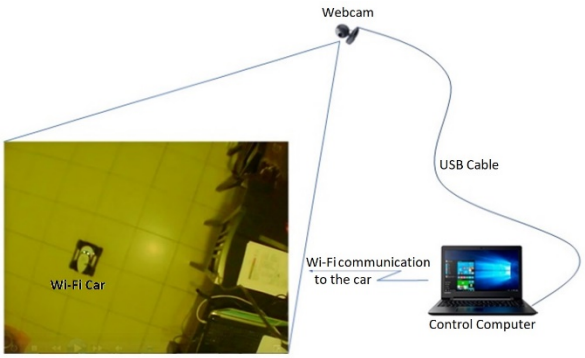

Fig. 2. The system components

SOFTWARE DESCRIPTION

Software General Description

Following is a list of the components in the system:

- Car – A game car of type iSpy. This car has Wi-Fi communication and an API to be controlled from a computer.
- Webcam – connected to the computer by USB cable.
- Control Computer – A computer running the software we developed. This computer connected to the webcam to get a live video of the area and give instructions to the car using Wi-Fi communication.

The software (Figure 3) is written in Python. Is build out of two files:

- ColorTrack.py – main file. This file contains all the flow control, logics, computer vision and the UI
- carControl.py – This file is where the communication with the car is done.

The following paragraph describe shortly the carControl.py structure. All the rest of the description in this document exist in ColorTrack.py file.

The carControl build as a class with regular __init__ function, where all the initializations for this class happened.

There is the "run" function. This is the thread control function. This function run in endless loop and wait for a command. A command received in the self.move variable. When this variable set to something that is different from "no" (no command), it will run a function according to the command:

- moveForCalib – This function use for calibration of a strait move.
- turnForCalib – This function use for calibration of a turn.
- goForward – Move forward function. It receives, as input, the distance to move in pixels and calculate the time to move and send by Wi-Fi the right command to the car.
- goBackword – Move backward function. It receives, as input, the distance to move in pixels and calculate the time to move and send by Wi-Fi the right command to the car.
- goLeft – Turn left function. It receives, as input, the angle, in degrees, for turn and calculate the time to move and send by Wi-Fi the right command to the car.
- goRight – Turn right function. It receives, as input, the angle, in degrees, for turn and calculate the time to move and send by Wi-Fi the right command to the car.

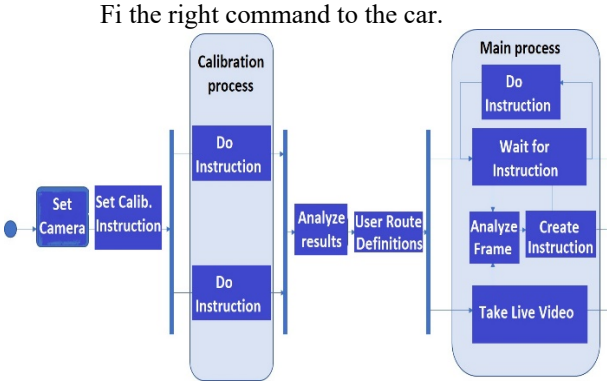

Fig. 3. State Diagram

Software Flowchart

In this paragraph we show the flowcharts of the software (Figures 4-6). It starts with the start flowchart and then show separately the flow for route mode driving and for random mode driving.

In the flowcharts, a rectangle that represent a function in the software, the function name is written in red and in parenthesis in the rectangle.

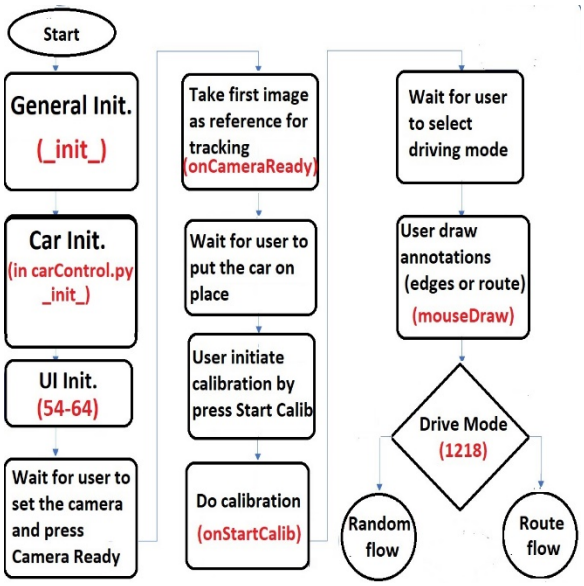

Fig. 4. Start Flowchart

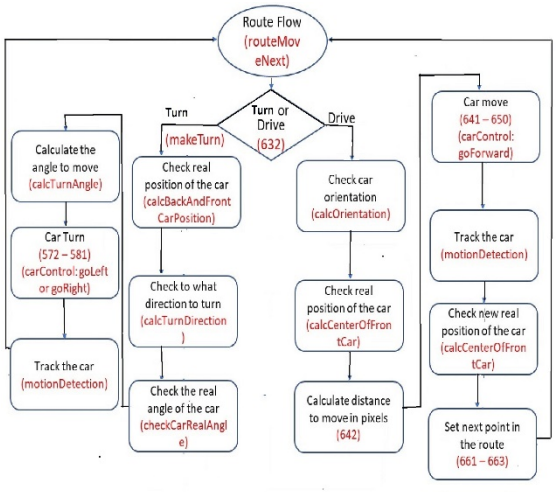

Fig. 5. Route Mode Drive Flowchart

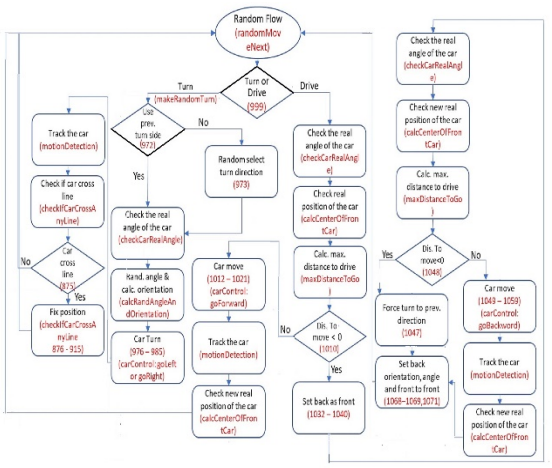

Fig. 6. Random Mode Drive

ALGORITHMS AND CALCULATIONS DESCRIPTION

Tracking Algorithm

The tracking algorithm is based on Motion Detection. It is based on OpenCV and example from OpenCV.org for implementation of motion detection.

Following is description of the algorithm:

1. Save an image of the area with no moving object in it – this image will be the reference image.
   a. In our case that's done when the user is press <Camera Ready> in function "onCameraReady"
2. The rest of the algorithm is implemented in the function "motionDetection". For each image the algorithm does:
   a. Change the image to gray level image
   b. Apply a Gaussian Blur on the gray level image
   c. Calculate absolute differentiation from the reference image
   d. Apply binary threshold for the result (will get black and white image where the different between the images is greater than threshold)
   e. Apply filter to reduce noises (dilate filter function from OpenCV) – the result is kept in image called "mask" (the masked image)
   f. The rest of the steps in this algorithm are implemented in function "showTrackingResults"
      i. Using OpenCV function "findContours" we find the contours of all the objects in the mask image
      ii. Using OpenCV function "max" we select the biggest object in the image
      iii. Using OpenCV function "minAreaRect" we define and save the enclosing rectangle of the car

Movement Calculations

General

All movement logics are based on the orientation of the car relatively to the images axes. We use in the software two parameters to describe the orientation:

1. carOrientation: this is the general direction of the car. The orientation names are:
   a. NW – north west
   b. NE – north east
   c. SE – south east
   d. SW – south west
2. carAngle: this is the exact angle of the car. We calculate it relatively to its general direction in the image. In other words, the angle of the car will always be in the range of 0-90 degrees.

The axes, the general directions and their names and the angle location for each direction is shown in figure 7.

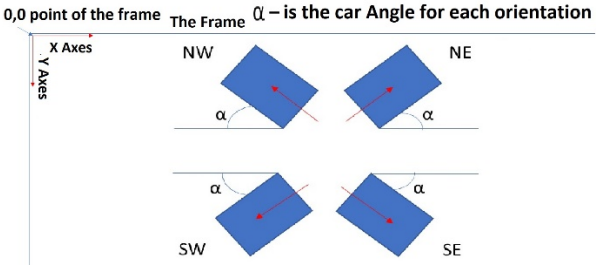

Fig. 7. The axes, the general directions and their names and the angle location for each direction

The frame of the car, which hold in array variable carBox in the software, is defined by 4 points. The first point (located in place 0 in the carBox array) will always be at the lowest point. From there the other points are kept clockwise as shown in figure 8.

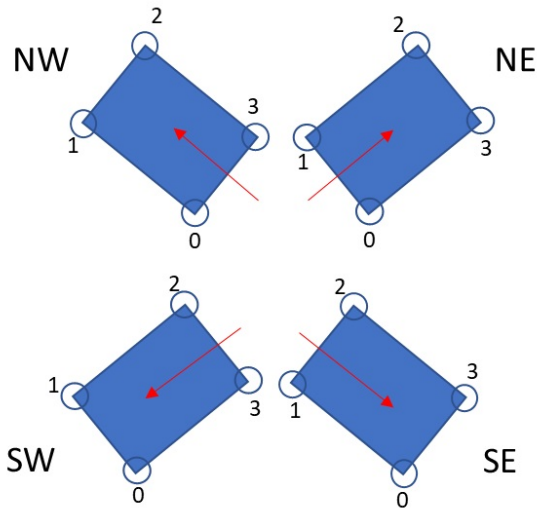

Fig. 8. The frame of the car is defined by 4 points

General Help Calculations

Based on the above explanation here are explanations on some help calculations done during the the flow of the software:

1) CALCULATING THE POSITION OF THE CAR

The position of the car is defined as the center of the front line of the car:

1. According to the orientation of the car (NW, NE, SE or SW) select the two points represent the front of the car:
   a. NW – points 1 and 2
   b. NE – points 2 and 3
   c. SE – points 3 and 0
   d. SW – points 0 and 1
2. Calculate the middle of this segment

2) CALCULATE THE REAL ANGLE OF THE CAR

1. According to the orientation of the car choose the two points along the car
2. Calculate the line angle = atan(dy/dx)

3) INTERSECTION BETWEEN TWO SEGMENTS

This calculation is implemented in function "find_intersection". It is based on an algorithm in Andre LeMothe's. The implementation was taken from [11].

There, you can also find a detailed explanation of the algorithm.

Route Mode Help Calculations

Now as we have the above help calculations and according to the above explanation on the orientations calculations such as: what side to turn, what is the angle of the turn are become straightforward.

To calculate the distance to drive to the next point is the Euclidean distance between the current location point to the destination location point.

Random Mode Help Calculations

1) TO CHECK IF THE CAR IS ON ONE OF THE LINES

1. Go over all the lines the user created on the video
2. For each line:
   a. Each two adjacent points, of the car, determined as a segment
   b. For each segment check intersection with the line

2) CALCULATE THE MAXIMUM DISTANCE THE CAR CAN MOVE

This calculation is implemented in function "maxDistanceToGo".

1. Check the shortest distance to the edge of the frame
2. Keep this distance in minDis variable
3. Go over all the lines the user created on the video
4. For each line:
   a. Create a vector for each side of the car:
      i. Example of a side: if the car orientation is NW one side will be points 2 and 3 and the other side will be 1 and 0
      ii. The vector goes from the back of the car to the front and on until the edge of the frame. For NW orientation, for example, the vector direction will be from point 3 to point 2 and the other vector will be from point 0 to point 1.
   b. For each segment check intersection with the line
   c. If there is intersection, calculate the distance to the line
   d. If the distance is smaller than minDis, keep this distance as the new minDis.

FUTURE PLANS AND CONCLUSION

We plan to create much more complicated prototype using Kamin grant (Israel).
The plane consists of the next stages:

1. Creating programs of video-navigation for airborne control from towers of ground robots on flat ground surface
2. Design and integration of robotic system: observation towers, controlling center, and ground robots
3. Testing robotic system and computer program, errors correction of robotic system and computer program
4. Rewriting programs for video-navigation than airborne control is made from tethered platform (drone or balloon) and ground robots on not-flat surface
5. Modernization of robotic system: creation of observation tethered platform (drone or balloon) and modernization of ground robots for not-flat surface
6. Testing robotic system and computer program, errors correction of robotic system and computer program

This system may be used for a wide class of robots: automated lawnmowers, robots for cleaning the rooms, tractors, snow-removal, garbage disposal and flushing vehicles, vehicles for people and goods transportation, agricultural and municipal vehicles, transport and so on. This system may be used for extra-terrestrial robots on other planets, for instance, for Mars rovers.

The system easily stays within the frames of the "smart home" or even "smart city" enabling to coordinate simultaneously a lot of actions, robots and other control objects and to solve many tasks - for instance, not only navigation but detection.

INFLUENCE OF THE FOUNDATION SIZE ON COLLAPSIBLE KHON KAEN LOESS

R. Thongpong[1] and R. Nuntasarn[2]
[1,2] Faculty of Civil Engineer, Khon Kaen University, Thailand

ABSTRACT

This paper presents the behavior of shallow foundation had a maximum load at 20 T/m^2,cast-in-situ sample for simulate old buildings at Khon Kaen University. Due to Khon Kaen loess in dry conditions have a high load capacity. However, these buildings are suffered when the soil under a shallow foundation is soaked. The volume of soil is significantly reduced, or soil is a collapse. Since the structure of this soil is a honeycomb structure, which is unstable. The size of a shallow foundation in Khon Kaen University has a variety of sizes depending on the service load. Almost the size foundation was designed by using soil parameters at the dry condition rather than a wet state. Therefore this research investigates the influence of the foundation size for bearing capacity on Khon Kaen loess in dry and wet conditions. The foundation sizes in this research are 1x1 meter and 1.2x1.2 meter, which is seated at a depth of 1.00 meters from the ground surface. Moreover, the site of testing is at Khon Kaen University. The study also considers the settlement of foundations — sudden subsidence from wet soil conditions and shear failure mode of soil. The Results on the experiment is the size of the foundation has an effect of subsidence. Larger more settlement at equal pressure and mode of shear failure is a local failure from both foundations. Suggest to prove in this study will be tested in dry condition.

Keywords: Shallow foundation, Khon Kaen Loess, Settlement, Soil parameters, Shear failure mode of soil

INTRODUCTION

The most buildings in Khon Kaen University have been built for a long time. The foundation of these old building was shallow with various sizes and depths. Due to the dry condition, the Khon Kaen loess has high strength. The foundation is the part of the structure used to support the entire building and transfer the load to the soil. Therefore engineering should be considered the engineering properties of the Khon Kaen loess to design the size of the foundation. Therefore this study investigates the effect of the foundation size on the bearing capacity at the same depth. Two sizes of the shallow foundation were 1x1 m, and 1.2x1.2 m at 1.00 m depth were studied. The result can be used in the design and actual operation, including repair and improve the strength of buildings. Moreover, this result can be worth the investment.

The objective of this paper is:

1. To study the behavior of the foundation size affecting the load capacity from the actual size foundation test
2. To study and compare the relationship between load-bearing capacity and settlement of foundations
3. To study the surface pattern caused by the mode of shear failures of soil

Udomchoke (1991) [1] explained about soil more very severe. Which can be considered that the wind-blow soil such as Khon Kaen loess have a sudden collapse. (Collapse Soil) In this type of soil is found in the arid area to the semi-arid area. Soils in this climate are mostly unsaturated. Because the underground water level is quite deep. In addition, the moisture content of the soil in the field of summer is about 3-5%. And in the rainy season is about 10-12%.

Ahmad et al. (2009) [2] presents an estimate of soil load capacity. From tests in the field and from the laboratory. To compare tests for determining the load carrying capacity of soil in the field and in the laboratory tests. The test in field is tested in 3 different areas. Depth are 2.5 meters and a circular steel sheet with an area of 1000 square centimeters. The unconfined compression test determined the shear strength of the soil sample. The results from field tests and laboratory tests, as shown in Table 1.

Table 1 Result from filed and laboratory test

Result	BH		
	1	2	3
Field Test Ks (kPa/m)	145283	152323	163443
Field Test q_{all} (kPa)	302.6	317.3	340.5
Laboratory Test (kPa)	276	320	401

The values obtained in the laboratory can confirm the determination of the load capacity from field tests, which can predict the load capacity in foundations which avoids surveying the entire area and saves both cost and time.

Briaud and Gibbens (1999) [3] used five concrete

footings sized 1x1, 1.5x1.5, 2.5x2.5, 3x3(South), and 3x3(North) m, all thick 1.5 m., and embedded 0.75 m in silty sand with a relatively constant profile of SPT blow count equal to 20 bpf. The water table deeps 4.9 m. The pressure versus settlement curves obtained from the load tests is shown in Fig. 1 the pressure under the footing was normalized by the average limit pressure of pre-boring pressure-meter tests performed within the depth of influence of the footing next to the footing. The settlement was normalized by the footing width. Fig. 2 shows that the normalization brings the five normalized curves into a narrow band. Therefore, in this case, the normalized curves are independent of footing width and can be represented by a unique curve.

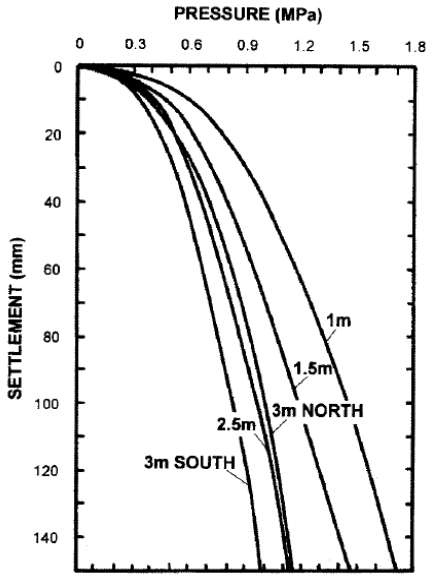

Fig. 1 The pressure versus settlement curves

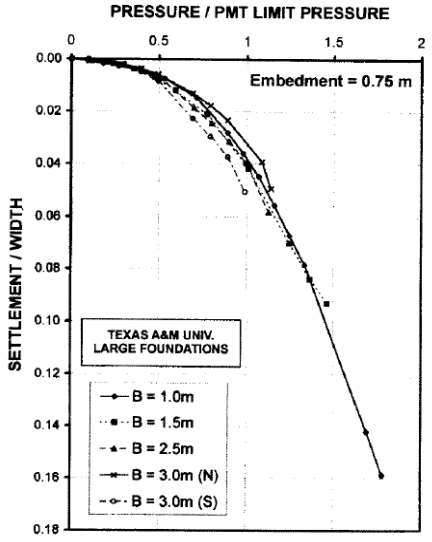

Fig. 2 The pressure/PMT versus settlement/width curves

Sanjeev et al. (2013) [4] made to study the bearing capacity and settlement characteristics of footings for develop an equation for predicting ultimate bearing capacity of two layered soils based on the test data. The footings subjected to central vertical load and resting on layered soil with the help of model tests, because in case of layer soil plate load test, the layer thickness is 2B or more, the effect of both layer will not be effected, However in case of actual large size footing the effect of lower layer will exist, Hence safe bearing capacity change. The tank size was 2000mm x 2000mm x1500mm (Length x Width x Depth). The depth below the base of the footing up to which the gravel is used is called as top layer thickness, and it thickness was varied as, 0.5B, 1.0B, 1.5B, and 2.0B, where B is the width of the plate. A total of 18 tests were conducted. For each test, load versus settlement curves were plotted and with the help of load-settlement curves, the ultimate bearing capacity of soil is determined. And the results of the tests on the field obtained

1) Same depth of sand, gravel layer. The load-bearing capacity will increase when the size of the plate load test increase, and the settlement decrease when increasing the size of the plate load test.

2) The gravel layer has a layer of sandy soil supported below. The load-bearing capacity increase when the gravel layer thickness is an increased in the test too. Moreover, the settlement is reduced.

3) The load-bearing capacity of the soil layer when L = 2B has a slightly different value from the other thickness on the gravel layer and the load-bearing capacity is constant.

Kim et al. (2017) [5] present that shallow foundations are usually located in the unsaturated area with high groundwater levels. This study investigated the influence of rainwater infiltration on subsidence behavior of shallow foundations by using numerical analysis to compare the numerical solution with experimental data from the field load test. The relative importance of density, rainwater falling in the area, and groundwater levels affecting the settlement of shallow foundations. Different groundwater levels that facilitate the absorption of rainfall, which requires numerical methods to calculate. General soil properties of the soil that are mostly residential in Korea is classified as the same type for use in numerical analysis. The study has a particular interest in the process of analyzing the flow of rain in the soil and soil deformation. The relationship between the load capacity and the subsidence obtained from that numerical method is currently consistent with field testing. The results of the parameterized study showed that the density of rainfall an important in the subsidence behavior of shallow foundations. In unsaturated soil with water changes in subsidence values during the rain have also been effective. The high groundwater levels show the affecting the change of gravity between soil grains (matric suction). Besides, it was found that the load capacity of the soil was high. Will have less permeability in the amount

of rainfall compared to the permeability of large amounts of rainfall the bearing capacity of the soil will be less. As shown in Figure 3 and 4 graph shows the relationship between settlement and stress occurring under a rainfall of two type soil conditions.

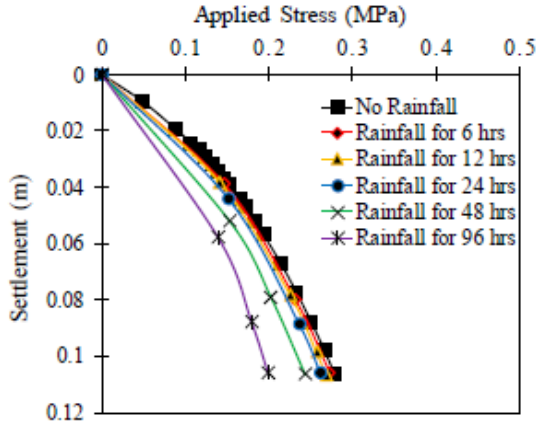

Fig. 3 Footing 5x5 m. Settlement and stress occurring under rainfall of soil type A.

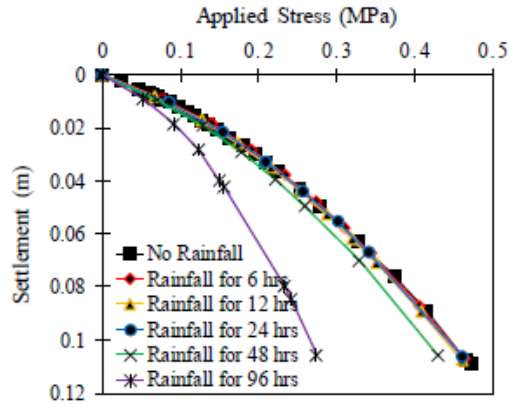

Fig. 4 Footing 5x5 m. Settlement and stress occurring under rainfall of soil type B.

METHODOLOGY

Isolated spreading footing -When the structure had a separate pillar that is reasonably separated. Where the load that is taken into the column was not very high and the soil layer is strong. Therefore, the area for weight loss does not require much space. The design is single footing for each column loading, which is economical and easy to constructed. In practice, these foundations are usually designed when the load-bearing area is not more than 10 square meters or the base area. Total not exceeding 50 percent of the building area. The characteristics of a single footing are shown in Fig. 5

Field test - The shallow foundation size of 1.0 x 1.0 m, and 1.2 x 1.2 m was installed at a depth of 1.00 m from the ground surface. Due to the limitation of the dead load, which is a pile, the maximum pressure was 20 ton per square meter. 50-ton hydraulic jack capacity was used to take pressure at 20 T/m^2 to the foundation size by size. Twenty piles were used as a dead load for 1.0 x 1.0 m, and Twenty nine piles were used as a dead load for 1.2 x 1.2 m. The equipment for settlement measurement was four LVDT attached to the reference beam at the corner of the foundation. Moreover, modes of shear failure surface measurement by elevation changing before and after taking a load to the foundation. It used ten footplates left and right of foundation long 3 times of wide foundation. The installation of the apparatus is detailed in Fig. 6, and Fig. 7.

Fig. 5 The single footing.

Fig. 6 LVDT Installation.

This study investigated the behavior of the foundation in a wet condition. The load increment in this study was 2 T/m2, and the load was maintained for 60 min. The maximum applied load was 20 T/m^2. After loading, the settlement was recorded at 1, 2, 4, 8, 15, 30, and 60 min each cycle of the load. The failure was defined as a total settlement of 25 mm. In addition, recommendations of European Committee for Standardization on Differential Settlement Parameters. [6] However, although the foundation reached the failure, the pressure was still applied to achieve 20 T/m^2.

In this study, the mode of shear failure was

studied by record the elevation of the ground surface as shown in Fig.8

Fig. 7 Footplate Installation.

After loading of to 20 T/m2, the foundation was prepared to soak condition — Embankment small dirt around the foundation for pit water. As shown on Fig. 9

In time soak condition maintain load 20 T/m2 all the time. Record settlement 30, 60, 90, 120, 150, 180 min that end of the circle for test 1.0x1.0 m, and 1.2x1.2 m to analyze behavior. Note 1x1 m. not soak condition.

Fig. 8 Recording ground surface settlement.

EXPERIMENT RESULTS

Basic Properties of Khon Kaen loess shown in Table 1. According to the hydrometer and sieve analysis found that Khon Kaen loess was classify as SM

Table 1 Basic Properties of Khon Kaen loess

Fig. 9 Soak condition

The results of foundation size 1x1 m and 1.2x1.2 m are shown in Fig. 10 and Fig. 11, respectively. The failure load of foundation size 1x1 m and 1.2x1.2 m was 8 and 10 ton/m2, respectively. Moreover, the settlement at the pressure of 20 ton/m^2 of foundation size 1x1 m, and 1.2x1.2 m was 55 and 60 mm, respectively. According to the result, there is no significant value load failure and settlement at a load of 20 ton/m^2 for both sizes of the foundation.

Moreover, the relationship between pressure and settlement for both sizes of foundation prior soaked show the local shear failure. After soaked, the foundation was settlement about one time in three hours, as shown in Fig. 11.

The elevation of the surface shown in Fig.12 and Fig. 13 respective from 1x1 m and 1.2x1.2 m foundation. The surface movement also showed the local shear failure, which was agreed with the relationship between pressure and settlement

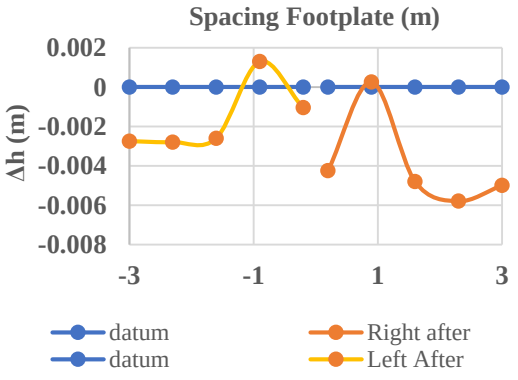

Fig. 12 Surface changing from foundation 1x1 m.

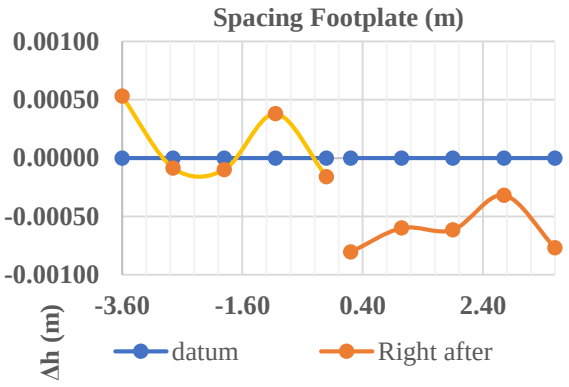

Fig. 13 Surface changing from foundation 1.2x1.2 m

DISCUSSION

The comparison of experimental results between two sizes of the foundation was present in Fig. 14. The graph shows no significant difference result between the two sizes of the foundation. The initial degree of saturation was slightly different.
Both of failure mode was a local shear failure, which is consistent with the surface displacement. Moreover, after soaking 3 hours the settlement was gained approximately 1 time. The rate of settlement was 0.05 mm per second.

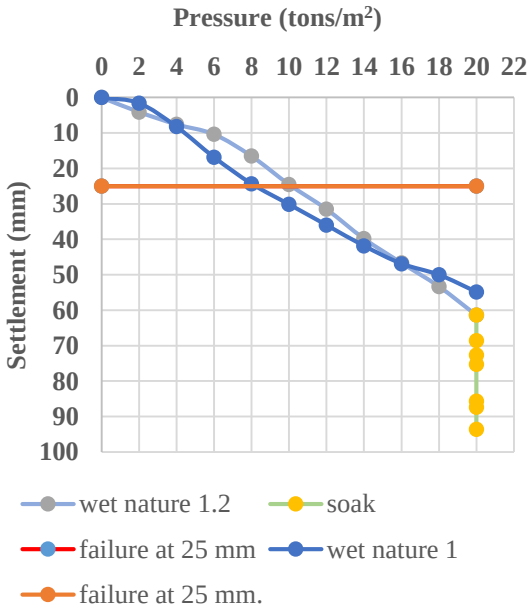

Fig. 14 Compare curve between 1.2x1.2 and 1x1 m.

CONCLUSIONS

The test result present that the size of the foundation does not affect the bearing capacity in the wet condition of Khon Kaen loess in this research. It may be the size of the foundation in this study is slightly different. Moreover, this study found that the failure mode of the foundation is local shear. Further

work, this study will investigate the shear strength parameter of Khon Kaen loess under saturated and unsaturated condition. Then the prediction bearing capacity from [7] and [8] will be compared with the field result. Meanwhile, the standard penetration test will also perform.

INFLUENCE OF A SHALLOW FOUNDATION DEPTH ON THE COLLAPSIBLE KHONKAEN LOESS

K. Piyasawat and R. Nuntasarn
Department of Civil Engineering, Faculty of Engineering, Khon Kaen University, Thailand

ABSTRACT

This research studied the bearing capacity and settlement of a shallow foundation on Khon Kaen loess. The bearing capacity and settlement of a shallow foundation was tested in the field by a static load test, at various depths for both natural and wet conditions. The foundation,1.0 x 1.0 m, seated at a depth of 1.0 meters and 1.5 meters. The foundation at a depth of 1.0 m was investigated only the wet condition but the foundations at a depth of 1.5 m were investigated in wet and dry condition. Four dial gauges were installed at the four corners of the foundation to measure the settlement due to the loading. The settlement of a 20 ton/m^2 load was observed in this study. The test result showed that the settlements of foundation at 1.5 m depth were 9 and 73 mm for dry and wet conditions, respectively and the settlement in a wet condition of foundation at 1.0 m depth was 55 mm. According to the theory, the deeper foundation has less settlement. Therefore the saturation degree was considered. The saturation degree of soil under foundation depth of 1.0 and 1.5 m was 30 and 33%, respectively. Hence it can be concluded that the degree of saturation of Khon Kaen loess is more effect to the bearing capacity rather than the depth of foundation.

Keywords: Shallow foundation, Bearing capacity, Collapsible soil, Khon Kaen loess, Static load test

INTRODUCTION

Loess is fine-grain soil which occurs extensively on Northeast Thailand. Loess has high bearing capacity when it is in a dry condition, but it has low bearing capacity when it is in a wet condition. That causes trouble in construction working.

Foundation is one of the most important structure because the vertical load of the building was transferred to the foundation. Therefore, the bearing capacity has to carry the apply load from the building.

In the past, the foundation of the building in Khon Kaen University usually used a shallow foundation because the strength of the soil is very high in the dry season. Without the consideration of the parameters in wet condition, therefore many buildings in Khon Kaen was damage due to the leaking water.

Hence, this study investigated the bearing capacity and settlement of shallow foundation on Khon Kaen loess at various depth for both natural and wet condition.

LITERATURE REVIEW

Udomchoke [1] present that the shear strength parameters of Khon Kaen loess are decreased when the moisture content is increased. Moreover, it also found that Khon Kaen loess is collapsible soil.

W.Gasaluck and R.Nuntasarn [2] present that Khon Kaen loess has a moderate degree of collapse. However, the collapse index of Khon Kaen loess is decreased by compaction at 95% by modified method. The strength of Khon Kaen loess is very high when the moisture content is low. Nevertheless, when the moisture content increases, the cohesion and friction angle are decrease and also damage to the building.

Hu Zhang et al. [3] study soil deflection in permafrost area with plate load test. Use the triangle plate and analyze by Burgers Viscoelasticity Model. This study also found that the frost heave effect on the rate of settlement. The rate of settlement increase with the ground surface temperature increase.

Bowles [4] The elastic settlement of a shallow foundation can be estimated by using the theory of elasticity (Se). The differential of the depth that the foundation seat effect on the settlement. The same type of soil will give the same modulus of elasticity and Poisson' s ratio. The net applied pressure on the foundation and depth factor are decrease when the depth of the soil increases. According to the theory, the deeper foundation has a less elastic settlement.

APPARATUS

In this study, the precast concrete size 1.0x1.0x 0.25 m was used as isolate shallow foundation, as shown in Fig 1. The counterweight was a group of pile size 0.35x0.35x5.0 m, as shown in Fig 2. Moreover, the load column, the capacity of 500 kN,

was used to measure the applied load. The settlement of the foundation was examined by using 4 Kyowa LVDTs. All electronic devices were connected to UCAM data logger, as shown in Fig 3, to record all data.

The ground surface settlement was also observed by used Leica sprinter digital levels, as shown in Fig. 4.

Fig. 1 Shallow foundation size 1 m x 1 m

Fig. 2 Electronic devices

METHODOLOGY

Khon Kaen loess was excavated at a depth of 1.0 and 1.5 m with a width of 1.4 m. Then the precast concrete as isolated spread footing was installed in the pitch. Four LVDTs were installed at the four corners of the foundation to measure the settlement due to loading. Hydraulic jack was installed at the center of the foundation for increase pressure during testing. The incremental loading was 2 ton/m^2. Reading out data from data logger at 0, 1, 2, 4, 8, 15, 30, and 60 minutes and repeat every tested pressure. In addition, footplates were installed at the side of the shallow foundation to measure ground surface displacement by Leica sprinter digital levels. The ground surface settlement was determined every loading. The foundation was soaked 3 hours, as shown in Fig.5 after pressure reach 20 tons/m^2. The pressure at soaked condition was maintained at 20 tons/m^2; meanwhile, the settlement of foundation was also measured every 30 mins.

Fig. 5 Soaked

LABORATORY RESULTS

The basic properties of Khon Kaen loess were present in Table 1. Khon Kaen loess was classified as

silty sand (SM) according to [4]. The majority of Khon Kaen loess is sand. The grain size distribution curve, as shown in Fig 6, was determined from sieve analysis and hydrometer analysis. The Atterberg limit, which is a liquid limit and plastic limit, showed a plasticity index of 2.6%. The specific gravity of 2.66.

% Passing #200	42.74
% Silt	21.75
% Clay	20.99

FIELD TEST RESULT

There were three foundations at the same size as 1.0x1.0x0.25 m. The first foundation was studied at a depth of 1.0 m in the wet condition. The initial degree of saturation was 30%. The relationship between settlement and pressure was illustrated in Fig. 7. As the definition of the foundation failure at 25 mm settlement, the failure load was 8 t/m^2. Moreover, the graph presents the bearing capacity failure mode as a local shear failure, which agreed with the ground surface displacement, as shown in Fig. 8.

The second foundation was studied at a depth of 1.5 m in the dry condition. The initial degree of saturation was 16%. The load and settlement curve, as illustrated in Fig. 9, was not present the failure load. Since the maximum applied load in this study was 20 ton/m^2. However, the failure occurs after soaking for approximately 1 hour. The settlement rate of the foundation after soaking was 17.64 mm/hr. Moreover, the graph presents the bearing capacity failure mode as a local shear failure, which agreed with the ground surface displacement, as shown in Fig. 10.

The third foundation was studied at a depth of 1.5 m in the wet condition. The initial degree of saturation was 33%. As the definition of the foundation failure at 25 mm settlement, the failure load was 5 t/m^2. The settlement rate of the foundation after soaking was 9.71 mm/hr. Moreover, the graph also presents the bearing capacity failure mode as a local shear failure, which agreed with the ground surface displacement, as shown in Fig. 12.

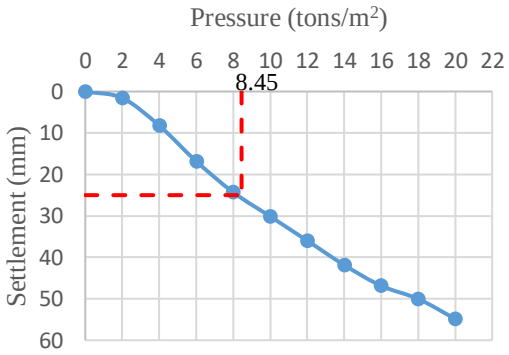

Fig. 7 Load - settlement curve of the first foundation

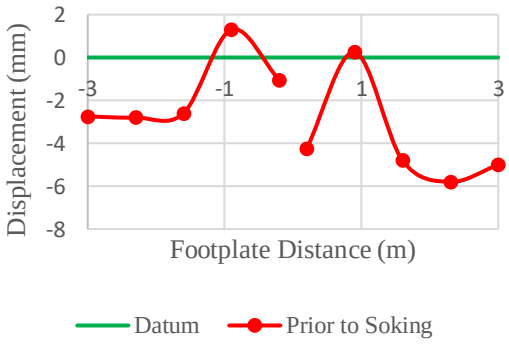

Fig. 8 Ground surface displacement of the first foundation

DISCUSSION

The comparison results between the first and the third foundation, which had the similar degree of saturation (approximately 32%) but different of the seating depth (Df), as shown in Fig. 13 found that

- The first and third foundation settlement at a pressure of 20 tons/m^2 before soak is 54.8 and 73.31 mm, respectively.

- The failure load at 25 mm settlement of the first and third foundation was 8 and 4.79 ton/m^2, respectively.

According to the theory, the foundation that seat on the deeper had a high bearing capacity and small settlement. However, the test shows otherwise. It might be the initial degree of saturation of the third foundation was higher than the first. Therefore, it can be concluded that the depth of the foundation was not entirely affected on the bearing capacity of Khon Kaen loess. However, the primary effect on the bearing capacity of Khon Kaen loess is the degree of saturation or moisture content of the soil.

The comparison results between the second and the third foundation, which had the same depth but different degree of saturation, as shown in Fig. 13 found that

- The saturation degree of the second and the third foundation was 16 and 33%, respectively.
- The second and the third foundation settlement at a pressure of 20 tons/m^2 before soaking was 9.06 and 73.31 mm, respectively.
- After soaking for 3 hours, the second and the third foundation settlement increased to be 61.97 and 102.43 mm, respectively.
- The incremental settlement of the second and the third foundation was 709.52 and 33.78%, respectively.
- The settlement rate of the second and the third foundation was 17.64 and 9.71%, respectively.
- The final moisture content of the second and the third foundation was 27.3 and 22.5%, respectively.

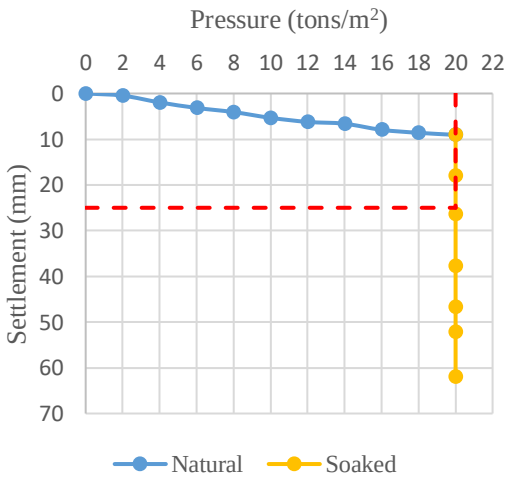

Fig. 9 Load settlement curve of the second foundation

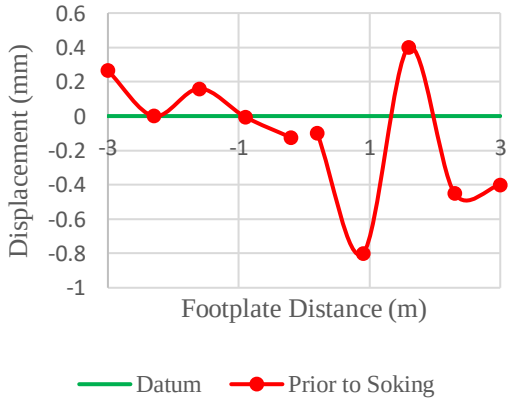

Fig. 12 Ground surface displacement of the third foundation

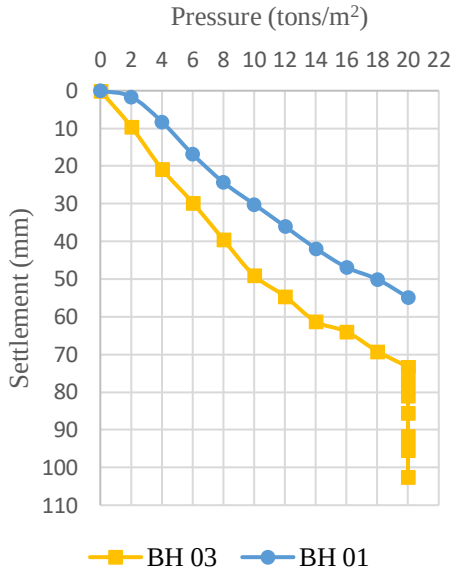

Fig. 13 Compare load settlement curve BH 01 and BH 03

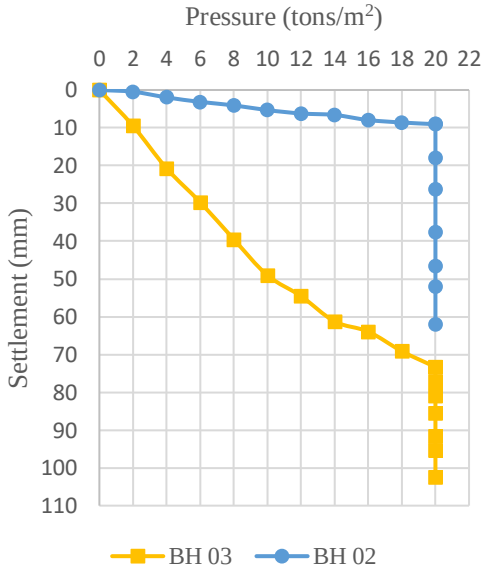

Fig. 14 Compare load settlement curve BH 02 and BH 03

CONCLUSIONS

The test results showed that the mode of failure was local shear failure. Moreover, the depth of the foundation was not entirely affected on the bearing capacity of Khon Kaen loess. However, the primary effect on the bearing capacity of Khon Kaen loess is the degree of saturation or moisture content of the soil.

ABSTRACT

Taking specimens from bored sample and conducting unconfined compression strength (USC) tests are common practice for strength estimation of cement improved soils. According to a Japanese practical guideline, 27 strengths in every 500 cement improved soil columns are recommended as a frequency of quality check for in-situ soil mixing method. On the other hand, the authors recognize that this frequency is the minimum level to estimate cement improvement works; it is clear that conducting more testing is ideal for further estimation to enhance work efficiency and to review design criteria. With these backgrounds, the authors are focusing on in-situ measurement of needle penetration resistance, i.e. a possible index to represent unconfined compressive strength, because it may realize multi point measurements without stepwise labors such as obtaining bored cores at site, bringing them to laboratory and shaping them to form UCS specimen. This paper deals with a fundamental study on in-situ measurement of needle penetration resistance on borehole walls prepared in cement improved layers. Using the prototype tool we have carried out the needle penetration tests in a model ground to obtain 100 trial measurements. In the same time, 2 cylindrical samples of the same model ground were prepared to measure each 25 needle penetration resistances on its surface by a conventional penetration system. Through the examination, we have found that both the measurements were consistent with each other. The results also revealed that required time for one measurement was just 72 seconds that may be effective for multi measurements at sites investigation.

Keywords: Improved soil, Penetration test, Unconfined compression strength, Quality management

INTRODUCTION

Taking specimens from bored sample and conducting unconfined compression strength (UCS) tests are most widely used for strength estimation of cement improved soils. For example, according to a quality management standard of deep mixing methods in Japan, 27 strengths in every 500 cement improved soil columns, adding 9 in another 250 columns, are recommended as a frequency of quality check in practice. While the standard is often referred to in practical works, the authors recognize that more testing is ideal for further estimation to enhance work efficiency and to review design criteria. On this occasion, just increasing the number of UCS test may be the simplest and easiest approach; it should be noted that several work steps, as described in the followings, are required before getting one UCS test result.

1) obtaining bored samples after solidification of cement improved soils
2) bringing them to laboratory
3) shaping them to form UCS test specimen
4) setting them on a test apparatus and conducting UCS test

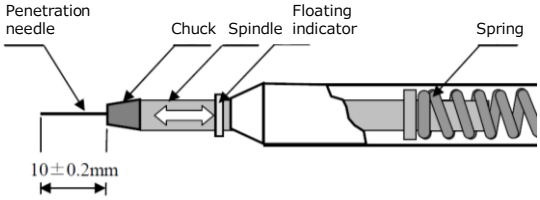
Since these would make UCS unsuitable for multi-point investigation, we have been studying extensive application of a needle penetration resistance which can get a possible index to represent UCS. As an alternative method of strength estimation of cement improved soils, we have proposed an in-situ measurement tool which measures needle penetration resistance efficiently on borehole walls prepared in cement improved layers.

In this paper, we firstly explain conventional needle penetration tests and introduce a prototype tool which measures needle penetration resistance on borehole walls. Then we secondarily implement it to trial measurements in a model ground and estimate the results to evaluate efficiency and accuracy of the new method.

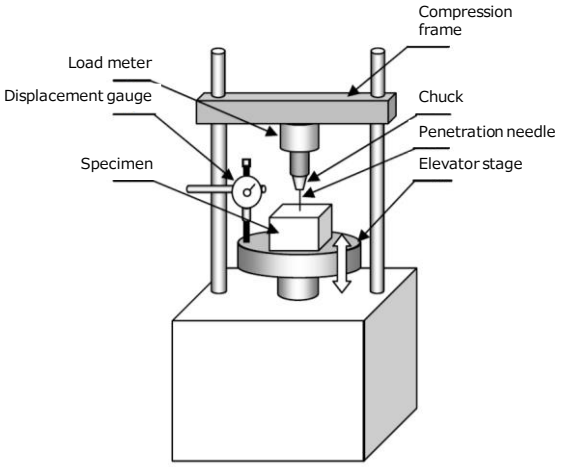
PROPOSAL OF NEW NEEDLE PENETRAION TEST

Conventional needle penetration tests

The needle penetration test, specified in Japanese Geotechnical Society Standard (JGS 3431-2012) [1], is a non-destructive test that has been designed to provide quick strength estimation for soft rocks and cement improved soils. In this test, the needle penetration resistance (N_p) is obtained as a penetration load divided by a penetration length. 10 mm penetration is normally employed as a standard length. The test method was originally established in



a) Portable type



b) Desktop type

Fig. 1 Needle penetration test apparatus

Japan, and now used practically and academically in other countries. Recently a study by Ulusay et al. (2012) developed a more generalized empirical relationship for indirect estimation of the UCS from N_p based on a total of 725 UCS-N_p data pairs obtained from soft rocks to very weak rocks [2]. Kahraman et al. (2017) investigated the predictability of coal strength based on N_p and a conversion factor, 0.35, for UCS- N_p linear ration was proposed for coal samples [3].

Two types of test apparatus are currently available as shown in Fig. 1, respectively.

A portable needle penetration test apparatus (Fig. 1a, hereinafter referred to portable type) is housed in a light weight casing and composed of the spring which is contracted in proportion to the penetration load during manual operation. The needle can be pushed into in-situ ground or bored samples in core containers by hand. When the needle penetration length reaches 10mm, or the penetration load reaches the maximum value, N_p can be quickly specified by reading the penetration length and load. While a typical merit of a portable type is easiness of handling and operation, accuracy of measurement is less because rate and angle of penetration is not strictly controlled.

A desktop needle penetration test apparatus (Fig. 1b, hereinafter referred to desktop type) controls the needle penetration rate at 20±5 mm/min and measures needle penetration load by an electronic cell in laboratory. In contrast to a portable type, it is possible

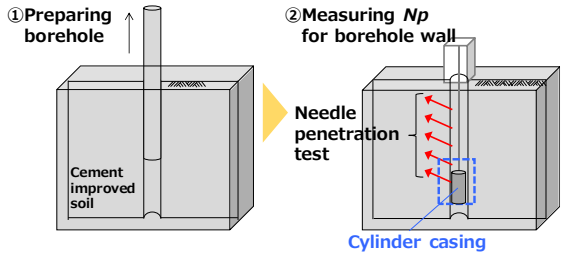


Fig. 2 Process of measuring N_p by borehole type

Fig. 3 Prototype tool

to record penetration load-length curves and obtain more reliable N_p. On the other hand, several work steps are required before conducting loading tests such as bringing sample to laboratory, shaping them to form specimen and setting them on a test apparatus, resulting in less easiness of handling and operation.

Proposal of borehole type

Considering the present two types of penetration test apparatus, we have studied concept of another method and pictured a new procedure as shown in Fig. 2. It is reasonable to be described as “a borehole type”, for which we can expect easiness of operation as well as accuracy of measurement. With further studies in detail parts, we have manufactured a prototype tool as depicted in Fig. 3. The main cylindrical casing of the tool has a diameter of 108 mm and a length of 443 mm, in which the following functions are built along with a needle penetration device:

- CCD camera (see Fig. 3A) which monitors needle penetration progress,
- reaction force device (see Fig. 3B) which pushes

the main casing onto a borehole wall to fix its position

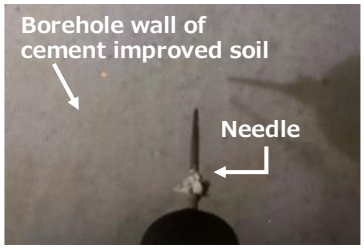
- and rotation wheels (see Fig. 3C) which adjust directions of penetration.

LABORATORY TESTS

Experimental outline

In order to evaluate efficiency and accuracy of the borehole type, we have planned the needle penetration tests as the followings:

a) Cement improved soil (a diameter of 300 mm and a length 1000 mm) keeping a borehole (a diameter of 114 mm) are prepared in a cardboard



a) Before penetrating

b) Penetrating in progress

Photo 1 Images of needle penetration

to take 100 measurements of N_p by the borehole type (see Fig. 4a)).

b) Two cylindrical specimens (each diameter of 100 mm and length 120 mm) of the same model ground are prepared to conduct each 25 measurements of N_p on its surface by the desktop type (see Fig. 4b)).

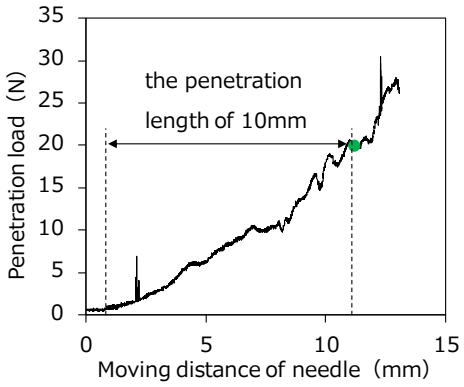
Model ground preparation

Table 1 shows mix proportions with which the model ground and two cylindrical specimens were prepared. The followings are the preparation procedure:

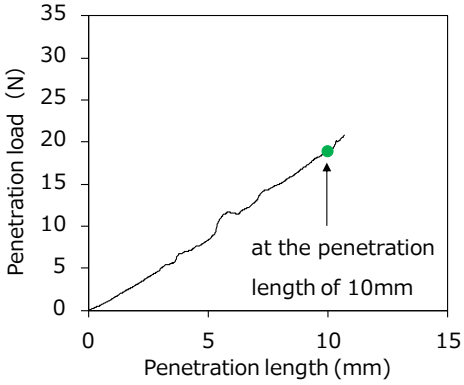
1) Kaolin powder and silica sand were mixed with water to produce clay slurry for 5 minutes.
2) Cement was mixed with water to produce cement slurry for 1 minute.
3) The cement slurry was poured into the clay slurry, and then they were mixed to produce cement improved soil for 1 minute.
4) The cement improved soil was poured into the clearance between the cardboard pipe and the polyvinyl chloride pipe which was inserted to create a borehole.
5) The polyvinyl chloride pipe was pulled out to produce borehole walls at the material age of one day.
6) In addition, the improved soil was poured into cylindrical molds to create specimens used for desktop type measurement.

Test results

Photo 1 shows examples of images during needle penetrating which are captured by CCD camera. These images indicate that the needle penetration of



a) Borehole type

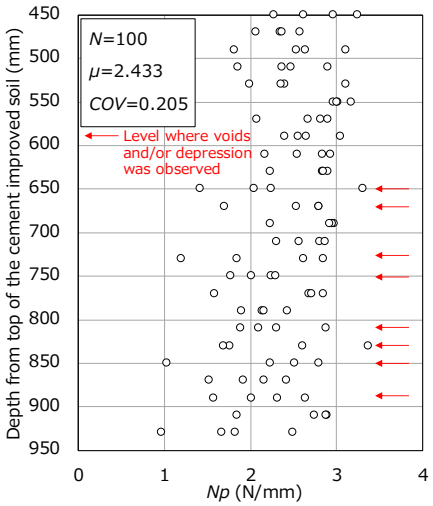


b) Desktop type

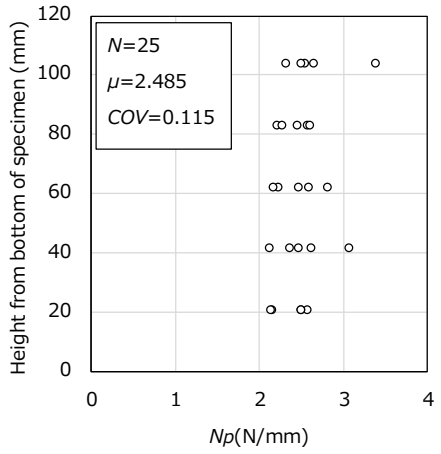
Fig. 5 The relationship between the penetration length and the penetration load

the borehole type was successfully controlled in a borehole.

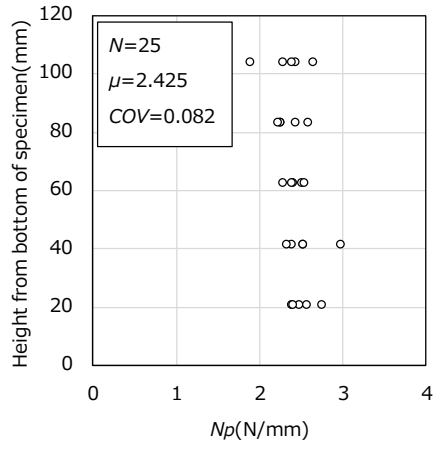
Fig. 5 shows examples of the penetration load which are measured by using a) the borehole type and b) the desktop type, respectively. In case of the borehole type, the penetration load is referred to "moving distance of the needle" because the needle started to move forward from a setback position in the cylindrical casing. Accordingly, as indicated in the Fig. 5(a) the penetration length was defined in the range where a certain level of load was detected. In case of desktop type, the tip of needle was firstly set on the surface of specimen and the needle penetration was started. Therefore, the penetration load is referred to "penetration length" as shown in Fig. 5 (b). It seems that the borehole type may still have rooms to be mechanically improved because i) there are remarkable variances in some length-load curves and ii) non-liner relationships of length-load curves are observed which are not consistent with results by the desktop type. On the other hand, the trial measurements revealed that required time for one measurement was just 72 seconds; this allows us to consider that such an efficient operation using the borehole type would contribute for challenge of multi measurements in ground improvement practice.



a) Borehole type



b) Desktop type (No.1 specimen)

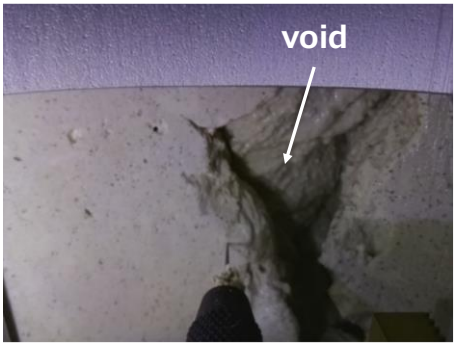


c) Desktop type (No.2 specimen)

Fig. 6 Results of N_p

Fig. 6 shows the distributions of N_p obtained from a) the borehole type, b) the desktop type (No.1 specimen) and c) the desktop type (No.2 specimen), respectively. It is clear the distribution of N_p by the

a) Depth of 670mm



b) Depth of 890mm

Photo 2 Images monitored by camera

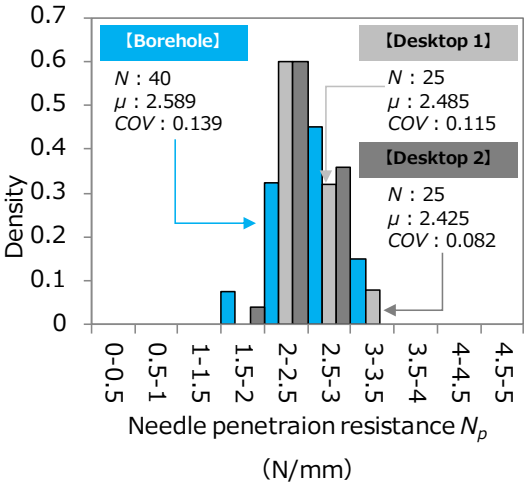


Fig. 7 Density distribution of each N_p

borehole type is more significant than ones by the desktop type. Furthermore, it may be said that the main distribution range of N_p by the borehole type is 2 to 3 N/mm having the additional distribution in the smaller range from 1 to 2 N/mm. Consequently, the coefficient variation of N_p by the borehole type is approximately twice as much as those measured by the desktop type.

In order to investigate the cause of the wider distributions of N_p, we have reviewed images captured by CCD camera during the penetration test. Photo 2 shows example images at a) depth of 670mm and b) depth of 890mm, respectively. Many voids and depressions were observed on the borehole walls which might have been created during the model ground preparation. This indicates that the cement mixed soil in these areas might be less compacted which may result in less strength. These kinds of the image were confirmed at many levels in the cement improved soil as indicated by the arrows in Fig. 6a. This leads us to consider the cement improved soil below 650mm may have been prepared improperly due to work difficulties affected by the deeper part of the carbonate pipe.

Finally, we reconfirmed the N_p by removing data below the 650 mm and the density distribution, defined as the frequency divided by its total number of data, was obtained as shown in Fig. 7. The remaining 40 measurements of N_p gives us the coefficient of variation of 0.139. It results that a frequency distribution of N_p by the borehole type is almost equivalent to one by the desktop type; the borehole type may be able to measure N_p of the model ground without a substantial difference from the desktop type.

CONCLUSIONS

In this study, we conducted needle penetration tests to evaluate efficiency and accuracy of the borehole type which was newly proposed as a device suitable for multi-point measurements. The following conclusions were obtained:

- The needle penetration of the borehole type was successfully controlled in a borehole, even though it has rooms to be mechanically improved.
- A frequency distribution of N_p can be obtained by the borehole type which is almost equivalent to one by the desktop type.
- Required time for one measurement of N_p was just 72 seconds by the borehole type, suggesting that it may be effective for multi measurements in fields.

In addition to the present work, we are focusing on upgrade of estimation formula of UCS based on N_p [4] and expecting better accuracy of UCS estimation. We wish these studies would be the first step of the development of a new system which can contribute to detailed analysis of ground improvement practice.

ABSTRACT

Autoclaved Aerated Concrete (AAC) is a lightweight cementitious material and has a unique structure characterized by a solid skeleton and pores (porous media). Currently, AAC is widely used in many building applications all over the world due to its advantages such as low density and thermal conductivity, high heat resistance, and so on. However, the quality of AAC including internal pore structure and network is highly dependent on materials and manufacturing process. In this study, using two different AAC block samples manufactured in Japan and Vietnam (JP-AAC and VN-AAC, respectively), 3-dimensional macropore structure and network (typical in > 30 μm diameters) were visualized and analyzed using a microfocus X-ray CT (MFXCT). The final goal of study is to characterize structure and network of macropores in AAC and to correlate the macropore characteristics to mass transport processes in AAC. First, the tested samples (~ 5 cm dimension cube) were scanned with different scanning resolution (SR) with 12, 30 and 50 μm /voxel and region of interest (ROI) with 300 voxels. Then, the pore structural parameters such as effective pore radius (r_{eff}), coordination number (N), and tortuosity in z direction (T_{zz}) were analyzed. The results show the difference in SR greatly affected the Mean value of r_{eff} for both JP-AAC and VN-AAC. A relatively difference can be observed in the Mean value and Standard Deviation (SD) of T_{zz}. For JP-AAC, the T_{zz} showed a SD ranging from 0.33 to 0.54. On the other hand, the measured T_{zz} for VN-AAC showed a SD ranging from 0.35 to 0.49.

INTRODUCTION

Autoclaved Aerated Concrete (AAC) is a lightweight cementitious material and has a unique structure characterized by a solid skeleton and pores (porous media). Currently, AAC is widely used in many building applications all over the world due to its advantages such as low density and thermal conductivity, high heat resistance, and so on [1].

A typical process for the production of AAC includes hydrothermal treatment of a mixture of quartz sand, lime, cement, gypsum and other additives at high temperature (typically, 180–200°C) under saturated steam pressure, which results in the formation of crystalline calcium silicate hydrates, namely, tobermorite ($Ca_5Si_6(O,OH,F)_{18}5H_2O$) [2]. Therefore, due to the influence of the manufacturing process, multiple pores are generated.

The diameter (d) of the pores is classified into Micropores of d <10 μm and Macropores of d≥10 μm. Micropores are mainly composed of Tobermorite. SEM images show the layered structure of Tobermorite [3]. Trong [4] shows the distributions of Pore size and pore volume of Japanese-made AAC (JP) and Vietnamese-made AAC (VN1 and VN2) measured by Mercury Intrusion Porosity (MIP). The pore size distribution of JP and VN1 are bimodal, whereas the curves of VN2 are almost single peak. However, the volume of fine pores with the pore radius of around 10 nm, is much higher in JP (about 0.594 ml/g) than that in VN1 (about 0.372 ml/g). That is the reason why, a clear difference was seen at d <10 μm in JP, VN1 and VN2, but no significant difference was seen at d≥10 μm of the MIP measurement.

However, although AAC possesses a clear difference in Micropore, up to now, only a few studies have shown differences due to differences in the manufacturing process at the macropore level.

Therefore, the purpose of this research is to visualize and analyze the structure of macropore level with Micro-Focus X-ray CT (MFXCT). That is visualization and analysis of structures of macropores using a MFXCT system and particle/pore network analysis software. On the other hand, the structure and network of pore of AAC control physical properties such as surface area, water retention, thermal conductivity, and gas diffusion. Therefore, macropores analysis results can be used to model

mass transfer coefficients (including water retention capacity) that control physical properties, and for quality control.

METHODS

First, the target materials are AAC from Japan (manufactured by Asahi Kasei Corporation): JP-AAC and AAC from Vietnam: VN-AAC1. The macropores of these two samples did not differ much with the naked eye.

These air-dried materials were cut on a rectangular solid so that the volume could be seen. The weight of the air-dried condition was then measured. The samples were then saturated to fill all the pores with water. From this saturated condition, water was removed by suction pressure method (pressure chamber method). The suction pressure is based on the relationship (1) of the pore diameter and the matrix potential by capillary action,

$$H = \frac{0.3}{d} \qquad (1)$$

where H is the matrix potential and d is the pore size. From this, the matrix potential H=-300 cm H_2O (ε_{300}) corresponding to the macropores (d> 10 μm or r> 5 μm) was calculated.

Scanning conditions for MFXCT system (inspeXio SMX-90CT, Shimadzu Co Ltd. Japan) include Energy level is 90 kV, 110 μA, View number is 1800, Average number is 4, Scan number is 1, Image size is 1024x1024 pixels, Scaling factor is 150, Scanning Resolution (SR) is 12, 30, 50 μm / voxel, FOV (XY) is 12.3, 30.7, 51.2 mm and FOV (Z) is 6.5 in Field of view (FOV), 16.2, 27.0 mm, and the number of slices is 541.

The CT image data of the sample scanned by MFXCT system was reconstructed and then analyzed by ExFact VR 2.1 (Nihon Visual Science Inc., Japan). Region of interest (ROI) is 300 voxels. The CT image data in this range was imaged into 8 bits and then binarized. The threshold value of luminance as a reference of the binarization is a value at ε_{300}, which is set to each of JP-AAC and VN-AAC1 samples. The threshold value as a reference of the binarization is a value at ε_{300}, which is set to each of JP-AAC and VN-AAC1 samples. From the above, the locations of macropores and solid and micropores of 8-bit CT image data could be seperated.

Next, the effective pore radius (r_{eff}) of Macropores is shown using ExFact VR 2.1.r_{eff} is the pore radius calculated by assuming each pore as a sphere. At the same time, Numbers of pores connected to a pore, the Coordination number (N), and Tortuosity (T_{zz}), which characterizes the tortuous path of pore, are shown.

T_{zz} is defined in (2).

$$T_{ZZ} = \frac{L}{L_s} \qquad (2)$$

where L is the actual path, and L_s is the shortest path.

RESULTS AND DISCUSSION

Table 1 shows the results of the porosity (φ) according to the dry density ρ_d (g/cm^3) and mineral density ρ_s (g/cm^3) of JP-AAC and VN-AAC1 samples and each condition.

Table 1 Comparison of density and porosity between JP-AAC and VNAAC1 samples

Items	ρ_d (g/cm^3)	ρ_s (g/cm^3)	φ (Total)	φ (ε_{300})
JP-AAC	0.50	2.15	0.77	0.34
VN-AAC1	0.53	2.71	0.80	0.46

According to Table 1, ρ_d is almost the same between JP-AAC and VN-AAC1 samples, in which ρ_s is larger in VN-AAC1 sample. It is found that Total φ is almost the same, and φ at ε_{300} is larger in VN-AAC1 sample.

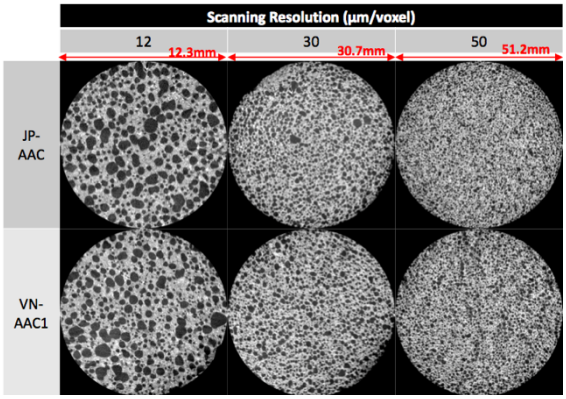

Fig. 1 MPR image (Brightness Level, Range: Auto).

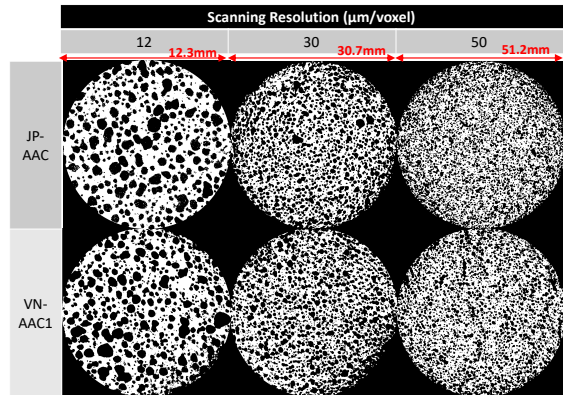

Fig. 2 MPR image (binarized with ε_{300}).

Fig. 1 shows a comparison of MPR images of (Brightness Level, Range: Auto) between JP-AAC and VN-AAC1 samples. With observed by the naked eye, no big difference can be seen in each SR. However, Fig. 2 shows a comparison of binarized MPR images with ε_{300}. The black zone shows macropores, and The white zone shows solids and micropores. Also, no big difference is seen in each SR.

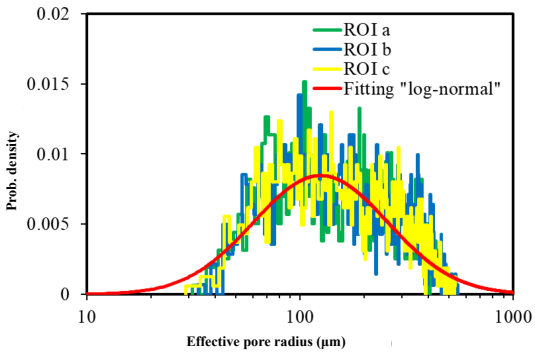

Fig. 3 Distribution of Effective pore radius (r_{eff}).

Fig. 3 shows an example of JP-AAC's Prob. Density and r_{eff}. From this, from the method of [5], three normal distribution curves were fit with ROI = 300 voxels. This result is given in Fig.4. Similarly, Fig.5 and Fig.6 show N and T_{zz} (All paths) are shown, respectively, where 3 normal distribution curves of the same posision of ROI = 300 voxels are fit. These fitting are based on the Shapiro-Wilk test, ANOVA test, and Kruskal-Wallis test ([6, 7]). Table 2 and Table 3 show the mean value (Mean) and standard deviation (SD) of r_{eff}. Similarly, Table 4 and Table 5 show the mean value (Mean) and standard deviation (SD) of T_{zz}.

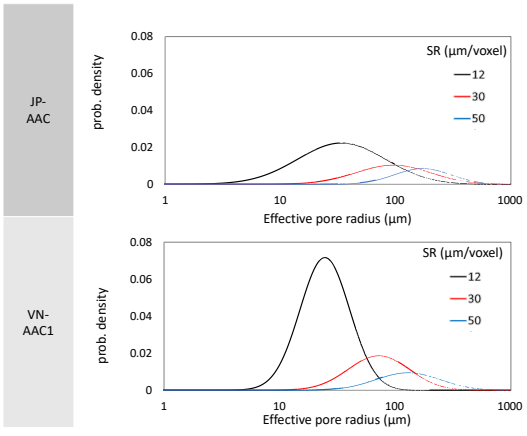

Fig. 4 Normal distribution of Effective pore radius (r_{eff}).

Table 2 Comparison of Mean value of r_{eff}

SR μm	12 Mean	30 Mean	50 Mean
JP-AAC	186.1	301.0	412.5
VN-AAC1	149.2	358.9	562.5

Table 3 Comparison of Standard Deviation (SD) of r_{eff}

SR μ m	12 SD	30 SD	50 SD
JP-AAC	115.9	164.6	228.1
VN-AAC1	107.9	221.3	347.4

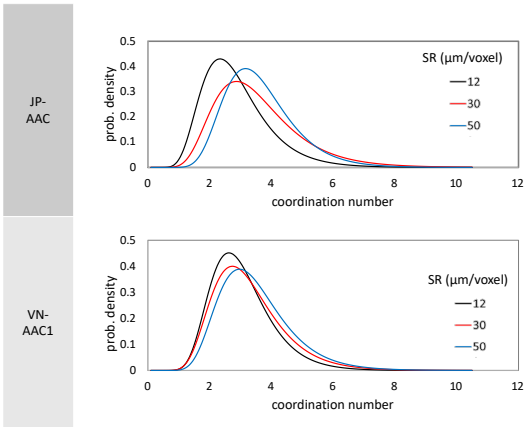

Fig. 5 Normal distribution of coordination number (N).

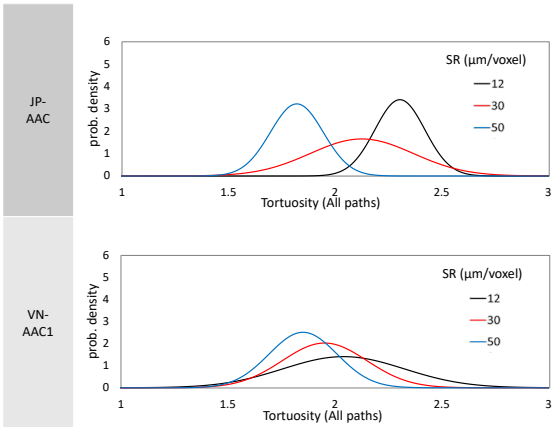

Fig. 6 Normal distribution of T_{zz} (All paths).

Table 4 Comparison of Mean value of T_{zz} (All paths)

SR	12	30	50
	Mean	Mean	Mean
JP-AAC	3.04	2.33	2.05
VN-AAC1	2.33	2.24	2.08

Table 5 Comparison of Standard Deviation (SD) of T_{zz} (All paths)

SR	12	30	50
	SD	SD	SD
JP-AAC	0.54	0.46	0.33
VN-AAC1	0.49	0.43	0.35

These data show no significant difference of N between JP-AAC and VN-AAC1 samples. Besides, in SR = 30, 50 of r_{eff}, the JP-AAC sample has a larger variation than the VN-AAC1 sample, and Mean is also larger in the VN-AAC1 sample. The difference in SR limits the minimum resolution, which may result in this, but the VN-AAC1 sample is larger. According to [5], there is a positive correlation between the r_{eff} and the air permiability, so it is considered that the VN-AAC1 sample is a material that is easier to ventilate.

Moreover, T_{zz} is larger in the JP-AAC sample at SR = 12, 30 and almost the same in SR = 50. However, T_{zz} of the JP-AAC sample is higher than that of the VN-AAC1 sample. According to [8], it is shown that T_{zz}, when converted, is close to the measured value of the gas diffusion coefficient. Moreover, since this T_{zz} is higher in the JP-AAC sample than in the VN-AAC1 sample, low air permeability is expected, and the heat insulation is considered to be higher than in the VN-AAC1 sample. In addition, the VN-AAC1 sample is expected to have low thermal insulation in comparison, and it can be said that it is a material suited to the conditions of high temperature and humidity in Vietnam, compared to the JP-AAC sample.

CONCLUSIONS

Focusing on the same macropores of JP-AAC and VN-AAC1 in appearance, to scan and visualize these by MFXCT system, then to use software and analyze the particle / pore network. The result is that r_{eff} is about 50-57 μm larger for VN-AAC1 sample and N is almost the same, and that T_{zz} is 0.03-0.05 for JP-AAC sample. From this, it is considered that a clear difference between JP-AAC and VN-AAC1 samples of the pore network of macropore.

RECYCLED GYPSUM AND RICE HUSK ASH AS ADDITIVES IN THE STABILIZATION OF EXPANSIVE SOIL

Jomari F. Tan[1], Mary Ann Q. Adajar[1]
[1]Department of Civil Engineering, College of Engineering, De La Salle University, Philippines

ABSTRACT

Expansive soils pose great risk to the structural integrity of many overlying structures. Given the impracticality of mechanical means of ground improvement in smaller projects, chemical stabilization is preferred. An economic and sustainable way of improving weak soils can be achieved with waste utilization of discarded materials as enhancing additives. Clay loam from Kauswagan, Lanao del Norte were treated with varied proportions of recycled gypsum and rice husk ash. Evaluation of the effectiveness of the admixtures were done based from criteria and laboratory tests listed by NSCP 2010 Section 303.5 and ASTM D4609. Addition of gypsum as lone additive increases plasticity, while further addition of RHA finally diminishes plasticity. Compaction characteristics at 15% gypsum + 10% RHA had maximum dry density increased by 1.918 kN/m^3 and optimum water content decreased by 26%. While overall decrease in swelling was observed, only specimens with 15% gypsum + 10% RHA were considered non-expansive (EI < 20) by NSCP 2010. Mean compressive strengths of specimen were enhanced with a peak value of 1.128 MPa at 15% gypsum. Considering criteria from ASTM D4609 and NSCP Section 303.5, an admixture combination of gypsum and RHA can be considered effective in improving expansive soils.

Keywords: Expansive soils, Recycled gypsum, Rice husk ash, Soil stability, Expansion index

INTRODUCTION

Expansive soils are a type of soil which exhibit significant changes in volume. Comprised primarily from volcanic material, its composition enables this change as manifested through a cyclic shrink-swell behavior. Climatic conditions influence the soil condition due to its dependence on moisture [1]. Torrid weather facilitates shrinking in soil, while heavy rainfall triggers consequent ground swelling. This soil characteristic is primarily determined by certain clayey minerals such as kaolinite and montmorillonite, components which allow greater water absorption [2]. Repeated shrink-swell cycles eventually result to differential ground movement, causing varying degrees of damage to overlying structures. Conventional solutions to poor soil conditions often implement soil replacement with better quality fill or compaction using heavy equipment. Despite their effectiveness, these practices raise concerns on their environmental footprint and economic viability. A more practical solution can be found through chemical soil stabilization. In this method, an additive is applied to the soil to improve engineering properties. Based from the National Structural Code of the Philippines, improvement by chemical means is recommended when designing foundations [3] to prevent potential damages to houses and buildings. Additives in soil stabilization often contain cementitious or pozzolanic properties which are known catalysts in improving soil conditions. While materials such as lime and cement are established additives already, these promote excessive carbon dioxide emissions during production, leaving a great environmental impact in the process. Waste and other discarded materials can be considered cheaper and more sustainable options.

Gypsum is chemically known as calcium sulfate. As an industrial material, gypsum is commonly used in cement and drywall production. Discarded forms of gypsum can be sourced from waste plasterboards and manufacturing rejects. Originating in Japan, the practice of recycling gypsum was done in response to the growth of their construction industry beginning in 1970 [4]. It has been used in ground improvement for road embankments and highways. Its cementitious properties were found to induce strength development in past studies [5],[6].

Challenges may be encountered with gypsum as a lone stabilizer in wet environments. Previous studies raised the necessity for a solidification agent to improve its performance as a stabilizer [5]. A second additive should be paired with recycled gypsum to achieve better soil conditions.

Rice husk is the most abundant agricultural waste in the Philippines. While its original form provides little to no beneficial or nutritional use, its incinerated form exhibits good characteristics. Rice husk ash contains rich amounts of silica and aluminum which exhibit pozzolanic properties that can facilitate strength development [7]. Moreover, RHA costs less and is produced in greater quantities compared to other chemical additives. Commonly, RHA is being used as fertilizer, fuel, or partial cement replacement.

The main objective of this study is to examine the effectiveness of a recycled gypsum-RHA mix in mitigating volume change and improving strength of expansive soils. Evaluation of results shall be measured using engineering properties such as Atterberg Limits, Maximum Dry Density (MDD), Optimum Moisture Content (OMC), Expansion Index (EI) and Unconfined Compression Strength (UCS). The study also determines the physical and chemical composition of the tested expansive soil and each additive. Finally, the study aims to find the best gypsum-RHA mix proportion that yields the most desirable result in reducing swelling and enhancing compressive strength.

Repurposing waste gypsum for soil stabilization is necessary given that its disposal poses harmful impacts to the environment. Organic materials may react with sulfates in discarded gypsum to form hydrogen sulfide gas. Hence, recycling gypsum reduces its environmental impact. Moreover, the use of RHA is highly encouraged, given that the Philippine rice production marks at 2 million tons annually [8]. The measure presented by this study leans towards low-cost sustainable approaches to improve weak expansive soils and to provide alternate disposal options for discarded materials.

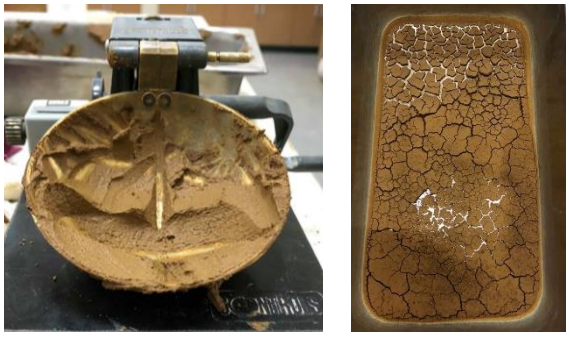
MATERIAL AND METHODS

Source of Expansive Soil

The soil to be investigated in this experiment was gathered from Kauswagan, a coastal municipality located in the province of Lanao del Norte in the Philippines. The specimen belongs under the Adtuyon soil series which was initially identified in barangay Adtuyon in the municipality of Pangantucan in Bukidnon. This soil series is characterized to have been developed from volcanic deposits which consist of basalt and andesite boulders. surface soils were observed to be brown, friable, and granular like clay. Meanwhile, the subsoil is generally darker in color with hints of reddish tint in some cases. Possessing clayey properties, the subsoil is plastic in the presence of moisture, but hard and brittle in dry conditions [9]. Moist soil samples changed the color into a darkened pale brown mixture (Fig 1a). A sticky and viscous texture was also observed among all test specimens. This was indicative of the cohesive trait found in all clayey and expansive soils. Dry samples exhibit significant cracking and reduction in volume, indicating its shrink-swell tendencies (Fig 1b).

Source of Recycled Gypsum

Recycled gypsum was sourced from a small wet market stall which sells the powder as plaster for nearby construction projects. Recycled gypsum is typically prepared from three different sources. Waste are obtained from excess and rejected plasterboard from manufacturing, new construction, and demolition. Contaminants from nails, screws, paint, wall coverings etc. are removed prior to recycling process. The collected waste gypsum is pulverized into powder form and is typically heated at 130℃ to 160℃ depending on the preference of the recycling company.



a) moist soil b) dry soil

Fig. 1 Moist and dry soil samples from the study

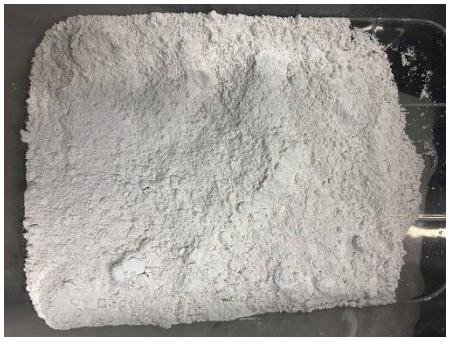


Fig. 2 Recycled gypsum samples used in the study

Source of Rice Husk Ash

Rice husk ash was obtained from Restored Energy Biomass Power Plant in Muntinlupa City, Metro Manila. The rice husk sourced from the plains of Nueva Ecija were incinerated by the said company at a fixed high temperature to create power using biomass energy [10]. The byproduct of this process yields roughly textured ash. The material was sourced from a lone power plant to preserve the consistency of its properties. Moreover, the ash samples were stored away from environments which may compromise its quality.

Experimental Procedure

Before proceeding with the primary laboratory tests required to determine additive effectiveness, test soil samples were subjected for verification on its expansivity in accordance with standards set by Section 303.5 of the NSCP 2010 [3].

Fig. 3 Rice husk ash samples used in the study

Parameters given by the NSCP criteria were obtained using ASTM laboratory tests. Section 303.5 indicates that expansive soils can identified through its plasticity and particle size characteristics. Table 1 enumerates the required values that would classify a test soil sample as expansive.

Table 1 NSCP Criteria to Identify Expansive Soils

Parameter	Criteria
Liquid Limit, LL (%)	Greater than 50
Plasticity Index, PI (%)	Greater than 15
Percentage of soil particles passing the #200 sieve (%)	More than 10% of the particles pass the #200 sieve
Percentage of soil particles less than 5μm in size (%)	More than 10% of the particles are less than 5μm in size
Expansion Index, EI	Greater than 20

The laboratory tests performed on untreated and treated samples are enumerated in Table 2. These procedures were based from ASTM standards to establish a reference in evaluating the index properties and potential for shrink-swell behavior of tested samples.

Table 2 Laboratory procedures based from ASTM standards to determine index properties and potential for shrink-swell behavior

Laboratory Test	ASTM Standard
Specific Gravity Test	ASTM D854
Grain Size Analysis (Mechanical and Hydrometer Method)	ASTM D422
Liquid Limit Test	ASTM D4318
Plastic Limit Test	ASTM D4318
Expansion Index Test	ASTM D4829

The effectiveness of recycled gypsum and RHA as additives were tested as per provisions indicated by ASTM D4609. The criteria for assessing the test samples is summarized in Table 3.

Table 3 Laboratory procedures based from ASTM standards to evaluate the effectiveness of recycled gypsum and RHA as admixtures.

Parameter	Criteria
Liquid Limit, LL (%)	Significant reduction
Plasticity Index, PI (%)	Significant reduction
Maximum Dry Density, MDD (kN/m^3)	Increase by 80kg/m^3 (0.785 kN/m^3)
Optimum Moisture Content, OMC (%)	Decrease by 15%
Unconfined Compressive Strength, q_u (kPa)	Increase by 345 kPa

Five experimental trials were performed for each soil-additive mixture. The test results from ASTM D4609 and ASTM D4829 were the basis for assessment on the effectiveness of the additives. The admixture is only considered effective when the sample meets the required value for expansion index and unconfined compressive strength.

Mixture Preparation

The tests were divided into two sets: gypsum-only and gypsum-RHA mixtures. Both mixture sets were made by replacing varying percentages of the soil volume with the admixture. Calculations were based from the index properties of the soil and the additives. Both sets were mixed with gypsum at percentages of 5%, 10% and 15%. For the gypsum-RHA set, the rice husk ash was mixed at a constant percentage of 10%. Mixtures were cured for minimum period of 16 hours prior to performing laboratory tests.

TEST RESULTS

Soil Classification

Table 4 displays the resulting index properties of the test soil sample required for classifying the soil.

Table 4 Summary of Soil Classification

Parameter	Criteria	Result	Remarks
Liquid Limit, LL (%)	> 50	64.78	Pass
Plasticity Index, PI (%)	> 15	18.64	Pass
Percentage passing #200 sieve (%)	> 10%	59.14	Pass
Percentage less than 5μm (%)	> 10%	0.00	Fail
Expansion Index, EI	> 20	98	Pass
USCS Classification	MH (high plasticity silt)		

The results indicated that the soil sample did not meet the criterion on particle size. However, the rest of the index properties classified the test soil as expansive as the value of the expansion index governs. The EI value of the test soil was found at 98. Based from the USCS Classification, Kauswagan soil is classified as MH (high plasticity silt).

Evaluation of Additives as Stabilizing Agents

Atterberg Limits

Atterberg limits are threshold markers which indicate the moisture content values which represent the transition of soil from one consistency to another. Table 5 provides the average values for the each Atterberg limit tested for the soil-additive mixtures. ASTM D4609 states that a soil additive is deemed effective when significant reduction in liquid limit and plasticity index.

Table 5 Atterberg Limits of Soil-Additive Mixtures

Mixture	Liquid Limit (%)	Plastic Limit (%)	Plasticity Index (%)
Kauswagan Soil	64.776	46.847	17.929
5% Gypsum	79.060	42.937	36.122
10% Gypsum	75.326	39.851	35.747
15% Gypsum	71.815	37.486	34.329
5% Gypsum + 10% RHA	59.372	36.237	23.135
10% Gypsum + 10% RHA	56.184	36.828	19.356
15% Gypsum + 10% RHA	53.270	36.887	16.383

Test results show the trend in liquid limit values in the two set of additive proportions follow distinct behaviors. The inclusion of gypsum in the plain soil increased the liquid limit of the soil, yet a gradual increase in gypsum resulted into incremental decrease in liquid limit. A decrease is usually expected when introducing stabilizer agents, but several studies have reported the reverse occurrence [11],[12]. Gypsum used in construction manifests its ability to improve strength at high moisture content since its composition allows higher water absorption capacity. The eventual decrease in liquid limit with increase in gypsum was due to reduction of clay particles.

On the other hand, samples with a constant 10% RHA content saw a general decrease in liquid limit with the increase in gypsum content. RHA does not exhibit plasticity when exposed to moisture. Further soil particle replacement with the addition of non-plastic ash was a cause of the eventual decrease in plasticity.

Compaction Characteristics

Soil compaction demonstrates the relationship between densifying effect of repeated mechanical effort and the amount of moisture present in soils. Compaction parameters – maximum dry density and optimum moisture content – indicate the condition required to reach the most compact state of soil. Table 6 presents the values of these compaction parameters obtained using the proctor method.

Table 6 Compaction Values of Soil-Additive Mixes

Mixture	Maximum Dry Density (kN/m^3)	Optimum Moisture Content
Kauswagan Soil	11.916	42.415%
5% Gypsum	12.185	41.184%
10% Gypsum	12.405	39.940%
15% Gypsum	12.627	37.168%
5% Gypsum + 10% RHA	13.384	34.279%
10% Gypsum + 10% RHA	13.729	32.626%
15% Gypsum + 10% RHA	13.835	31.395%

ASTM 4609 requires a decrease of 15% for optimum moisture content and increase in $80kg/m^3$ for maximum dry density. When converted into kN/m^3, the required increase in density is 0.785 kN/m^3. A maximum decrease of 12.37% in moisture content for gypsum-only specimen and 25.98% for gypsum-RHA specimen was observed. Moreover, increases of 0.711 kN/m^3 and 1.918 kN/m^3 were obtained for gypsum only and gypsum + 10% RHA samples respectively. The resulting values suggest that 15% gypsum was nearly statistically effective in stabilizing the tested soil, but a minimum content of 5% gypsum + 10% RHA was adequate to be considered effective. However, it should be noted that the conditions from ASTM D4609 were suggested values to ensure experimental error did not affect results. Individual trial results were found to be consistent in values, which allows the additives to be considered effective.

Unconfined Compressive Strength

The unconfined compression strength of a given soil specimen is the peak axial stress resisted by an unconfined cylindrical soil specimen. The absence of confining pressure in the specimen eases the determination of the undrained shear strength. Figure 4 displays the trend between the strength of each soil-additive mixture and the curing period. The weekly values indicate that longer curing improves strength.

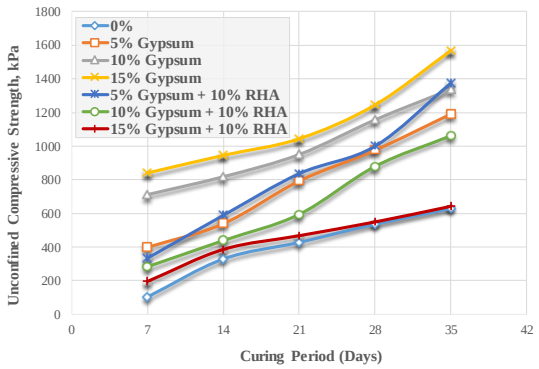

Fig. 4 Unconfined compressive strength of soil-additive mixtures vs. curing period

Reconstituted laboratory samples cannot recreate strength at in-situ conditions. However, particle rearrangement occurs when the remolded specimens were kept undisturbed during curing period. Constant moisture and composition when curing allows partial strength gains [13].

ASTM D4609 considers an additive effective when UCS increases by at least 345 kPa (50psi). The results shown by Figure 5 show that UCS of gypsum-only increase significantly with addition of gypsum for all curing period. Meanwhile, Figure 6 indicates that adding gypsum-RHA mix initially increases strength before decreasing eventually.

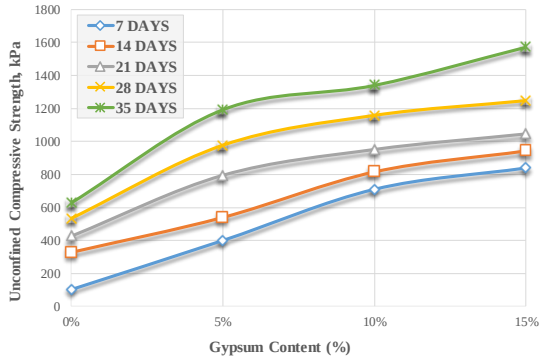

Fig. 5 UCS values of gypsum-only soil specimen vs. gypsum content

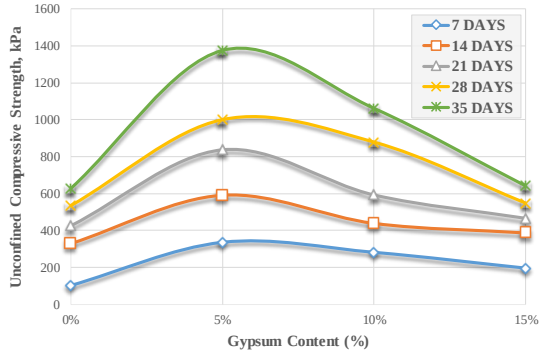

Fig. 6 UCS values of gypsum-only soil specimen vs. gypsum content

Gypsum has cementitious characteristics which enabled samples to gain strength over time. However, RHA is a non-cohesive material which deterred the strength development of the soil over time, resulting to the decrease for gypsum-RHA specimen.

Expansion Index

Expansion index measures the swelling potential of a given specimen. NSCP 2010 Section 303.5 defines EI as the determinant of the expansiveness of a given soil. The section states that a value exceeding 20 is considered expansive. Identifying the degree of expansiveness of a soil type is an important task in geotechnical engineering, considering the risks posed by weak soils to overlying structures. This parameter influences design considerations in foundations. Table 6 provides the mean expansion indices of each mixture.

Table 6 Expansion Index of Soil-Additive Mixtures

Mixture	Expansion Index	Potential Expansion
Kauswagan Soil	98	High
5% Gypsum	72	Medium
10% Gypsum	54	Medium
15% Gypsum	33	Low
5% Gypsum + 10% RHA	52	Medium
10% Gypsum + 10% RHA	28	Low
15% Gypsum + 10% RHA	11	Very Low

The EI of the soil saw a diminishing trend with each addition of gypsum and rice husk ash into the specimen. Introducing 15% gypsum reduced EI from 98 to 33, while adding 10% RHA decreased EI further to 11. An expansion index of 11 is considered non-expansive by NSCP 2010. The significant dip in expansiveness of the specimen was a consequence of clay particles replaced by material with either cementitious or non-plastic properties. The soil contains large portions of clay particles which can be linked to its high plasticity and expansion index. The calcium content of gypsum promoted particle hardening which limited the soil swelling. Moreover, RHA possessed good adsorption capacity which limited the attraction of water with clay particles when the specimen was fully inundated, eventually reducing EI into 11.

CONCLUSION

The summation of findings from the conducted study which introduced recycled gypsum and rice husk ash into expansive soil conclude the following:

Initial addition of gypsum increased liquid limit by 22%. However, a mixture of 15% gypsum and rice husk ash decreased liquid limit by 11.5%. This behavior cannot confirm the effectivity of the admixtures in diminishing plasticity of soil. Favorable results were found with compaction characteristics, with gypsum providing an increase in dry unit weight by 0.71 kN/m^3 and a decrease in OMC by 12.37%. Gypsum + RHA was more effective with improvements of 1.918 kN/m^3 and 26% respectively. Gypsum also greatly enhanced strength of 35-day samples with 15% gypsum providing 945 kPa mean increase compared to untreated samples. Slight increases in strength were observed with gypsum-RHA treated specimen, but improvement lessens with added gypsum content. Highest reduction in expansion index was achieved with 15% gypsum + RHA from 98 to 11. This is considered non-expansive based from NSCP Section 303.5.

Future work on this research are encouraged to focus on shear strength of soil based on short-term and long-term loading scenarios. Other agricultural wastes may also be considered as complementary to recycled gypsum.

ALLOWABLE SOIL BEARING CAPACITY REFERENCE FOR QUEZON CITY, PHILIPPINES

Jonathan R. Dungca[1]
[1]Faculty, De La Salle University, Philippines

ABSTRACT

Quezon City is the largest city in the National Capital Region of the Philippines. This city has several other cities and provinces that bound it. North Caloocan and the province of Bulacan bound the northern portions of the city. The eastern side of the city is bounded by Marikina city, the city of Manila and the province of Rizal. Mandaluyong, Pasig and San Juan bound the southern portions of the city. And finally, the western portions of the city are bounded by the cities of Valenzuela and South Caloocan. This paper provides the estimated allowable soil bearing capacity at different locations within the city. The allowable soil bearing capacity is being used by structural engineers when determining the required sizes of the shallow foundation for the structures that they are going to build. Several borehole data were collected to estimate the geotechnical parameters. The geotechnical parameters such as the angle of internal friction, cohesion, and unit weight were estimated using the SPT values derived from the collected borehole data. These geotechnical parameters were then used to estimate the allowable soil bearing capacity using Terzaghi equation for bearing capacity. The final output is a map of the city showing the contours of different colors which correspond to the different values of the allowable soil bearing capacities. Due to the presence of Guadalupe tuff formation at shallow depths, the estimated allowable soil bearing capacity ranges from a low od 100 kPa near the ground surface to as high as 1000kPa at a depth of five meters.

Keywords: Soil Bearing Capacity, Foundation Design, Standard Penetration Test, Geotechnical Properties

INTRODUCTION

Quezon City is located near the center of Metro Manila, towards the northeastern portion of the metropolis. It is bordered by Manila City in the southwest, Caloocan City and Valenzuela city in the west and northwest, San Juan City and Mandaluyong City in the south, while Pasig City and Marikina City in the southeast. It has a total land area of 161.126 km^2, which is one-fourth the area of the National Capital Region of the Philippines.

Quezon city is underlain by a thick sequence of predominantly water laid tuff and tuffaceous clastics collectively known as the Guadalupe Tuff Formation. The formation consists of lithified volcanic ash, lapili and crystal sands. Beds rich in sand and not directly derived from volcanic activity are common, especially in the upper section. They are generally compacted and slightly lithified or cemented by precipitated silica and/or clay. The underlying Tuff bedrock is generally well consolidated and cemented, however, varying degrees of chemical decomposition and disintegration are indicated at different intervals in the section with beds alternating with hard and unaltered layers [1].

There are 130 borehole locations that were used in this study. Borehole data from standard penetration tests (SPT) were collected within the city. The distribution of these data points is shown in Figure 1.

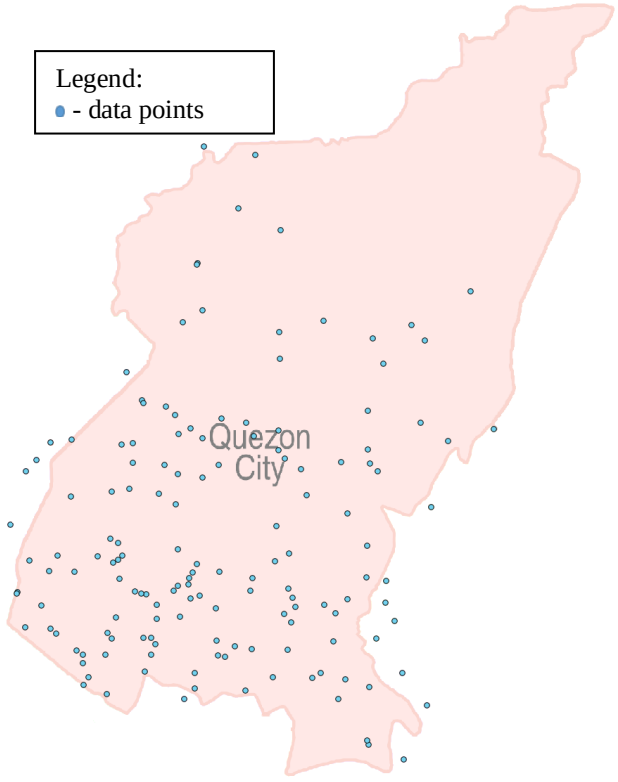

Fig. 1 Distribution of soil data in Quezon City

GEOTECHNICAL CHARACTERISTICS

The northern section of Quezon City is predominantly composed of silty sand, and high plasticity silts and clay up to the second meter; well-graded sand, low plasticity silts, and high plasticity silts and clays are the dominant soil type in the succeeding depths. Minor presences of poorly-graded sand and clayey sand are also observed. The central section is predominantly underlain by well-graded sand, silty sand, and high plasticity silts and clay with minor presences of clayey sand and low plasticity silt. Traces of well-graded gravel and poorly-graded sand are also observed. The southwestern section is predominantly underlain by silty sand, high plasticity silts and clays for depths reaching two meters; well-graded sand, low plasticity silts and high plasticity clays dominate the succeeding depths. Minor presence of clayey sand is observed as well as traces of poorly-graded sand and organic materials. The southeastern section is predominantly underlain by silty sand, high plasticity silts and clays up to a depth of two meters; well-graded sand, low plasticity silts and high plasticity clays dominate the lower depths. Minor presence of clayey sand is observed as well as traces of poorly-graded sand [2]. Table 1 further shows the distribution of the different soil types of both sections in varying depths up to a depth of five (5) meters. Table 2 shows the relevant design parameters that can be used for the designs of foundation in this area.

In soil sampling procedure, all sections are generally done by SPT up to the 2nd meter with mixed preference of SPT and RQD in the 3rd meter, and then the use of RQD in the succeeding depths.

METHODOLOGY

Quezon City has an approximate land surface area of 160 square kilometers. a density of 0.80 borehole locations per square kilometer was used to describe the geotechnical characteristics and possible foundation design parameters of the said area. Borehole logs were collected for a total of 130 locations all over Quezon City.

The amount of borehole logs alone is not the only criterion in gathering data for the study. It is just as important as, that the locations of the borehole logs be properly distributed. To check their distribution, each of the locations of the borehole logs was plotted in a map of Quezon City. After this, the distribution was visually inspected and the areas that needed more data were determined. Aside from these, borehole logs that seemed erroneous were removed and disregarded.

In properly designing shallow foundations, the geotechnical characteristics and allowable bearing capacity of the soil must be known. This is because the design would largely depend on the strength and the behavior of the soil. The bearing capacities are computed using the SPT-N values found in the borehole logs which were corrected using the procedures discussed in [1], [3]-[5], also shown in Equation 1.

$$N_{60} = \frac{E_m C_B C_S C_R C_N N}{0.6} \qquad \text{(Eq. 1)}$$

Where: N_{60} is the corrected SPT-N value (blows/ft), E_m is the hammer efficiency, C_B is the borehole diameter correction, C_S is the sampler correction, C_R is the rod length correction, C_N is the overburden pressure correction and N is the SPT-N recorded in the field.

The corrected SPT, N_{60}, values were then used to compute for various geotechnical parameters such as relative density, undrained shear strength and angle of internal friction using different correlation factors [6]-[10]. As such, the group computed the ultimate bearing capacity. The Terzaghi's and Vesic's bearing capacity formulas, shown on Equations 2 and 3 respectively, were used to achieve this [11]- [13].

$$q_{ult} = 1.2cN_c + \gamma D_f N_q + 0.4\gamma B N_\gamma \qquad \text{(Eq. 2)}$$

where: q_{ult} is the ultimate bearing capacity, γ is the effective unit weight, B is the width of foundation, D_f is the depth of foundation below ground surface, N_c, N_γ and N_q are the Terzaghi's factors.

$$q_{ult} = c' N_c s_c d_c i_c b_c g_c + \sigma'_{zD} N_q s_q d_q i_q b_q g_q + 0.5\gamma' N_\gamma s_\gamma d_\gamma i_\gamma b_\gamma g_\gamma \qquad \text{(Eq. 3)}$$

Where: s_c, s_q, s_γ are shape factors; d_c, d_q, d_γ are depth factors; i_c, i_q, i_γ are load inclination factors; b_c, b_q, b_γ are base inclination factors; and g_c, g_q, g_γ are ground inclination factors.

A factor of safety of 3.0 was divided to ultimate bearing capacity to determine the allowable soil bearing capacity of the soil. The allowable soil bearing capacities at different locations were then plotted on to the maps at 1-meter, 2-meters, 3-meters , 4-meters and 5-meter depths. Contour maps were created to visually classify and analyze the allowable bearing capacities at different locations in Metro Manila.

BEARING CAPACITY ESTIMATES

The allowable soil bearing capacity of Quezon City at one-meter depth from the ground surface is in the range of 200 to 300 kPa, as represented by the color red in Figure 2. The north, southwest, and some scattered portion of the center part of the city has bearing capacity values of 100 to 200kPa. Compared to other cities in Metro Manila, this is quite high for the first meter depth.

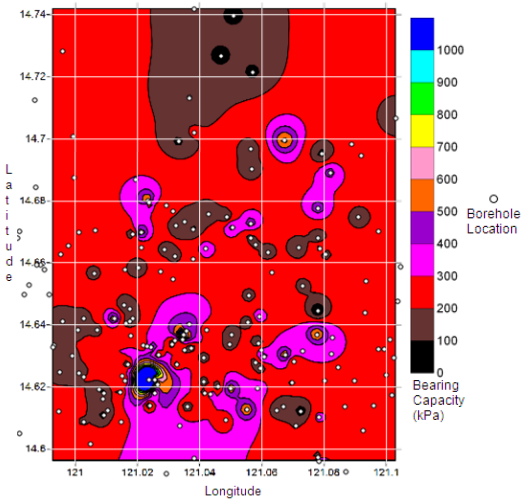

Fig. 2 Soil bearing capacity at 1-meter depth

At a depth of two meters from the ground surface, as shown in Figure 3, a significant increase in allowable soil bearing capacity is observed. The allowable soil bearing capacity is in the range of 400 kPa to 500 kPa. This is dominant on the central to the eastern side of the city. The northern and some parts of the south-eastern part of the city have a bearing capacity of 300 kPa. The north- western part of the city has reached 600 kPa. It is also seen that there are certain portions that already reached more than 1000 kPa, specifically the south-western part of the city. Those with high bearing capacities are those in the higher elevation areas.

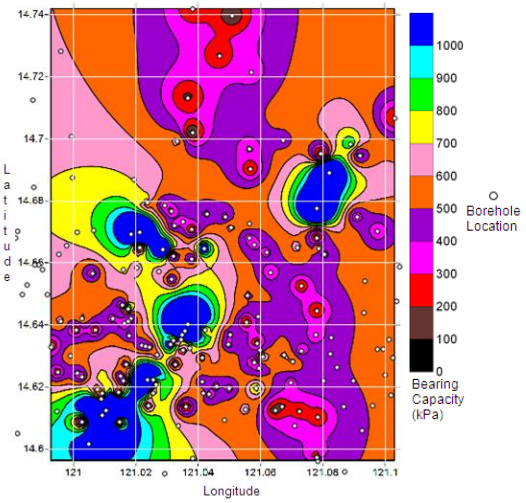

Fig. 3 Soil bearing capacity at 2-meter depth

At three-meter depth, there is a further increase in the allowable soil bearing capacity, as shown in Figure 4. Majority of the bearing capacity that was computed is now split into three ranges: 700 to 800 kPa, 800 to 900 kPa, and more than 1000 kPa. The north and southeast part of the city has the least bearing capacity of around 600 kPa, while the central, southwest, and east part of the city now has the strongest, with more than1000 kPa. One can observe that it still follows the trend that as the elevation increases, the bearing capacity also increases.

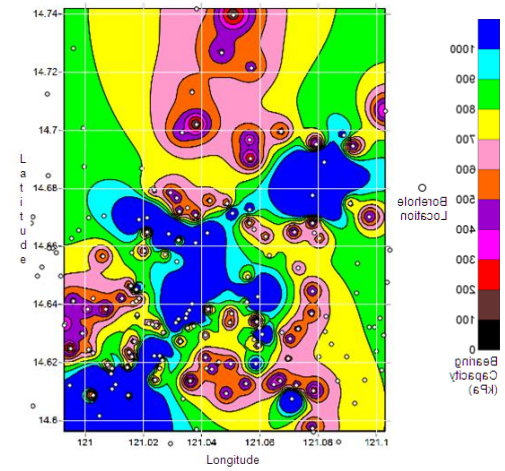

Fig. 4 Soil bearing capacity at 3-meter depth

An even larger increase in the allowable soil bearing capacity in the whole vicinity of Quezon City is seen at four-meter depth from the ground surface, as shown in Figure 5. Take note of the south portion though, as the bearing capacity decreased from 1000 kPa to an average value of 500 to 600 kPa. Since the rock formation at this area has lower RQD index as seen from the borehole logs, the equivalent bearing capacity is much smaller compared to the layer above it.

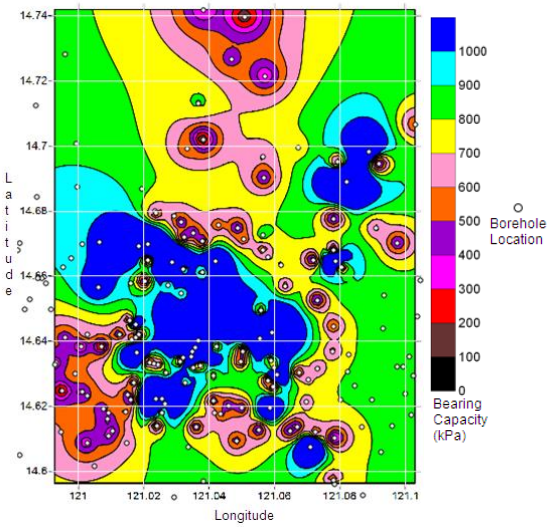

Fig. 5 Soil bearing capacity at 4-meter depth

At 5 meters depth from the ground surface, as shown in Figure 6, there is a further increase in the allowable soil bearing capacity, wherein the 800 kPa to over 1000 kPa range is the dominant allowable soil bearing capacity. The lowest capacity easily seen here is the 400 kPa (violet) in the southwest and south parts of the city, while the highest still remains at those positions that are high in elevation, which are in the central and western parts of the city.

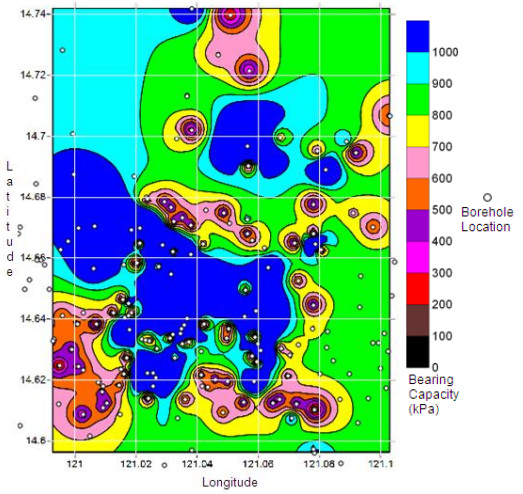

Fig. 6 Soil bearing capacity at five-meter

Figure 7 shows the geological map of Metro Manila [14]. Quezon City is in the central part of Metro Manila. Quezon City has a different surface geology compared to its neighboring cities. Tuff was primarily observed in this area, and rock formations are common below the surface. SPT blows depend on the amount of deposits that are present and increase as the soil goes deeper. SPT refusal was achieved at shallow depths of 2 to 3 meters in the outer regions and as shallow as the ground surface in the inner regions.

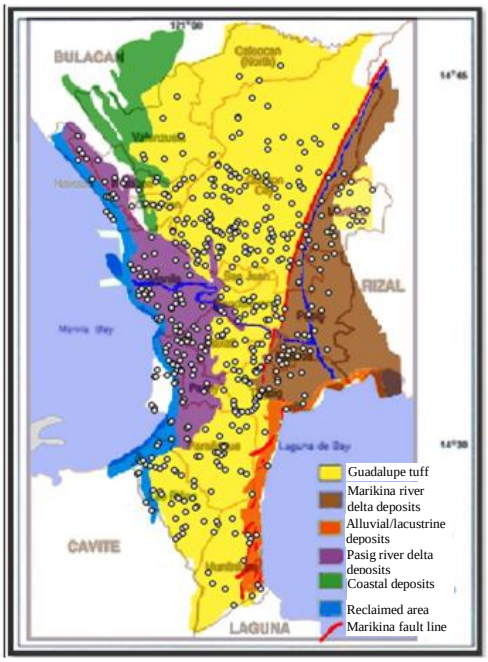

Fig. 7 Geologic Map of Metro Manila [13]

Since the surface geology of this area is reported as tuff, it can be generalized that the city is mostly made up of rocks. In accordance to this, the allowable soil bearing capacities of the rocks should have high values compared to soils and it is in this premise that the estimated soil bearing capacities in the different areas in Quezon city are relative high.

CONCLUSIONS

Borehole logs were collected for a total of 130 locations all over Quezon City, Philippines. Maps were also created in order to show the locations of the collected boreholes throughout the city.

Using a spreadsheets, different geotechnical properties of the collected boreholes were computed. Some examples of this are the unit weight and the angle of internal friction. Also using the same spreadsheet, the allowable soil bearing capacity of the entire Quezon City was estimated and evaluated per meter depth until a depth of 5 meters. Contour maps of the allowable bearing capacities at each of the depths were also made and analyzed.

Because of the shallow rock formations beneath the surface of the city, high allowable soil bearing capacities were observed at shallow depths. It is recommended to place the foundations on these refusal levels since it is more than capable of carrying loads that are suited for shallow foundations. Nevertheless, caution must be taken when placing structures in these areas, as the Valley Fault System is nearby, making the area prone to earthquakes.

The soil in the Quezon City area shows an increasing trend in the bearing capacity at every meter deeper. High-rise building can be easily built in the area without many struggles in the foundation design. Because of this, settlement in the said area can be considered minimal, thus, structures can be built confidently to resist such phenomena. This reference can be used by structural engineers and city engineers in properly designing the foundation of structures and can also be used for disaster mitigating activities of the city.

ABSTRACT

Currently, the reinforced earth construction method using the steel strip reinforcement, which is the most frequently used in Japan, has been carried out in many snow-covered cold districts such as Hokkaido, but there have been reported some cases of deformation attributable to the freezing of back fill materials. However, the detailed mechanism of the deformation in the steel strip reinforced soil wall is still unclear.

In this study, we constructed a steel strip reinforced soil wall of full scale size by using a good-quality back fill material and a back fill having freezing property, intentionally deformed the reinforced soil wall using a freezing back fill by infiltration of cold air during winter, and examined the effect of tension acting on the reinforcement material at that time on the deformation of the reinforced soil wall. As a result, it was confirmed that a large tensile force acts on the reinforcing material laid in the embankment having a high freezing property when the soil behind the wall panel freezes up under the condition that a certain degree of overloading pressure acts on the reinforcing material.

Keywords: Reinforced Soil Walls, Snowy Cold Areas, Deformation Behavior, Freezing and Thawing

INTRODUCTION

The reinforced soil wall method using the steel strip reinforcement was developed in France in 1963, and it is the reinforced soil wall method which is adopted most frequently in Japan at present. A number of construction projects have been carried out in snow-covered cold areas in Japan, but there have been reports of changes caused by the freezing of embankment materials [1]. Photo 1 shows two cases which are considered to have been deformed by freezing. However, it can be confirmed that the wall panel was broken at the connection between the wall panel and the reinforcing material, and the wall panel was dropped off. In the steel strip reinforced earth wall construction method, even when the deformation occurs by the external force such as earthquake or record rainfall, it is an extremely rare phenomenon that the wall panel falls out as shown in Photo 1. In addition, the fall of wall panels like Photo 1 is a problem comparable to earthquakes and recorded rainfall in snow-covered cold districts because it is difficult to grasp signs at present and occurs during the snow melting season. When a freezing force acts on a wall panel in severe winter, a relatively large force is expected to act on the reinforcing material. However, there are many questions about the detailed mechanism of the change, such as at what timing the freezing force acts and whether the reinforcing material will not be pulled out before breaking.

In this study, the full-scale size steel strip reinforced soil wall was constructed by using good quality back fill material and back fill material with freezing property. The full-scale reinforced soil wall was constructed in Kitami-city, Hokkaido (E143˚53’44.9’’ N43˚48’14.4’’). The tensile force

Photo 1 Deformation case of reinforced soil walls

acting on the reinforcing material and the deformation mode of the reinforcing soil wall were measured when the embankment of the actual large-scale steel reinforcing soil wall frozen up. This paper reports the measurement results from November 2017 to May 2019.

OUTLINE OF REINFORCED SOIL WALLS

Photo 2 shows the construction process of the constructed full-scale steel reinforced soil wall. Fig. 1 is a schematic diagram summarizing the dimensions of the reinforced soil wall and the installation location of the measuring instrument in the A-A cross-section of Photo 2d). Fig. 2 and Fig. 3 compare the particle size distributions and compaction curves of the two types of embankment materials used, respectively. Case A is a soil with a high freezing property classified as fine-grained gravel sand as a filling material. Case B is a soil with low freezing property classified as gravel sand.

The wall panel of the steel strip reinforced soil wall uses 1.5×1.5×0.14 m concrete skin, and the reinforcement uses 0.06×4.5 to 5.5×0.004 m steel strip (Photo 2b). Six reinforcements are attached to the uppermost wall panel and four reinforcements are attached to the other wall panels. In each case, after arranging the panels in one row, the reinforcement was placed by rolling to a height at which the reinforcement was laid to a finished thickness of 0.25 m (Photo 2c). This operation was repeated to construct a reinforced soil wall having a height of 6 m and an extension of about 34 m. In addition, each case is partitioned by providing a buffer area with a width of about 1 m (Photo 2d)).

As shown in Fig. 1, in addition to a thermocouple

d) embankment material spreading e) Connection of panel and reinforcement material f) Situation after completion

Photo 2 Construction situation of full-scale steel strip reinforced soil walls

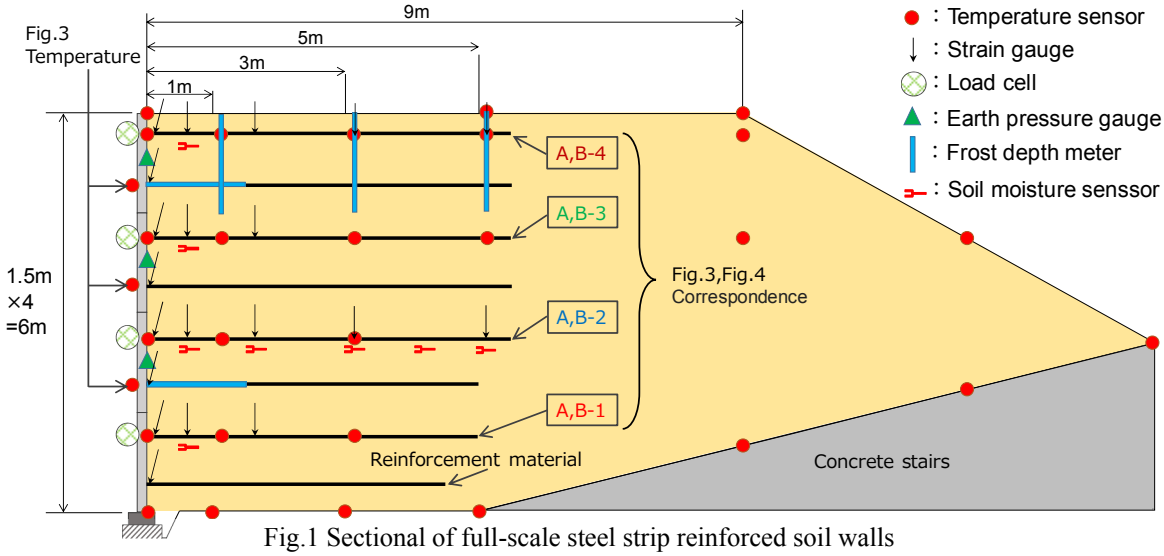

Fig.1 Sectional of full-scale steel strip reinforced soil walls

for temperature measurement, a methylene blue freezing depth meter is installed in the reinforced soil wall to grasp the shape of the freezing line. In each case, a reinforcement material to which a strain gauge is attached is connected to the upper part of the wall panels 1 to 4, a soil moisture sensor is arranged in the periphery of the reinforcement material, and an earth pressure gauge is arranged in the wall panels 2 to 4.

Fig. 4a) and b) show the distribution of dry density, ρ_d and water content, w in the reinforced region obtained from RI measurement [2], respectively. RI measurement was carried out at 9 points in the transverse direction at a wall height of 1 m at the time of construction of the reinforced soil wall. Case A, which is composed of an embankment material having a high freezing property, has a larger variation of ρ_d than that of case B, and it is possible to confirm a lowered region of ρ_d on the back surface of the wall panel having $Y = 2$ to 4 m. On the other hand, in the case B, although the value of ρ_d is large at the center of the reinforcement region, the extreme lowering region of ρ_d cannot be confirmed at the rear surface of the wall panel, and in case A, w is slightly low at the lower portion of the reinforcement region.

In case A, the average value of the number of 54 points was ρ_d=1.43g/cm^3, w=23.1%, and D_c=83.1%. Note that, D_c (%) is ρ_d /ρ_{dmax} *100. In case B, ρ_d=1.47 g/cm^3, w=5.5%, D_c =85.0%. In both cases, D_c is lower than the standard value (D_c > 95.0%) in current

FIELED OBSERVATION REAULTS IN THE FREEZING PERIOD

(1) Freezing condition of backfill, panel displacement

Figs. 5 and 6 show the frozen line and the change of the wall surface displacement in the reinforced soil wall cross sections of Case A and Case B, respectively. Wall displacement was measured periodically at a total station. The frozen line represents the 0° C. line estimated by the freeze depth meter. Looking at changes in the frozen line, in both case A (Fig. 5) and B (Fig. 6), the frozen line has a shape parallel to the crown and the wall surface because cold air enters the wall surface and the crown of the backfill. In addition, in the shoulder portion of the reinforced soil wall, cold air enters from both directions of the crown and the wall surface. Therefore, the freezing lines are not parallel [4][5], and the freezing depth reaches about 1.5 m at the maximum from the wall surface. In both 2018 and 2019, the depth of freezing was almost the same.

As for the change of the horizontal displacement of the wall panel, in case A (Fig. 5), all the wall panels are displaced forward at the stage of 2017/11/22. However, it does not reach 3% of the wall height, which is the construction management value. As shown in Fig. 4, it is expected that the reason for this is that there was a locally lowered portion of ρ_d in the backfill soil near the wall surface. Thereafter, it can be seen that in case A, as the frozen line progresses to the backfill soil, the level of the wall panel in the forward direction increases. In addition, the displacement is larger in 2019 than in 2018.

Next, in case of B, although the freezing line is located at the same position as in case A, the horizontal displacement of the wall panel in the forward direction (Fig. 6) is not measured.

(2) Force acting on the reinforcement material

Fig. 7 compares the measured values of Case A as typical data of the outside air temperature by thermocouples installed on wall panels, and the measured values of load meters connected to reinforcements installed on each stage of wall panels. The initial value of the load cell is acquired during construction. In Case A, the tensile force was applied to the reinforcement material in accordance with the decrease of outside air temperature in both 2017-2018 and 2018-2019. This is because the inside of the reinforced soil wall freezes due to a decrease in the outside air temperature, and the soil freezes up to generate the soil pressure. A large tensile force is applied to the reinforcing members (A-1, A-2) of panel 1 and the second stage in which the upper loading pressure is large. The direction of action of the freezing pressure generated in association with the freezing is perpendicular to the freezing line. Therefore, it is considered that the tensile force increased in the wall panel under the reinforced soil wall in which the frozen line shown in Figs. 5 and 6 were relatively parallel to the wall panel.

In 2018-2019, a tensile force of about 44 kN at the maximum was exerted on the first stage A-1, which had a large overload pressure, and the tensile force increased to a value close to 44.4 kN when the allowable stress level of the reinforcement used in this study was converted into a load. This is probably due to the large wall surface displacements associated with freezing in 2018-2019.

It is expected that the restraint pressure acting on the reinforcement material is small in the panels 3 and 4 (A-3 and A-4) having a small tensile force due to a small overburden pressure, thereby reducing the pulling resistance of the reinforcement material, and excessive tensile force is not generated because the reinforcement material is pulled out.

Next, in case B, since the filling material having a low freezing property is used, the volume changes of the backfilling soil due to freezing is extremely small. From this, it is considered that the generation amount of the upward freezing pressure for pulling out the reinforcing material is small, and the tensile force does not act on the reinforcing material.

From the above results, in order to estimate the

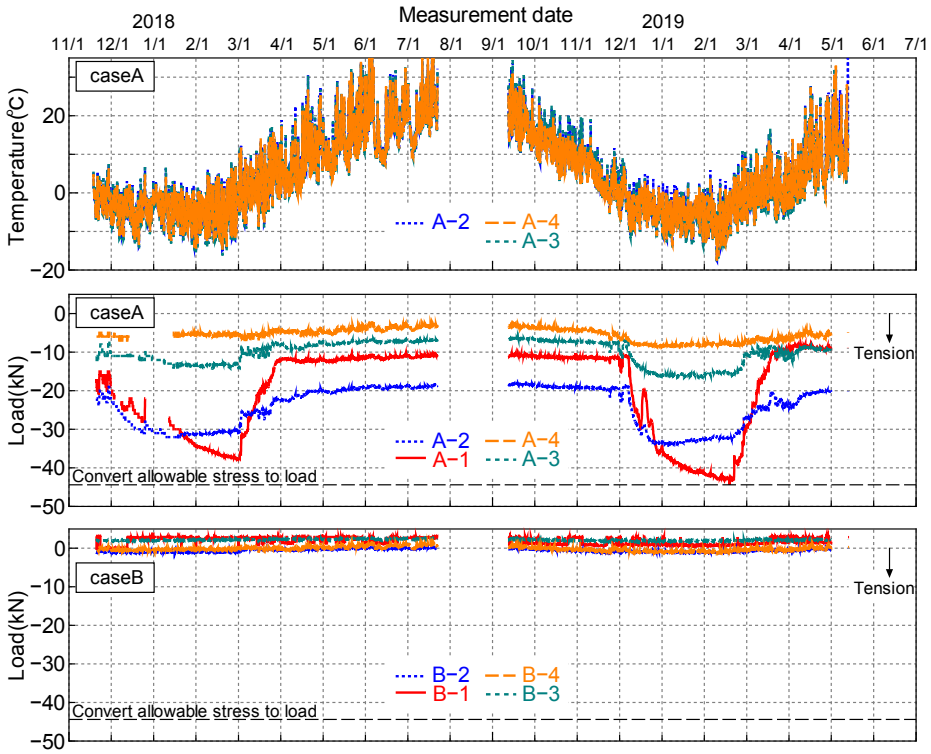

Fig.7 Seasonal change of outside temperature and load of reinforcement material

magnitude of the tensile force acting on the reinforcing material, it is important to estimate the frozen region inside the reinforcing soil wall. Therefore, in this study, the reproducibility of the frozen wire estimation using the commercially available two-dimensional heat conduction analysis software was examined.

(3) Freezing condition of backfill soil by two-dimensional thermal conductivity analysis

For the analysis carried out in this study, commercially available two-dimensional thermal conductivity analysis software TEMP /W [6][7] were used. The analytical model reproduced the reinforced soil wall. Table 1 summarizes the thermos-physical properties of the materials used in the analysis. Thermo-physical property values of ground materials were estimated from the calculation formulas shown by Kersten Equation [8] (thermal conductivity) and Ifuku be [9] (volume heat capacity), which can be calculated using only dry densities and water content ratios as parameters. In this study, the average values of the dry density and the water content ratio shown in Fig. 4 were used as parameters. Fig. 7 shows the temperature distribution on the day (February 21, 2019) when the maximum freezing depth parallel to the wall panel was recorded in Case A in 2019, out of the results of analyzing the temperature change in the reinforced soil wall using the measured wall surface and top edge as external force conditions. The results confirm that the temperature sensor in the reinforced soil wall is generally consistent.

From the results of this analysis, it was found that the frozen lines were present in parallel in the wall panels of the first and second steps, as shown in the transition of the frozen lines estimated in Fig. 5. That is, when the outside air temperature can be correctly set in addition to the dry density and the water content ratio of the reinforced soil wall to be targeted, it can be said that the frozen region of the reinforced soil wall can be estimated with a certain degree of accuracy by using commercially analysis software.

Figure 8 shows the results of an analysis of the external temperature of 1976-1977, which was the lowest temperature in the history of observation in Hokkaido City, on the wall panel. Figure 7 shows the results of the analysis on the same day (February 21, 1997). The frozen line parallel to the wall panel travels into the approximately 40 cm reinforced soil wall. In the future, the estimation of the progress process of the freezing line in the reinforced soil wall in which the wall surface panel dropped out is tried by giving the outside air temperature in the region in which the disaster case actually occurred.

CONCLUSIONS

(1) The deformation of the wall surface during the winter period in which the cold air infiltrates, when the embankment material having a high freezing property is used, becomes larger in the forward direction compared to the case of the embankment material having a low freezing property.

(2) It was found that the soil behind the wall panel

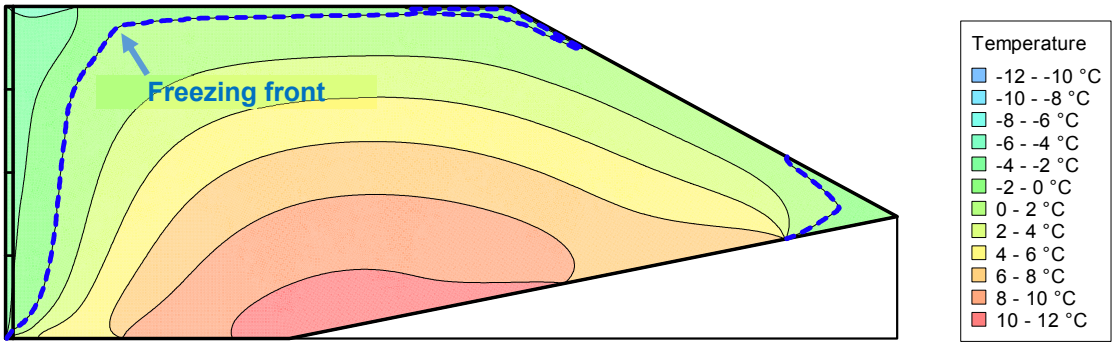

Fig.8 Temperature distribution in 2019 by two-dimensional thermal conductivity analysis

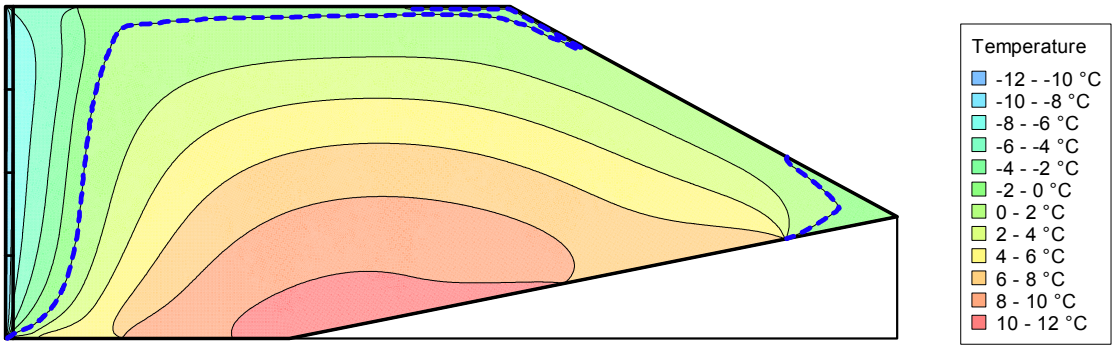

Fig.9 Temperature distribution in 1977 by two-dimensional thermal conductivity analysis

freezes up, especially under the condition that a certain restraining force is applied, and a large tensile force acts on the reinforcing material laid in the embankment material having a high freezing property at the position where the frozen wire enters in parallel with the wall panel.

ACKNOWLEDGMENTS

Mr. Naoki Shimura and other members of HIROSE REINFORCED SOIL corporation gave great cooperation on the construction of reinforced soil walls. Furthermore, with regard to the construction of reinforced soil walls, we obtained the cooperation of Mr. Uno and other BIHORO CARGO CAR corporation member. We express my deep appreciation.

ABSTRACT

At present, underground geological disposal at depths greater than 300 m is considered a viable disposal option for high-level radioactive waste generated from the reprocessing of spent fuel used in nuclear power plants. In geological disposal, bentonite is employed as the primary component of buffer material filling gaps between waste and geologic rock. Bentonite has remarkable water absorption swelling and low permeability characteristics. Bentonite buffers are generally mixed with silica sand to improve workability and economy. However, specification details have yet to be completely determined. It is anticipated that the buffer material will be exposed to high temperature due to the heat generated by the vitrified solid. This study aims to understand the mechanical properties of bentonite buffer material by employing uniaxial compression tests after applying temperatures between 30 ℃ to 90℃ to bentonite specimens with different silica sand contents and particle sizes. Results of the experiment confirmed that uniaxial compressive strength tends to decrease with higher blending ratios of silica sand greater particle sizes and temperatures.

Keywords: Bentonite, Geological disposal , temperature, Uniaxial compression test

1. INTRODUCTION

At present, the use of bentonite as a buffer material for geological disposal is being examined. Bentonite fills gaps due to its water intake swelling properties and low permeability, thus preventing the leakage of groundwater contaminated with high levels of radiation. In Japan, various tests, such as swelling pressure tests and uniaxial compression tests, have helped to characterize swelling performance and mechanical properties of bentonite [1]. In addition, workers have examined the method for mixing silica sand with bentonite from the viewpoint of workability and economic efficiency. However, complete specifications for this method have yet to be determined. In this study, to understand the mechanical properties of bentonite buffer material, uniaxial compression tests were conducted by applying temperatures in the range of 30℃ to 90℃ to bentonite specimens with different silica sand contents and particle sizes.

2. TEST METHOD

The initial conditions were set at a dry density of 1.6 Mg/m^3 and a saturation of 30%. Temperatures of 30 ℃, 50 ℃, 70 ℃ and 90 ℃ were applied to bentonite (Kunigel V1) with No. 3, 5 and 8 silica sand ratios of 20%, 30% and 40%. Table 1 summarizes the physical and chemical properties of Kunigel V1 and silica sand.

Table 1 Physical and chemical properties of Kunigel V1 and silica sand

soil particle density(Mg/m^3)	2.61
Montmorillonite content(%)	51
Silica sand No. 3 particle density(Mg/m^3)	2.691
Silica sand No. 5 particle density(Mg/m^3)	2.62
Silica sand No. 8 particle density(Mg/m^3)	2.701
Silica sand No. 3 particle size(mm)	1.2~2.4
Silica sand No. 5 particle size(mm)	0.3~0.8
Silica sand No. 8 particle size(mm)	0.08~0.2

2.1 Sample preparation method

A mixed sample of bentonite and silica sand was prepared at ratios of 6:4, 7:3, and 8:2 for Kunigel V1 and silica sand particle sizes, nos. 3, 5, and 8. The montmorillonite content of bentonite in Table 1 was measured with reference to the Methylene Blue adsorption measurement method [3] of AIST. The properties of each sample are

shown in Tables 2, 3, and 4.Equation (1) was used for the effective clay density[4] of JAEA.

$$\rho_e = \frac{\rho_d(100 - R_s)}{(100 - \frac{\rho_d R_s}{\rho_s})} \quad (1)$$

(1) where, ρ_e : effective clay density , ρ_d :dry density, ρ_s : soil particle density of silica sand, R_s : silica sand mixing ratio

Table 2 Properties of each sample at the 6:4 mixing ratio

silica sand No.	No.3	No.5	No.8
Mixed soil particle density(Mg/m^3)	2.64	2.612	2.644
Void ratio	0.650	0.632	0.653
Effective clay density(Mg/m^3)	1.260	1.270	1.258

Table 3 Properties of each sample at the 7:3 mixing ratio

silica sand No.	No.3	No.5	No.8
Mixed soil particle density(Mg/m^3)	2.632	2.610	2.635
Void ratio	0.645	0.631	0.647
Effective clay density(Mg/m^3)	1.363	1.371	1.362

Table4 Properties of each sample at the 8:2 mixing ratio

silica sand No.	No.3	No.5	No.8
Mixed soil particle density(Mg/m^3)	2.623	2.609	2.625
Void ratio	0.639	0.631	0.641
Effective clay density(Mg/m^3)	1.453	1.458	1.452

2.2 Water content adjustment

The water content of the mixed samples was adjusted to a saturation of 30%. The water content was measured using a microwave oven (500 W, 15 min) to shorten the time.

2.3 Specimen molding

The sample was divided into five layers, placed in the mold, and compacted. Afterwards, static compaction (40 MPa, 10 min) was applied with a hydraulic jack to produce the test specimen.
Equations (2) and (3) were used for the mass of the specimen, assuming that the volume of the specimen was constant.

$$e = \frac{\rho_s}{\rho_d} - 1 \quad (2)$$

$$S_r = \frac{w\rho_s}{e\rho_w} \quad (3)$$

(2) where, e:void ratio, ρ_s:soil particle density, ρ_d: dry density ; (3)and where, Sr : degree of saturation, w:water content , ρ_s : soil particle density e: void ratio, ρ_w : water density (1.00Mg/m^3).

2.4 Temperature change

Specimen temperature was achieved by curing the sample for 1 day in a constant-temperature water tank. A water interception sheet prevented the specimen from touching the water.

2.4 Uniaxial compression test

The compression test was carried out at a fixed loading speed of 0.4 (mm/min). An electric screw jack system of 10 kN capacity was employed as a testing machine. A schematic diagram of the tester is shown in Fig. 1.

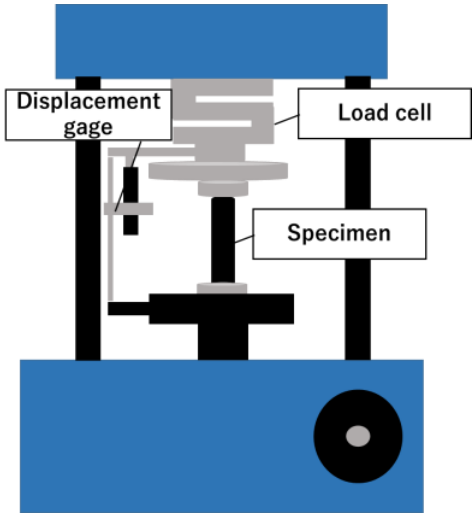

Fig.1 Schematic diagram of the test machine

3. TEST RESULTS AND DISCUSSION

Fig. 2, Fig. 3, and Fig. 4 show the results of the uniaxial compression tests in which the temperature and silica sand content were varied according to silica sand particle size. Fig. 5, Fig. 6, and Fig. 7 show the results of the uniaxial compression test in which the temperature and the type of silica sand particles were varied for each silica sand content.

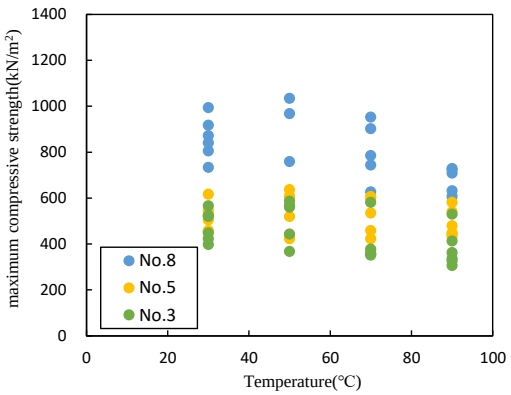

Fig.6 Relationship between temperature and maximum compressive strength (7:3)

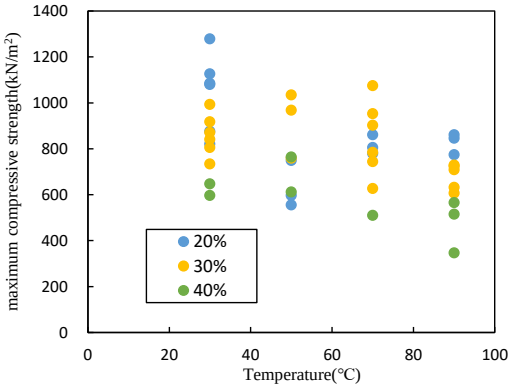

Fig.4 Relationship between temperature and maximum compressive strength (Silica sand No.8)

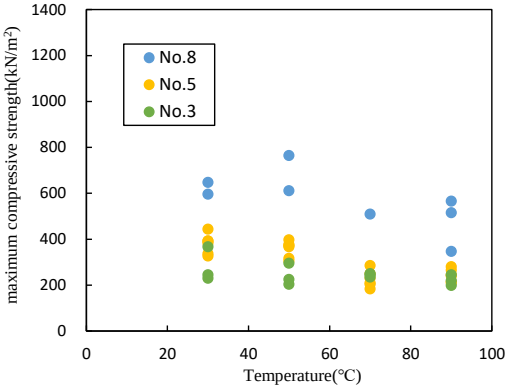

Fig.7 Relationship between temperature and maximum compressive strength (8:2)

3.1 Results of tests varying silica sand content, silica sand particle size, and temperature

Figs. 2 to 7 illustrate that maximum

compressive strength decreases linearly with increasing temperature under all conditions. Fig. 9 shows the changes in the modulus of elasticity for silica sand No. 3 at different compositions, and Fig. 11 shows the changes in the elastic modulus of silica sand for a silica sand composition of 40% with varying silica sand particle size (Nos. 3, 5, or 8). The elastic modulus demonstrated the same tendency as compressive strength with increasing temperature. The same tendency was also observed under other conditions. There are several possible reasons why the maximum compressive strength and elastic modulus decrease. The first is the expansion of the specimen volume. Fig. 8 shows the rate of volume change of silica sand No.3 at different temperatures and silica sand contents. Fig. 10 shows the volume change rate with temperature for a silica sand content of 40% and different silica sand particle sizes (Nos. 3, 5, or 8). Figs. 8 and 10 confirm that the rate of volume change tends to increase with rising temperature during curing. Therefore, it is possible that at higher temperatures, with a lower dry density and smaller cracks, strength characteristics were lower. Expansion of the specimen may be caused by the difficulty in discharging the pore water and air expanded by heat due to bentonite's low water and air permeability. The effects of cracks caused by drying shrinkage of the specimen surface could also be a factor. As temperature increased during curing, the amount of evaporation from the surface of the specimen increased, and the number of cracks due to drying shrinkage also increased, which may have decreased material strength. For this test, specific cracks inside of the specimen were not confirmed. However, that interior cracks were generated was confirmed due to the remarkable shrinkage after curing, especially on the specimen surface. Since this effect increases with temperature, compressive strength is also considered to decrease as the temperature increases.

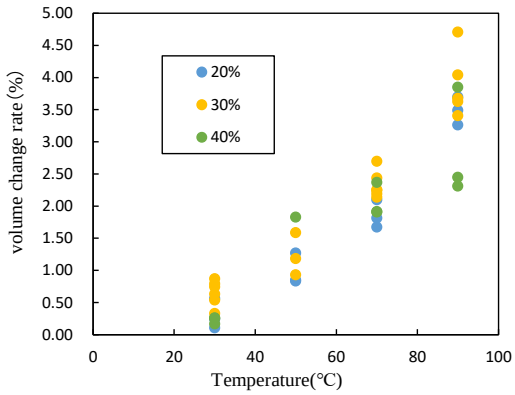

Fig.8 Relationship between temperature and volume change rate (Silica sand No.3)

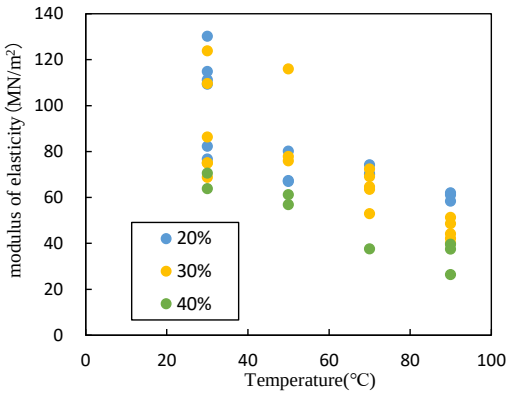

Fig.9 Relationship between temperature and the modulus of elasticity (Silica sand No.3)

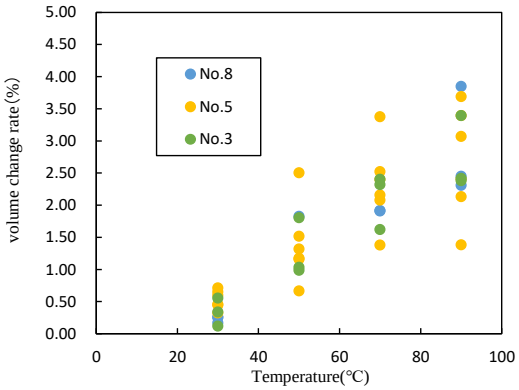

Fig.10 Relationship between temperature and volume change rate (6:4)

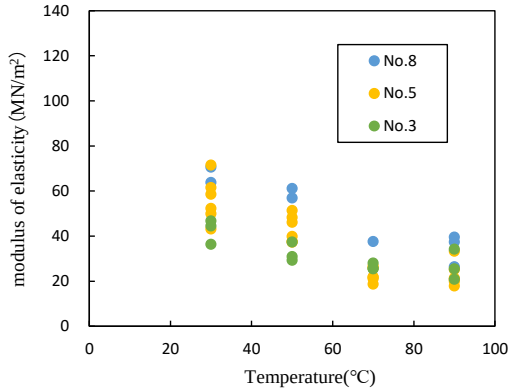

Fig.11 Relationship between temperature and the modulus of elasticity (6:4)

3.2 Results of tests in which the silica sand content and silica sand particle size (Nos. 3, 5, or 8) at each temperature were varied

Figs. 12 and 13 show the relationship between silica sand particle size (Nos. 3, 5, or 8) and

maximum compressive strength at temperatures of 30 ° C, 90 ° C and silica sand contents of 20%, 30% and 40%. Both figures confirm that maximum compressive strength increased as the particle size of silica sand decreased. The increase of maximum compressive strength with the decrease of silica sand particle size may result from a smaller particle size The increase of the maximum compressive strength with the decrease of the silica sand particle size considered to be the increase of the forming pressure by the decrease of the silica sand particle size. These results also confirmed that the smaller the silica sand particle size, the higher the strength, under constant silica sand content. This is due to suction. Suction is the attractive force of pore water to soil particles in dry unsaturated soil and is calculated as the difference between pore air and water pressures. Generally, the greater the suction, the more the apparent adhesive force, and the better the strength and deformation characteristics. In other words, the smaller the particle size of silica sand, the larger the area of contact between silica sand and water. Therefore, it is considered that the smaller the particle size of silica sand, the greater the strength. Figs. 14 and 15 show the relationship between silica sand content and maximum compressive strength at temperatures of 30 ° C and 90 ° C and silica sand numbers of 3, 5 and 8. In both figures, the maximum compressive strength decreases with increasing silica sand content. With this result, compaction is considered the cause. According to Masuda et al[4], at higher montmorillonite contents, the compaction property worsens, and the molding pressure can be reduced by increasing the silica sand mixing ratio. In this case, montmorillonite content decreases with increasing silica sand content, and the strength is considered to decrease because the energy of compaction is reduced.

4. CONCLUSION

In this study, uniaxial compression tests investigated the mechanical properties of bentonite mixed with silica sand, considering the effects of

temperature. The findings obtained in this study are as follows.

(1) As temperature rises, the dry density of the bentonite mixed with silica sand decreases due to volume expansion caused by expanded pore water and air exiting the specimen. In addition, cracks occur on the surface and inside of the specimen due to drying shrinkage. Based on the above, maximum compressive strength is also considered to decrease.

(2) As the silica sand number increases, suction between silica sand particles increases. Maximum compressive strength is considered to further increase with this increase.

(3) Montmorillonite content decreases with increasing silica sand content. It is conceivable that the compressive strength of the specimen is decreased by reducing the energy used on the compression molding for higher sand specimens, compared to when the sand ratio is low.

The above results experimentally demonstrate the temperature dependence of bentonite mixed with silica sand and that suction and montmorillonite content affect strength characteristics. In future work, it is desirable to improve the accuracy of the data by continuously carrying out tests. Furthermore, when considering re-submergence of a geological disposal facility after construction, it is likely that not only the mixing ratio of silica sand and silica sand particle size, but also change in the degree of saturation affect the strength characteristics. Therefore, change in the degree of saturation of bentonite specimens with different silica sand contents and particle sizes should be tested. In addition, by considering the effect of heat generated from high-level radioactive waste, we hope that the uniaxial compression test with temperature change applied to the silica-sand mixed bentonite specimen will contribute to the performance design of bentonite buffer material from the viewpoints of workability, economy, and thermal conductivity.

ABSTRACT

In the nuclear fuel cycle of nuclear power generation, reprocessing generates high-level radioactive waste. Geological disposal is a widely accepted disposal method for high-level radioactive waste. This method can isolate waste from the human environment for a very long time. Geological disposal utilizes bentonite as a buffer material in order to suppress the transfer of radioactive materials to groundwater. In practice, waste may be exposed to a high-temperature environment due to decay heat or geothermal heat, or heated groundwater may permeate the water. Nonetheless, few studies consider the effect of heat on bentonite, and it is difficult to understand the long-term swelling performance of bentonite material under these conditions. Therefore, it is necessary to investigate the effect of temperature on bentonite. In this study, swelling properties of bentonite were investigated by performing a swelling pressure test considering temperature history and temperature change. Results demonstrated that swelling pressure tended to increase with increasing temperature. Furthermore, a threshold value for the equilibrium swelling pressure may exist.

Keywords: bentonite, swelling pressure, temperature, geological disposal, High-level radioactive waste

INTRODUCTION

In the nuclear fuel cycle, which reuses nuclear fuel, radioactive effluent is generated when uranium and plutonium are extracted. The mixture of radioactive effluent and glass into canister is called high-level radioactive waste. In Japan, geological disposal is employed for the safe disposal of high-level radioactive waste. It is believed that this method can safely dispose of high-level radioactive waste via the multiple barrier system, which combines an engineered barrier system and a natural barrier system. In Japan, Bentonite is used as a buffer material. Since bentonite has swelling properties, low permeability, and cation exchange properties, it is expected to fill gaps, control transfer of radioactive material, and control groundwater invasion. In the actual disposal environment, the buffer material is exposed to high temperatures. Because of this, it is necessary to examine the effects high temperature on the buffer. High temperature environments arise from the decay heat of the vitrified body, the geothermal energy of the rock mass, permeation of heated groundwater. However, there are few studies considering the effect of heat on bentonite, which poses a problem or understanding the material swelling performance of the long-term. In this study, the swelling characteristics of bentonite were investigated using a swelling pressure test and considering the temperature history of the buffer material exposed to high temperatures and the infiltration of heated groundwater.

MATERIALS AND METHODS

Materials

In this study, a 70% bentonite and 30% silica sand mixture was used, because of its excellent workability and economy. The mixture comprised Kunigel V1 for bentonite and sillica sand particle size diameter of 212 μm or less. Table 1 shows the physical properties of Kunigel V1. The samples were placed in stainless steel vats and heated in a drying oven at 30 ° C, 60 ° C and 100 ° C for 14 or 90 days, respectively, to obtain the temperature history. Since the water content of the sample after drying was as low as 1 ~ 2%, and the preparation of the sample was difficult, the water content of the sample was adjusted using ion exchange water. The sample was then placed in a desiccator until the reaching nearly uniform water content. The temperature history and test conditions for each heating period are summarized in Tables 2, 3 and 4. The montmorillonite content shown in Tables 2, 3 and 4 is the value of a mixed sample of bentonite and silica sand. The montmorillonite content was determined by the boiling method of methylene blue adsorption determination in [3].

Method for Producing Test Material

Specimens with a dry density of 1.6 Mg/m3, a diameter of 28 mm, and a height of 10 mm were prepared by static consolidation using the mixtures prepared by the above method. Each specimen was treated with a given temperature history described above. The mass assigned to the specimen was calculated for each test condition such that the dry density was 1.6 Mg/m3 when compacted to the target specimen height. Test equipment consisted of a hydraulic jack, a reaction frame, and a piston, which can load a maximum pressure of 100 MPa. First, the sample was put into a metal mold with an inner diameter of 28 mm. A compaction rod was put into the mold. Then, the piston was lowered to the upper part of the compaction rod. The specimen was then compressed and molded using a hydraulic jack so that the sample height was 10 mm. The compaction pressure was about 8MPa, and the pressure retention time was 10 minutes. After unloading, the compaction rod was removed, and testing was performed with the specimen in the mold.

Test Method

The main components of the swelling pressure testing equipment are a reaction frame, load cell, compressor, air cylinder, displacement gauge, water tank, temperature control tool, and thermocouple, as shown in the schematic diagram, Fig. 1. The piston of the testing machine can load at maximum of 1 tf using compressed air. The load cell is connected to a data logger and a PC, and data can be collected every second. The specimen was moved to the pedestal of the tester for each mold, and the upper and lower pedestals were fixed with screws. A membrane filter and a porous metal were inserted as filter materials between the specimen and the pedestal. The piston was lowered to the top plate of the testing machine, and the vertical displacement was fixed by a clamp knob. The initial vertical pressure was defined as the vertical pressure at this time. The initial vertical pressure was about 50 N. After this, ion exchange water warmed to the target test temperature was supplied to a water tank, and the specimen wetted to start the swelling pressure measurement. The water supply was applied only from the underside of the specimen, as ground water only permeate from one side of the buffer material in the actual disposal environment. The test water temperature was controlled by a hot water circulator (or a heater and a thermocouple) so that the water temperature was ± 3 °

C of the target temperature. Temperature was measured by the thermocouple. The reason why the temperature control was carried out by either a hot water circulation equipment or a heater and a thermocouple is that, when the temperature of the test water was high, it dropped to less than -3 ° C of the target temperature during its transfer through a hose. Therefore, hot water circulation equipment was only used for tests using 30 ° C water. At 60 ° C and 100 ° C, a heater and thermocouple was used. To suppress evaporation from the water surface during testing, an evaporation inhibitor (pp sphere) was set up, and ion exchange water, heated to a target temperature, was injected as needed so that the water level could be maintained at about 50 mm from the upper part of the specimen. In addition, to confirm that the specimen position was maintained during the test, a displacement meter was installed on the upper part of the specimen, and the displacement amount during the test was measured. A displacement gauge capable of measuring up to a minimum of 0.001 mm was used. The test period was about 1 to 2 weeks, during which time the swelling pressure of bentonite was considered to reach equilibrium. After the completion of the test, each specimen was immediately sliced into 2 mm sections, and the water content distribution at each height was measured. The test results showed that the maximum swelling pressure and the equilibrium swelling pressure correlated with temperature.

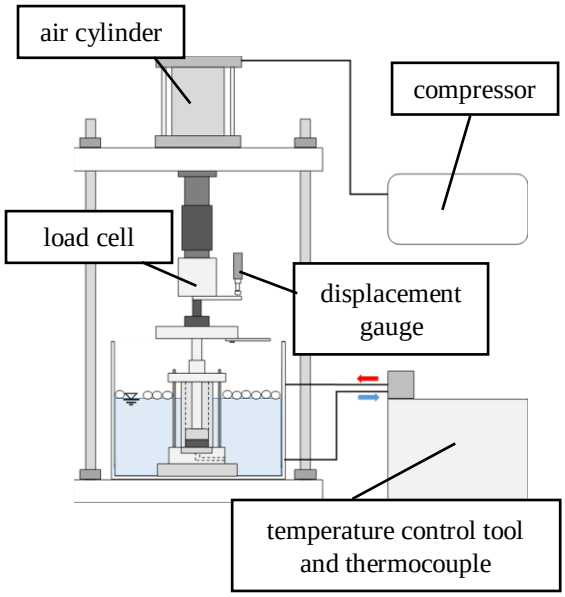

Fig. 1 Swelling pressure tester

RESULTS AND DISCUSSION

Changes in Swelling Pressure with Time

Figures 2 to 8 shows changes in swelling pressure over time.

In all test results, the swelling pressure rapidly increased after receiving water, decreased after reaching the peak swelling pressure, and then increased again to reach the equilibrium state. Under some test conditions, the swelling pressure at equilibrium was larger than at the initial peak. Pressure peaked about 7 hours after the start of the test at 30 ° C and about 0.3 hours after the start of the tests at 60 ° C and 90 ° C. The slope of the initial swelling pressure graph, which increase with increases temperature, indicates that with higher temperature, the time until the swelling pressure reaches the equilibrium state decreases. In addition, for tests at 90 ° C, the swelling pressure after the peak repeatedly increased and decreased by about 100kPa.

That the time until the swelling pressure reaches the equilibrium state becomes shorter as the temperature rises is thought to be facilitated by a faster hydration reaction with rising temperature. Bentonite swells when water molecules enter between the layers of montmorillonite crystals due to the hydration reaction between interlayer cations and solution water. In addition, the hydration reaction is accelerated at higher temperatures. Therefore, the hydration reaction likely advanced more rapidly as the temperature rose. The reaction ended when the hydration number reached the upper limit, and the swelling pressure reached equilibrium state.

The reason that the swelling pressure after the peak repeatedly increased and decreased by about 100kPa at the test temperature of 90 ° C is likely caused by the use of a heater and a thermocouple for temperature control of the test water. The heater cools after reaching the target temperature, and when the temperature decreases by about 3 ° C from the target temperature, the heater repeatedly activates to control the temperature. Since the time course of the swelling pressure after the peak agrees with the heating and cooling cycles of the heater, swelling pressure likely changes due to the change in the temperature.

Maximum Swelling Pressure

Maximum swelling pressure increased with increasing temperature under all test conditions. In addition, maximum swelling pressure of samples with temperature history decreased slightly at a test temperature of 30 ° C, and increased by about 100 ~ 200kPa at test temperatures of 90 ° C and 60 ° C. This suggests that the higher the test temperature, the greater the effect on the maximum swelling pressure of samples with temperature history, regardless of the

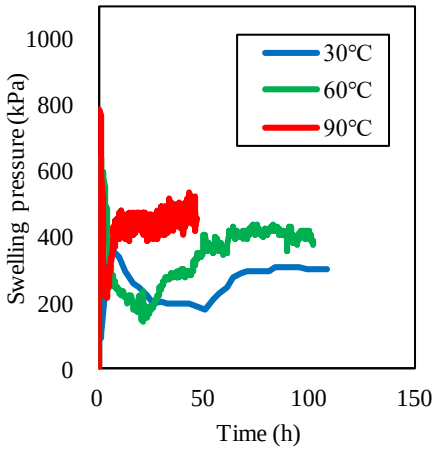

Fig. 2 Samples with no history

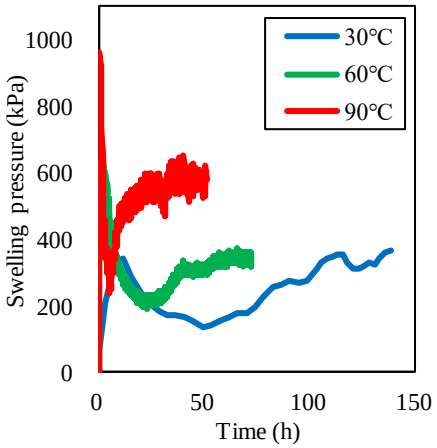

Fig. 4 Heating period of 14 days and temperature history of 60 ° C

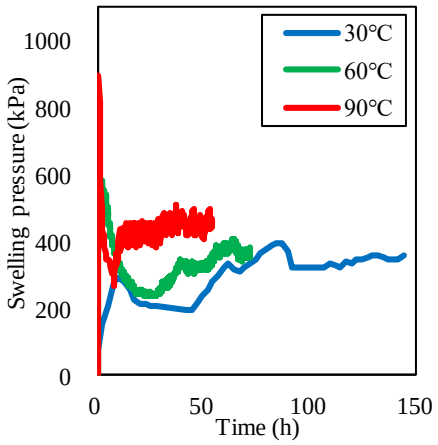

Fig. 5 Heating period of 14 days and temperature history of 100 ° C

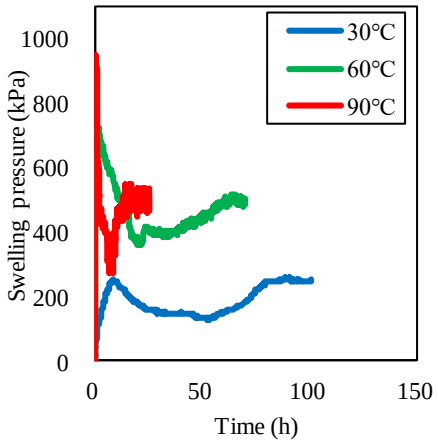

Fig. 6 Heating period of 90 days and temperature history of 30 ° C

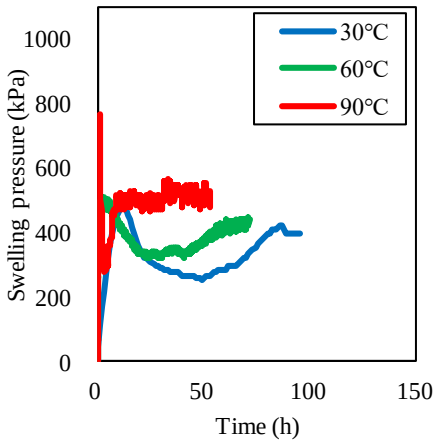

Fig. 7 Heating period of 90 days and temperature history of 60 ° C

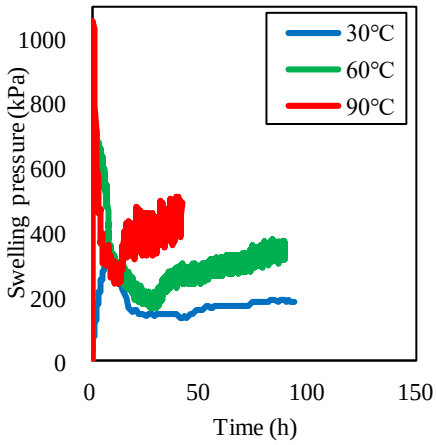

Fig. 8 Heating period of 14 days and temperature history of 100 ° C

heating period or specific temperature history.

The increase in maximum swelling pressure is caused by the expansion of the diffusion electric double layer and the increase in osmotic pressure. First, we will discuss the expansion of the diffusive electric double layer. Since the surface of clay minerals is charged, an electric double layer is formed. Debye distance (1/κ) is defined as a parameter representing the thickness of the electric double layer. Equation (1) is Debye distance magnitude.

$$\frac{1}{\kappa} = \sqrt{\frac{\varepsilon_r \varepsilon_0 kT}{2e^2 n_0 z^2}} \quad (1)$$

where e:elementary charge, n0: ion molar concentration, z: valence of ion, εr: dielectric constant, ε0: dielectric constant of vacuum, k: Boltzmann constant, and T: absolute temperature. Debye distance increases with increasing absolute temperature. Overlapping electric double layers generate repulsive forces, and as the Debye distance increases, the area where the electric double layers overlap grows larger. Therefore, it is thought that the repulsive force and the swelling pressure both increased.

Secondly, we consider osmotic pressure. Bentonite swells by the hydration reaction of water molecules with interlayer cations. Large osmotic pressure is considered to be generated by the ion concentration difference between the ion exchange water and montmorillonite layers. Since the osmotic pressure increases with increasing temperature, it is likely that the swelling pressure increases because water molecules entry between the layers becomes easier.

The decrease in the maximum swelling pressure of the sample with a temperature history of 30 ° C is thought to be due to the decrease in the montmorillonite content of the sample with increasing temperature history. As the montmorillonite content decreased by about 3% in the 14- day history period and by about 2% in the 90- day history period, the maximum swelling pressure of the sample during the 90- day history period is thought to be lower than that of the sample without a temperature history. However, clay minerals may be altered by drying if the water content falls below 7%. Since the water content of the sample taken out of the drying furnace after the temperature history was as low as 1 ~ 2%, the decrease of montmorillonite content is considered to be due to the alteration of bentonite by drying. Necessary future analysis should include examination of temperature history application to prevent sample drying and clarify the causal of montmorillonite content reduction. Since the maximum swelling pressure increases at the test temperatures of 60 ° C and 90 ° C, further collection of data is necessary.

Equilibrium Swelling Pressure

The equilibrium swelling pressure increased with increasing temperature, and the swelling pressure tended to increase more slowly than the maximum swelling pressure under all test conditions. A sample with a history temperature of 60 ° C shows a larger equilibrium swelling pressure than a sample without a temperature history. In addition, it was confirmed that the equilibrium swelling pressure of the sample with a temperature history decreased by about 100kPa at the test temperature of 30 ° C.

First, the expansion of the diffusion electric double layer is considered to cause an increase in the equilibrium swelling pressure with the rise in temperature. The previous section explained that the diffusion electric double layer expands with rising temperature, a trend observed even to equilibrium swelling pressure. The repulsive forces are considered to increases due to the expansion of the electric double layer and the equilibrium swelling pressure increases due to the repulsive force of the particles.

The gradual increase in swelling pressure compared with the increase in maximum swelling pressure is thought to be due to the decrease in osmotic pressure and dehydration of interlayer water. Although the osmotic pressure increased with increasing temperature, the osmotic pressure likely decreased because water entered the interlayer and the ion concentration difference between the peripheral solution and the interlayer decreased. As for the dehydration of the interlayer water, the increase in the swelling pressure likely slowed, due to the separation of the interlayer cations and hydrated water molecules with increasing temperature. A TG (thermogravimetric decrease) index exists, which illustrates the relation between temperature and mass. In this, TG is defined as a method to measure the mass of the sample as a function of temperature, while the

temperature of the sample is changed according to a fixed program. By this method, weight reduction was confirmed even at temperatures below 100 ° C. in [5]. The higher the test temperature, the more the water molecules in the montmorillonite layers become dehydrated, because higher temperatures enhance dehydration. Therefore, the tendency of the equilibrium swelling pressure to increase became less pronounced the distance between layers decreased. However, since the rate of the hydration reaction and the time until specimen saturated are unknown, it is necessary to estimate from the water content distribution of the specimen in the initial stage of swelling by changing the duration of the swelling pressure test.

The decrease in equilibrium swelling pressure at a test temperature of 30 ° C for samples with a temperature history (regardless of the specific temperature history or heating period) is likely caused by the decrease in montmorillonite content due to the temperature history. However, since the swelling pressure increased at a test temperature of 90 ° C and a hysteresis temperature of 60 ° C, it is necessary to continue testing and data collection.

CONCLUSIONS

In this study, the swelling pressure test was used to understand the swelling characteristics of bentonite buffer material, considering temperature history and temperature change.

First, it was confirmed that the swelling pressure rapidly increased at the start of water supply, decreased after reaching the peak swelling pressure, and then increased again to reach the equilibrium state. This tendency was confirmed in all test conditions. It was also confirmed that the slope of the graph in the initial stage of swelling increased and that the time to reach the equilibrium state was shorter with increasing test temperature.

Second, the maximum swelling pressure tended to increase as the temperature of the test water increased. Expansion of the diffusion electric double layer and an increase in the osmotic pressure are considered as important factors for this.

Thirdly, the equilibrium swelling pressure tended to increase with increasing temperature of the test water. This is likely due to the expansion of the diffusion electric double layer.

Finally, various condition tests will be conducted in the future to understand the swelling characteristics of bentonite.

DETECTION OF CONCEALED ACTIVE FAULTS BY MICROTREMOR AT RIVER WATER DISAPPEAR SECTION

Minoru Yamanaka[1], Shuichi Hasegawa[1] and Shuichi Miyaji[2]
[1]Kagawa University, Japan; [2]Chiken Inc. Ltd., Japan

ABSTRACT

Big earthquake caused by unknown active fault occurs frequently in recent years in Japan. A surface earthquake fault which develops in an alluvial fan above the earthquake source fault becomes indefinitely by erosion and accumulation during repeated floods. An existence of the concealed active fault is very difficult to distinct by topography investigation in the alluvial fan. On the other hands, a river water disappears into underground during a dry season. This phenomenon is considered as a change of depth of permeable layer at a concealed active fault crosses. Therefore it is necessary to survey the suddenly change of the layer in order to detect the distribution of concealed active fault along the river at the alluvial fan.

In this study, the microtremor measurement as new geophysical exploration technique in order to detect the concealed active fault were carried out at 2 river sites where the distribution of two active faults is revealed yet. As a result of this study, the principal peak frequency changes largely at the river water disappear section, and it can be clear that there is meaningful difference in the depth of basement rock at the location of the estimated fault.

Keywords: Physical exploration, Active faults, Microtremor, Vibration analysis, River

INTRODUCTION

Big earthquakes caused by an active fault such as the 2016 Kumamoto Earthquake or the 2018 Hokkaido Eastern Iburi Earthquake occurred frequency in Japan. Many active faults are distributed over about 2000 points over Japan. A trace of active fault is not clear on an alluvial fan or an alluvial low plain, then it is difficult to detect the active fault in the topography [1].

A mysteries phenomenon that a river water disappears continuously from a riverbed at a certain section occurs frequency in a small river during dry season. The authors consider that this phenomenon which river water disappears into underground happens by difference of depth of permeable layer at a concealed active fault crosses [2], [3].

The boring exploration and the reflective exploration method, etc. are used as a conventional active fault detection method [4], but these methods are needed many days and expensive cost, and more these methods cannot carried out easily for detection of an active fault. Therefore development of new detection method of active fault is expected.

The purpose of this study is to estimate on application of microtremor measurement as the new geophysical exploration method to detect a concealed active fault at river water disappear section. It can be considered that it's possible to detect the sudden depth change of stratum from the difference in the vibration characteristics gained by setting some microtremors along the traverse line which crossed an active fault.

In this study, the microtremor measurements was carried out at 2 river sites where the distribution of the active fault is revealed yet and is not yet. And change of the principal peak frequency and difference in the depth of the basement rock at the location of active fault were discussed.

DETECTION METHODS OF ACTIVE FAULT BY GEOPHYSICAL EXPLORATION

So many researches on survey method of an active fault distribution were carried out until now [5], [6]. Geophysical exploration is used widely as a method to grasp a location or an extension of active fault and to clear a property of active fault under an alluvial plains covered by thick accumulated layer in particular [7]-[9]. But a trench and boring survey within shallow layer as a survey method of active fault is not enough because a fault displacement is very small or almost zero at ground surface in an alluvial plain.

Generally, seismic reflection survey, acoustic survey, electric survey, electromagnetic survey, gravity survey and radio-metric survey etc. can be listed as geophysical exploring methods for active fault investigation. But these methods can't carried out easily because of its necessary days and much expense. The authors proposed the microtremor as a survey method to detect an active fault more easily and conveniently [10]. The microtremor has utilized widely on in the field of the geophysical exploration [11], but it seems that the application study of microtremor to detect a concealed active fault under alluvial plain is very few [12].

DISAPPEAR OF RIVER STREAM AT CONCEALED ACTIVE FAULTS

River water disappears frequency into underground during a dry season at a small river which flows on an alluvial fan, and this phenomenon is called as "*Segire*" in Japanese [13]. The authors supposed that *Segire* is related closely to a change in the stratum structure. It is considered that *Segire* occurs because of sudden change of the depth or thickness of stream strata at the cross part of concealed active fault.

ACTIVE FAULT AND SEGIRE IN KAGAWA PREFECTURE

Takamatsu Plain

Outline of geology

Takamatsu plain is formed at the alluvial fan by Koto river mainly, and the flood plain by Kasuga river and Shin river is distributed at the east area. Headwaters of Koto river is located at Sanuki mountains in toward to south of the plain. The gravel composed of Izumi layer group is accumulated mainly in the riverbed.

The geological feature is divided roughly into the alluvium layer, Mitoyo layer group and basement rock (granite) from the ground surface. The low permeability layer with much fine soil particles is distributed in the boundary of the alluvium layer and Mitoyo layer group. The thickness of aquifer in the upper part is about 20 m of depth.

Nagao fault

Nagao fault is located in the south in Takamatsu plain. This fault is distributed over eastern and western direction, and is about 20 km of length. Nagao fault inclines toward the south side, and is reverse fault which rises to south side. The unit length of displacement is estimated to be 0.5-2.0m with the right-lateral strike-slip component [14], [15].

Segire of Koto river

Segire phenomenon occurs sometimes at the middle reaches area along Koto river in Takamatsu plains. A section of *Segire* of Koto river is about 2 km in length. The low fault scarp and flexure by the active fault isn't confirmed along the *Segire* section.

Marugame Plain

Outline of geology

Doki river which flows from Sanuki mountains forms Marugame plain. The geological feature of Marugame plain consists of the alluvial fan with gravel mainly, Mitoyo layer group which is alternation of gravel, sand and cohesive soil strata, and granite as a basement rock.

Okada fault and Kami-hogunji fault

Okada and Kami-hogunji faults are distributed in the south-eastern area in Marugame plain. The length is short, and is spread in NW-SE direction. For Kami-hogunji fault, the length on ground surface is about 5 km, the ground level rises at north side, and the inclination of fault plane is unclear.

Segire of Doki river

Segire occurs at 2.8 km in length along middle reaches of Doki river during a dry season. The low fault scarp and flexure is not confirmed along the *Segire* section. The depth of granite (basement rock) is more than 50 m at the downstream side of *Segire* point in Doki river according to the past boring data.

Furthermore the sudden change of depth of the engineering base surface is estimated around this *Segire* according to the microtremor carried out in Marugame plane [16]. The distribution of concealed active fault at near of *Segire* is suggested.

MICROTREMORE INVESTIGATION

Investigation Site

Koto river

Segire points where river water disappears at Koto river was investigated 3 times from June, 2012 to January, 2013. These *Segire* points were divided into 2 section with the stable section where *Segire* occurs continuously and the unstable section intermittently during this investigation period.

Doki river

According to reports on occurrence of *Segire* by Ministry of land, infrastructure, transport and tourism Shikoku regional development bureau from 2004 to 2017, it was revealed that there are an unstable section and a stable section of *Segire* at the middle reaches in Doki river.

Method of Microtremor

Microtremors measurement was used McSEIS-MT NEO (OYO Corp.) which is possible to measure an acceleration of three direction (2 horizontal and 1 vertical). The main axis of the measurement correspond to the north, and it was set levelly in a flat surface on the ground. Measurement time is about 40 minutes for 1 point. A spectrum analyzed a measured data was performed a smoothing process by Pazen window of band width 0.3 Hz.

RESULTS OF MICROTREMOR

Site at Koto River

Fig.1 shows the measuring points of microtremor investigation at Koto river. Total of 11 points of K1-

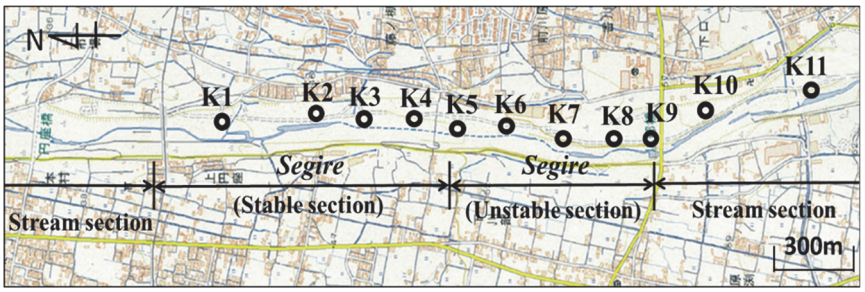

Fig.1 *Segire* section and microtremor measurement points at Koto river

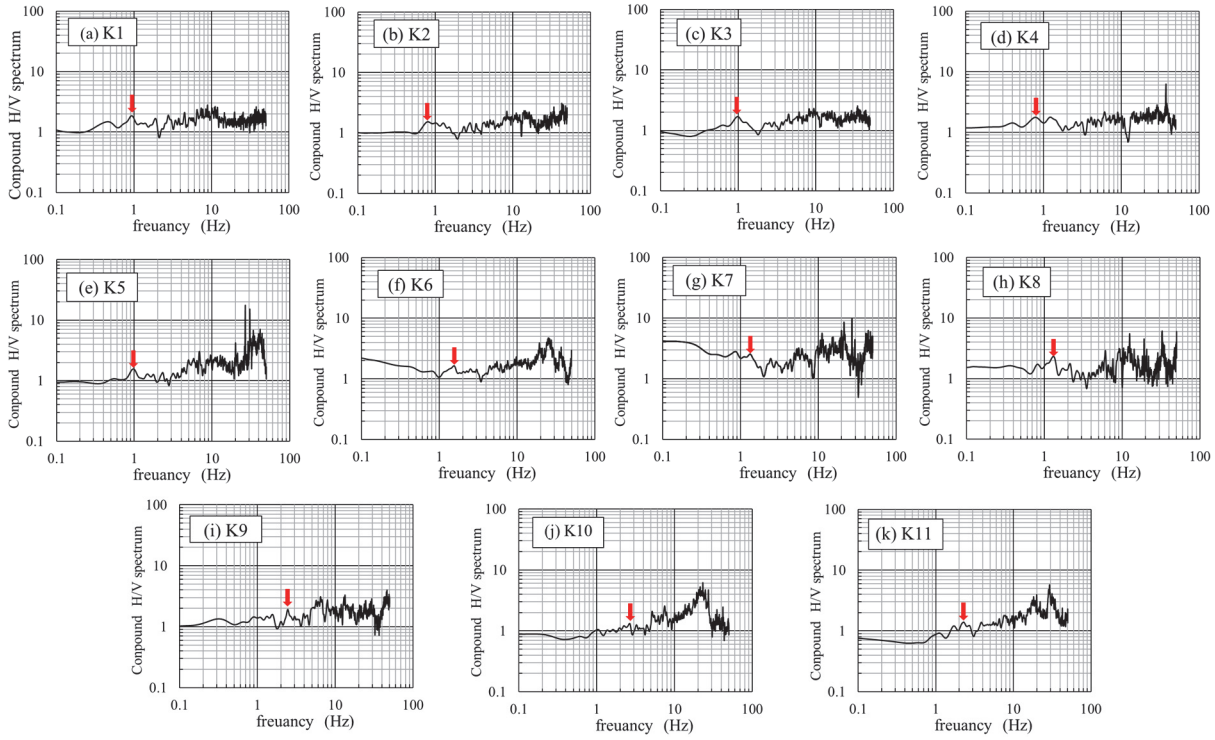

Fig. 2 Compound H/V spectrum obtained by microtremor investigation in Koto river

K11 were set on the flood plain along these two sections and at its upstream side.

Fig.2 (a)-(k) show the compound H/V spectrum obtained by microtremor investigation in Koto river. The composed H/V spectrum is obtained that the square root of summation of square of EW and NE directional (horizontal) spectrum is divided by UD directional (vertical) spectrum. The frequency in the first peak from low frequency side which reflects the depth of granite (basement rock) is indicated by the red arrow. The value of composed H/V spectrum is relatively small, but it is revealed that the first peak indicates around the frequency 1-3Hz at each spot.

Fig.3 shows change the first peak frequency at Koto river. This is about 1 Hz at K1 to K5 point where ranges in the stable section of *Segire*, is about 1.5 Hz at K6 to K8 where ranges in the unstable section of *Segire*, and is over 2 Hz at K9 to K11 where streams river water. It can be say the first peak frequency decreases meaningfully at *Segire* section.

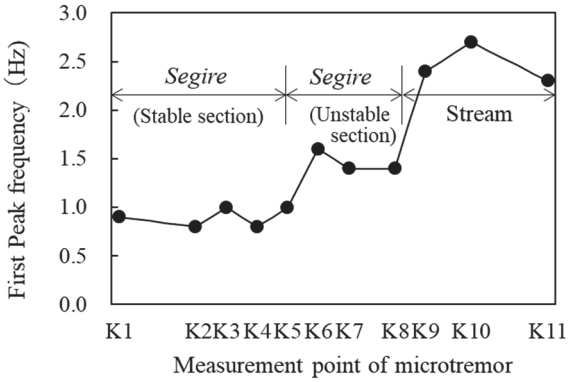

Fig. 3 Change of first peak frequency at Koto river

Site at Doki River

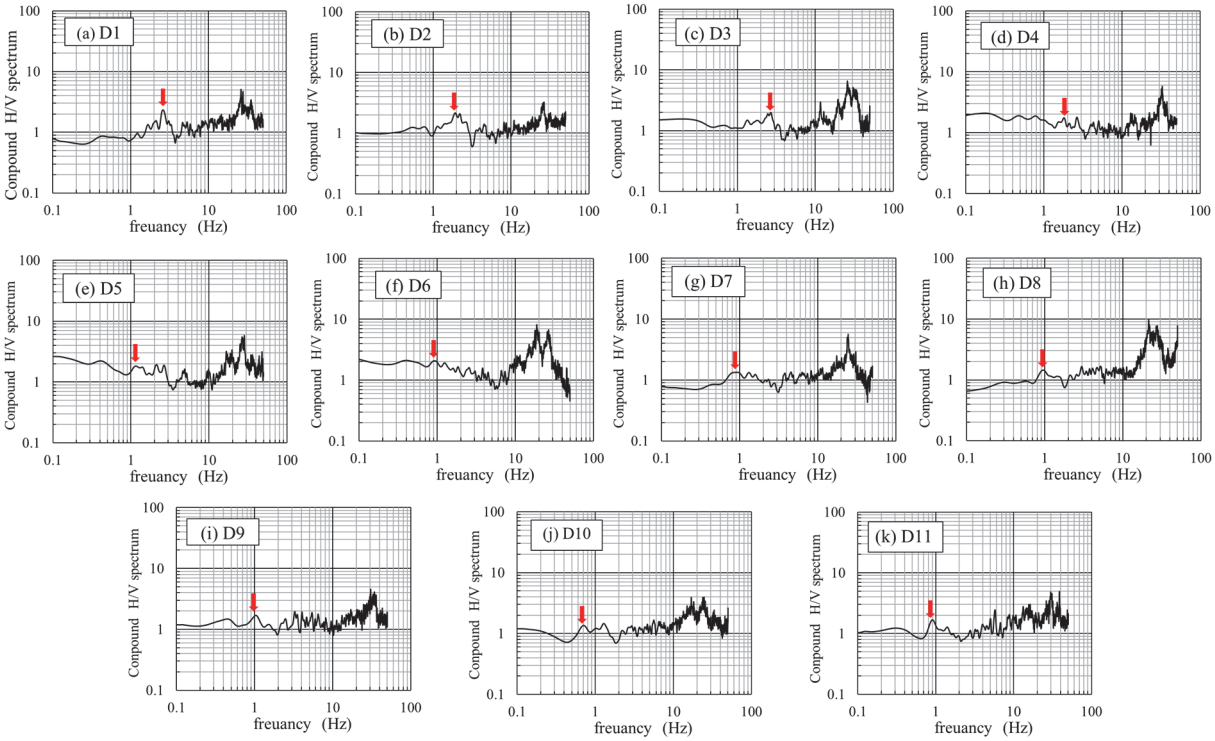

Fig. 5 Compound H/V spectrum obtained by microtremor investigation in Doki river

Fig.5 (a)-(k) show the compound H/V spectrum obtained by microtremor at D1 to D11 points in Doki river. The first peak frequency indicates by the red arrow, the red arrow indicates from about 1 to 3.

Fig.6 shows change the first peak frequency at Doki river. The peak frequency is about 2.7 Hz at D1 to 1.3 Hz at D4 where ranges in the stable section of *Segire*, and is about 0.9 to 0.7 at D6 to D11 where ranges in the unstable section of *Segire*.

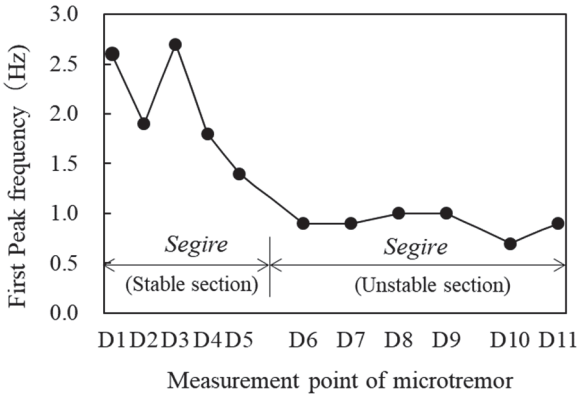

Fig. 6 Change of first peak frequency at Doki river

Estimation of Depth of Concealed Active Fault

If the equation $H=V_s/4f$ defined as 1/4 wavelength law which calculates a thickness of surface layer of ground composed with 2 layers is used, the thickness H becomes so large when a peak frequency f changes so small. Because *Segire* stable section could assume that the depth of basement rock which is the concealed active fault is relatively deep, it means that distribution of concealed active fault is harmonized with the estimated result.

CONCLUSIONS

Microtremors measurement was carried out at the river water disappeared section "*Segire"* in Koto river and Doki river in Kagawa Pref., Japan where can expect crossing of unknown concealed active fault.

As a result of this study, the followings could be obtained;

1) The first peak frequency is about 1 Hz in the stable section of *Segire*, is about 1.5 Hz in the unstable section of *Segire*, and is over 2 Hz at streaming water in Koto river.
2) The peak frequency is about 2.7 Hz at the stable section of *Segire*, and is about 0.9 to 0.7 in the unstable section of *Segire* in Doki river.
3) The first peak frequency decreases meaningfully at *Segire* section at both rivers.
4) The stable section of *Segire* could assume that the depth of basement rock which is the concealed active fault is relatively deep, it means that distribution of concealed active fault is harmonized with the estimated result by 1/4 wavelength law.

ACKNOWLEDGMENTS

The authors would like to appreciate Mrs. Ting Wang of former master course student, and Mr. Ryo Hayashibara and Mr. Shinkichi Natsumeda of former bachelor course student of Kagawa University for their support of microtremor survey in this study.

PERFORMANCE EVALUATION OF PEAT WITH LOCAL SPECIAL CEMENTS, *GGBFS*, AND SUPERPLASTICIZER

Ahmad Numan[1], Fahmi Aldiamar[1] and Hirochika Hayashi[2]
[1]Institute of Road Engineering (IRE), Bandung, Indonesia; [2] Civil Engineering Research Institute for Cold Region (CERI), Sapporo, Japan

ABSTRACT

Road construction over peat is a big challenge in Indonesia because it still requires the right technology to be applied. One of the options for bearing capacity improvement for peat is through deep cement stabilization in the form of columns that requires extensive research. A laboratory study of unconfined compressive strength (*UCS*) of cemented peat is fundamental to formulate a suitable and economical mix design of stabilized peat columns. The use of Ground Granulated Blast Furnace Slag (*GGBFS*) reduces the consumption of cement so that efficiency is expected in the construction. This paper aims to evaluate the increase of *UCS* between original peat from Ambarawa, Indonesia and peat stabilized with several special cements produced in Indonesia, Ordinary Portland Cement (*OPC*), mixture of *OPC* with *GGBFS*, and including superplasticizer (*SPC*) as additives. To characterize the strength behavior of cemented peat, 28 different mix designs of the cemented peat were prepared and tested in unconfined compression tests. The results revealed that specimen with a mix design of 50% binder dosage (25% *OPC* and 25% *GGBFS*) by mass of wet peat and 2.5% superplasticizer by mass of binder gave the highest unconfined compressive strength of 416.1 kPa after 7 air-curing days and 1034.6 kPa after 28 air-curing days which show the effectiveness of strength incremental for bearing capacity improvement.

Keywords: Cement stablilization, Ground granulated blast furnace slag, Superplasticizer, Peat, Unconfined compressive strength.

INTRODUCTION

Indonesia cover more than 18 million hectares of peat making it the third largest country in the world in terms of peat deposit [1]. Peat originates from plant and denotes the various stages in the humification process where the plant structure can be discerned [2]. Some key problems related to peat are low shear strength, low bearing capacity and high compressibility leading to excessive settlements [3]. It is a growing challenge in Indonesia as a developing country to construct a road over peat which has very soft consistency hence low bearing capacity also large and differential deformation were incurred as a result. Many options available to overcome those concerns, one of them is through deep cement stabilization in the form of columns which requires extensive research in particular for low bearing capacity problems. Foundations constructed using deep cement stabilization techniques have been applied to support structures, embankments and excavations in countries like Japan, Scandinavia, the United States, and central Europe [4]. The properties of the improved soil column may reflect the characteristics of the native soil, mixing method, and the binder characteristics [5].

Hence a laboratory study of *UCS* of cemented peat is fundamental to formulate a suitable and economical mix design of stabilized peat columns.

Table 1 Soil consistency from unconfined compressive strength value, q_u [6]

Consistency	q_u (kPa)
Very Soft	< 24
Soft	24 - < 48
Medium	48 - < 96
Stiff	96 - < 192
Very Stiff	192 - < 383
Firm	> 383

The aim of this paper is to evaluate the increase of *UCS* between original peat with a number of ordinary and special cements produced in Indonesia, slag, and including additives.

METHODOLOGY

A laboratory mixing test was performed on Indonesian peat with several special cements produced in Indonesia, *OPC*, mixture of *OPC* with *GGBFS*, and included superplasticizer as additive which all specimens were tested for unconfined compression tests.

Peat properties

Peat samples for the laboratory test was collected from Ambarawa, Central of Java, Indonesia. Table 2 shows engineering soil properties of the peat sample which resulted in a high water content of over 200%, ignition loss of over 90% and low pH value of 1.6.

In this study, the content of addition cement ratio, defined in Eq. (1), were 10%, 15%, 20%, 25%, 30%, 40% and 50%. Where, WC is the dry weight of the cement and WP is the wet weight of peat.

$$\text{Addition Cement Ratio (\%)} = (W_C / W_P) \times 100 \qquad (1)$$

Table 2 Engineering properties of peat sample

GGBFS	3880	34.8	14.8	45.2	1.7	1.3	1.0

Test Procedure

To characterize the strength behavior of cemented peat, 28 different mix designs of the cemented peat were prepared and tested for unconfined compression tests. Three cylindrical specimens (triplo) were made for each mix design, as a measure to minimize errors.

Since there have not been any standard method in Indonesia to test cemented peat specimens for each mix design, the tests were conducted according to [7] a standard defined by the Japanese Geotechnical Society. Specimens 5.2 cm in diameter and 10.4 cm in height were made as follows. First, peat and cement slurry with W/C (W: weight of water, C: dry weight of cement) of 0.60 for each addition cement ratio were poured into an electric mixer and mixed well for 10 minutes. Next, the mixture was put in a mold in three layers, without compaction. Then, the specimens were tamped to avoid voids.

The method for unconfined compression test refers to [8] and the test was conducted after 3, 7, 14 and 28 air-curing days.

RESULTS AND DISCUSSION

Strength of *OPC* and special cement-treated peat

Figure 2 shows the relationship between the addition of cement ratio and the *UCS* value of stabilized peat using *OPC*, special cement A, special cement B, and special cement C after 3, 7, 14, and 28 days curing respectively. The *UCS* value of stabilized peat increased roughly with the increase of the addition cement ratio. It can be seen that the *UCS* value of stabilized peat varied depending on the type of cement. 50% addition cement ratio gave the best result of *UCS* value. In cases which *OPC* was used, the maximum *UCS* value was 268 kPa. Special cement A performed better than *OPC* with 371 kPa of maximum *UCS* value but Special cement C gave best performance with 428 kPa of *UCS* value. Special cement B had the lowest value of maximum *UCS* with 205 kPa.

Fig. 1 Unconfined compression tests were conducted for each specimen.

Fig. 2 Relationship between Cement Ratio and *UCS* of stabilized peat.

Strength of *OPC* with *GGBFS*-treated peat

Granulated Blast Furnace Slag (*GBFS*) sometimes simply referred to as slag, is a glassy granular material formed when molten blast-furnace was rapidly chilled, as by immersion in water. It is the residue of combustion in the furnace of steel refining process or by-products of the steel plant. The mineralogical composition and reactivity of the slag vary depending on the rate of cooling after leaving the blast furnace (1500 °C). Slow cooling results in a crystalline, quite unreactive slag, while rapid cooling produces an amorphous, glassy, latent reactive slag. Granulated blast furnace slag is a product of fast cooling and is thus a latent reactive slag [9]. *GBFS* forming elements are lime, silica and alumina has a chemical composition that does not differ from natural mineral compunds found in *OPC*.

GGBFS is a *GBFS* which has been finely grounded. It has cementitious properties like cement and can serves as an adhesive aggregate. On a certain finer condition of *GGBFS* after being grounded, it can be a substitute for *OPC* in a wide range of equal mass replacement ratios. The use of *GGBFS* reduces the consumption of cement hence construction is expected to be more efficient, which is the aim of the second series trial.

The ratio of the cementitious binder was maintained at a ratio of 50% to the wet weight of peat (since 50% addition cement ratio gave the best result of *UCS* value in previous trial). The binding material consisting *OPC* cement and *GGBFS* was then varied according to the composition shown in Fig. 3.

The test results of compressive strength using a combination of variations in the composition of *OPC* and *GGBFS* showed that variations in the ratio of addition cement in a mixture of binding materials did not have a significant effect as seen on Fig. 4. The maximum *UCS* value was 330 kPa at 25% addition cement ratio (in this case is *OPC*) at 28 days curing time. The performance is quite satisfying since the cases in which *OPC* was used, the maximum *UCS* value was 268 kPa with a 50% addition cement ratio. With less cement ratio (25% from wet weight of peat) combined with *GGBFS*, the *UCS* value is bigger.

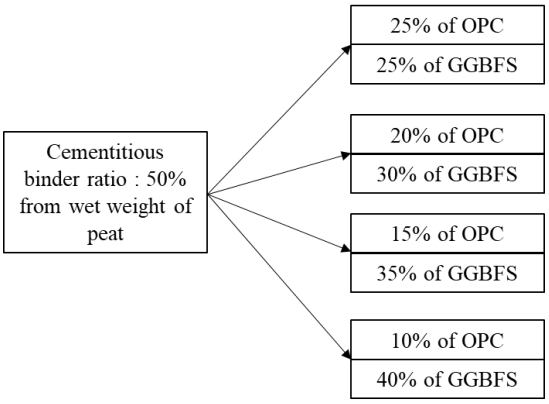

Fig. 3 Variations of cementitious binder ratio

Strength of *OPC* with *GGBFS* and superplasticizer-treated peat

The last trial aimed to have higher *UCS* value with less amount of cement addition ratio. The basic method to increase the strength of concrete is using less W/C. In this case, to have higher mechanical strength of cement-treated peat, the same method was used. The problem which appeared was the lower workability caused by clogging in Deep Concrete Mixing (*DCM*) machine pipe. To extend workability retention, acrylic polymer-based superplasticizer as a chemical admixture was used in this trial.

1% and 2.5% dosage of superplasticizer from the total weight of cementitious binders were used in this

trial. For a 1% dosage superplasticizer, the W/C was lower down to 0.37 and for 2.5% dosage plasticizer, W/C was lower down to 0.30.

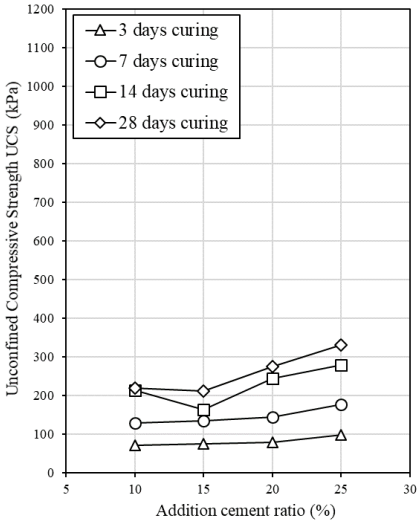

Fig. 4 Relationship between Cement Ratio and *UCS* of stabilized peat using *OPC* with *GGBFS*.

The compressive strength significantly increased along with the amount of addition ratio of superplasticizer as seen in Fig. 5 and Fig. 6 although variations of addition cement ratio in a mixture of binding materials did not contribute significant effect for the addition of 1% superplasticizer.

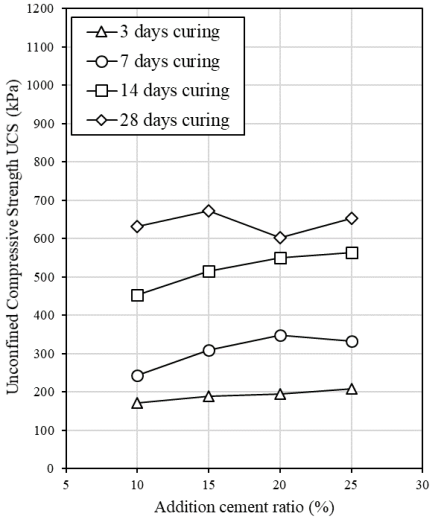

Fig. 5 Relationship between addition cement ratio and *UCS* of stabilized peat using *OPC* with *GGBFS* and 1% superplasticizer.

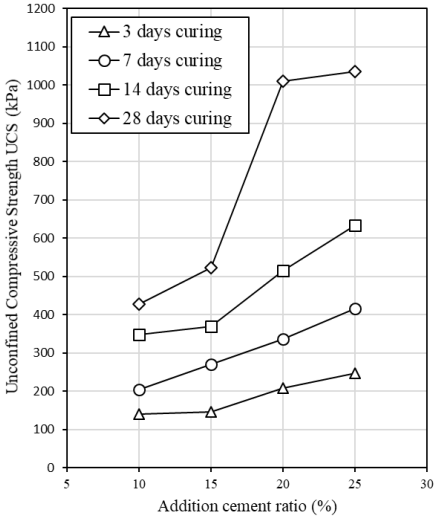

Fig. 6 Relationship between addition cement ratio and *UCS* of stabilized peat using *OPC* with *GGBFS* and 2.5% superplasticizer.

Gain strength of stabilized peat

In the case of all specimens, the *UCS* after 28 days curing increased from 3 days curing as shown in Fig. 2, Fig. 4, Fig. 5 and Fig 6. To clarify this trend, the relationship between the *UCS* after 3 days and 28 days is shown in Fig. 7. The *UCS* after 28 days curing ranged from 1.6 to 4 times the *UCS* after 3 days curing.

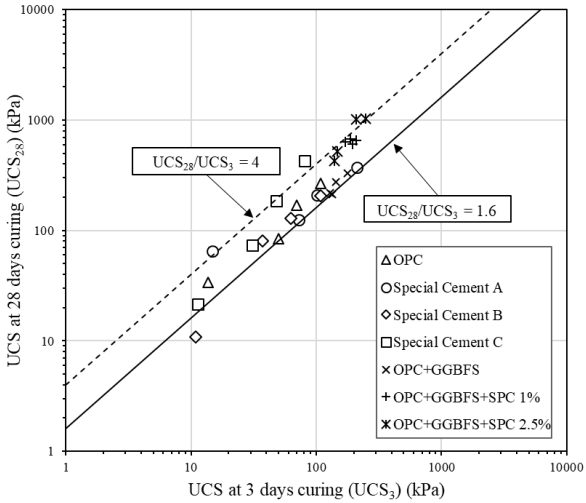

Fig. 7 Relationship between *UCS* of stabilized peat after 3 days and after 28 days curing.

The general in-situ *UCS* ranges from 200 to 500 kPa which is commonly used in Japan [10]. In Scandinavia countries, the general value is from 100 to 200 kPa. The difference in the strength naturally causes differences in the relative stiffness of stabilized and unstabilized soils, which strongly influences the overall behavior of the improved

ground as a system [4]. In-situ *UCS* is generally between 1/2 and 1/5 (ave. is 1/3) of laboratory *UCS* due to mixing accuracy of in-situ mixing is lower than laboratory mixing [9]. Hence, the laboratory *UCS* value was expected to be around 300 ～ 1500 kPa when the target of improvement is to prevent lateral slip flow or the site condition consists of peat and soft clay.

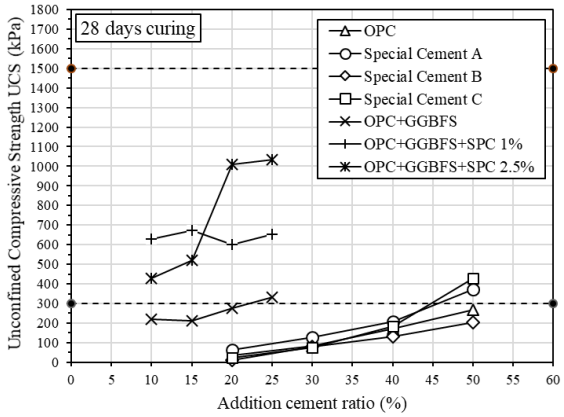

Fig. 8 Relationship between cement ratio and lab. *UCS* of stabilized peat.

The results revealed that specimen with a mix design of 50% binder dosage (25% *OPC* and 25% *GBFS*) by mass of wet peat and 2.5% superplasticizer by mass of binder gave the highest unconfined compressive strength of 1034.6 kPa after 28 air-curing days which shown the effectiveness of strength incremental for bearing capacity improvement as seen in Fig. 8.

CONCLUSIONS

In this study, peat from Ambarawa, Indonesia was stabilized with different amount of binder, primarily consisting of several special cements produced in Indonesia, Ordinary Portland Cement (*OPC*), and mixture of *OPC* with Ground Granulated Blast Furnace Slag (*GGBFS*). Ground Granulated Blast Furnace Slag (*GGBFS*), an industrial waste was found to be suitable for use in stabilizing peat through a number of experiments. The use of *GGBFS* reduces the consumption of cement so that efficiency is expected in the construction.

The design compressive strength will vary based on the purpose and target strength of soil improvement. Hence, if all test results were formulated at 28 days curing time as shown in Fig. 8, a cement ratio above 50% was needed for Special Cement A and Special Cement C to meet the requirement of laboratory compressive strength design range **(**300 ～ 1500 kPa). Whereas, if a mixture of ***OPC*** with ***GGBFS*** were used then the use of a 25% cement ratio can fulfill the common value of laboratory compressive strength design range. Then, the use of superplasticizer additives can be used if a high compressive strength value above 400 kPa is needed.

Because the experiment is limited for laboratory conditions, the result needs to be confirmed for actual field conditions in future work.

EFFECTS OF THE MEDIAN TECTONIC LINE ON SHIKOKU EXPRESSWAYS

Hironobu Ito[1], Shuichi Hasegawa[2], Junji Uchida[1]
[1] West Nippon Expressway Engineering Shikoku Co. Ltd, Japan; [2] kagawa University, Japan

ABSTRACT

In the Shikoku region, the Median Tectonic Line, which is a large-scale tectonic line, extends in the east-west direction. Shikoku region are built close to the Median Tectonic Line. This causes various problems from the construction stage to the maintenance stage on the expressway. Soil structures such as cuttings and tunnels in fragile fractured zones affected by the Median Tectonic Line collapsed or deformed at the construction stage. In addition, clay minerals such as Smectite and Illite produced by hydrothermal alteration form slip clay of landslide because shear strength decreases. Also, they exhibit swelling properties. It causes the roadbed in the tunnel to ridge. Besides these effects, hydrothermal alteration produces pyrite in the soil. When pyrite comes in contact with air and groundwater, sulfuric acid is generated to form acidic soil. On cut slopes where acid soils are distributed, poor vegetation will cause slope failure during rainfall. In this paper, we report several cases in which those Median Tectonic Line affected the expressways in Shikoku region.

Keywords: Median Tectonic Line, Cut slope, Landslide, Hydrothermal alteration

1. Introduction

The Median Tectonic Line is a large fault that divides southwest Japan into the Ryoke zone on the north side and the Sanbagawa body on the south side, and in the Shikoku region, it was an active fault that has active right lateral faulting in the Quaternary.

Yadabe et al. (2000)[1] suggest that the heterogeneity of the deep underground may suggest the influence of past large-scale landslides, fault movements and hydrothermal alteration.

In Hasegawa (2002)[2], there is a high possibility that the granite body is hidden Shikoku Southwest Japan Outer Zone. These igneous activities may provide a site of slope change (geographical predisposition) by constructing a prototype of the Shikoku mountain range by uplift, and also a geological predisposition by bedrock degradation accompanied by hydrothermal alteration Point out to offer.

Tamura et al. (2007)[3] What is the mineral composition of the landslide clay of the cut slope along the Median Tectonic Line and the clays around it Similar to the mineral composition of the hydrothermal alteration fault fracture zone, there are many alteration zones and clay veins on the slope of the cut surface, and the hydrothermal alteration also extends to the landslide point. From these facts, on the expressway constructed near the Shikoku Median Tectonic Line, uneven rock mass was distributed deep in the underground area under the influence of hydrothermal alteration, and many problems of hydrothermal alteration clay and fracture zone occurred.

2. Cut slopes affected by fault fracture zone

The case of Tokushima Expressway Hanazono district is introduced as an example affected by the fault fracture zone by the Median Tectonic Line.

The Tokushima Expressway Hanazono district is a district where several occurrences of deformation occurred and measures were taken each time.

Since the cut slope is planned on the Median Tectonic Line, fault fracture zone clay is excavated. Therefore, this change has been going on for a long time.

Fig.1 Location map of the Hanazono area

There is a steel tower at the top of the cut slope. In addition, there was no time for construction. For this reason, the earth removal method was not adopted. Therefore, measures are taken such as ground anchors and catchment wells.

Pic.1 Full view at Hanazono area

2.1 Hanazono district topography, geology summary

The topology of the Hanazono area of almost parallel to the Yoshinogawa River along the southern rim of the Sanuki Mountain Range, and the slope of the cutting is on the Mino fault, one of the active faults in Median Tectonic Line, as shown in Fig.1.

The Mino fault is located on the northern bank of the Yoshinogawa River, and it consists of the following four formations: 1) Izumi Group at the Cretaceous, late Mesozoic as a basement rock, 2) Dotyu Formation, at Pliocene to Middle Pleistocene, 3) the middle or lower terraced sediments at late Pleistocene, and 4) the Alluvial Formation at Holocene, as shown in Fig.2,3.

The geology consists of the fan-shaped gravel formation at the Cenozoic Quaternary and the mudstone formation of the Izumi Group at Cretaceous, Mesozoic as shown in Fig. 1, and there is a fault crush zone of partly degraded mudstone between them, as shown in Fig.4.

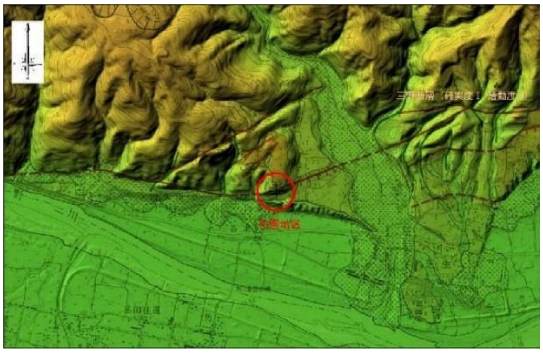

Fig.2 Around the topographic map

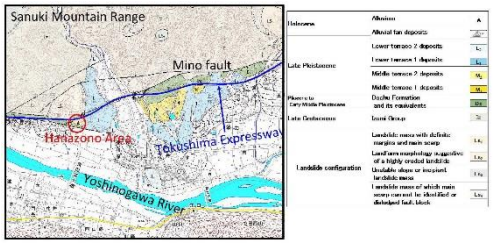

Fig.3 Surrounding geological map

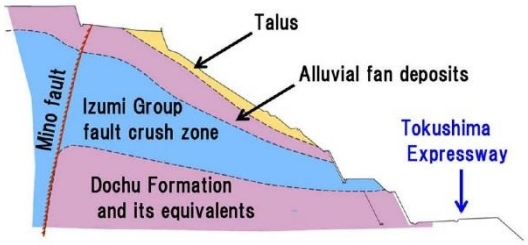

Fig.4 Geologic cross section

2.3 Deformations during construction

In Hanazono area, we began cutting works from July 1997, but when the cumulative rainfall reached 190 mm because of the rainy season in July 1997, a deformation occurred at STA 339 where the town road crossed. So a small-scale ground anchor work was done as a measure countermeasures. In September 1998, the cumulative rainfall reached 557 mm due to a typhoon attack,5 Moreover, landslide cracks were observed at around the tower of mobile phone and cracks at the structures such as retaining walls. The landslide scale by this deformation was a medium-sized landslide block, as shown in Fig4. As a temporary countermeasure against this landslide deformation. As a permanent countermeasure ground anchors were installed through the reverse winding construction method, and two collection wells were also installed (total 34m long). The expressway opened to traffic in March 2000.

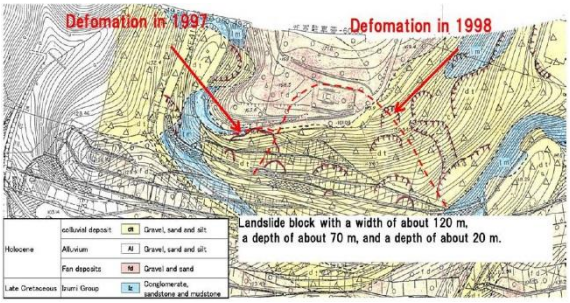

Fig.5 Landslide area map

2.4 Predisposition and attraction of collapse in Hanazono district

The following events were considered as landslide factors. The predisposing factor is the distribution of fragile fractured zones of the Mino fault and the mudstone of the Izumi group The main fault fracture zone clay and the stratum composed of fan beds and diluvial beds are distributed, and it can be mentioned that the shear strength constant was originally low.

3. The effect of clay minerals on tunnel construction

Matonoo tunnel (extension: 213.5 m) is located in Nakanoshou-cho, Shikoku Chuo, Ehime Prefecture

as shown in Fig.5, within the Shredding zone of the Median Tectonic Line (outbound lane 222 m) and in the Fault fracture zone (inbound lane 205 m) It is a tunnel built on.

At the top of the mountain, there is a transmission tower, and at the top of the tunnel is Route 319, and at the bottom of the west slope is Mishima Nishi Junior High School.

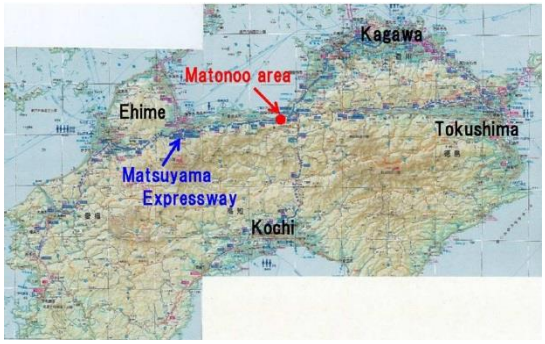

Fig.6 Location map of the Hanazono area

The construction of the relevant tunnel was started in January 1980 as Shikoku's first expressway construction, but landslide fluctuation became apparent along with the tunnel construction, and it took about 40 months to construct the landslide countermeasure construction tunnel. Was completed.

Guide drilling was started in April 1980, but it was difficult to drill at the point where it was more than 20 meters long and drilling was discontinued. After that, I adopted the concept of NATM and changed it to construction with shotcrete. After completion of the outbound lane mountain tunnel, landslides were activated by inbound lane tunnel excavation, and it was estimated that the tunneling and landslide behavior were linked, so the excavation was temporarily suspended, and landslide countermeasure work was carried out. In order to prevent landslides, we have put in place prevention pile and we used a combination of earth filling and drainage boring. As a result of the countermeasure construction, the inbound lane was completed in December 1982. Landslide movement has become apparent again from the time the drilling passes near the summit, but by extending the tunnel at the west wellhead by 10 m and adding a fill-up work and drainage bore, July 1983 outbound lane was also completed. The Matonoo Tunnel was completed in February 1984, but ongoing inspections and dynamic observation in the tunnel are still being conducted.

3.1 Geomorphology and geology of Matonoo area

Matonoo area is located at the end of the ridge between the Otani River, which flows steeply from the Pope Mountains, which is a branch of the Ishizuchi Mountains, and the Ishibe River. The boundary between mountains and plains that are clearly divided by the Ishizuchi fault, as shown in Fig.7,8.

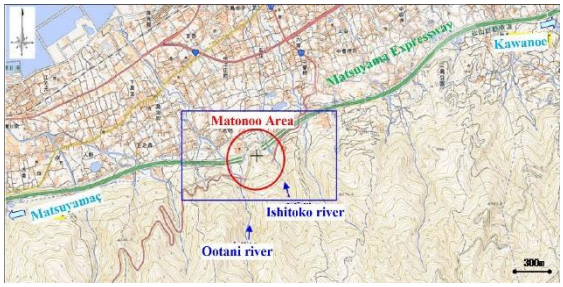

Fig.7 Topographical map around Matonoo area

Fig.8 Topographical map around Matonoo area

The Ikeda fault also runs parallel to the east-west direction to the north of the Ishizuchi fault. Along these faults, plateau-like separation hills remain at the foot of the mountain and fault ridges are partially formed near the boundaries. The separation hills in the Motonoo area are sedimentary deposits of old cliffs and extend northward in a peninsular manner.

On the other hand, in the valleys found on both sides of the hill, the fan-shaped ground of the new-age fan deposits spreads to the north and leads to the alluvial plain. The geology of the area is based on crystalline schists in the Sanbagawa belt originating from pre-lived sediments and sandstone and mudstone in the Upper Cretaceous Izumi Group, and these are Quaternary ancient cliff cones above them It is a geology covered by sediments and fan deposits.

Fig.9 Surrounding geological map

The geology of the area is based on crystalline schists in the Sanbagawa belt originating from pre-lived sediments and sandstone and mudstone in the Upper Cretaceous Izumi Group, and these are

Quaternary ancient cliff cones above them It is a geology covered by sediments and fan deposits.

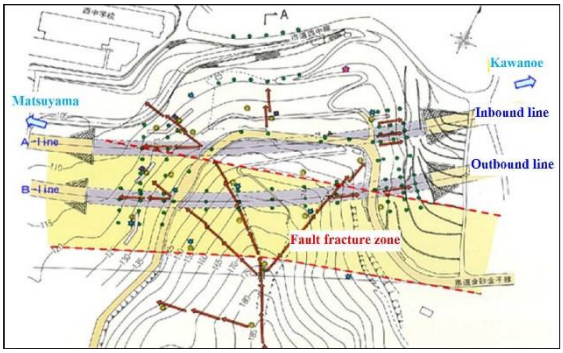

Fig.10 Map plan matonoo area

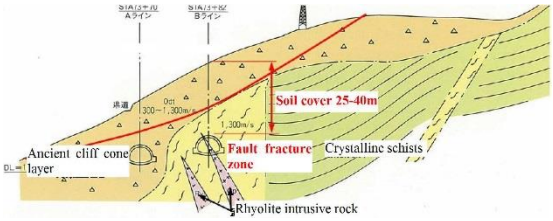

Fig.11 Geologic cross section matonoo area

Bedrocks are divided by a narrowly defined central tectonic line extending diagonally below the route.

Bordering it, the north side is sandstone and mudstone of Izumi Group, and the south side is pelitic crystal schist of Sanbagawa belt. These basement rocks are widely fractured by faulting. In addition, a rhyolitic dike assumed to have been intruded in the Neogene along the fracture zone was recognized, and the horned to sediment-like formation was remarkable, and in part the clayification generated by hydrothermal alteration progressed doing, as shown in Pic 2.

Pic. 2 Penetrating into the shatter zone Rhyolite dike

Since the loose paleo cliff sediment layer of the intervening and relative density of the above fault fracture zone is present thickness 20m ~ 30m, these geological conditions are predisposed to landslide occurrence.

3.2 Predisposition and attraction of collapse in Matonoo district

The predisposition of landslides includes the formation of an old cliff cone layer with the intervention of the low engineering strength including clay minerals affected by hydrothermal alteration and the origin of these geology.

In addition, the low terrain conditions of the side friction of the ridge are considered to be one of the predispositions. As a landslide inducement, since the tunnel excavation and landslide variant from the variable background is closely related, the loosening of the ground due to the thin tunnel excavation becomes an incentive, a plurality of landslides in the vicinity of the stratum boundary is considered to have occurred.

4. Distribution of acidic soils by the influence of hydrothermal alteration

The acidic soil, the soil in which the pH is low, refers to the soil pH of the soil suspension is 7.0 or less.

Acidic soil, vegetation failure in greening the surface, elution of acidic water, causing problems such as plate blister and concrete deterioration of the foundation ground.

The mechanism by which the acidic soil is generated is that the pyrite-containing soil is oxidized to form sulfuric acid, and pyrite (sulfide ore) retains the crystal structure at the time of formation in the deep underground, but the atmosphere (It is generally known that in the weathered layer near the surface, which is easily accessible to oxygen) and surface water, it is converted to chemically stable sulfur that is compatible with this environment.

Pyrite, a source of acid soil, is strongly influenced by marine sedimentary rocks and sediments, and also by volcanic activity, and Quaternary volcanic geology that had large scale volcanism with caldera formation It has been confirmed in the hydrothermal alteration zone.

There are few cases where acid soil is a problem in Shikoku so far, because it is characterized by the geology where the acid soil has been reported so far and there is hardly any geology corresponding to that feature in Shikoku.

Acidic soil is considered to be characterized by the geologic age that occurs, and is often sedimentary rock of marine origin, and its geologic age has been geological since the Tertiary. However, strata and rocks distributed in Shikoku are strata groups mainly composed of Mesozoic and Paleozoic that are distributed in a zonal belt structure. In addition, hydrothermal alteration is considered to be influenced by the Quaternary volcanic origin geology, etc. where large-scale volcanism with caldera formation was strongly influenced by volcanic activity. It is pointed out that the geology affected by the hydrothermal alteration is overlooked because the Quaternary volcanoes are not distributed in Shikoku and the distribution of the

Neogene igneous rocks is also small. Because of that, until now, the fault of acid soil in Shikoku has not received much attention.

However, on the large-scale cut slopes associated with the construction of the Shikoku Expressway, obstacles in the acid soil have become apparent, and in November 2006 the Takamatsu Expressway Naruto to Itano Vegetation failure is said to have spread as much as about 33,000 m2, and poor reforestation such as poor growth of vegetation and discoloration and deterioration of concrete have been confirmed.

Pic. 5 Discoloration of concrete by acid soil

4.1 Distribution of acid soil in Shikoku

The distribution of acid soils of 3.9 or less, which is a very strong acid soil in Shikoku, is shown in Fig.1. According to the results, acid soil is concentrated along the Median Tectonic Line, and it occurs along the geological boundary at other points. Focusing on the geology zone, it has been confirmed that the rock types do not depend on granite, conglomerate, sandstone, shale and rock types, including the Izumi Group, the Sanbagawa Belt and the Shimanto Belt.

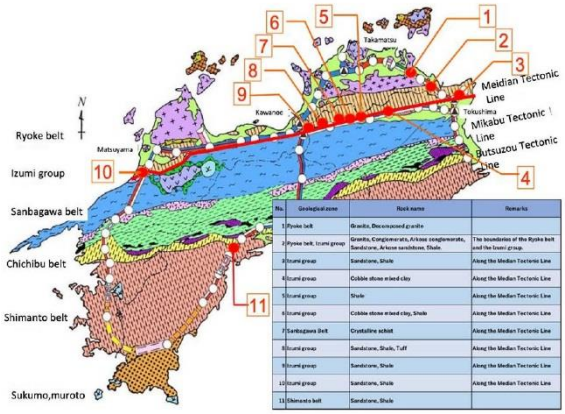

Fig.12 Distribution of acid soil in Shikoku

The distribution of acid soil in Shikoku is also confirmed in areas where geology other than marine clay is distributed. Sandstone of the Izumi group is distributed on the slope No.2 in Fig.11 in areas showing strong acidity, pyrite is identified along with illite and quartz of clay minerals. In addition, in many slopes where geology other than marine clay origin is distributed among other slopes, it is confirmed along the stratum boundary. It can be said that this is likely that the hot water that has flowed into the fault fracture zone deep in the fault contributes to the formation of pyrite. Therefore, it can be said that pyrite is generated near the Median Tectonic Line of Shikoku and other tectonic lines, etc., and acidic soil is likely to be distributed on cut slopes where large-scale excavation has been conducted.

5. Conclusion

In this paper, we report various problems caused by the influence of the Median Tectonic Line in Shikoku. Those problems were constructed in the era when the various effects of the Chuo Tectonic Line were not recognized. At present, there are many findings obtained by constructing expressways in Shikoku, but even at this stage, the detailed mechanism of landslides, especially the origin of deep slip surfaces that form large-scale landslides, has not been fully elucidated. is there. It is important

to solve these problems, and it is important to apply them to construction and maintenance based on the knowledge obtained so far.

ABSTRACT

Soft soil reinforced by rigid inclusion is one of the methods to homogenize and reduce the settlements of earth structures. Various cases of structures under cyclic loading are commonly encountered in the practice, which requires the understanding of this technique under cyclic and/or dynamic loading. This paper is aimed to present a series of experimental studies performed at 1g laboratory scale to simulate soft soil reinforced by rigid inclusions subjected to cyclic loading. Tests were performed with two kinds of embankment or load transfer platform (LTP), i.e., sand and gravel. The parametric study performed with this physical model allowed us to study the influence of the sequence of cyclic loading at the surface of the load transfer platform. The experimental results highlighted the efficiency of load transfer and the accumulation of the settlements during the cyclic loading.

Keywords: Rigid inclusions, soft soil reinforcement, efficiency, cyclic loading

INTRODUCTION

Constructions of roads, railways and other engineering structures in areas, where loose or soft cohesive deposits are found, usually involve with problems such as excessive settlements, deformations and stability problems. These problems have been one of the major challenge for infrastructure planning and implementation.

An interesting– alternative construction technique on soft soil reinforced by rigid inclusions involving granular platforms is widely implemented across the world due to rapid construction, low cost and small total/differential settlements ([1], [8]-[10], [12]-[14]). This technique consists in driving a rigid pile network through the soft soil layer, in order to transmit the loads towards a more competent stratum (in general, the substratum is situated at a depth of a few meters up to 15-20m). The rigid piles can also have pile caps or enlarged heads, in order to increase the surface covered by the piles. This technique is different from those of classical deep foundations, because the piles are not directly connected to the superstructure: a load transfer platform (LTP) or an embankment is built over the improved soil layer, where shearing mechanisms termed as “arching effects” take place. This arching effect partially transmits the load from the surface to the piles, thus permitting to reduce and homogenize the surface settlements. An additional geosynthetic layer can also be placed at the platform base. This layer takes part to the load transfer due to the membrane effect.

The French project ASIRI (Amélioration des Sols par Inclusions Rigides) has brought responses concerning the behaviour of pile improved geotechnical structures and recommendations for the design and installation were published ([7]). However, these studies were only focused on the case of monotonic loading. In case of cyclic loading, a principal citation work in laboratory scale, carried out by Heitz et al. [4], is relevant to the case of dynamic cyclic loading with high frequencies (1-5 Hz). Special investigations have also been performed to described the cyclic mechanism of a granular earth-platform with rigid pile reinforcement by centrifuge modeling ([1], [12]), but only few number of cycles have been prescribed. Houda et al. [5]-[6] also investigated the physical evidence of the effect of vertical cyclic loading (N<50) on soil improvement by rigid piles with a small-scale laboratory experiment. Many such mechanisms, i.e., the use of granular layer, geosynthetic reinforcement, are sophisticated and their description by means of analytical design scheme remains problematic.

This paper describes some of experimental results carried out from a series of experimental observations on soft soil reinforcement by rigid inclusions subjected to cyclic loading using a 3D small-scale physical model. The effects of two kinds of embankment over the soft soil, preloading and boundary conditions are described.

PHYSICAL MODELLING

Test set-up

In order to study the behavior of soft soil reinforcement by rigid inclusions, a 3D laboratory

physical model has been developed (Fig. 1), according to [2], [5]-[6]. This model is under normal gravity at 1/10th scale on the lengths. The device consists of a rigid steel tank of 1x1 m^2. It contains 16 steel pipes with a diameter of 40 mm and a height of 600 mm. In this approach, the modeled inclusions have to be sufficiently rigid and experienced insignificant deformation. Then, the steel pipes were filled with a concrete mix at compressive strength of 23.5 MPa (cube at 28 day). The inclusions were spaced in a square mesh of 200 mm, center to center. In plane surface covered by the inclusions (or pile caps), a recovery ratio (α) can be expressed as;

$$\alpha = \frac{A_p}{A} \quad (1)$$

where A_p is the inclusion section and A is the unit cell surface. Therefore, this spacing provides a recovery ratio equal to 3.14 %. In addition 4 half-inclusions were arranged along an edge of the work, behind a window made of acrylic which allows the observation of deformation. A major disadvantage of this 1-g model is that a small scale model may not entirely respect the prototype due to the scaling law. However, this model can provide a first step for a qualitative analysis of the mechanical behavior of soft soil reinforcement by rigid inclusions. In addition, the parametric experimental studies obtained from this model can be used as a database to calibrate and verify the numerical models ([5], [6]).

The device is instrumented with force sensors at the top of the inclusions and settlement sensors at the base of the granular platform. The load transfer platform (LTP) has a thickness of 300 mm in this part of the study. The loading (monotone or cyclic) was applied to the surface via a cushion under air pressure (P_m), allowing the application of a uniform vertical load over the entire section of the device.

The complex analysis of soil-structure interactions that develop in this model requires appropriate instrumentation. For this study, the following parameters were measured in the central zone, far from the boundaries:

- Forces transmitted to the top of the four central incluaions are measured by 5 kN force sensors; F1, F2, F3 and F4
- Settlement of soft soil was measured at two points (D1 and D2) by 50 mm – displacement transducers.

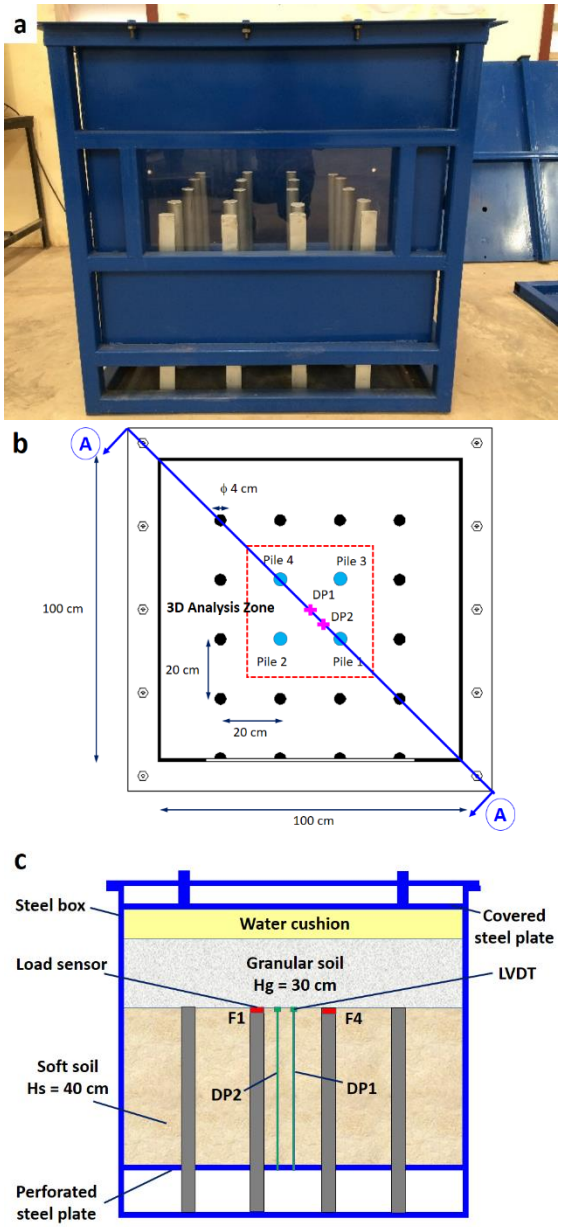

Fig. 1 (a) Photograph of the model; (b) schematic plane view of test set-up; (c) cross section of test set-up with instrumentation

Materials

The soft soil used in this study was simulated by a mixture of expanded polystyrene balls, sand and water (Fig. 2a). Fig. 2b shows the grain size of the soft soil (a mixture of polystyrene balls and sand) in this study. This mixture can represent the compressibility characteristics similar to the real soft soil. This analogue soil also provides an advantage of being easy to set-up and of having a homogeneous density. In addition, a satisfying repeatability from one experiment to another can be achieved.

Soft soil was prepared with the ratio of sand:

water: polystyrene balls at 40: 4: 1 by weight. The presence of the water contributed to the homogenization of the sand with polystyrene. The average density of the mixture in this study was 5.8 kN/m^3.

An embankment of 0.3 m height as a LTP was constructed over the soft soil layer reinforced by the inclusions. Two kinds of embankment or load transfer platform, i.e., sand and gravel, with grain size D_{50} of 1.2 mm and 3.4 mm, respectively, were used. The sand was prepared by the pluviation and tamping methods providing the average unit weight of 16.67 kN/m^3. The friction angle of 45° was examined from triaxial test. While gravel was prepared by tamping method which gave the average unit weight of 15.4 kN/m^3. With this unit weight, the friction angle of 35° could be achieved.

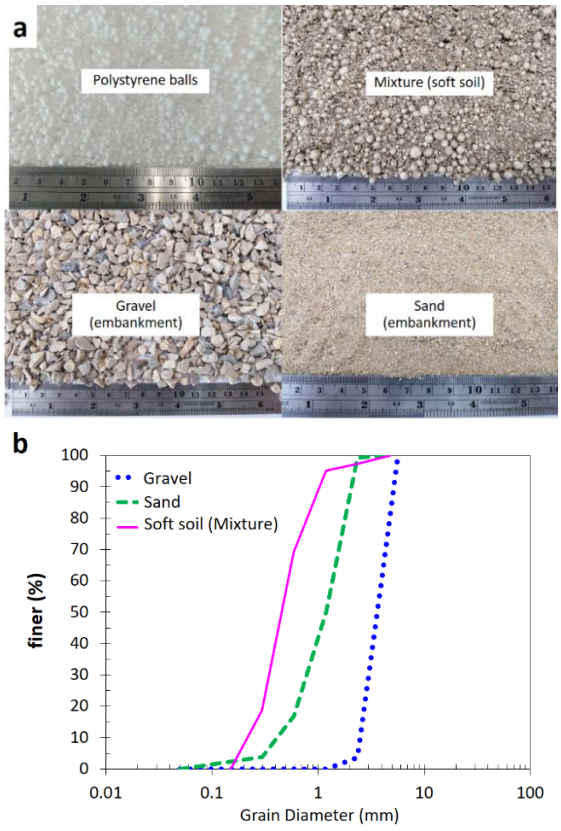

Fig. 2 Materials and Grain size distribution of materials used in this study.

Test program

Table 1 summarizes the preliminary test campaign with different loading conditions in this study. The test set-up was first performed by:

- Filling the model with soft soil
- Construction of the embankment layer
- Placing the air cushion on the top of the embankment
- Closing the tank with the covered steel plate
- Consolidation as a result of the weight of embankment for 12 hours.
- Application of loading, P_m.

Three levels of loading P_m = 5, 15 and 25 kPa, for 3 hours each, followed by an unloading to P_m = 0 kPa for monotonic test series were performed. In case of cyclic loading, two patterns (P_m between 2-15 and 15-25 kPa) with the period of 8 min were applied.

Table 1 Program of experimental tests

Test	Type of embankment	P_m (kPa)	Number of cycles
M_s	Sand	5-15-25	-
M_g	Gravel	5-15-25	-
Cy_s1	Sand	5-15	500
Cy_s2	Sand	15-25	500
Cy_g1	Gravel	5-15	500
Cy_g2	Gravel	15-25	500

TEST RESULTS

Fig. 3 shows typical results under monotonic loading of the test M_S. After a consolidation period of 12 hours, the step of loading (5, 15 and 25 kPa) was applied. The forces on the four central inclusions and the displacements were measured. The values of F_i (in this study, i from 1 – 4, Fig. 3b) were not different and indicated that the distribution of the load in the system was homogeneous. The settlements measured beneath the embankment showed a prominent value at mid-span (DP1, Fig. 3c). A small increase in settlements was observed when P_m was kept constant for 3 hours.

Fig. 3d shows the average efficiency of the four central inclusions as a function of time. The efficiency of the system (E) can be defined as the ratio of the load acting on the inclusion (F) to the total load applied on a unit cell (weight of embankment (W) and surface pressure, P_m):

$$E = \frac{F}{W + P_m} \quad (2)$$

In this study, after finishing the construction of embankment, the consolidation period of 12 hours was performed. At this stage an inclusion only supported the weight of embankment for a unit cell of A = 0.04 m^2). Then, the application of surface pressure, P_m was performed. It can be seen that at the beginning of applying the surface pressure, P_m = 5 kPa, while the surface pressure was applied, the force on the inclusion did not increased coincidently. The

increase rate of force on the inclusion was slower than that of the surface pressure. After that the mobilization of the force took place.

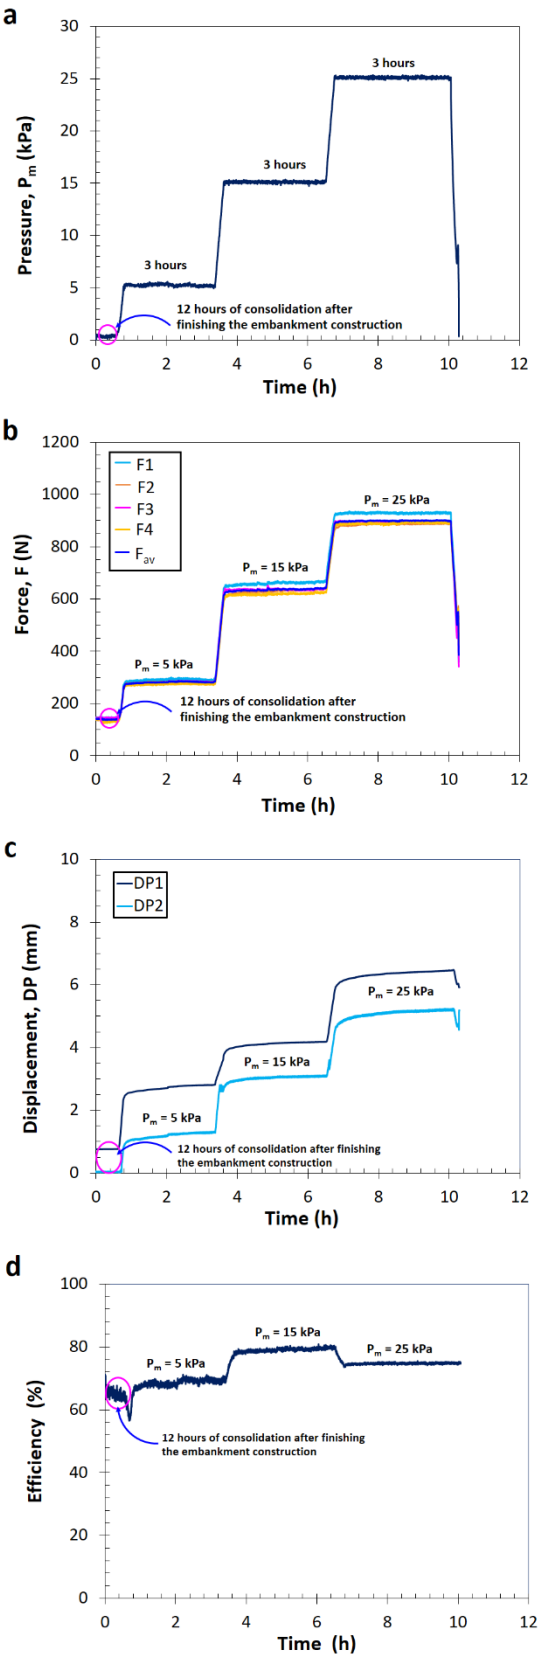

Fig. 3 Monotonic test, M_s, on sand embankment.

The increase in surface pressure at P_m = 5 kPa provided an increase in the average efficiency of 68%. When P_m = 15 kPa was applied, the average efficiency could reach 80%. However, the average efficiency decreased to 75% when applying P_m = 25 kPa.

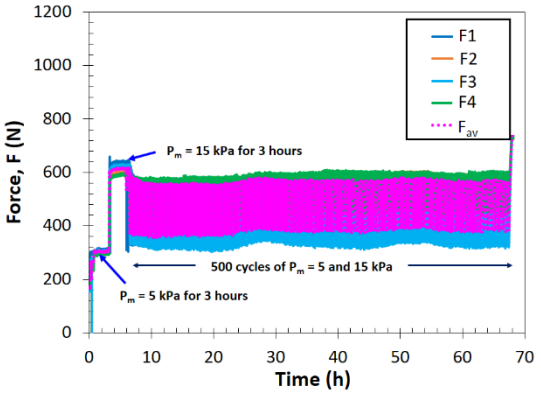

Fig. 4 Evolution of force on the head of four central inclusion with sand embankment (test Cy_s1)

The cyclic tests of two kinds of embankment were performed with the same geometrical configuration. Two patterns of load sequence (monotonic and cyclic) were performed. The effect of stress level, at which the cyclic loadings of 500 cycles were performed, was highlighted. Before applying the cyclic loading, each test experienced the static loading for three hours. Fig. 4 shows the forces on the inclusions of the test Cy_s1 consisting of applying two stages of static loading P_m = 5 kPa and then P_m = 15 kPa followed by an application of cyclic loading by means of ΔP_m = 10 kPa (P_m = 5 and 15 kPa). During cyclic loading, the variation of the forces measured on each inclusion could be found. However, the force repartition on the four inclusions could be satisfactory. The maximum difference of 12 % between the average value (F_{av}) and the value of F_i on each inclusion was found (the maximum difference of 10% was reported by [5], [6]).

Fig. 5 shows the evolution of average efficiency of four central inclusions as a function of number of cycles for two kinds of embankment. These average values were computed by taking into account the center of cycle. It can be seen that the initial values of efficiency of gravel embankment were lower than those of sand embankment due to the friction angel. Starting with the low level of cyclic loading (P_m = 5 and 15 kPa), the efficiency of 79% and 70% could respectively be found for sand (Cy_s1) and gravel (Cy_g1) embankments. During cyclic loading, there was no significant variation in efficiency for both

kinds of embankment. Okkay et al., [11] performed a centrifuge model and reported that the loading-unloading cycles did not influence the behavior of pile group on soft soil. Their results also showed the similar efficiency values for monotonic and cyclic loading tests.

When starting with the higher level of cyclic loading (P_m = 15 and 25 kPa), the average efficiency decreased slightly as a function of number of cycles. In comparison between two embankments, a higher reduction rate in efficiency was observed on gravel embankment (Fig. 5b). The efficiency started at 64 % after the consolidation period of 12 hours and then decreased until reaching 58 %.

When considering the settlement of the system, Fig. 6 shows the satisfactory repeatability of the monotonic loadings before applying the cyclic loadings. The application of cyclic loading induced an accumulation of settlement. The accumulation settlement due to cyclic loading on gravel embankment (Fig. 6b) was found to be greater than that on sand embankment as a result of low efficiency.

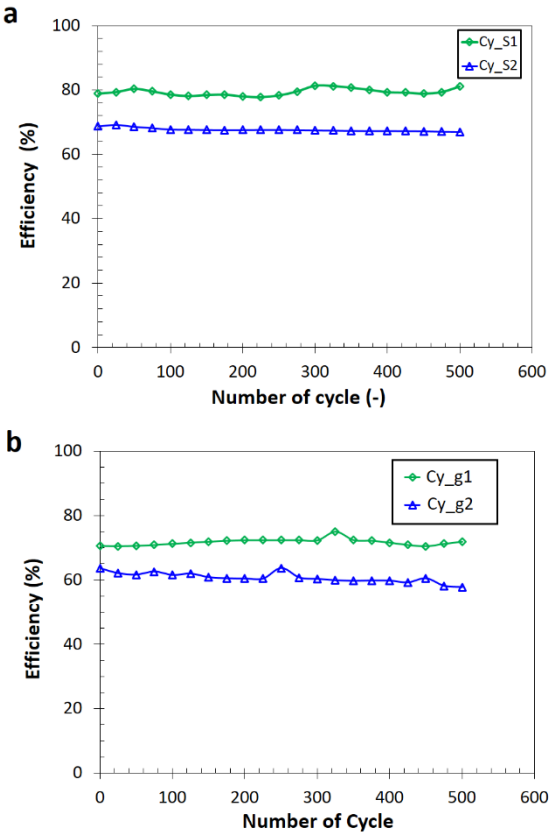

Fig. 5 evolution of the average efficiency at the head of four central inclusions as a function of number of cycles: (a) sand embankment; (b) gravel embankment.

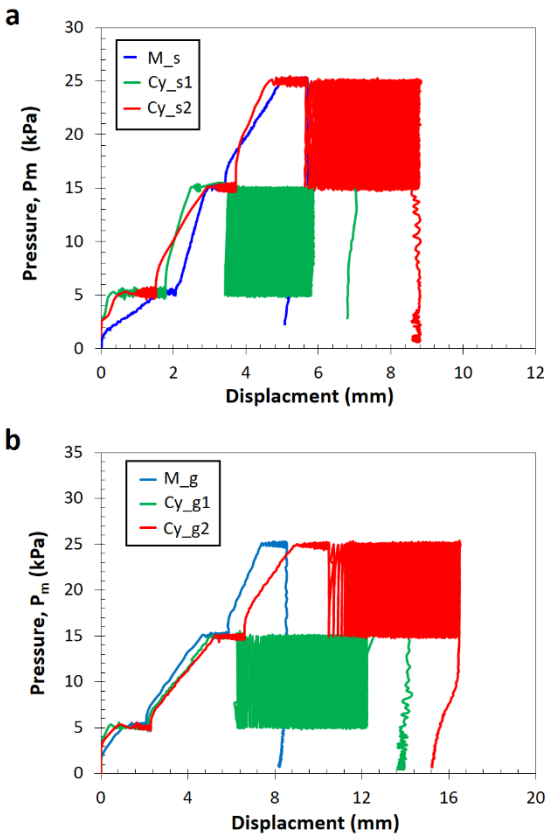

Fig. 6 Settlement evolution with the applied surface pressure: (a) sand embankment; (b) gravel embankment.

CONCLUSIONS

Based on experimental investigation on soft soil reinforced by rigid inclusions in laboratory scale, the preliminary results for two kinds of embankment were presented and analyzed. With 1-g scale model, a drawback still exists because of the scaling law. However, a parametric study obtained from this model allows access to a better understanding of the mechanical behavior of soft soil reinforced by rigid inclusions. This includes the constitution of a large experimental studies to develop and validate numerical approaches.

Monotonic test results serving as the reference tests consisted of applying three levels of surface pressure (5, 15 and 25 kPa) and each loading level was kept constant for 3 hours. On both kinds of embankment, the efficiency increased as a function of applied surface pressure for a certain values. When P_m = 25 kPa was applied, a reduction in efficiency could be observed. The average efficiency of gravel embankment was less than that of sand embankment as a result of unit weight and friction angle.

Under cyclic loading, at low level of surface pressure (5 and 15 kPa) the evolution of average efficiency as a function of number of cycles had no significant variation on both embankments. This is in accordance with the results carried out by centrifuge tests [11]. Comparing the basal settlement between two kinds of embankment, low density and low friction angle could induce more settlement accumulation.

A NON-DESTRUCTIVE METHOD FOR INVESTIGATING SOIL LAYERS OF AN INDIVIDUAL VULNERABLE SLOPE

Eko Andi Suryo[1], Yulvi Zaika[1], Chaminda Galage[2] and Bambang Trigunarsyah[3]
[1]Faculty of Engineering, Brawijaya University, Indonesia; [2,]Science and Engineering Faculty, QUT, Australia; [3]Construction and Project Management, RMIT, Australia.

ABSTRACT

Soil stability analysis becomes main concern in the preliminary design of new construction project. In a critical soil slope, the stability can be affected by the additional load and water infiltration significantly. This is due to additional overturning moment and decreasing of shear strength of the slope material. In such scenario, the non-destructive soil investigation method is needed to analyze the stability. This paper examines the use of Electrical Resistivity Tomography (ERT) to investigate soil layers in a critical slope and to measure parameters of soil shear strength indirectly. Two ERT methods used in this research were dipole-dipole array and square array resistivity (SAR). The results of ERT were verified using geotechnical testing (Bore-hole and Standard Penetration Test) results by investigating the presence of high porosity and water content with soil resistivity. The results of Dipole-dipole array and SAR at selected locations are consistent and suggest a possible crack at the location was reflected by the low soil resistivity value. Furthermore, the results of the SAR confirmed the existence of the deep crack as a continuance of visible cracks on the surface. The results of ERT can be used to detect deep cracks in the subsoil if ERT is conducted in the wet seasons, due to the existence of infiltrated rainwater. Due to the limitations of this technique, the ERT result should be interpreted cautiously. The study demonstrated the benefits of the use of electrical resistivity for the detection of soil layers in residual soil slope.

Keywords: Soil layers detection, Electrical resistivity tomography, Geotechnical investigation, Soil crack

INTRODUCTION

Analyses in stability of slope can be well undertaken by knowing the soil layers underground. Including cracks in soil slopes that has a significant effect on rain-induced slope instability. The stability of slopes associated with surface cracks and rain-water infiltration, has been widely investigated [1], [2], [3], [4], [5]. Surface cracks in soils can be easily seen. In contrast, it is difficult to detect deep cracks unless special equipment for subsoil investigations, such as geophysical tools, is used. The application of geophysical methods may be useful for subsoil investigations, especially at the reconnaissance stage. Based on different physical principles, there are three techniques that can be used to identify soil cracks are based on seismic refraction, electromagnetic wave refraction, and electrical resistivity.

Ground investigations using Electrical Resistivity Tomography (ERT), have been used by [6], [7], [8], [9], [10], [11]. The electrical resistivity method determines the soil type by using electrical resistances differences in different soil types. The flow of an electrical current can move through a soil due to electrolytic action. Water content and the concentration of salts will then measure the resistivity of soil. For example, a saturated soil with a high void ratio would be detected as having low resistivity, due to the significant quantity of pore water and free ions in the water.

Samouëlian et al. [6] have reviewed the application of ERT for characterization of soils, including the early detection of soil layers. Colangelo et al. [12] have used ERT to obtain information on the deep characteristics of landslide bodies, such as sliding surface location and thickness of the slide materials, by comparing information with previous geological maps. Some researchers have attempted to verify the results of geophysical application by using in-situ geotechnical tests such as Standard Penetration Test (SPT) and Dynamic Cone Penetrometers test (DCPT) by [11], [13], [14].

Although attempts at soil characterization have been made, to integrate the results of geophysical application testing and geotechnical data, there is still a lack of investigations of soil slopes associated with deep cracks using ERT, field and laboratory geotechnical testing. This paper discusses the results of soil investigations to detect soil layers with deep cracks on unsaturated residual soil slopes using an electrical resistivity tomography (ERT). The results then being verified using data from field and laboratory geotechnical testing.

SITE CHARACTERISTICS

A residual soil slope in the hilly terrain of East Java Province in Indonesia was selected for this study as shown in Fig. 1. This slope is located at a high seismically active zone [15] and experience a high

average annual rainfall of about 2,700 mm [16]. Figure 2 shows the distribution of slope angle in the study area. The result of a land survey conducted on the slope was used to generate the geometry of slope along AA' with the average slope angle being measured at 20^0.

There is evidence of past rainfall-induced residual soil slope failures in the study area. Local authorities had reported that areas downstream of the targeted slope had experienced a sliding one year before this research was conducted by [17]. Some surface cracks subsequently emerged on the upper side of the soil slope.

There were three profile lines (see Fig. 1), each 150 m long and separated by a distance of 5 m (from A to A'), with one profile line (line 4) of 100 m crossing the other profile lines (from C to C'). To obtain a sub-soil resistivity profile for the slope, an ERT survey using the Dipole-Dipole array method was conducted along profile lines 1, 2, 3, and 4 with 15 electrode points at a spacing of 10 m. The total length of each profile line, from A to A', was 150 m.

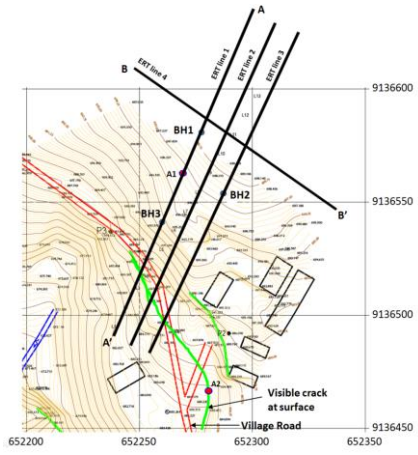

Fig. 1 Map of the study area showing ERT and borehole locations (BH)

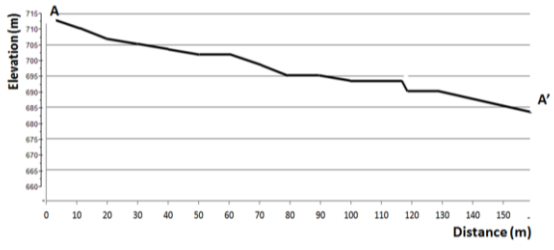

Fig. 2 Cross section long A-A' of the selected slope

METHODOLOGY

To provide electrical resistivity and soil parameters, two soil investigation methods were used in the study: field and laboratory geotechnical testing; and Electrical Resistivity Tomography (ERT).

From the field and laboratory geotechnical testing, selected relevant soil parameters were measured such as water content, porosity and clay content. The electrical resistivity of the subsoil identified the location and provided geometrical information relating to subsoil cracks [6], [7], [8], [9, [10], [11]. Soil resistivity can be affected by soil water content, porosity, and clay content. Sub-surface cracks or deep cracks can be associated with high porosity and high water content in wet seasons, providing low resistivity. The location of deep cracks was confirmed when a low resistivity value was found in the subsoil, in association with high porosity, high water content, and low clay content. The results of SPT test and other laboratory tests conducted on soil samples obtained from the bore-holes were used to verify the location of the deep cracks detected by ERT.

Geotechnical Test Method

In this study, geotechnical investigations carried out in the selected slope in order to characterize the sub-surface soils. Three borehole tests were conducted at BH1, BH2 and BH3, as shown at Fig. 1. At every 2 m depth interval in each borehole, an SPT test was performed following the procedure of the American Society for Testing and Material (ASTM) Standard. Soil samples collected at every 1 m depth in each borehole were used to determine water content, specific gravity, Atterberg limits, dry unit weight, grain size distribution, and shear strength using direct shear test in the laboratory following ASTM testing procedures.

Geophysical Application Method

ERT was used for subsurface exploration along four profile lines at observed slope locations, as illustrated in Fig 1. The objective of the ERT was to detect deep cracks in the upper side of the soil slope. Two ERT methods used in this research were Dipole-dipole array and Square array.

Dipole-dipole array provides the highest resolution, when compared with other arrays such as Wenner arrays and Schlumberger arrays, most sensitive to vertical resistivity boundaries as is needed for deep-crack detection [18], [19], [20], more efficient for delineating the direction of faults [20], suitable for vertical structures, vertical discontinuities, and cavities [21], produced a better lateral extension of the subsurface features [22]. Therefore, in this research, the ERT survey was carried out using the Dipole-dipole array method along the profile lines (shown in Fig. 1) at an acceptable inter electrode spacing of 10 m, as applied by [12]. To gain comprehensive results, there were three profile lines, each 150 m long, with a 5 m spacing.

An ERT survey using the Dipole-Dipole array can be conducted on the profile lines on the slope. A

direct current (D.C.) is driven into the ground through particular electrode position as shown in Fig. 3 to initiate electrical responses (labelled C1, C2, P1 and P2) are put in place. The 45-degree angle is used to plot the pseudo section data point. The electrical current is activated to measure soil resistivity which is recorded using the resistivity meter device.

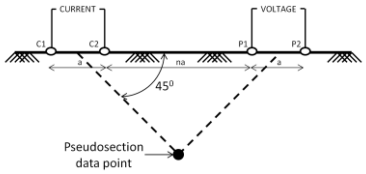

Fig. 3 Basic Dipole-dipole array method configuration

The next step requires that the electrodes are moved across the surface, following marked locations to measure all subsurface data points. For example, Fig. 4 illustrates the 3rd step of taking measurements to get data at selected locations; whereas C1 and C2 are inserted in the same poles, the P1 and P2 electrodes are moved to pole numbers 5 and 6.

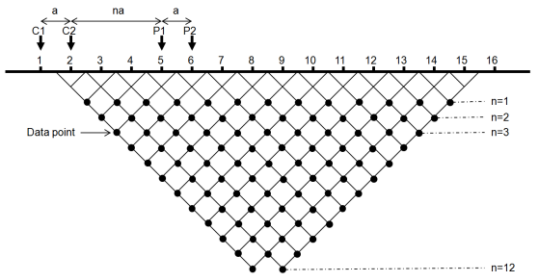

Fig. 4 Third measurement step using the Dipole-Dipole array method

Possible location of deep crack can be interpreted from the ERT result by detecting the zone with lower resistivities. The low resistivity value can be an indication of increased water content due to higher porosity in that zone. However, clay content of the soil matrix also affects soil resistivity. A mobile cloud of additional ions can be formed around each clay particle by the ion exchange properties of clay. As these ions will facilitate easy flow of electrical current, the electrical resistivity in fine-grained soils, such as clay, is always lower than expected [23]. Therefore, the results from ERT need to be verified using a geotechnical test, to ensure that the deep crack has shown a low resistivity value due to high porosity.

To obtain detailed identification of deep cracks in subsoils, ERT application using Square array Resistivity (SAR) technique was used in the potential soil cracks zone detected from Dipole-Dipole array method. Basically, the principle of SAR is similar to Dipole-Dipole array, but in SAR the configuration is modified into a square and rotated measurement [24]. As shown in Fig. 1, there were two locations for the SAR: at the middle of Profile Line 1 (location A1) and on the nearby visible surface crack (location A2).

In general, the nature of anisotropy can be interpreted as cracks in a soil layer. SAR techniques can be used to determine the direction of vertical cracks in the soil [24], [25], [26]. The SAR technique was selected for use in this study to support the result of Dipole-dipole array method by indicates the existence of anisotropy in the soil with low resistivity value.

The SAR technique characterizes the soil crack by using minor resistivity, which indicates the angle direction of the soil crack and the influential depth of the crack zones. The measurement is obtained by inserting four electrodes into the ground following the square array illustrated in Fig. 5. In this square array, the measurement point is located at the centre of the square. The azhimuth of the measurement is represented by the line connecting the current electrodes (A and B).

An incremental array size (a) from 2 m to 12 m was used. The plot of pseudosection data points is located at a 45-degree angle from the horizontal line between the electrode pole and the centre. Therefore, the depth of the measured data point (D) will be determined by:

$$D = \frac{1}{2}a\sqrt{2} \quad (1)$$

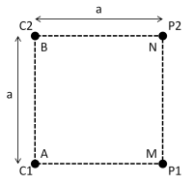

Fig. 5 Azimuthal square array configuration

In accordance with the electrode configuration of the square array as shown in Fig. 5, the value of apparent resistivity ρa is calculated as:

$$\rho_a = \frac{K\,\Delta V}{I} \quad (2)$$

Where:

ρ_a = resistivity (Ω m)
K = geometric factor
ΔV = potential difference between P1 and P2 (volts)
I = electric current (amps)

Furthermore, the geometric factor, K, can be substituted with the side length of square (a):

$$K = \frac{2\pi a}{2-\sqrt{2}} \quad (3)$$

Changes in the rotation angle (azimuth) can be made in 15º increments to 360º, in accordance with the rules of the British National Grid (BNG). Therefore, 24 parts with different resistivity values can be obtained at every depth.

This SAR method will produce decreasing resistivity values if there is a crack inside the

subsurface layer. Such a medium is called anisotropic and will produce an ellipse resistivity value plotted in polar coordinates, as shown in Fig. 6a. If the observed ground has an isotropy medium, the relationship will be seen as rounder as illustrated in Fig. 6b. The direction of the observed crack can be determined by viewing the results of a polar graph at each point of measurement, with the direction of the crack coinciding with the minor axis. If the polar graph is an ellipse-shape, then a crack can be found.

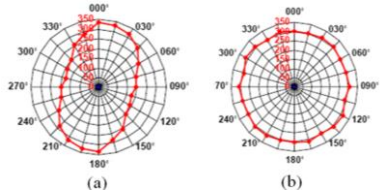

Fig. 6 Polar graphics of azimuthal square array

However, Busby and Jackson [25] have stated that to be assumed as anisotropy, an ellipse polar graph has to have a coefficient of anisotropy of more than 1.16, based on the ratio of minor and major axis:

$$\lambda = \sqrt{\frac{p_l}{p_t}} \quad (4)$$

RESULTS AND DISCUSSION

Detection of Possible Crack Location based on Soil Resistivity

Figure 7 presents the ERT Dipole-dipole array results, showing the soil resistivity distribution of the subsurface soil in the study area. A significant variation in soil resistivity at different depths along the profile lines can be observed. The soil resistivity in the area ranges from 1 to 2000 Ωm, indicating a wide variation in soil type, clay content, porosity, and water content. In general, low soil resistivity was measured for the surface soil layers (5 – 10 m depth). This would be due to high water content in the surface soil, as this test was conducted in the rainy season.

Local zones with very low resistivity (3 – 30 Ωm) could be potential locations for cracks. Soil crack zones have very high porosity and high water content in the rainy season, as rain water can easily seep into the cracks. This hypothesis was justified in profile line 1 (Fig. 7.a), as the visible surface crack coincided with the very low resistivity zone in the subsoil. However, it was not possible to perform a resistivity test in the vicinity of the surface crack in profile line 2 (Fig. 7.b) and profile line 3 (Fig. 7.c), due to the accessibility issues in the area.

The low resistivity zones at the horizontal distance (from A) between 60 m to 130 m and at depth 2 to 12 m, were consistent in all profiles. This suggests possible transverse cracks in this area, as shown in profile line 4 (Fig. 7.d) that crosses over the three other profile lines. This possible transverse crack can also be observed in Fig. 7.d, whereas a local zone with very low soil resistivity was found at the horizontal distance (from B) between 35 m to 55 m and at depth 2 to 12 m.

Possible cracks could be investigated by using the results of SAR technique in the selected locations, as shown in Fig. 8. It was found that: at location A1, cracks in the soil were detected in a direction of 135° from the north, 0 to 5.65 m deep; at location A2, a non linear crack direction was found. From the surface to a depth of 1.41 m, the crack began at an angle of 165˚ from the north (N 165 E). From the depth of 1.41 m to 4.24 m, the direction of the crack changed to an angle of 180˚ from the north (N 180 E). Then from a depth of 4.24 m to 5.65 m, the crack direction was found to lie between an angle of 180˚-195˚ from the north (N 180-195 E).

The results of Dipole-dipole array and SAR at A1 are consistent and suggest a possible crack at this location was reflected by the low soil resistivity value. The results of the SAR conducted at A2 confirmed the existence of the deep crack as a continuance of visible cracks on the surface (see Fig. 1).

(a) A1 location results (b) A2 location results

Fig. 8 Results of SAR Technique

Verification of possible crack location using geotechnical data

Since soil resistivity is affected by clay content and soil density, in addition to soil water content, it is important to use the measured soil parameters such as density, grain-size distribution and water content of the soil in the site, to verify the size and location of the cracks detected by ERT. The existence of cracks can be determined by the presence of high porosity and water content in the wet season. Verification was undertaken to all Bore Hole (BH-1, BH-2 and BH-3).

At bore hole location 1 (BH-1), it can be seen that a low soil resistivity zone was found at a depth of 6 m to 10 m (less than 50 Ωm), as illustrated in Fig. 9. At this depth, there was an average volumetric water content of 65%, and an average clay content of 20%. Therefore, the low resistivity at the depth 6 m to 10 m could have been mainly due to the high-water content, rather than an effect of the clay content. Based on the above information, it might be concluded that a deep crack could be located at the depth of 6 m to 10 m. It was further confirmed that the soil at 6 m to 10 m depth has a high porosity and low unit weight of around 68% and 14 kN/m3, respectively. Similar analyses were undertaken for BH-2 and BH-3 whereas possible crack location at a depth of 7 m to 9 m in BH-2 and at 2 m to 5 m depth in BH-3.

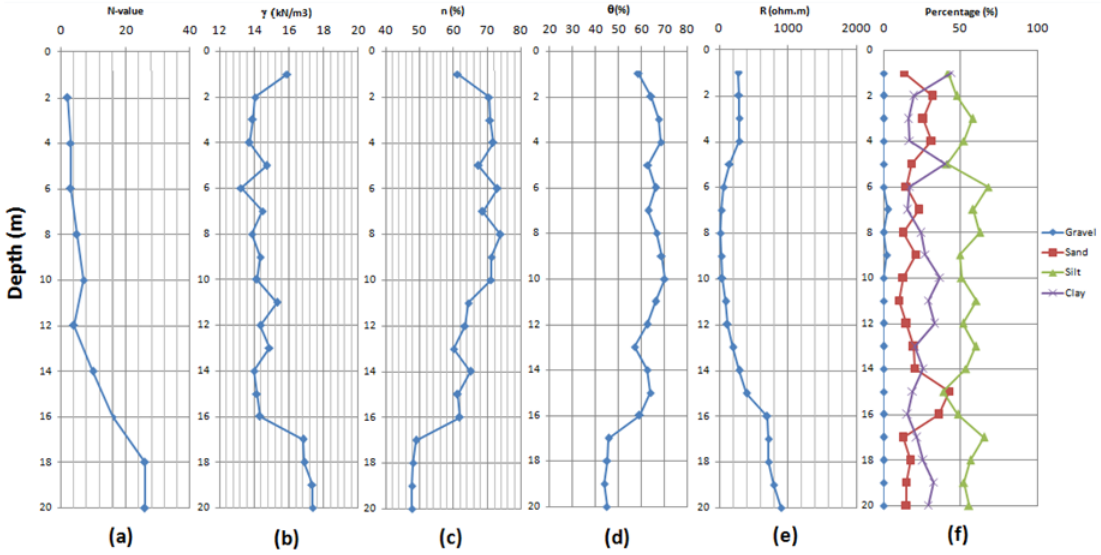

Fig. 9 Soil parameters at BH-1: (a) N-value, (b) Unit weight, (c) Porosity, (d) Volumetric water content, (e) Resistivity, (f) Grain-size distribution

CONCLUSIONS

The following conclusions can be drawn from this study that the results of ERT can be used to detect deep cracks in the subsoil if ERT is conducted in the wet seasons, due to the existence of infiltrated rainwater. However, the ERT result should be interpreted cautiously due to its limitations.

ABSTRACT

This paper proposes a method to estimate the instability of the slope surface layer by elastic wave attenuation which changes with soil moisture and deformation. The objective of this study is to investigate the effect of soil moisture and deformation on wave attenuation of soil. Two experiments were conducted, the first one was a laboratory experiment using a multi-layer shear model, and the second one was an on-site monitoring wave attenuation with soil moisture. In laboratory experiments, wave attenuation at various soil moisture and deformation were measured. The relationships between wave attenuation and soil moisture were found to have hysteresis, that is, difference paths were observed in rain and drain process. The attenuation of wave energy increased about 20%~40% when the VWC grew up near saturation. With increasing the displacement, the wave attenuation also increased, and the wave energy ratio dropped by 40% during a 3 mm of displacement. The results of on-site monitoring showed that wave attenuation decreased with the increasing soil moisture in the rain events and increased during the drain stages. Since most of the rain-induced landslides start failure in nearly saturated conditions, and the elastic wave attenuation in soil can indicate the status of saturation, monitoring elastic wave in the surface layer of slope can detect its instabilities.

Keywords: Landslide, Early warning, Wave propagation, Attenuation

INTRODUCTION

Rainfall-induced landslide occurred commonly in mountainous areas and caused severe human and infrastructure damages[1],[2],[3],[4]. Most of the Rainfall-induced landslide occur at shallow depths, generally less than 3 m[5][6]. In Japan the average depth is 1.2m, 90% is under 2.5m, 500,000 potentially dangerous slopes exist[7][8].

Early warning system can help people safely escape from the dangerous area. It is an economic and effective method to prevent and mitigate rainfall-induced landslide. Rainfall threshold has been used to predict the slope failure[9][10]. The current early warning systems are mainly focused on monitoring the slope's movements by MEMS (Micro Electro Mechanical Systems) tilt sensors or inclinometers and soil moisture by volumetric water content sensors[11],[12]. To cover a wide area of potential danger slope, a large number of tilt sensors would be required[13]. An alternative method to predict slope failure method applied elastic wave propagation in soil has been proposed, which can detect the soil moisture and deformation of a wide area slope. Irfan and Uchimura found that the velocities of both of shear wave(S-wave) and compression wave(P-wave) velocities decreased with increasing degree of saturation by laboratory triaxial tests[14],[15],[16]. In a series model tests, elastic wave velocity has been observed that it responded sensitively to soil moisture content and deformation [17],[18],[19]. Thus, many studies were conducted focusing on the velocities of elastic wave, however, precise measurement of travel time is needed to measure the wave velocities.

In this paper, a method using wave attenuation is presented to monitor slope deformations and soil moisture variations. It is an application of geometric spreading, which is as the wave moves away from the source, the area that the wave energy covers becomes larger and thus wave intensity decreases, and wave energy loss due to inelastic material behavior or internal friction during wave propagation [20]. Laboratory experiments using Multi-layer shear model were conducted, wave attenuation affected by shear forces and corresponding with deformations on every layer, and the soil moistures in wet and dry processes have been investigated. To investigate the behavior of elastic wave propagation in slope surface layer, an elastic wave monitoring system including one exciter and several revivers have been developed and installed in a nature unstable slope. Wave attenuation and soil moisture were analyzed.

METHODOLOGY OF MODEL TEST

The material used in this study is comprised of Silica sand No4, No5, No7 and No8 mixed with ratio of 1:1:3:1 to be near the particle size distribution of soils of the typical natural slopes. It had a dry density around 1.481 g/cm^3. It's minimum and maximum dry density were found out to be 1.308 g/cm^3 and 1.707 g/cm^3 (Figure 1). The relative density was 50% and Volume Water Content was 7.4% at the initial state.

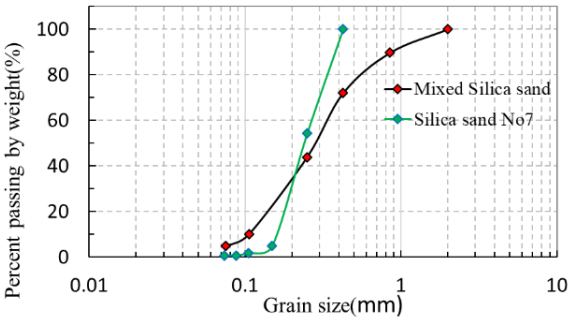

Fig. 1 Grain size accumulation curve

The Multi-layer shear model is shown in Figure 4. It is a model including 20 layers with a total height of 1m to simulate a part of slope surface layer. Every layer has a height of 0.05m, length of 0.6m and width of 0.54m. Shear force is applied on every interface between the layers by air cylinders to simulate the shear force corresponding to the slope angle. Displacement meters are also set at every layer. Rainfall intensity of 60mm/h is given with a nozzle controlled by constant water pressure. Rainwater infiltrates into the top layer of model and drains out from the bottom. Elastic wave is generated by exciter (Figure 2) and detected by receivers (Figure 3). Exciters, receivers and soil moisture sensors are set in the model.

The elastic wave attenuation is defined by the wave energy ratio, calculated by

$$\text{Energy ratio} = E_n/E_0 (\text{n=1,2, 3…}) \quad (1)$$

where E_0 is energy of the receiver near the exciter (r0 in figure 4), E_n is others receiver' energy which far away from exciter(r1~r8). Energy is defined as

$$E = \sum_{f=1}^{f=3000} \left(\frac{1}{2}\right) * 4\pi^2 \rho (f * A_f)^2 \quad (2)$$

where ρ is the density of material, f is frequency, A_f is the amplitude of wave. Frequency is resolved from 1~3000Hz by FFT (Fast Fourier Transformation).

TEST CONDITIONS

Table 1 Test conditions

Test Case	Moisture Control	Slope Angle	Shear Displacement
1	Rain/Drain	0	0
2-1	Rain/Drain	27	0
2-2	Rain/Drain	29	0
2-3	Rain/Drain	31	0
3	Constant	33	5cm

Three test cases were conducted with the conditions in Table 1. In Test Case 1, slope angle was zero, it means no shear force put on any layer of the model. Rainfall was applied for 4 hours until VWC (Volume Water Content) became stable, then rainfall was stopped, and water was drained out by gravity about 20hours (Figure 5a). In Test Case 2, the slope angle was set to be 27, 29, and 31-degree. Displacement was not found changing during the artificial rainfall(24hours) and drain(24hours) events. In Test Case 3, the slope angle was set to 33-degree (Figure 7). No rain was applied but the displacement continuously increased until failure.

RESULTS

Figure 5a shows the changes of wave energy ratio with VWC during the rainfall and drain event in the time series observed in Test Case1. It took 4 hours rainfall to make the VWC be stable, and more than 20 hours to drain the water out. The deeper from the surface, the higher moisture was observed. Figure 5b shows energy ratio changes in the time series. With soil moisture increased in the rainfall event, the energy ratio decreased. During the drain stage, energy ratio increased. Figure 5c and 5d show the energy ratio at every receiver against the VWC averaged between the nearer and farther receivers. The energy ratio reduced 20%~50% when the VWC grew up from 0.1 to 0.25 m^3/m^3.

Effects of soil moisture on the wave energy ratio could be explained by matric suction. When the soil moisture becomes higher, the matric suction decreases, and the weaker of force between soil partials results in lower of wave energy propagation. There is hysteresis in the path of energy ratio and VWC between rainfall and drain event. This may be related to the hysteresis observed in the relationship between soil moisture and matric suction.

The response of energy ratio at different shear force corresponding to slope angle during rainfall and drain event is shown in Figure 6, which is the results of the Test Case 2. The stronger shear force applied, the lower energy ratio is observed. Wave energy ratio reduced 20%~40% when shear force increases from 27 to 31degrees. For example, in Figure 6a, at the 0.1 m^3/m^3 of VWC, when shear force was set to 27-degrees, 29-degrees and 31-degrees, the energy ratio decreased from 0.18, 0.14, and 0.11, wave energy ratio reduced from 22% to 38%.

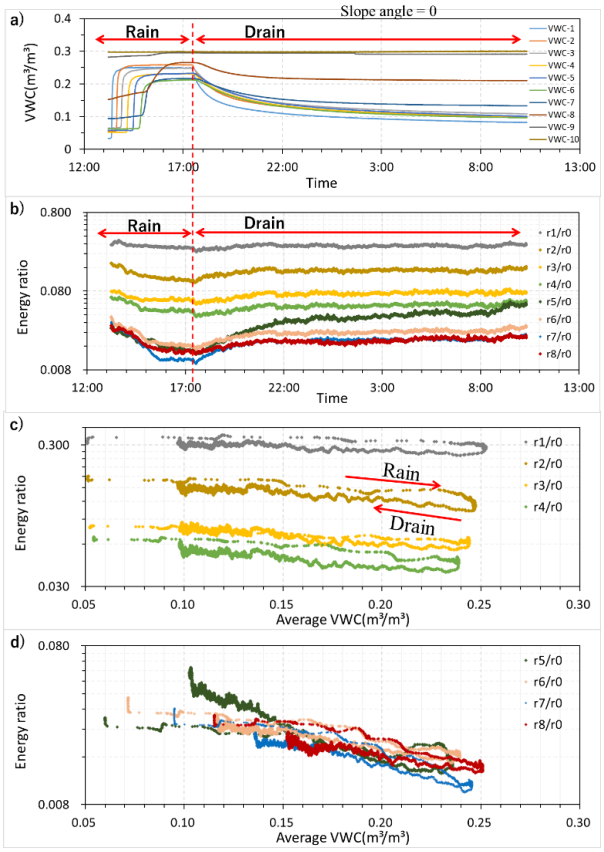

Fig. 5 Energy ratio changes with VWC (slope angle = 0)

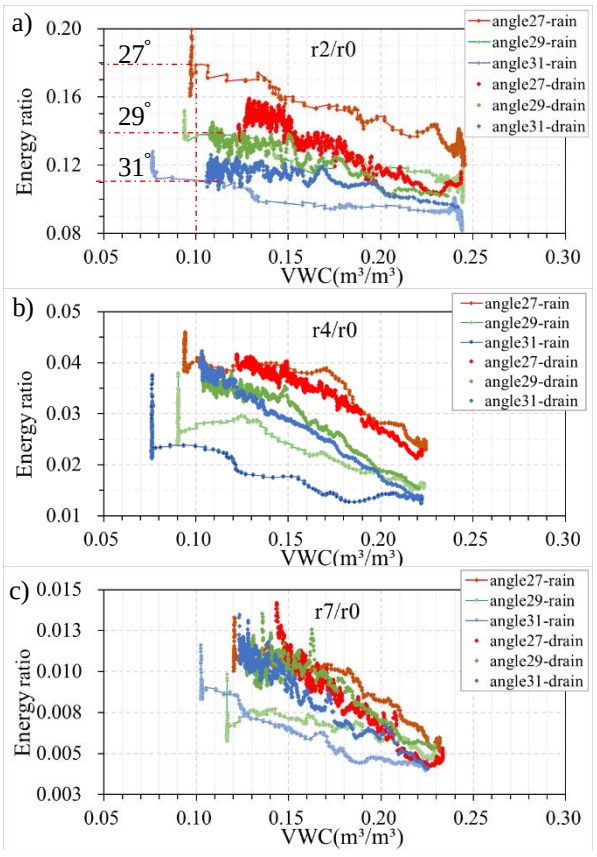

Fig.6 Energy ratio changes with VWC (slope angle = 27, 29,31)

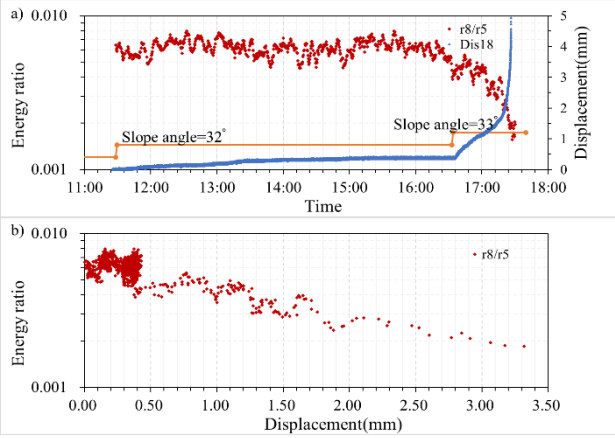

Fig.7 Elastic wave energy ratio changes with displacement

Figure 7a shows the response of wave energy ratio and displacement during shearing in the Test Case 3. VWC did not change in this test. After the shear force was set corresponding to the slope angle of 33-degree, the displacement started with an average 0.3cm/h of moving speed, then accelerated and finally failed, which observed at the displacement sensor No18, so energy ratio of r8/r5 was analyzed. With the increasing displacement, the wave energy ratio also decreased rapidly. Figure 7b shows the wave attenuation against the displacement. Wave energy ratio dropped by 50% during a 3 mm of displacement.

ELASTIC WAVE MONITORING ON-SITE

To investigate the behavior of elastic wave propagation in natural slope surface layer, elastic wave monitoring has been conducted at a slope located at Aso-shi, Kumamoto, Japan. This slope was suffered from the 2016 Kumamoto Earthquakes and some big cracks appeared on the slope surface. It is a typically unstable slope.

Figure 8 shows elastic wave monitoring devices. It has a fully automatic to generate elastic wave by exciter, measure the wave signal by receivers. It includes a controller and data collection device, an exciter, 4 receivers, and a VWC sensor. Exciter is made with a Solenoid Electromagnet, which is controlled by the controller, it can generate pulse elastic wave per 10 minutes. Receivers are 3- axis MEMS accelerometers, ADXL354, a production of Analog Devices. The controller and data collection device control the timing of exciter, handle the wave data received by the receiver with a 7kHz of sampling rate, and store wave data into SD card. The VWC sensor is a soil moisture sensor EC-5 to measure the volume water content in the soil. The power is supplied by the arrangement of lead-acid battery, which is charged by a solar panel (Figure 9), to be continually running for a long term.

Figure 9 shows the elastic wave monitoring system installed on an unstable slope. Dotted line in the photo shows the survey line of elastic wave. Sensors and exciter were set in the underground. The exciter and VWC sensor were installed at a depth of 0.2 m. The receiver (CH1) was set at a horizontal distance of 0.01 m and a depth of 0.1 m from the exciter. Receiver (CH3) has a horizontal distance of 0.2 m from the exciter and a depth of 0.1 m; receiver (CH5) has a horizontal distance of 0.2 m from the exciter, a depth of 0.4 m; receiver (CH6) was installed at a depth of 0.1 m at a horizontal distance of 1.5 m from the exciter.

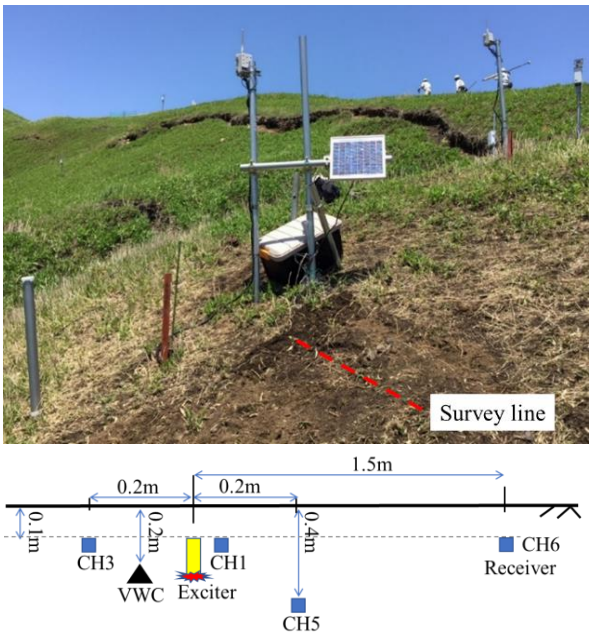

Fig. 9 Elastic wave monitoring system installed on an unstable natural slope. Dotted line shows the survey line of elastic wave. The layout of sensors and exciter underground.

Fig.8 Elastic wave monitoring devices. It can automatically generate elastic wave and measure wave signal.

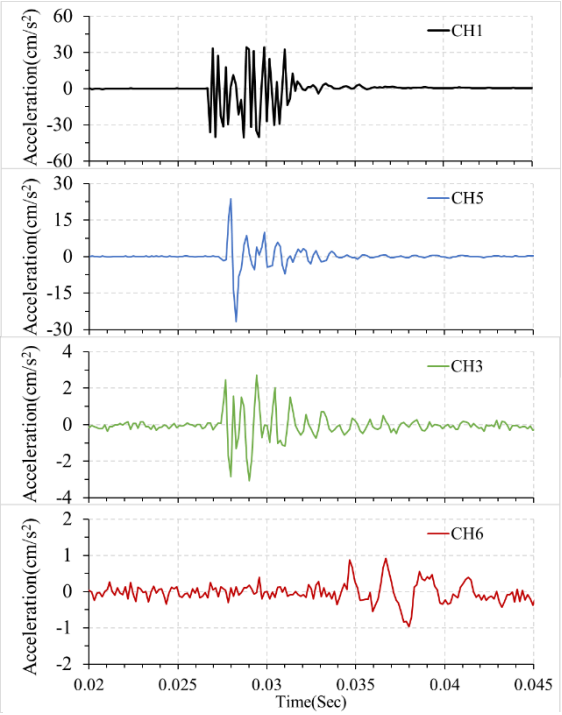

Fig.10 Examples of waveforms of a pulse elastic wave observed by receivers.

Figure10 shows the examples of waveforms of a pulse elastic wave observed by received by each acceleration sensor. CH1, the nearest with exciter, could detect the strongest signal around 30 cm/s^2, whereas CH6, the farthest from the exciter, detected the weakest signal around 1 cm/s^2. It indicates that wave amplitudes reduced quickly with distance.

Figure 11 shows VWC and energy ratio plot in time series from 2018/9/24 to 2018/12/20. In the dry process, the energy ratio of the elastic wave tends to increase with the decrease of VWC. On the contrary, in the wet process (rainfall events), the energy ratio of the elastic wave tends to decrease with the increase of VWC.

Figure 12 shows energy ratio response with VWC. Wet process is the cases of rain event, the dry process is a drain event. In CH5/CH1, wave energy ratio dropped down 60% when VWC increased from 0.39 to 0.41 m^3/m^3. In CH3/CH1, wave energy ratio dropped down 70% when VWC increased from 0.39 to 0.44 m^3/m^3. Whereas CH6, the farthest from the exciter, not clear changes trend. Hysteresis had been observed in CH3/CH1, that is similar to the results in laboratory experiments.

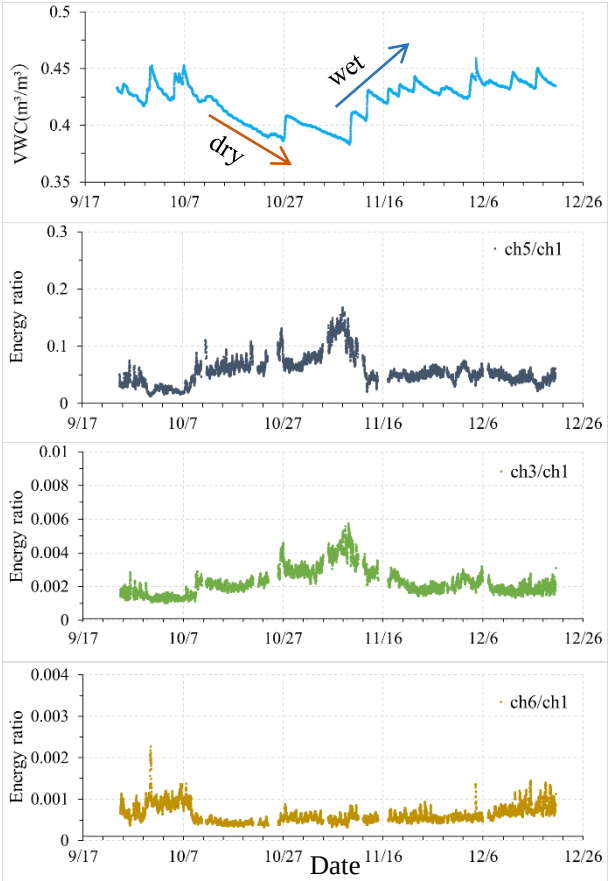

Fig.11 VWC and energy ratio plot in time series. Elastic wave data was collected from 2018/9/24 to 2018/12/20 on-site.

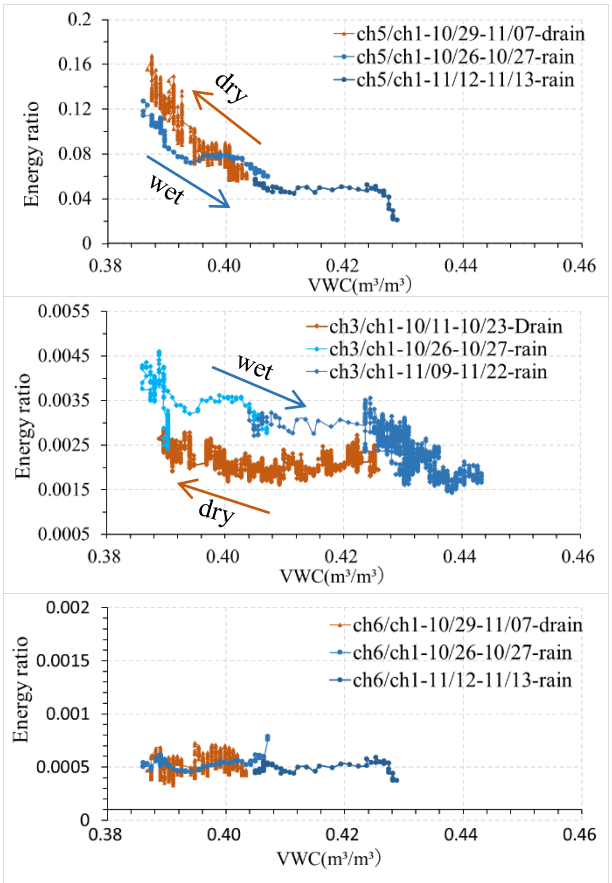

Fig.12 Energy ratio responses with VWC. Wet and dry process are the cases of rain event and drain event.

CONCLUSION

In this research, a method using elastic wave attenuation to predicts slope failure is presented. Laboratory experiment using multi-layer shear model was conducted to observe the changes of elastic wave propagation in slope surface layer. The results show that the wave attenuation increased with the increasing soil moisture, the wave energy reduced by 20%~50% when the VWC grew up from 0.1 to 0.25 m^3/m^3. The stronger shear force applied, the lower energy ratio observed. With increasing the displacement, the wave attenuation also increased.

An elastic wave monitoring system including one exciter and several revivers have been developed and installed in a nature unstable slope. The results show that wave attenuation behaviors with soil moisture on-site is similar to laboratory experiments.

Monitoring wave attenuation in slope surface layer can indicate the status of saturation state and shear deformation. Slope instabilities may be predicted based on its historical record.

THREE-DIMENSIONAL ANALYSES OF EXISTING TUNNEL RESPONSES DUE TO ADJACENT LOADED PILES ROW

N. Heama[1], P. Luepersert[1], S. Suwansawatt[1]
[1]Faculty of Engineering, King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand

ABSTRACT

In urban area, Tunnel Boring Machine shield (TBMs) is recommended to construct a tunnel to solve the traffic congestion problems. Although the tunnel is generally aligned under the major road to avoid the building, a new adjacent infrastructure such as flyovers, elevated trains, crossing bridge and tall building are continually construction as the same time. In the soft ground condition as Bangkok, Thailand, the pile foundations as pile foundations are used to support the new infrastructures. Then, the existing tunnel is inevitably affected by the adjacent piles row under loading. Many researches use the three-dimension finite element method (3D FEM) to investigate the effect of loaded pile row on existing tunnel. However, a few researches study the influence of number of piles in term of fully effect on existing tunnel. Thus, this study focused on the effect of the various pile row conditions, the number and spacing of 1 m loaded bore pile (D_P) in single row are varied, on existing tunnel by PLAXIS 3D Version 2018. The cases study was divided into pile length of 17.35 m (short pile row case) and 57 m (long pile row case). The properties of Bangkok sub soil and data of MRTA Blue line project were used in this study. The results obtained from 3D models were shown in terms the maximum of tunnel deformations (ΔC and ΔE) and additional structure forces in tunnel lining (ΔN and ΔM). The number and spacing of pile in row for modeling in which the tunnel response become constant are 11, 7, 5 and 5 piles with $3D_P$, $4D_P$, $5D_P$ and $6D_P$, respectively. The pile row lengths considered from monitoring plane (L/2) at which the maximum changes in tunnel diameter become constant are 15 m with respect to the number and spacing of pile in row.

Keywords: 3D FEM, Adjacent Piles row, Existing tunnel, Embedded pile

INTRODUCTION

The tunnel construction with Tunnel Boring Machine shield (TBMs) play an important role to solve the traffic congestion problems in the urban development. Generally, the tunnel is aligned under the major roads to avoid their effect on adjacent structures. Simultaneously, a new adjacent infrastructure such as flyovers, elevated trains, crossing bridge and tall building are also constructed to be the urbanization. In the soft ground condition as Bangkok, Thailand, the pile foundations are required to support the infrastructures. Then, the adjacent piles under loading is inevitably affected on the existing tunnel. Thus, an evaluation of the effect of loaded pile on the stability and integrity of tunnel is essential.

The many researches use a three-dimension finite element (3D FE) method to investigate the influence of this problems [1]-[5]. In the Bangkok, Thailand, the effect of adjacent single pile under loading on existing tunnel in Bangkok soft clay was studied [6], [7]. However, the effect of single loaded pile on existing tunnel is hardly ever met in engineering practice. With characteristic of tunnel structure (a longer underpass containing a road), the pile row condition with various numbers of piles in single row is often affected on the existing tunnel. Only a few researches studied the impact on the existing tunnel due to loaded pile row. In previous research, the two-dimension finite element (2D FE) under plane strain condition was considered to analyze the pile row and existing tunnel problem. The pile row in 2D FE under plane strain condition must be used the transformation technique to convert the properties or sizes of pile row [8], [9]. Besides, the interaction between soil and pile in the 2D plane strain analysis cannot evaluate [10]. Therefore, the 3D FE method is needed to analyze the effect of piles on existing tunnel. Heama [11] studies the number of loaded piles in row is great enough to evaluate the fully effect on existing tunnel in cases studies with Bangkok clay parameters by 3D FEM. In this analysis, the pile spacing was kept witch $3D_P$, and the analysis results were presented in terms of only the fully maximum tunnel deformations.

This research has a goal of understanding the influence of number and spacing of adjacent piles in row on the tunnel response**.** Various number and spacing of piles in single row are considered by using the 3D FE method. The Bangkok subsoil obtained the data from the Mass Rapid Transit Authority (MRTA) projects were considered in this study. The results are presented in terms of tunnel deformation and additional forces in tunnel lining.

CHARACTERISTICS OF THE CASE STUDIES

The data of the MRTA blue line project was chosen to be the case study in this analysis. The modeling of the tunnel lining was simulated into the continuous lining. The outer diameter of tunnel, D_T, of 6.3 m, lining thicknesses, T, of 0.3 m, and the tunnel depth (from ground surface to the center of the tunnel), Z_T, of 20.5 m are fixed throughout this study. The distance between edge of tunnel and edge of pile, C, are fixed at 0.5 m. The bored pile dimeter, D_P, of 1.0 m and the pile lengths of 17.35 m and 57 m are defined. The pile spacing, S, are varied witch $3D_P$, $4D_P$, $5D_P$ and $6D_P$ as shown in Fig 1.

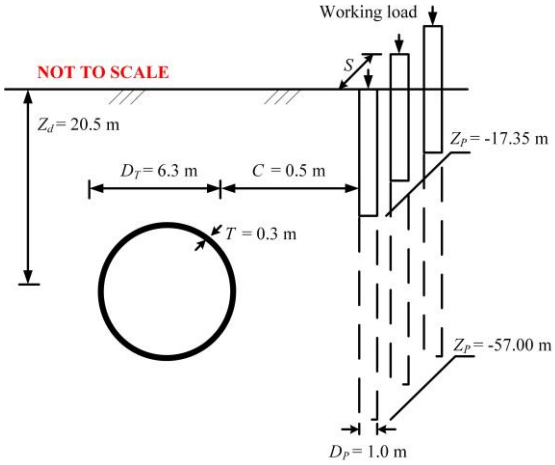

Fig. 1 Geometrical parameters

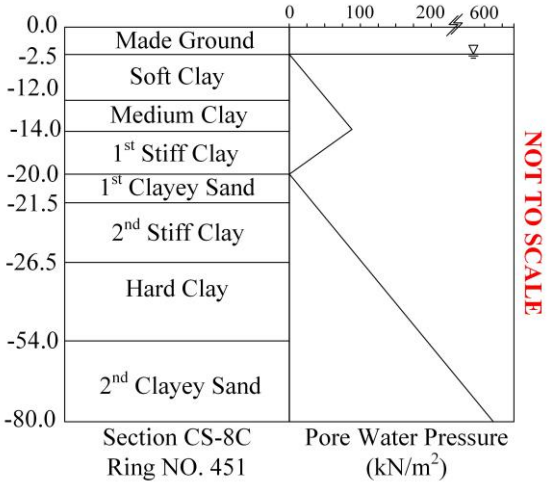

Fig. 2 Bangkok subsoil and pore water pressure profiles

The soil profile at Sukhumvit Station obtained forms a part of the Mass Rapid Transit Authority (MRTA) Blue Line Project was considered. Geological conditions can be divided into (1) Made Ground or fill material at 0–2.5 m, (2) Soft Clays at 2.5–12 m, (3) Medium Clays at12–14 m, (4) First Stiff Clays at 14–20 m, (5) A thin seam of First Clayey Sand is found at 20-21.5 m, (6) Second Stiff Clays at 21.5-26.5 m, (7) Hard Clays at 26.5-54 m and then (8) Dense Sand at 54–80 m. A typical pore water pressure profile in Bangkok is a piezometric drawdown, as shown in the Fig. 2.

FINITE ELEMENT METHOD

Constitutive model and material properties

The finite element (FE) method based on software PLAXIS 3D is used for investigating the impact of adjacent row pile under loading on existing tunnel. The made ground layer was assumed by hardening soil model (HS). The hardening soil with small strain stiffness (HSS) was assumed to simulate as all layers below the made ground layer. The tunnel geometry is comprised the grouting and lining layers, the details will be described in section numerical procedure. The soil and grouting layers were simulated by the solid elements or the 10-node tetrahedral elements. the tunnel lining and EPB were considered into the 6-node triangular plate elements. In this study, the bore piles were modeled by the embedded pile (*EP*) as the function in PLAXIS 3D. The *EP* is attractive method to reduce the complexity of the solid pile models [13]. An *EP* were modeled by the beam elements or 3-node line element. The soil properties were obtained from the MRTA projects and laboratory testing data [14], [15]. The tunnel lining, tail void grouting layer and bored pile are assumed to be linear elastic. The material parameters of FE analysis are summarized in Table 1, Table 2 and Table 3. The interface friction value (R_{inter}) between surrounding soil and the structural elements (EPB, tunnel lining or bored piles) was chosen to be 0.9 [16].

Finite element mesh

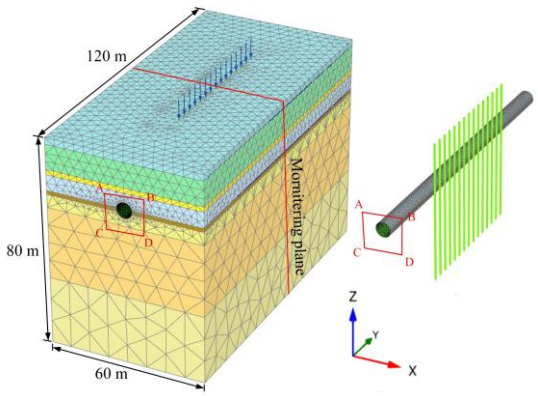

Fig. 3 models and meshes

The dimension of FE mesh in the transverse direction of 60 m (≈$9.5D_T$), the longitudinal direction of 120 m (≈$19D_T$) and vertical direction of 80 m

(≈12.5D_T) were shown in Fig. 3. The boundary size of FE meshes are lager to avoid the boundary effect [17]. The FE models were meshed with the 420,000 elements and 550,000 nodes were approximately. For boundary conditions, the lateral movement was fixed in x and y directions while vertical displacement in z-direction was allowed. The bottom of the models was restrained against displacements in all directions.

Table 3 Material properties

	Young modulus [E] (kN/m³)	Poisson's ratio [ν]	Unit weight [γ] (kN/m³)
Tunnel lining	31 x 10^6	0.20	24
Bore pile	31 x 10^6	0.20	24
EPB shield	210 x 10^6	0.28	78
Grouting layer	1 x 10^6	0.30	21

Numerical procedure

The simulation process was divided into two stages. The tunneling process with EPB shield proposed by the study of Lueprasert [18] was simulated in the first stages. The measured data of MRTA project were investigated by [19]. At the considered section of MRTA project (CS-8C), face pressure of 150 - 200 kPa are applied on the face of shield (applied pressure of 150 kPa at the crown and linearly increased to 200 kPa at the invert of tunnel). The grouting pressure of 200 kPa was applied on the perimeter of the excavation zone with uniformly distributed pressure. The measured data of MRTA project was considered and compared with the tunneling results. In the second stage, the pile row located on the one side of existing tunnel was modeled. The applied working loads on pile were calculated based on the alpha method with safety factor of 2.5 [20]. The working load of 1,406 kN and 4,905 kN applied on pile length of 17.35 m and 57 m, respectively. The wished-in-place pile row is considered in this study. The FE models were calibrated by comparison between the numerical results and in-situ measurements of surface settlement and static pile load test at the section CS-8C and Sukhumvit Soi 23, respectively [21].

ANALYSIS RESULTS

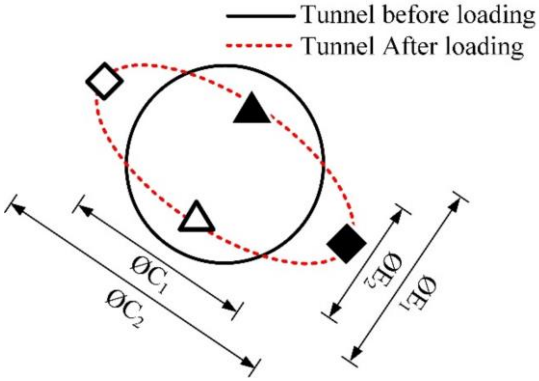

Fig. 4 Positions to observe the structural forces in tunnel lining and tunnel deformations

In this section, the results were discussed in terms of the maximum tunnel deformations and additional forces in tunnel lining. The maximum changes of tunnel diameter were calculated in terms of both the maximum contraction change (ΔC) and the maximum extension change (ΔE) inferred from assessment of the unsymmetrical distortion of shell structure shapes or the out-of-roundness [22]. The ΔC and ΔE represent the largest shortening and extending of the tunnel diameter due to loaded pile row. The calculation of the ΔC and ΔE were shown in Eq. (1) and (2). When $\emptyset_1$ and $\emptyset_2$ are tunnel diameters before and after the effect of pile rows under loading, respectively.

ΔE = maximum extension changes of tunnel dimeter

$$\Delta E = \emptyset E_2 - \emptyset E_1 \quad (1)$$

ΔC = maximum extension changes of tunnel dimeter

$$\Delta C = \emptyset C_2 - \emptyset C_1 \quad (2)$$

For changes in lining forces, axial force and bending moment were obtained at the same position of the maximum changes of tunnel diameter as shown in Fig. 4.

Models calibrations

The model parameters and numerical procedure were calibrated by the comparison between the computed results from FE analysis and in-situ measurements data. Figure 5a shows the measured of ground surface settlements at the section CS-8C and numerical results in tunneling stage. The contraction ratio of 0.4% and volumetric strain of 5.5% applied in grouting layer are used to model in tunneling process. The results of pile under loading simulation is illustrated in Fig. 5b. The result of FE analysis and the pile head settlement from the static pile loaded test is satisfaction. Note that the results were obtained from only single pile under loading simulation without tunneling**.**

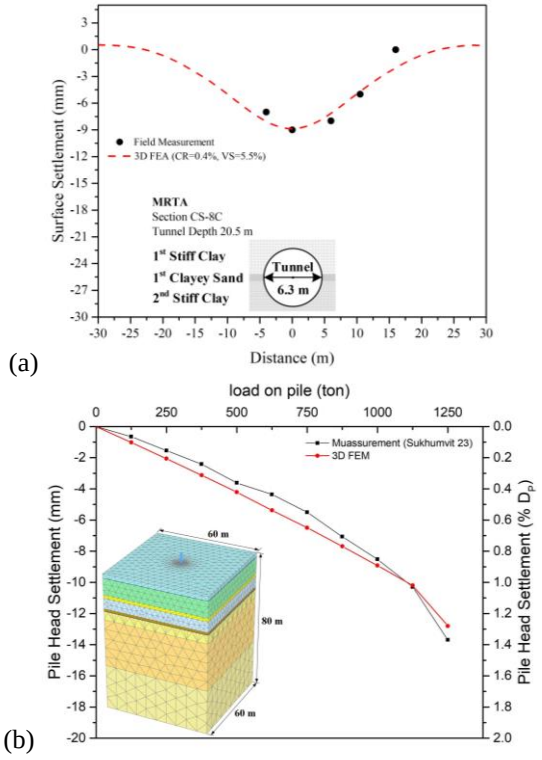

Fig. 5 The model parameters and numerical procedure (a) calibration of tunneling process (b) calibration of pile simulation

Tunnel deformations

Figure 6 depicts the maximum tunnel deformations due to nearby pile row under loading for various number of piles in row and pile spacing. The negative sign is the maximum contraction change (ΔC) and positive sign is the maximum extension change (ΔE) in y-axis. The distribution patterns of analysis results are similar in both of effect of short pile row (CASE 1) and long pile row (CASE 2). The magnitudes of ΔC and ΔE gradually increase with increasing pile number and decrease with increasing pile spacing and the effect of long pile row is larger than short pile row. In CASE 1 and CASE 2, the impact of adjacent loaded pile with various numbers and spacings of piles on ΔC and ΔE becomes constant when the number of piles is more than 11, 7, and 5 piles in row for pile spacing of $3D_P$, $4D_P$ and both of $5D_P$ and $6D_P$, respectively. In consideration of length of pile spacing (L), the pile row lengths considered from monitoring plane (L/2) at which the maximum changes in tunnel diameter become constant are 15 m, 12 m, 10 m, 12 m in case of $3D_P$, $4D_P$, $5D_P$ and $6D_P$, with 11, 7, 5 and 5 piles, respectively.

It is postulated that the pile row lengths considered from monitoring plane (L/2) at which the maximum changes in tunnel diameter become constant are 15 m with respect to the number and spacing of pile in row.

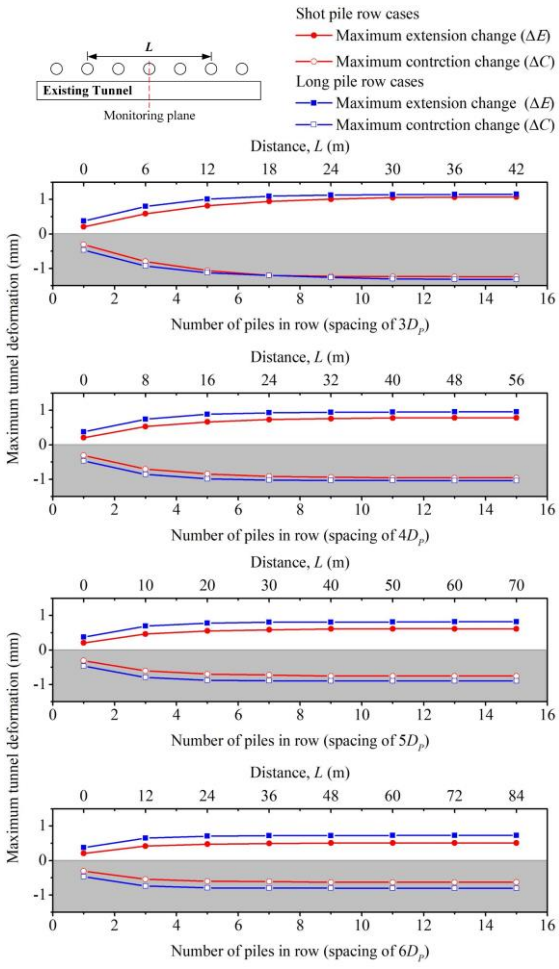

Fig. 6 Maximum tunnel deformations

The value of distortion degrees of maximum contraction change (β) is range of 40^0-45^0 and 30^0-35^0 for the distortion degrees of maximum extension change (α) as shown in Fig. 7.

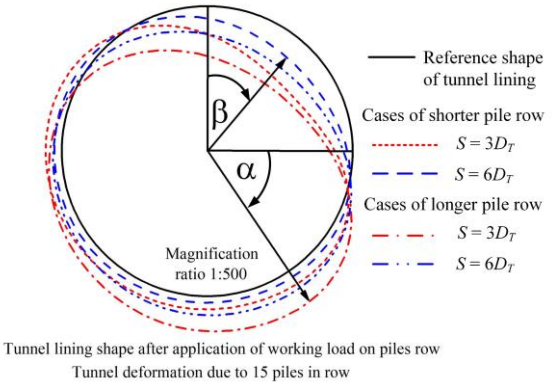

Fig. 7 Change of lining tunnel diameters distortion

Change of lining forces

The additional lining forces due to the effect of number of piles in row and pile spacing were investigated at the same position of maximum tunnel deformations. Figure 8 and 9 show the changes of axial forces and bending moment (the negative and positive signs referred the increasing of compression and tensile bending moment, respectively). The case of adjacent loaded pile spacing of $3D_P$ and $6D_P$ are only presented in this study. In short pile row case (CASE 1), change of axial forces (ΔN) and the change of bending moment (ΔM) decrease with increasing pile spacing. CASE 1, the increasing axial forces at the ΔC axis and the ΔE axis increase 5 to 90 and 10 to 200 kN, respectively. While the additional bending moment decrease -2 to -18 at the ΔC axis and increase 1 to 20 at the ΔE axis. With increasing 3 and 5 piles in row, the ΔN and ΔM dramatically increases. The maximum values of ΔN and ΔM become constant or remains unchanged with the 11 and 5 piles for pile spacing of $3D_P$ and $6D_P$, respectively. The results in this section again confirm that the pile row lengths considered from monitoring plane (L/2) at which the maximum changes in lining become constant are 15 m and 12 m in case of $3D_P$ and $6D_P$, with 11 and 5 piles as same as the results in terms of tunnel deformation. For long pile row (CASE 2), a similar tendency to can be observed.

It again confirms that the pile row lengths considered from monitoring plane (L/2) of 15 m with respect to the number and spacing of pile in row should be modeled to obtain the constant or fully effect on tunnel response due to adjacent loaded pile row.

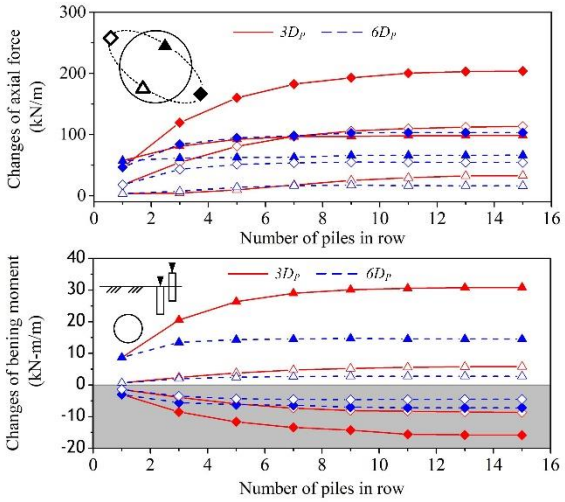

Fig. 8 Change of lining forces in cases of short pile row

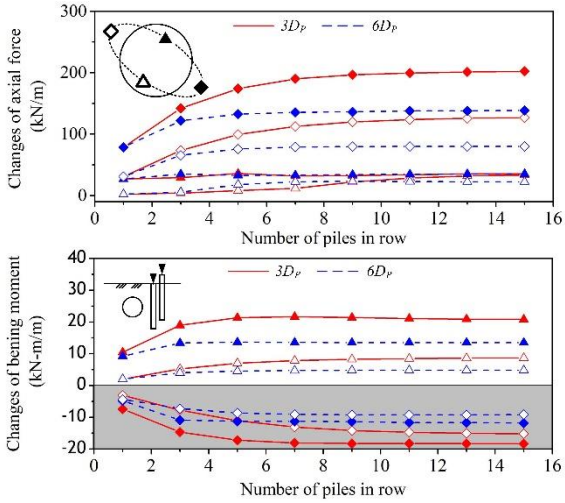

Fig. 9 Change of lining forces in case of long pile row

CONCLUSIONS

This paper studies the effect on existing tunnel due to adjacent loaded pile row in terms of short and long pile row by 3D finite element method. The tunnel deformations and changes of lining forces are observed. The main results of the analysis are as follows:

1. It is postulated that the pile row lengths considered from monitoring plane (L/2) at which the maximum changes in tunnel diameter become constant are 15 m with respect to the number and spacing of pile in row. The number and spacing of pile in row for modeling in which the tunnel response become constant are 11, 7, 5 and 5 piles with $3D_P$, $4D_P$, $5D_P$ and $6D_P$, respectively

2. The increasing of structural forces in the tunnel lining due to adjacent pile row under loaded should be paid attention. In tunnel lining design, the designer should be considered the possible increasing structural forces in the future construction. Otherwise, the lining must be checked if it can resist the additional forces and tunnel deformation in terms of serviceability and safety.

ASSESSMENT OF LANDSLIDE SUSCEPTIBILITY: A CASE STUDY OF CARABAO MOUNTAIN IN BAGUIO CITY

Miller DL. Cutora[1], Mary Ann Q. Adajar[2], Maria Cecilia R. Paringit[3], and Eleazar H. Santiago[4]
[1,2,3,4]Civil Engineering Department, De La Salle University, Manila, Philippines

ABSTRACT

Baguio City is one of the most visited places in the Philippines especially during summer season. Due to its topography, soil characteristics, land use classification, and exposure to different calamities immense rainfall, Baguio City is prone to landslide. Lack of information and warning system regarding rainfall puts a challenge to decrease casualties and losses. The study evaluated in this study is a portion of the Carabao Mountain located in Baguio City. The degree of saturation of the soil and the imposed loading due to land use are considered as the main external factors for assessing the stability of earth slopes. Mohr-Coulomb failure criteria parameters are used in the determination of initial factor of safety. Using different scenarios, a general factor of safety is obtained and then use to develop a landslide susceptibility map. The loading imposed by land use developments such as settlement and road networks induce a great impact on the weight carried by the underlying soil which results to a greater decrease of factor of safety. The impact of the saturation as an added weight to the soil is lower as compared to the loading of structures. The general factor of safety indicates that as the degree of saturation of soil increases, the moderate susceptible area increases, and some are close to high susceptible degree with factor of safety close to a value of 1, which is located at residential zone. Possible addition of loading may decrease further the factor of safety which will cause landslide.

INTRODUCTION

The City of Baguio is popularly known as the Summer Capital of the Philippines and as the City of Pines. It is a highly urbanized city in the Northern part of Luzon in the Philippines. Baguio City has a flying distance of 206 km and about a driving distance of 250 km from Manila City, the Capital City of the Philippines. Baguio City is nestled on Cordillera Mountain Range with elevation ranging from 900 to 1,600 m above sea level. Due to its geographical location in a very high plateau, Baguio is commonly exposed to storms and heavy rainfalls. With such, landslide is very prevalent in the City. Shown in Table 1 is the lists of reported landslide incidents during typhoons according to City Disaster Risk Reduction and Management Council (CDRRMC) of the City of Baguio.

Landslide is a hazard that causes properties to a massive damage, and sometimes the cause of life loss. Landslides may be induced or triggered by other natural activities such as immense rain or earthquake. During storms or heavy rainfalls as well as during earthquake, landslides are prevalent to the City of Baguio, which causes some of the thoroughfare to stop their operations as well as cause damage to different properties. The closure of road arteries put a challenge in the supply of food and other commodities of the city which causes establishments to close.

Landslides cause damage to buildings, infrastructure, agricultural land and crops. Landslides and slope stability are two important issues to consider in planning cities located in mountainous regions. Rainfall-induced landslide hazard has been growing all over the world, due to the fast population increase, often accompanied by uncontrolled urban

sprawl [1]. In regions where urban residential areas coincide with mountainous terrains, the risk is higher for people and the economic costs include relocating communities, repairing physical structures, and restoring water quality in streams and rivers [2].

Landslide is one of the causes of deaths in the city during calamities. The susceptibility to landslide of areas is high due to the formation of the terrain, type of soil, as well as changes in land use. Lack of information and warning system regarding rainfall puts a challenge to the fight to decrease casualties. Susceptibility maps that may be used as tools for predicting movement of soil for warning system implementation will be needed.

Baguio City is prone to landslide due to its topography, soil characteristics, land use, as well as natural factor such as rainfall. The Mines & Geosciences Bureau of Cordillera Administrative Region (MGB-CAR) of the Department of the Environmental and Natural Resources (DENR) GeoHazard Map that will present the susceptible areas to landslide with consideration of assessment parameters. The assessment was done with the geologists' perception with the defined tools. Upon the evaluation of the existing parameters, the assessment tools lack technical aspect, specifically the inclusion of soil strength parameters, and some relevant triggering mechanisms such as the land use of the area, and the development of the saturation of soil due to the immense rainfall.

With these considerations, this study investigates if a slope is susceptible to failure using soil parameters related to slope stability and will incorporate the additional assessment tools, which will improve the existing susceptibility map. In addition, the landslide susceptibility levels and the areas that are of high susceptibility levels during massive rainfall is identified.

This study is geared to create assessment tool for rainfall-induced landslide and identify the landslide susceptible areas at Baguio City for planning and preparedness. To attain this goal, the stability of the identified sloping areas was assessed and evaluated considering the geotechnical characteristics of the ground and incorporating other triggering factors like saturation of the soil due to rainfall, presence of vegetation, and land use-imposed loading. Using a Quantum Geographic Information System (QGIS), a free and open-source GIS program, a landslide susceptibility map is developed for rapid assessment.

RAINFALL INDUCED LANDSLIDES

Slope failures occur frequently during or following period of heavy rainfall [3]. The infiltration of rainwater causes a reduction in this negative pore water pressure and an increase in the soil unit weight (due to an increased saturation [4]), both of which have a destabilizing influence. Rainfall-initiated landslides continue to inflict damages and and take the lives of people at any places throughout the world. According to [5], rainfall-initiated landslides involve highly dynamic hydrologic, earth surface, and ecological processes that persist over a range of spatial and temporal scales; however, guidance for overcoming these challenges has been elusive. Based on the study of [6], the process for quantitative risk assessment are seepage analysis, slope stability assessment, and risk assessment. The triggering mechanisms for a rainfall induced landslide have also been highlighted by the pore water pressure distributions at failure [6]. When the pore water pressure reaches a critical state, the effective shear strength of the soil diminished, inducing the landslide's formation [7].

LANDSLIDE SUSCEPTIBILITY ASSESSMENT

Numerous methods and practices such as frequency ratio, logistic regression, spatial regression, geographically weighted regression, and analytical hierarchy process, ordered weighted averaging, fuzzy logic and artificial neural networks [8] are used as landslide assessment tools.

The stability index is defined as the probability that a location is stable assuming uniform distributions of parameters over the uncertainty ranges. It does not predict that shallow translational slope movements will occur, but it forecasts that if they do, where they are more likely to initiate given the assumptions and input parameters used in the analysis [3].

According to the study of [9], an approach for establishment of an analytical risk assessment model to evaluate the risk index for soil erosion by water is proposed, in which the remote sensing, GIS, the analytical hierarchy process (AHP), and modeling techniques are integrated through investigation of soil erosion by water. The risk assessment model constructed through this approach in this study can be consistently used for understanding of the risk or potential of soil erosion by water, under either current site conditions or assumed certain changes of pertinent dominating factors, in a large area of interest.

The study of [10] aimed to develop a landslide model by using GIS and remote sensing techniques for landslide susceptibility mapping. The study employs several parameters with weights which are assigned according to the potential cause of landslide.

The studies investigated and analyzed the selected areas with different methodologies in generating the tools in identifying the state of a slope. This considers assessment scores to generate the stability score of the areas investigated. These studies served as a guide in generation and improvement of the slope stability assessment tools and scores in this study, which will be used together with slope stability analysis.

GEOHAZARD ASSESSMENT OF BAGUIO CITY

With the expertise and perception of the trained Geohazard Assessment Team of MGB-CAR, it was limited to the barangays and other areas of recent typhoon and dependent on the eighty-three observation stations in landslide-prone areas. This assessment is the basis for the formulation of the existing geohazard (landslide) map of the City of Baguio as shown in Fig. 1.

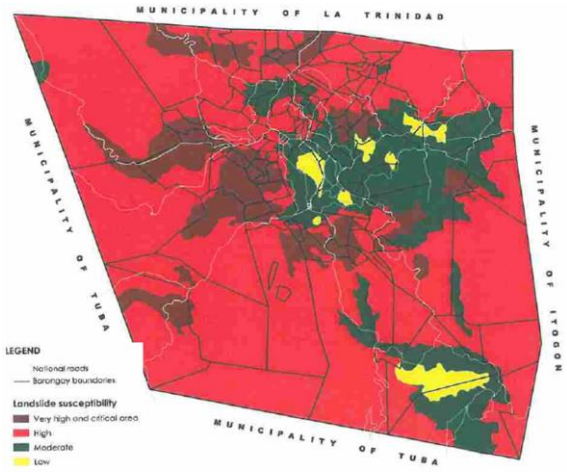

Fig. 1 GeoHazard map of Baguio City [11].

RAINFALL WARNING SYSTEM

A warning system was established by the Philippine Atmospheric, Geophysical, and Astronomical Service Administration (PAG-ASA) for monitoring, alert and evacuation purposes. This system is presented in three different colors which is presented in Table 3. These new color-coded advisories aimed to help the communities and concerned government agencies prepare for floods, landslides and dam spills.

Table 3 PAG-ASA Warning system.

Color Code	Rainfall Intensity, mm/hr	Rainfall Type	Remarks
Yellow	7.5 to 15.0	Heavy	Monitor
Orange	15.0 to 30.0	Intense	Alert
Red	more than 30.0	Torrential	Evacuation

METHODOLOGY

The study employed descriptive and analytical research. Descriptive research was used to describe, classify, measure and compare the present state of the area for the identification of scores for the different assessment tools. Analytical research was used to analyze the current situation of the area and make critical evaluation as to the susceptibility of the area to landslide based on the assessment tools.

Population and Locale of the Study

Baguio City occupies about 57 square kilometers of hilly land in the southwestern portion of the Cordillera Central mountain range in northern Luzon in the Philippines. It is completely surrounded by the province of Benguet, bordered by the municipality of Tuba to the south and west, by Itogon to the east and to the north by Benguet's capital, La Trinidad. The weather follows the typical Philippines' seasons: Dry Season from October to May and Wet Season from June to September.

As of 2015 census as per Philippine Statistics Authority - Cordillera, Baguio has a population of 345,000 which is about 20 percent of the region's population. The population density during that time is about 6,005 persons per square kilometer. The average annual population growth rate is 2.36 [13].

The research covered the north - left portion of the Central Business District of the City of Baguio, since these areas are of high density, and prone to landslide as per CDRRMC of Baguio City as shown in Fig. 2. This area is popular by its name as the Carabao Mountain which was intended to be the pastureland of the Camdas Clan. The portions of the Carabao Mountain considered are Quirino Hill and Pinget area which is limited by the yellow boundaries.

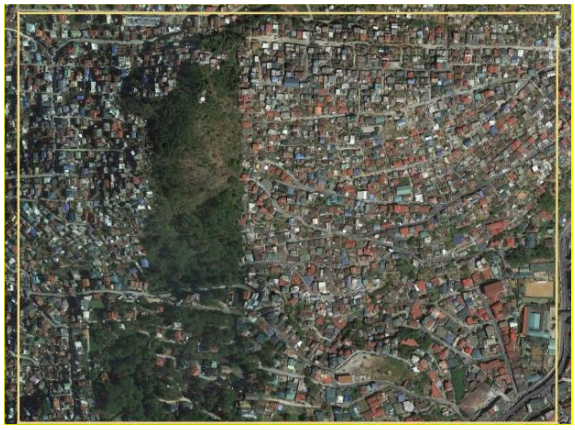

Fig. 2 Carabao Mountain, Baguio City

Research Design

The study evaluated the state of the slope with the aid of computer program and incorporating the effects of triggering factors. Figure 3 summarizes the research design of the study.

The geotechnical data was requested from BIP Steadfast Grounds Inc. The soil data available are the

Standard Penetration Number (SPT) and unit weight. The topographic map was issued City Planning and Development Office. The data acquired was aided with site inspection and inputs from MGB.

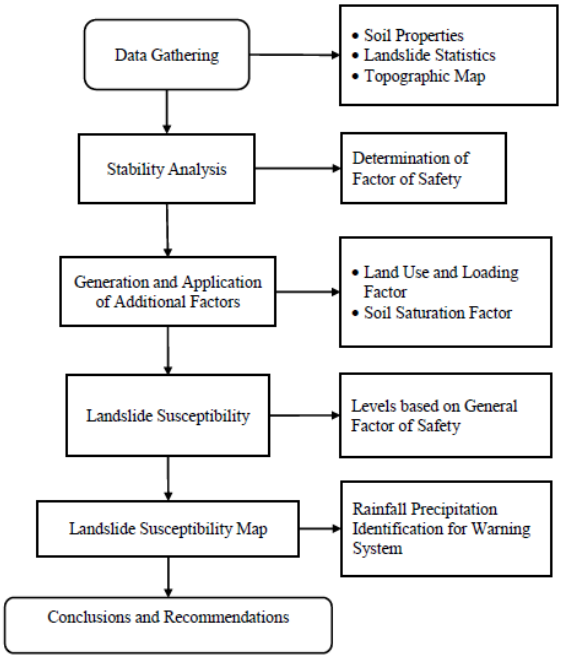

Fig. 3 Research design

Slope Stability Analysis

The area considered is about 1000m × 760m. The area was divided into 10m × 10m grids, while sections for slope stability analysis are of 20m intervals and using the topographic map as elevation guide. The factor of safety for the two columns of grids considered 1 section for analysis. The division was based on sections with slopes.

The SPT was used in predicting the value of soil shear strength parameters namely, cohesion and angle of internal friction, which are the parameters of Mohr-Columb Failure Criteria.

The data was processed and analyzed using the GEO-SLOPE: SLOPE/W software. The slope was analyzed whether it is safe or susceptible to landslide. The input parameters are the cohesion, angle of internal friction, and unit weight of soil, as well as the topography of the slope. The stable slopes were further processed by considering other triggering factors in the form of landslide assessment additive factors.

Landslide Assessment Tools

The addition of loading will decrease the strength of soil, therefore the value of the factor of safety will decline. These additional factors are the land use change in form of vegetation, settlement and roads, and rainfall which will increase the unit weight of soil due to the saturation.

There are several methods available to weight the evaluation criteria including direct ranking, swing weights ranking, rating, pairwise comparison, trade off analysis, and qualitative translation. This study employed the use of additional rating method.

The values of the additional factors were generated based on the difference of factor of safety of the initial state of the slope and the slope affected by the triggering factors. These values underwent regression process to identify possible relationship with the parameters. The regression model defines the formula which determined the values of the additional factors for the tools which was used for the assessment.

General Factor of Safety, FS_G

The General Factor of Safety was obtained from the sum of the initial factor of safety from slope stability analysis and external factors as presented in Eq. (1). This was derived by the methodology employed by [10] which is the summation of impact of every factor.

$$\boldsymbol{FS_G = FS + L_i + S_i} \quad (1)$$

Where:

$\boldsymbol{FS_G}$ = General Factor of Safety
$\boldsymbol{L_i}$ = Land Use and Loading Tool
$\boldsymbol{S_i}$ = Saturation of Soil due to Rainfall Tool

The values were then evaluated to generalize the susceptibility levels of the area and compare it to Table 4.

Table 4 Susceptibility Levels

Factor of Safety	Color Coding	Susceptibility Level	Remarks
1.5 ≤ FS	Yellow	Low Susceptible	Safe (as suggested by design criteria)
1.0 ≤ FS ≤ 1.5	Orange	Moderate Susceptible	Relatively Safe
FS < 1.0	Red	High Susceptible	Under State of Failure

Landslide Susceptibility Map

The evaluated scores and identified hazard prone areas at different group of rainfall intensities criteria were digitized using QGIS for easier view and appreciation. The scale of the map was based on the proximity of the span of the test evaluation. Evacuation site was recommended from the analysis of the proposed area. An evacuation site is sitting at the safe or almost flat zone that is free from landslide and accessible to different utilities and needs.

Rainfall Intensity and Warning System

The slopes ponding time and infiltration capability was determined based on the criteria of Green and Ampt parameters for the subsurface soil with soil type that is ML or Silty Loam. The parameters were used to generate different values of ponding time and the saturation depth of the soil as the time of constant rainfall increases. The values were examined and compared with PAGASA rainfall warning system for developing the warning systems which will be used for landslide susceptibility maps during rainfall, as well as the response guidelines by the CDRRMC.

RESULTS AND DISCUSSIONS

Soil Data

The data obtained from BIP Steadfast Ground Inc. includes standard penetration test (SPT) number, *N*, unit weight of the soil, γ, specific gravity, G_S, compression index, C_C, liquid limit, *LL*, plasticity index, *PI*, and moisture content, *w*, and percent finer than the No. 200 sieve. The data which were used for the study are the unit weight, and Standard Penetration Test (SPT) number which was used for calculating the cohesion and angle of internal friction. The type of soil in the area is ML which is classified as Silty Loam. The SPT data considered is about 1.5 m (5 feet) below the ground surface. Inverse-distance weighing interpolation method [14] is used to assume the soil data which represents the soil properties that are along the critical slope.

Land Use Assessment Additive Factor, L_i

The three different land use factors that are considered are vegetation (open space and with trees), road network, and settlement (buildings). For the generation of the factor, it will consider a 10 m tributary width for load distribution.

Table 5 Distributive Load for Land Use Impact and Land Use Tool (L_i)

Details	Distributive Load	L_i
Vegetation		
Open Space/grassland	0.0 kN/m	0.000
Pine Trees	141.9 kN/m	-0.081
Road Network		
Reinforced Concrete Pavement	67.2 kN/m	
Converted Truck Load	130.0 kN/m	
Total	197.2 kN/m	-0.136
Factored Residential Load (3 storeys)		
Dead Load	360.0 kN/m	
Live Load	91.2 kN/m	
Total	451.2 kN/m	-0.390

Saturation od Soil Assessment Additive Factor, S_i

The saturation of soil additive was based on the degree of saturation of the soil. With the preliminary values of soil parameters and computing the values of void ratio (e) and degree of saturation (S), the value of soil unit weight with different saturation was calculated which must be higher than the saturation level of the soils being considered that is about 70%.

Table 6 Saturation of Soil Tool (S_i)

Degree of Saturation	S_i
70%	0.000
80%	-0.018
90%	-0.036
100%	-0.054

General Factor of Safety

Using Eq (1), the general value of the factor of safety combined with the external factors were identified. The addition of the land use additive was added first. By using the available satellite imagery by google earth, the portions of the different land use were established. This data was added to the initial factor of safety and to the different saturation levels of the soil.

The color coding established in Table 4 was used for easier construction of maps as presented in Figure 5.5. Majority of the area are safe, but as the saturation increases some are already exposed to danger since the value of the lowest factor of safety for saturation values of 70%, 80%, 90%, and 100%, are 1.061, 1.043, 1.025, and 1.007, respectively. The critical area or the area with lowest factor of safety was highlighted in Fig. 4 is at Barangay Pinget, Baguio City. Portions that are close to a value equal to 1 are already at the verge of failure, necessary precautions and engineering interventions must be accounted.

Susceptibility Maps of the Area

The map was created using Quantum Geographic Information System (QGIS). Color coding specified in Table 4 was used to identify the level of susceptibility of respective area.

Figure 4 is layered with the actual satellite map, presents the level of susceptibility of the area to landslide due to varying saturation of the soil. The areas that are still in yellow code are still safe. Some areas are near the critical value which is 1 presented in orange color, therefore needs caution when massive rainfall occurs. Based map developed, the critical portion is residential area which is located at Barangay Pinget, Baguio City. If the area exceeds the assumed loadings, there will be a decrease in the factor of safety which will now result to soil slip failure, mass movement or landslide.

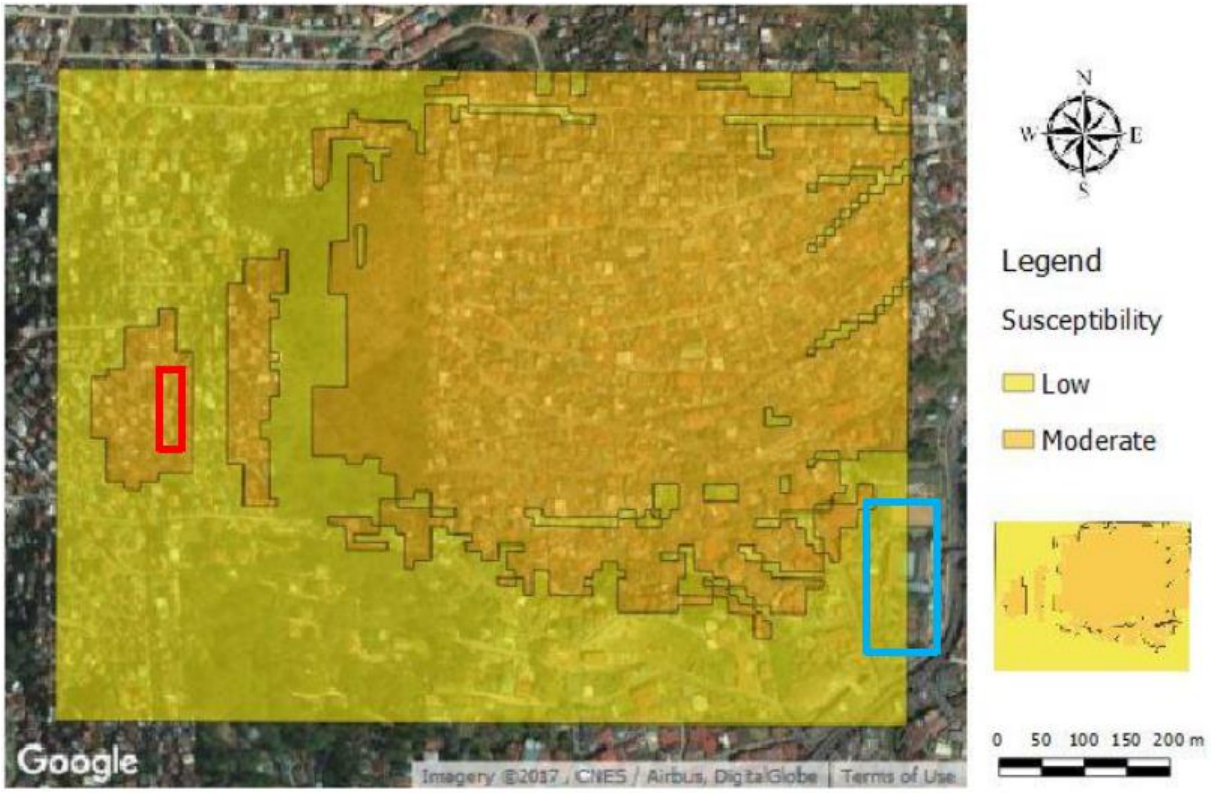

Fig. 4 Landslide Susceptibility Map

The area which is under moderate susceptibility is increasing as the value of saturation increases. The areas that are now susceptible to landslide are portions of Barangay Pinget and Barangay Quirino Hill in Baguio City.

Time of Ponding for Different Rainfall Intensities

Based on the values of ponding time, the values for rainfall intensity which is 20 and 30 are 56.26 and 21.55 mins, respectively. It can be noticed that the time for the surface to be saturated is quite long before infiltration occurs. Comparing to the warning system of PAGASA, 15 to 30 mm/hr precipitation is under the orange rainfall advisory. On the other hand, the rainfall intensity which is 40 and above has a shorter period of time of ponding, thus, infiltration is accelerated. According to [14], a continuous rainfall of 40 mm or over will cause slope failures. Comparing to the warning system of PAGASA, greater than 30 mm/hr precipitation is under red rainfall advisory. At this level of precipitation, the depth of soil under saturation state escalate as time increases, thus the early warning system of PAGASA might be adopted for landslide warning system.

At 40 mm/hr or more rainfall, the soil will begin to saturate, therefore, the factor of safety of the soil will be the general factor of safety that considers saturated soil additive, which is presented as the saturated soil susceptibility map. At this rainfall precipitation, evacuation at the susceptible areas such as Barangay Quirino Hill and Portions of Barangay Pinget must be raised for safety of the residences.

CONCLUSIONS

This study was intended to predict the possible role of external factors such as land use and saturation of soil due to rainfall on the factor of safety of slopes which is the deterministic factor of stability of earth slopes. Based on the results, land use loading and saturation of soil reduce the shear strength of the soil thus reducing the factor of safety of the soil.

For rapid assessment, the study considered land use tool and saturation of soil tool. As factors to slope stability, these tools are additives to the initial factor of safety. The values of additives are 0, -0.081, -0.136, and -0.390 for open space/grassland, vegetation (trees), road network and residential structures, respectively for land use tool. While 0, -0.018, -0.036, and -0.054 for initial, 0.8, 0.9, and 1.0 degree of saturation, respectively for saturation of soil tool.

The loading imposed by land use developments such as settlement and road networks induce great impact on the weight carried by the underlying soil which results to a greater decrease of factor of safety that is about 0.39. The impact of the saturation as an

added weight to the soil is lower as compared to the loading of structures since it only decreases the factor of safety to about 0.054.

The area that is close to the critical factor of safety which is 1 is a residential area located at Barangay Pinget, Baguio City as presented in Figure 4 which is highlighted in red box, thus addition of loading on that area would be risky. The residential areas at Barangay Quirino Hill, Baguio City, highlighted in blue box, are already below the ideal factor of safety which is 1.5. This implies the possibility of landslide in the area, especially if the load in the area is higher than the assumed values. The map generated can used as a guide in identifying the areas that are susceptible to landslide.

This landslide susceptibility map shall be used together with warning system for necessary actions during immense rainfall.

The warning system of PAGASA which is Red Warning will be adopted for precipitation which is 40 mm/hr and above. At this level, upon the release of thePAGASA warning, the preemptive action will be an immediate evacuation rendered by the concerned government bodies such as CDRRMC.

EFFECT OF THE INDUCED ANISOTROPY ON THE STIFFNESS OF FLY-ASH TREATED SOILS

Valentina Guerrero[1], Jhon Roldán[1] and Javier Camacho-Tauta[1]
[1]Faculty of Engineering, Universidad Militar Nueva Granada, Colombia

ABSTRACT

Granular materials conforming geotechnical structures use to be subjected to typically anisotropic loading conditions. For this reason, it is reasonable to consider the influence of a variety of stress combinations on the elastic parameters effectively used in design of these types of structures. Elastic parameters in soils can be evaluated in laboratory by imposing different stress conditions while strains in two directions are carefully measured. In this work, it was evaluated the effect of the stress-induced anisotropy on the vertical stiffness of a granular material treated with fly ash. On this purpose, a Bishop & Wesley triaxial cell was used to apply different stress conditions on soil specimens while deformations were measured by local sensors in order to obtain the small-strain moduli under unloading and reloading compression. Results exhibit the relationship between the induced stress anisotropy and soil stiffness for different fly-ash contents of the specimens. Finally, the results were compared against a model that allows taking into account the stress anisotropy on the stiffness.

Keywords: Anisotropy, Shear modulus, Small-strain, Stiffness

INTRODUCTION

The stiffness of soils is a function of different characteristics that depend of density, particle shape, grain-size distribution, accommodation structure of particles, among others [1], [2]. Inherent anisotropy is a result of the formation process of the soil deposit, mainly due to particles shape and their orientation. The soil is subjected to horizontal and vertical stresses of different magnitude along its history. Such stresses generate stress-induced anisotropy. The degree of anisotropy is affected by the stress path imposed to the soil mass [3]–[5].

In laboratory, stress-induced anisotropy in soils can be evaluated by tests procedures in which different combination of stresses are applied while small strains are measured carefully by local sensors [6]. Strains can be categorized as small when they are lower than 10^{-3}% [7].

There are different consitutive models to evaluate the effect of the stress-induced anisotropy on the soil stiffness [8]–[11]. Li and Zeng [12] state that the construction of earth structures induce anisotropic conditions on soils. For this reason, some authors have studied the influence of the stress anisotropy on the shear modulus [3], [13]. It is well recognized that the maximum shear modulus (G_{max}) mainly depends on the void ratio (e) and the mean effective stress (p') [14]–[16]. A model able to include the effect of the particle shape, grain-size distribution and the stress anisotropy could be useful to this more general condition [13].

This work deals with the evaluation of the effect of the stress-induced anisotropy on the stiffness of a sand treated with fly ash. The methodology includes physical characterization of mixtures with different percentages of fly ash and compaction of soil specimens. These specimens were tested in a Bishop & Wesley triaxial cell equipped with local sensors. Soil stiffness was measured under different compression effective stress conditions. Results were compared against a model that includes the anisotropic effect of stresses [13]. It was found the relationship between the degree of anisotropy and the shear modulus for the different soil mixtures.

MATERIALS, EQUIPMENT AND METHODS

This section describes the materials used in the experimental work and the methods to obtain the soil properties. The materials used are sand and fly-ash. The description of equipment and methods is focused on the characterization of the shear modulus. Also, the model used for analysis is described in this section.

Materials

It was used a colluvial granular material coming from sandstone rocks [17]. The grain-size distribution (Fig. 1) was measured using the ASTM D422 standard method [18]. Specific gravity of solids (G_s) and plasticity limits (LL and PL) were obtained by the standard methods ASTM D854 [19] and ASTM D4315 [20], respectively. In addition, the modified compaction test ASTM D698 [21] was used to obtain the maximum dry unit weight (γ_{dmax}) and the optimum water content (ω_{opt}). Table 1 presents the results of the physical characterization of the soil.

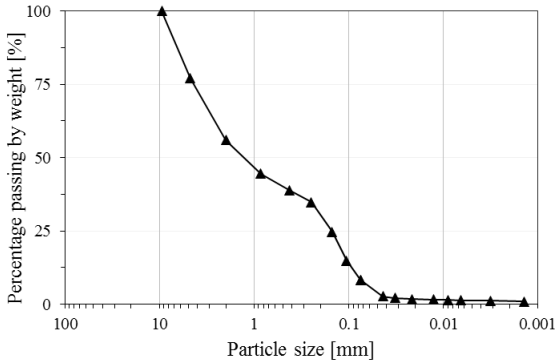

Fig. 1 Grain-size distribution of the soil.

Table 1 Physical properties of the soil.

Parameter	Unit	Value
G_s	-	2.52
C_u	-	31.3
C_c	-	0.20
d_{50}	*mm*	1.25
ω_{opt}	*%*	11.8
γ_{dmax}	kN/m^3	19.5
LL	*%*	*NP*
PL	*%*	*NP*

The fly-ash comes from a local thermoelectric plant (Termopaipa). This fly-ash classifies as a F-type ash. The main components are SiO_2 and Al_2O_3. Also, the components include quartz, mullite, hematite and a low percentage of CaO_2 [22].

Equipment

The Bishop & Wesley triaxial cell is a triaxial apparatus capable of imposing independent control of vertical and radial stresses on a cylindrical soil specimen. The device comprises three automatic pressure-volume controllers (cell pressure, back pressure and vertical pressure) with 0.1 kPa and 1 mm^3 accuracy. The set of sensors is composed by a submersible load cell (8kN capacity), a radial and two axials local LVDT sensors (0.1 µm accuracy) and a pore pressure sensor (0.1 kPa accuracy). Figure 2 shows the local sensors installed in a soil specimen before closing the triaxial cell.

Experimental method

Five specimens of 70mm in diameter and 140 mm in height were prepared by compaction. Specimens were compacted with optimum water content using an energy amount equivalent to the modified Proctor test ASTM D698 [21]. Each specimen was compacted with different fly-ash content (0%, 4%, 8%, 12% and 16%). Figure 3 shows two examples of the specimens prepared.

Fig. 2 Local sensors installed on the soil specimen.

a) b)

Fig. 3 Specimens: a) 0% fly-ash; b) 16% fly-ash.

Once the specimen was prepared and installed in the triaxial cell, the saturation process was applied until obtaining a B-Skempton parameter above 0.98. At this point, the specimen was consolidated under isotropic conditions of 50 kPa. Then, cycles of loading and unloading with different deviatoric levels (q) under constant radial cell pressure were applied to the specimen. Given the low amount of strain imposed on the specimen, a new confining pressure of 100 kPa was applied for consolidation and a loading-unloading cycle was applied. The procedure was repeated for 200 kPa confining pressure. For each cycle the deviatoric stress was increased by 50 kPa being the maximum deviatoric stress depending on the confining pressure.

Anisotropic model for soil stiffness

The model used to evaluate the effect of anisotropy is presented in Eq. (1) [13].

$$G_{\max} = A \cdot f(e) \cdot \left(\frac{p'}{Pa} \right)^{n} \cdot (\eta'+1)^{\alpha_1 \cdot \alpha_2} \quad (1)$$

Where A and n are model parameters obtained by experimental correlation, $f(e)$ is an empiric function of void ratio, p' is the effective mean stress, Pa is the atmospheric pressure equivalent to 100 kPa, $\eta'=q/p'$ is the anisotropy ratio, α_1 and α_2 are parameters depending of the coefficient of uniformity (C_u), the mean grain size (d_{50}) and the particle shape. The following empiric void ratio function was used in this paper [23]:

$$f(e) = e^{-1,29} \quad (2)$$

The model estates different values for α_1 and α_2 when different grain distributions and particle shapes are involved. However, in this case it is used a single value of the exponent α given the insignificant variation in the grain characteristics of the soil mixtures studied.

RESULTS AND DISCUSSION

By direct measurement of vertical and radial strains with local sensors during the unloading-reloading cycles, it was possible to compute the small-strain shear moduli for each radial confinement and anisotropy ratio. Figure 4 shows the stress-strain curves for each specimen and radial confinement. As can be seen, deviatoric stress is increased by 100 kPa intervals and then unloaded 50 kPa. The procedure is repeated different times depending on the confining pressure but ensuring positive deviatoric stress.

The response of the soil is the axial strain, given the test is stress controlled. Also, the pore pressure exhibits a variation because the tests were done under undrained conditions. The added fly-ash produced a stiffening of the soil depending on its percentage and hence the soil without treatment showed greater axial strains. The specimen with 16% added fly-ash presented lower strain levels, which means a stiffer material.

Figure 5 shows the stress paths in the p' - q plane. Despite the cyclic nature of the deviatoric stress, the path did not presented accumulation of pore pressure per cycle, which is an evidence of the small-strain regime. Figure 5a) shows the stress path for the untreated material and Fig. 5b) shows the stress path for the soil with 4% added fly-ash.

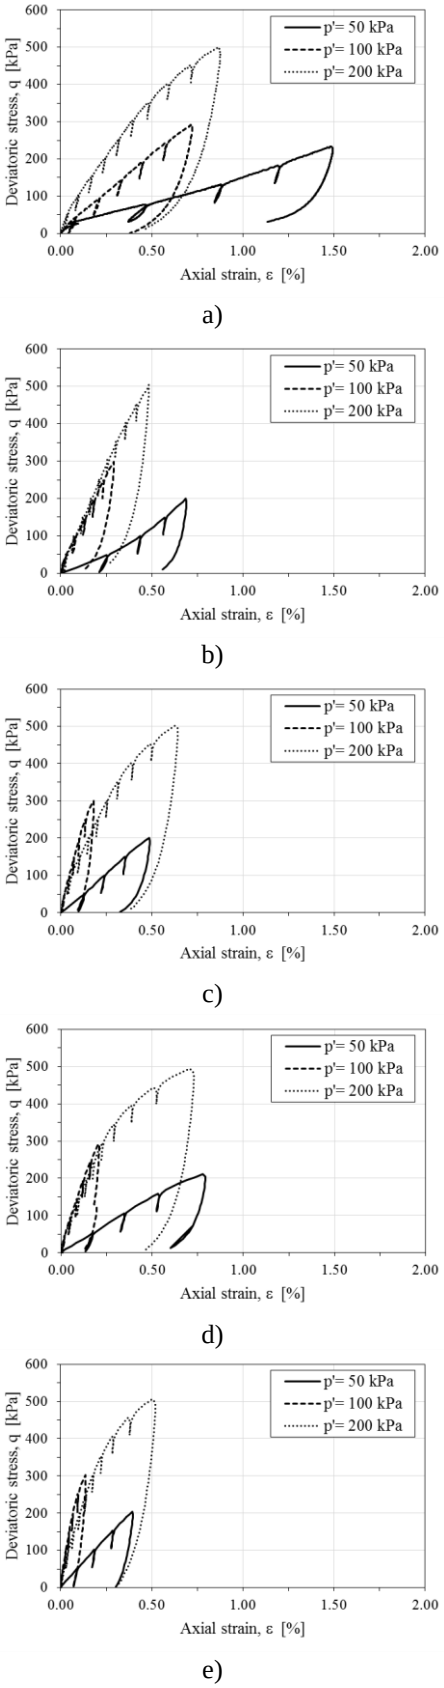

Fig. 4 Loading-unloading cycles for different fly-ash content: a) 0%, b) 4%, c) 8%, d) 12%, e) 16%.

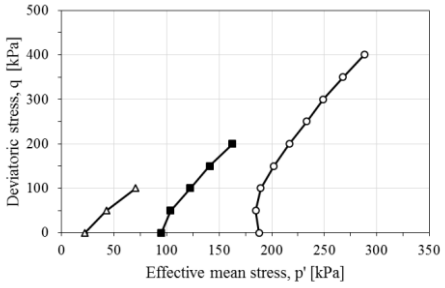
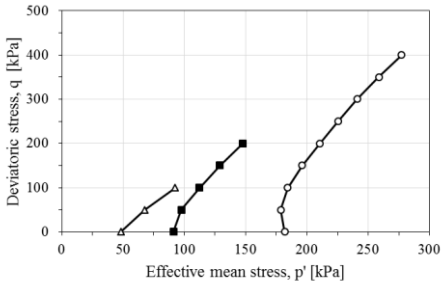


a)



b)

Fig. 5 Effective stress-paths: a) 0% fly-ash content; b) 4% fly-ash content.

Computed shear moduli for the different specimens are plotted as a function of the anisotropy ratio in Fig. 6. In all the cases, the shear modulus is higher as the anisotropy ratio increases. The effect of the fly-ash is notorious when compared with the untreated specimen (Fig. 6a). However, this positive effect does not increase for higher fly-ash contents. It suggests that the optimum fly-ash content (from the point of view of stiffness) is around 4%. The fly-ash used has low content of CaO_2 and therefore its pozzolanic effect is limited. Additional fly-ash does not increase the cementation of the soil, but the resulting higher fine content transforms the soil into a more compressible material. In addition, high contents of fly-ash do not increase the stiffness at high confinement at the same rate as for los and medium confinement.

Figure 7 presents the same data but organized by confinement. This arrangement shows that high fly-ash content (16%) increases the shear modulus in specimens at low confinement level (Fig. 7a) and at medium confinement level (Fig. 7b) but for 200 kPa, 8% is the optimum fly-ash content (Fig. 7c). The gradual positive effect of the added fly-ash is clear in Fig 7a, but as the confinement level increases the influence of higher amount of fly-ash is less clear.

Experimental data was used to obtain by curve fitting the parameters of the model in Eq. 1. Table 2 shows the parameters for the five mixtures and their respective correlation coefficient (r^2). The best adjustment was for the soil with no fly-ash addition. In general, the correlation coefficient goes down as the addition of fly-ash increases

Table 2 Parameters of the anisotropic model.

Fly-ash content (%)	A (MPa)	n	α	r^2
0	5.49	0.70	0.55	0.93
4	20.93	0.96	0.67	0.76
8	46.00	0.62	0.54	0.63
12	*26.35*	*0.76*	0.69	0.55
16	*37.62*	*0.48*	*0.56*	*0.61*

Well correlation coefficient could be due to a better application of this model for sands. The parameter α did not showed a trend but oscillated in a narrow range, which is caused by the no variation of the shape and gradation of the sand. The significant difference in the A value is a result of the stiffening caused by the addition of fly-ash. The parameter n does not show a trend but most of the values differ from the usual exponent, which is near 0.5.

CONCLUSIONS

An experimental campaign to study the improvement of a sand by adding fly-ash was carried out and results were presented in this paper. The use of an instrumented stress-path triaxial cell let to measure the evolution of the shear modulus respect to different fly-ash contents, anisotropic conditions and confinement levels.

The type of fly-ash used in this work contains a low pozzolanic effect and therefore the optimum amount of addition is not high. More fly-ash than the necessary could produce a contrary effect.

A shear modulus model considering the effect of stress-induced anisotropy was used satisfactorily. The parameters found for the different soil mixtures contributed to reveal the effect to the fly-ash and the degree of stress anisotropy on the soil stiffness.

FOUNDATION DESIGN AND SLOPE FAILURE PROTECTION FOR A LARGE COMMUNITY BUILDING IN KHANOM, NAKHON SI THAMMARAT

Chollada Kanjanakul[1]
[1]Department of Civil Engineering, College of Industrial Technology and Management, Rajamangala University of technology Srivijaya Country, Thailand

ABSTRACT

In geotechnical engineering, the bearing capacity of soil to support the building loads applied to the ground and slope failure behaviour analysis have significance for design protection in important buildings (e.g., roads, dams, soil embankment), and land filling procedure before construction in Thailand. Frequent landslides and mistake on foundation design occur in khanom, causing property damage and loss of human life. This paper aimed to analyze ultimate bearing capacity of soil and study the influence of unsaturated slope stability on a hill range in one particular southern part of Thailand (Khanom district in Nakhon Si Thammarat province). A GIS survey, the area's geology, geotechnical laboratory results and rainfall intensity were carried out and analyzed in order to verify the use of factor of safety for an early warning indicator. Moreover, the research focuses on designing foundation and calculation ultimate bearing capacity of soil that necessary for a site engineer at large communication building in khanom, Nakhon si thammarat. In the analysis result, suitable shallow foundation is 0.7 x0.7 m^2 of square footing put on lower soil (SM) 70 cm with the ultimate bearing capacity 82.54 t/m^2.

Keywords: Factor of Safety, Bearing Capacity, Foundation Design, Slope Failure Protection, Finite Element Method

INTRODUCTION

Foundation design process is the most significant part of any structure because foundation gets the load of the total building [1]. The main objective of foundations is to structurally support the building by transferring the loads of the building through the surrounding soil. There are difficult to determine the exact ultimate bearing capacity of shallow foundation, because of variability parameters in unsaturated soil slope such as permeability behaviour (e.g., rainfall characteristics, the amount of water in the soil and suction drawn on a curve called Soil Water Characteristic Curve (SWCC), k-function), soil properties (e.g., unit weight, angle of friction, cohesion of soil), hydrogeology (e.g., hydraulic conductivity, moisture content, groundwater table), and others such as vegetation cover. Overall, rainwater infiltration is among the most significant triggering factors [2].

The mistake on foundation design lead to loss of properties and human life. The two standard to be satisfied in the analysis and design of a shallow foundation in Khanom slope are A mechanical behaviour based on the basic physical properties (grainsize distribution, sieve analysis, atterberg's limits) and permeability behaviour in slope stability analysis landslide triggering by rain infiltration.

Unstandard laboratory testing that determines soil properties and wrong procedure from the laboratory testing that determines the type of soil lead to mistake in soil data base and waste the time to design construction for building.A bearing capacity analysis for a shallow foundation has been necessitated by the result of soil laboratory at khanom site.

Determining permeability function at a site can be measured directly through various in-situ and laboratory tests [3]. Chollada K., Tanan C., and Panupong T. [4] used the temporal pore water pressure distributions derived from the seepage analysis. Slope stability analysis with regard to the outcome of Factor of safety (F.S.) was produced for case study area. These result indicated that unsaturated slope at case study area in Southern part of Thailand will collaps at 50 hours with the average factor of safety (F.S.) = 0.940.

In this research, the permeability function from soil laboratory were used as input parameters to estimate surface infiltration rates for slope stability analysis. SEEP/W was employed to model fluctuations in pore-water pressure during a rainfall, using the computed water infiltration rates as surface boundary conditions. SLOPE/W was then carried out to compute their factors of safety. Slope at the site became unstable (F.S. less than 1) at 80 hours.

This research focuses on determining the ultimate bearing capacity of shallow foundation on soil structure and factor of safety on slope stability analysis at Khanom in the Nakhon-Si-Thammarat province of Thailand for the construction of 45 large community houses and early warning of landslides.

DESCRIPTION OF THE STUDY AREA

This paper aimed to study and analyze the influence of unsaturated-soil slope stability on a khanom hill range in one particular southern part of Thailand. A GIS survey, the area's geology geotechnical laboratory results and rainfall intensity data with regard to the outcome of calculated F.S. were carried out and analyzed in order to verify the use of FS_{cr} for an early warning indicator. the slope geometry in this study were based on typical residual soils in the tropical region and the works by Chollada K. [5]. Two types of soil samples were collected: Lower layer samples, to evaluate physical and basic engineering properties such as sieve analysis (D_{10},D_{30},D_{60}), grain size distribution (Cu,Cc), and atterberg's limits (LL,PL,PI) ; and Upper layer samples, to evaluate the effective soil cohesion, soil unit weight and undrained shear strength of soil for estimating dimension for foundation design.

Plate. 1 Study site at Nakhon Si Thammarat.

Parameters affecting shallow foundation design and landslide occurrences, such as slope geometry, related geotechnical and laboratory data, and rainfall intensity are usually needed in analytical processes that will describe in methodology (Fig 1).

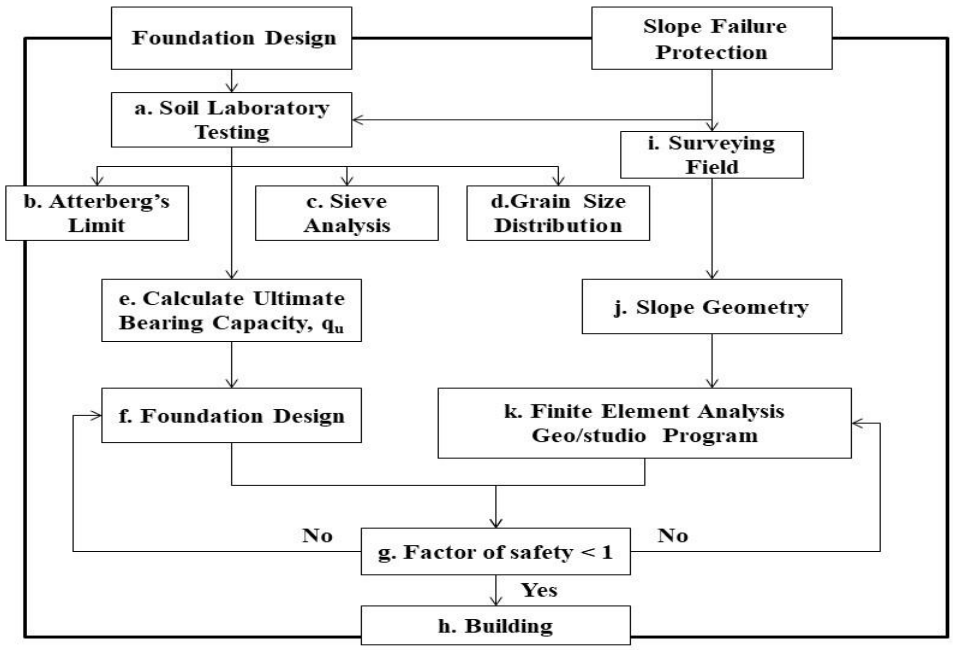

Fig. 1 Methodology.

Bearing Capacity

The ultimate bearing capacity aims at determining the load that the soil under the foundation can handle before shear failure [1]. Some studies on stability of foundations have been reported by [6]-[8]. This paper attempts to report on analysis of shallow foundations on soil slope in Nakhon Si Thammarat. The subject shows that the majority of the bearing capacity theories involve heterogeneous soils under the foundations. Soil properties were used for the bearing capacity analysis, and therefore analytical solutions, like Terzaghi's bearing capacity theory, matched with the experimental results. [9] Developed the bearing capacity expression for footing design as follow:

$$q_{ult} = c\,N_c + q\,N_q + 0.5\,\gamma\,B\,N_\gamma \quad (1)$$

Where

q_{ult} is the ultimate bearing capacity
c is cohesion of soil, γ is soil unit weight of soil
B is width of footing

N_C, N_q, Nγ is Terzaghi's bearing capacity factors depend on soil friction angle (ϕ)

[10] recommends that for the computation of ultimate bearing capacity of a shallow foundation in general shear failure, following Equation may be used:

$$q_{ult} = S_C W_C c N_c + S_q W_q q N_q + S_\gamma W_\gamma 0.5 \gamma B N_\gamma \quad (2)$$

Where

q_{ult} is the ultimate bearing capacity
c is cohesion of soil, γ is unit weight of soil
B is width of footing

N_C, N_q, Nγ is Terzaghi's bearing capacity factors depend on soil friction angle (ϕ)

S_C, S_q, Sγ is shape correction factors where

$$S_C = 1 - \frac{B}{L}\left(\frac{N_q}{N_C}\right) \text{ for rectangle shape} \quad (3)$$

$$S_C = 1 - \left(\frac{N_q}{N_C}\right) \text{ for circular shape} \quad (4)$$

$$S_q = 1 + \frac{B}{L}(\tan\varphi) \text{ for rectangle shape} \quad (5)$$

$$S_q = 1 + \tan\varphi \text{ for circular shape} \quad (6)$$

$$S_\gamma = 1 - 0.4\frac{B}{L} \text{ for rectangle shape} \quad (7)$$

$$S_\gamma = 0.6 \text{ for circular shape} \quad (8)$$

W_C, W_q, Wγ is water correction factors where

$$W_C = 1.0 \quad (9)$$

for water table below and upper foundation

$$W_q = 1.0 \quad (10)$$

for water table below foundation

$$W_q = 1.0 - (0.5)\left(\frac{a}{D_f}\right) \quad (11)$$

for water table upper foundation

$$W\gamma = 0.5 \quad (12)$$

for water table upper foundation

$$W\gamma = 0.5\left(1 + \frac{d}{B}\right) \quad (13)$$

for water table lower foundation

Unified Soil Classification System (USCS)

The Unified Soil Classification System is a soil classification system used in geotechnical engineering to explain the type and grain size of a soil. In USCS system, the basic physical parameters that can be used to identify soil characteristics and behaviour are D_{10}, D_{30}, and D_{60} (Sieve analysis laboratory), Cu and Cu (Grainsize distribution laboratory) and LL, PL and PI (Atterberg limits laboratory). The details are described below.

Sieve Analysis

Sieve Analysis is a procedure for determining the particle size distribution of a granular material to pass through a series of sieves of progressively smaller mesh size and weighing the amount of material that is stopped by each sieve as a fraction of the whole mass. The results of a sieve analysis are plotted as a grain size distribution curve and analyzed to determine the soil gradation of the particular soil [11]. A particle-size distribution curve can be used to determine the following parameters for a given soil:

A. Effective size (D_{10} , D_{30} , and D_{60}): This parameter is the diameter in the particle-size distribution curve corresponding to 10%, 30% and 60% finer. The effective size of a granular soil is a good measure to estimate the hydraulic conductivity and drainage through soil.

B. The uniformity coefficient, C_u is a crude shape parameter and is defined as

$$C_u = \frac{D_{60}}{D_{10}} \quad (14)$$

where D_{60} is the grain diameter at 60% passing, and D_{10} is the grain diameter at 10% passing.

C. The coefficient of gradation, C_c is a shape parameter and is calculated using the following equation:

$$C_C = \frac{(D_{30})^2}{D_{10}D_{60}} \quad (15)$$

Where D_{60} is the grain diameter at 60% passing, D_{30} is the grain diameter at 30% passing, and D_{10} is the grain diameter at 10% passing.

Atterberg's limits

Aterberg limits method is a standard measure of the water content of fine-grained soils. Atterberg defined the boundaries of four states (solid, semi-solid, plastic and liquid) in terms of limits as follows:

- *Liquid Limit (LL),* determines the water content at which the behavior of a clayey soil changes from plastic to liquid. Liquid Limit can be determined using the Casagrande cup method when the soil specimen is just fluid enough for a groove to close when jarred in a specified manner.

- *Plastic Limit (Pl)* is defined as the moisture content where the thread breaks apart at a diameter of 3.2 mm (about 1/8 inch). A soil is considered non-plastic if a thread cannot be rolled out down to 3.2 mm at any moisture possible.

- *Plasticity Index (PI)* is calculated as the Plastic Limit subtracted from the Liquid Limit and is an important value when classifying soil types.

METHODOLOGY

Fig. 1: Three stages were conducted in this research: (i) Determining soil laboratory testing; (ii) Slope stability analysis from SEEP/W and SLOPE/W; (iii) Calculated ultimate bearing capacity and foundation design**.** These are described in more details in next section, thus:

Determining Physical Parameters Result from In-Situ Soil Sampling Laboratory on Study Area

In this topic, result from soil sampling are significant on the stability of foundation design

- Result from soil sampling laboratory

From laboratory result, SM Soil properties (Lower layer) Liquid Limit (LL) obtained from Atterberg limits laboratory testing (ASTM D 4318-04) are: 36.7 , Plastic limit (PL); 26.37, and 10.33, Plastic Index (PI).

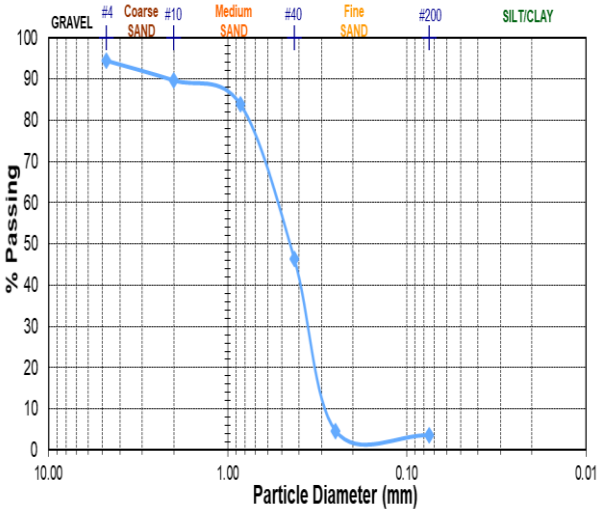

Fig. 2 Grain size distribution for lower layer

As shown in Fig. 2**,** Soil properties size fom lower layer in mm such that 10%, 30% and 60% of particles are finer than this size ($D_{10,}$ D_{30} and D_{60}) from Sieve Analysis laboratory testing are: 2.00, 0.08 and 0.3. The coefficient of uniformity (C_U) are 0.15 and 1.01, the coefficient of curvature (C_C). From upper layer laboratory test, SP Soil properties (Upper layer) Liquid Limit (LL) obtained from Atterberg limits laboratory testing (ASTM D 4318-04) are: 35.5 , Plastic limit (PL); 30.14, and 5.36, Plastic Index (PI).

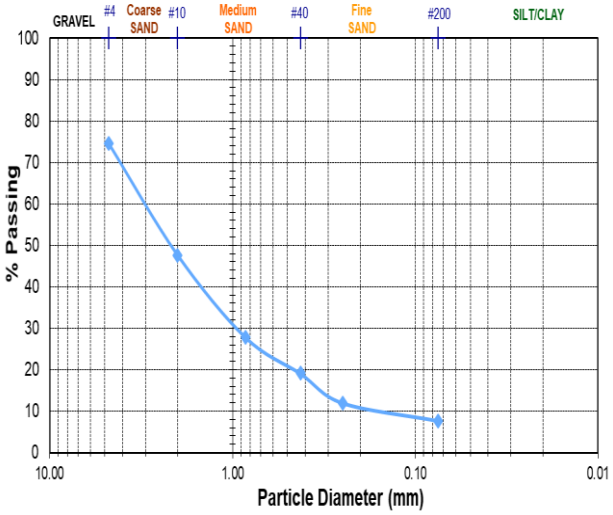

Fig. 3 Grain size distribution for upper layer

As shown in Fig. 3**,** Soil properties size from upper layer in mm such that 10%, 30% and 60% of particles are finer than this size ($D_{10,}$ D_{30} and D_{60}) from Sieve Analysis laboratory testing are: 2.00, 0.80 and 0.25. The coefficient of uniformity (C_U) are 0.125 and 1.28, the coefficient of curvature (C_C).

Estimation Water Volume Change Characteristics of Soil from Seep/w Results and Calculation Factor of safety (F.S.) from SLOPE/W Results

the slope geometry in this study were based on typical residual soils in the tropical region and the works by [4]. the study slope to be used in the mathematical models. There is a 80 m thick silty sand (SM) soil layer. The slope height is 80 m and the slope degree 27°. In the finite element analysis, the slope profile was divided into meshes of equal quadrilateral elements with a total number of more than 1,000 elements. The rainfall intensities 6-36 mm/hr used in the sensitivity analysis were adopted from the intensity-duration-frequency (IDF) curve for the southern part of Thailand. Boundary conditions utilized for the transient seepage analysis are: Zero flux for the lower horizontal and the left vertical bed boundaries (there is no seepage through the base of the soil slope) and a rainfall intensity Ir for the upper horizontal boundary.

Calculated Ultimate Bearing Capacity and Foundation Design

Fig. 4 idealizes the foundation to be used in the mathematical models. There is a 70 cm thick graded sand (SP) of upper soil layer with the soil unit weight 2.6 t/m^3 , cohesion of soil 0 and soil friction angle 25° In lower layer of soil, there is silty sand (SM) soil with the soil unit weight 2.68 t/m^3 , cohesion of soil 10.5 and soil friction angle 14°

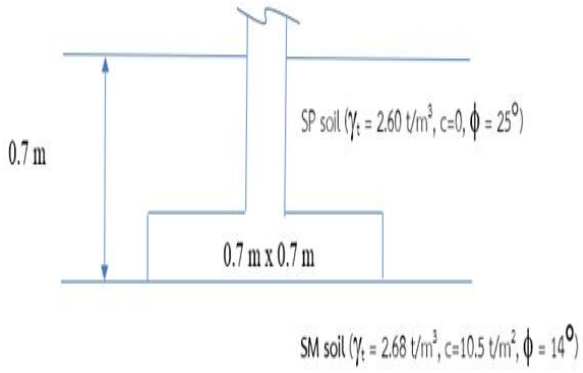

Fig. 4 Foundation and soil property of the site.

- Step by step bearing capacity problem solver

Step1 Find N_c, N_q, N_γ (In silty sand soil: ϕ=14°) N_c=11, N_q=4, N_γ=1.2

Step2 Find S_c, S_q, S_γ (Shape correction) When BxL = 0.7x0.7 m^2

$S_c = 1-\frac{B}{L}(\frac{N_q}{N_c})=0.63$

$S_q = 1+\frac{B}{L}\tan\phi = 1.25$

$S_\gamma = 1-0.4\frac{B}{L} = 0.60$

Step3 Find q_{ult}

$q_{ult} = S_C\, cN_c + S_q\, qN_q + S_\gamma \frac{1}{2}\gamma BN_\gamma$

$q_{ult} = 82.54$ t/m^2

soil laboratory parameters and Terzaghi's bearing capacity theory was adopted to calculate the ultimate bearing capacity for foundation design. The results were showing the ultimate bearing capacity 82.54 t/m^2

RESULT AND DISCUSSION

Two stages were conducted in this topic: (i) Results from slope stability analysis; (ii) Results from the soil sampling laboratory for foundation design. These are described in more details in the next paragraph:

Results for The Khanom Case Study

A GIS survey, the area's geology, geotechnical laboratory results and rainfall intensity were carried out and analyzed in order to verify the use of factor of safety for an early warning indicator. Program SEEP/W was used to model fluctuations in pore-water pressure with rainfall intensities from the Thailand's intensity-duration-frequency curve, using the computed water inltration rates as surface boundary conditions. The program SLOPE/W were calculate factors of safety and time when slope become unstable. Results for the Khanom case study show that slope at the site became unstable at 80 hours with the factor of safety (F.S.) = 0.960.

Results from The Soil Sampling Laboratory for Foundation Design.

The basic properties results from the soil sampling laboratory (Sieve Analysis, Grain Size Distribution, Liquid Limit, Plastic Limit, Shrikage Limit) for upper and lower soil layer were compared were shown in Table.2 for estimating dimension for foundation design that necessary for an engineer at Khanom site.

Table 2 The Soil Sampling Laboratory for Foundation Design.

Sample	Case Study	Case Study
Soil Properties	Position	Position
	Khanom (Lower layer)	Khanom (Upper layer)
Liquid Limit (LL %)	36.7	35.51
Plastic Limit (PL %)	26.37	30.15
Plastic Index (PI %)	10.33	5.36
Soil Classification	Silty-Sand (SM)	Graded-Sand (SP)
The coefficient of uniformity, Cu	0.15	0.125
The coefficient of curvature, Cc	0.01	1.28
D10	2.00	2.00
D30	0.08	0.80
D60	0.3	0.25

CONCLUSIONS

This paper focuses on determining factor of safety on slope stability analysis and the ultimate bearing capacity of shallow foundation on soil structure at Khanom in the Nakhon-Si-Thammarat province of Thailand for the construction of 45 large community houses and early warning of landslides. SEEP/W was employed to model fluctuations in pore-water pressure during a rainfall, using the computed water infiltration rates as surface boundary conditions. SLOPE/W was then carried out to compute their factors of safety. Increasing rainfall intensity induces increased matric suction and decreased shear strength in soil mass. Increasing amount of moisture from the rainfall leads to reduced slope stability. The F.S. is an inverse relationship with rainfall precipitation, moisture content and coefficient of permeability changes. Slope at the site became unstable at 80 hours with the factor of safety (F.S.) = 0.960. It can be used as an early warning indicator for landslide. For suitable shallow foundation in this case study, The results were showing 0.7 x 0.7 m^2 of square footing put on lower soil (SM) 70 cm the ultimate bearing capacity 82.54 t/m^2.

ACKNOWLEDGMENTS

I am very grateful to the Thailand Royal Irrigation Department is kindly acknowledged for providing the30-year monthly rainfall data in its vicinity. Thanks are due to a former RMUTSV Trang lecturer,

Mr.Daniel Edward Guiney, in rendering helpful reviews and in polishing up somewhat the English of the paper.

ABSTRACT

The paper presents the results of an experimental investigation on the influence of salt content on the unconfined compressive strength of Bangkok clay admixed with cement. The soil sample was added with sodium chloride (NaCl) and sodium sulphate ($NaSO_4$) at varying salt content of 3%, 5%, 10% and 15% by weight of soil. Based on the results of the study, it was found out that as the salinity increases, the diffusion double layer decreases. Hence, resulting to a decrease on the liquid limit (LL), plastic limit (PL), and plasticity index (PI). Moreover, at a certain moisture content, cement content, and curing time, the unconfined compressive strength of saline (sodium chloride and sodium sulphate) Bangkok clay admixed cement decreases with the increase of salt content. It was observed that the compressive strength of Bangkok clay admixed cement mixed with sodium sulphate ($NaSO_4$) exhibited higher compressive strength than the one mixed with sodium chloride (NaCl) for all curing times and mixing ratios. Moreover, it was noted that it has compressive strength than the natural clay admixed with cement.

Keywords: Sodium chloride, Sodium sulphate, Bangkok clay, Diffusion double layer

INTRODUCTION

Bangkok and its metropolitan areas are well known as soft clay. Bangkok clay occurred from the accumulation of subsoil layer by layer at the points of low lands or estuary caused by water flow. It is found that Bangkok and its metropolitan consist of soft clay with high moisture content and large settlement. This soft clay becomes harder in accordance with the depth consisted of sand and gravel layers alternatively deep into the ground until the rock layer. Bangkok clay is classified as non- to low swelling [1] as per free swelling test [2].

Nowadays, before the construction of buildings, roads, or embankments in the area of soft clay, chemical soil improvement is the popular solution to be used. This method uses soft clay mix with cement to improve the engineering properties of soil admixed cement. However, in the nature, there always be many kinds of mixed substances embedded in the soil which provide some effects to the engineering properties of the soil such as chemical substances, organics, salts (sulphate and chloride), acidity, basicity, etc. These chemical substances help enhance the properties of soft clay.

The effect caused by chloride and sulphate are one of the factors that causes some problems in soil admixed cement improvement such as reduction in soil bearing capacity and compressive strength. Hence, the investigation or prevention from the damages which could happen from sulphate and chloride are very important factors and should not be missed in the improvement of soil admixed cement properties. Davidson [3] reported that the chemical composition of soils causes soil particle to have reactions with cement in different forms subjected to anion (negative ion) in the soil particles, especially for organic soils, the reaction will be changed such as slow stabilization. Whereas, the soil consisted of sulphate will be swelled causing its compressive strength to be reduced. Sherwood [4] studied about the influence of organic matters by finding the relationship between the compressive strength and the pH value of soil admixed cement obtained by the combination of soil and cement in the ratio of 1:10.. The results showed that if pH is less than 12.1, it means that the soil consists of organic substances consequently slow down the solidification of soil admixed cement and significantly reduce the compressive strength even if the same cement content is maintained.

This paper aims to study about the influences of salts (chloride and sulphate) on unconfined compressive strength of soft clay admixed cement considering the cement ratio, type of salt, and curing time.

MATERIAL AND METHODOLOGY

Soil Samples Preparation

The unconfined compressive strength of saline soft clay is discussed (chloride and sulphate). The

soil samples used in this study were collected from Soi Sukhumvit 103, Bang Na District, Bangkok, Thailand at 3-5 meters depth. Soil samples were brought and placed under the sun until it become dry. A rubber hammer was used to break the soil samples into pieces and sift through the sieve No.20 to remove the shells, roots, and other waste materials in the soil samples. Subsequently, the soil samples were mixed with water until its liquidity index is equal to 1.5 times the moisture content. Then, the sample is mixed with Portland cement type I subject to some variables (cement content, chloride and sulphate content, and curing time). Salt components consisted of sodium chloride and sodium sulphate.

Table 1: Test and soil samples used in the test

Soil cement sample		
Variable	No.	Note
Soil sample	1	Clayey soil at Soi Sukhumvit 103, Bang Na District, Bangkok, Thailand
Chloride and sulphate	2	Sodium chloride and sodium sulphate
Moisture content	1	Moisture content with the Liquidity Index = 1.5%
Cement content	3	10%, 20%, and 30% by weight of soil
Chloride and sulphate content	5	0%, 3%, 5%, 10%, and 15% by weight of soil
Curing time	4	7, 14, 28, and 60 days
Number of sample	3	Three samples per test

Soil admixed cement, chloride, and sulphate sample preparations

Table 1 shows the detail of the soil sample used in this test. The soil sample passed through the sieve No.20 in order to adjust the level of water content until its liquidity index (LI) equals to 1.5%. Then the cement content was varied at 10%, 20%, and 30% by weight of soil. The chloride and sulphate content were also varied from 0%, 3%, 5%, 10%, and 15% by weight of soil. Altogether, mix the component samples for about 10 minutes until it becomes homogenous. Subsequently, put the soil sample in a cylinder with a 45 mm diameter and 90 mm height. Then the sample in 3 layers, and one layer needs to be compacted for 30 time to remove air from the soil. Prepare at least 3 soil samples for each test. Remove the cylinders after 24 hours and then the samples were wrapped using a food preservation film. Then cure the sample in the water for about 7, 14, 28, and 60 days. After curing, take the soil samples to the laboratory and test its unconfined compressive strength.

Unconfined compressive strength

Prior to the compressive strength test, the diameter, height, and weight of the samples were recorded. The measurement should be detailed until 0.1 mm by using a Vernier Caliper. The pressing speed of the unconfined compression testing machine was set at 1.4 (please indicate the unit). During the test, record the new height of the sample in order to determine the maximum value of unconfined compressive strength. Then the average of the test results obtained in the 3 samples with the same curing time were determined.

RESULTS AND DISCUSSION

Fundamental properties of soil

The soil sample used in this study has liquid limit and plastic limit of 64.5% and 30%, respectively. Its specific gravity is 2.68, and is classified as clay high plasticity (CH). Based on the Unified Soil Classification System (USCS), this type of soil has electrical conductivity (EC) of 1.8 dS/m, and according to the US Soil Salinity Laboratory Staff 1954, it can be counted as a saline soil [5].

Table 2: Salinity of soil and its influence on plants [5]

EC (dS/m)	Salt content (%)	Salinity	Influence on plants
<2	< 0.1	Not salty	No influence on plants
2–4	0.1– 0.2	Slightly salty	Grow slowly
4–8	0.2– 0.4	Moderate salty	Limit the growth of many kinds of plants
8–16	0.4– 0.8	Very salty Absolutely salty	Only salt-tolerant plants can grow
>16	>0.8	Very salty Absolutely salty	Only some salt-resistant plants cannot grow

Influence of salt content to physical properties of soil

Figure 1 shows that as the salt content increases, the liquid limit (LL) and plastic limit (PL) decreases, and the resulting plasticity index (PI) also decreases since the liquid limit (LL) of soil is occupied by shearing resistance and diffuse double layer

thickness [6]. The salinity components mixed in the sample consisted of cation (positive ion) in the form of sodium (Na+).

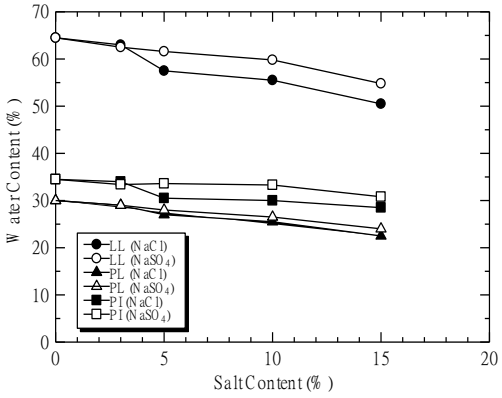

Fig. 1 Influence of salt content on Atterberg's limit.

When the cation gets melt in the water, it goes and sticks into the space between soil particles so that the soil particles moved closely to each other; and the diffuse double layer thickness decreases, resulting to a decreases in the liquid limit (LL).

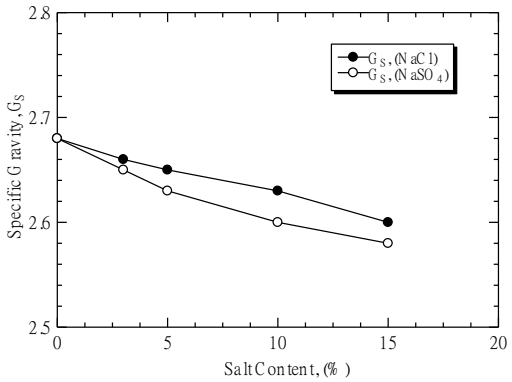

Fig. 2 Influence of salinity on specific gravity

Figure 2 shows about the influence of salinity on specific gravity. When salt content increases, it causes the specific gravity to decreases since salts (sodium chloride and sodium sulphate) are chemical substances consisted of specific gravity less than soil. The addition of salts into the soil causes organic substances to occur, hence, causes a decrease specific gravity.

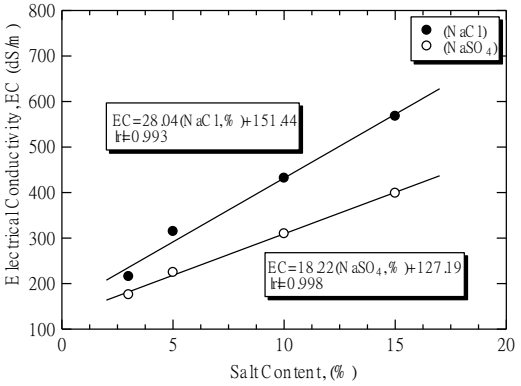

Fig.3 Relationship between salt content and electrical conductivity

Figure 3 illustrates the relationship between electrical conductivity (EC) and salt content added into the soil sample. The results show that when NaCl in added, the electrical conductivity is higher than adding $NaSO_4$ since $NaSO_4$ causes the soil to become more acidity than NaCl. Moreover, NaCl is the salt which can melt easily in water, resulting to a higher electrical conductivity in the soil than using $NaSO_4$.

Influence of salt content to the unconfined compressive strength of soil cement

Figure 4 proves about the test results when using 10%, 20%, and 30% of cement content and 81.75% of moisture content (LI=1.5) at various curing times. It shows that when mixing soil admixed cement with NaCl more than 3% by weight of soil, its unconfined compressive strength is lower than the unconfined compressive strength of the natural soil admixed cement at all curing times since the positive ion (cation) in NaCl causes soil particles get swelled. At the same moisture content and curing time of soil mixed with NaCl, its unconfined compressive strength decreases in accordance with the increase of salt content because at the same moisture content the low salinity soil will provide low value of e/e_L (matric suction). The bonding strength between soil particles happened from the hydration reaction, are similar to each other since the hydration reaction varies as a function of moisture content.[7]

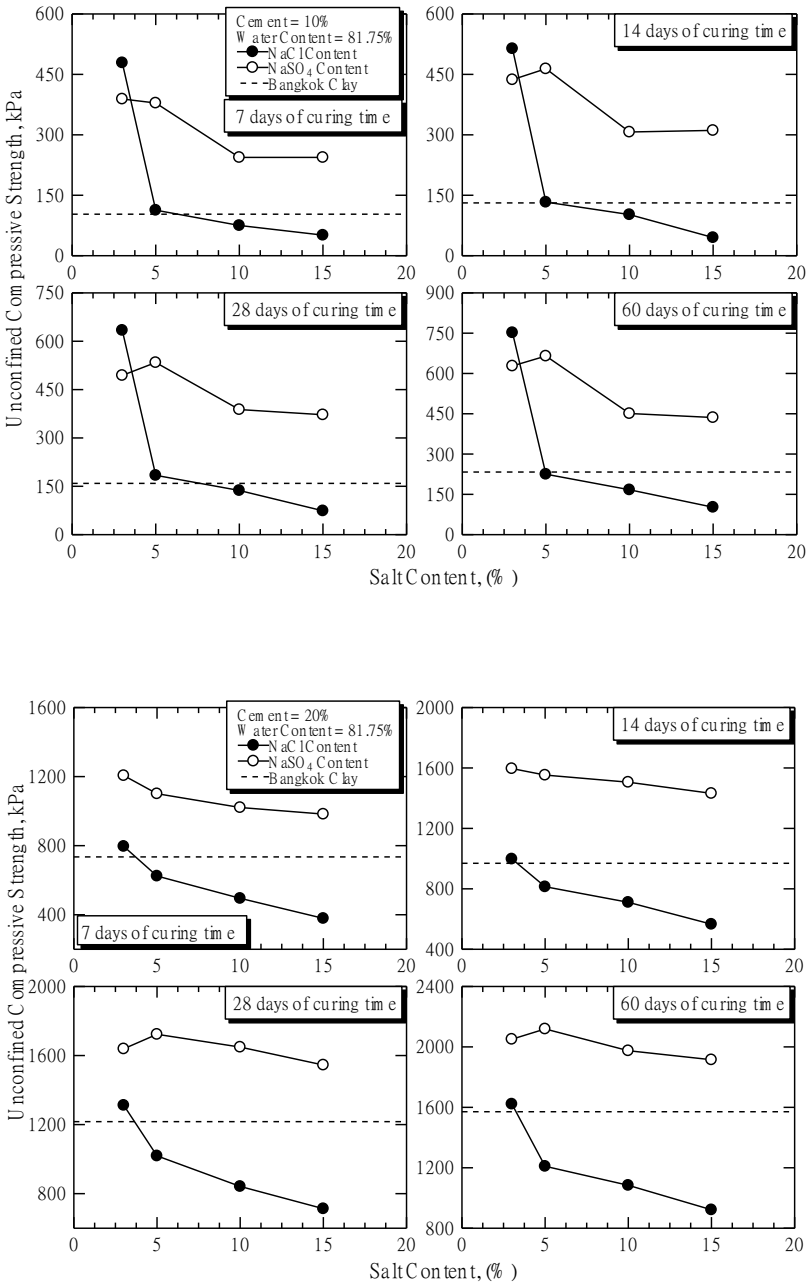

Fig.4 Influence of salt content on compressive strength of Bangkok clay

In the soil sample contained $NaSO_4$, its unconfined compressive strength decreases as the amount of salt content increases. All mixing ratios have unconfined compressive strength higher than the natural clayey soil admixed cement at all curing periods. When using 10% of cement content, soil admixed cement mixed with $NaSO_4$ exhibited higher unconfined compressive strength than natural soil at all curing periods and the differentiation of unconfined compressive strength decreases in accordance with the increase of 20% and 30% of cement content. The increase of $NaSO_4$ content causes the unconfined compressive strength to decreased because sulphate reacts with calcium hydroxide ($Ca(OH)_2$ and the calcium aluminate hydrate which occurred from the reaction between water and cement (hydration reaction) causes the strength of cement to decreases and the compressive strength of soil admixed cement also decreases.

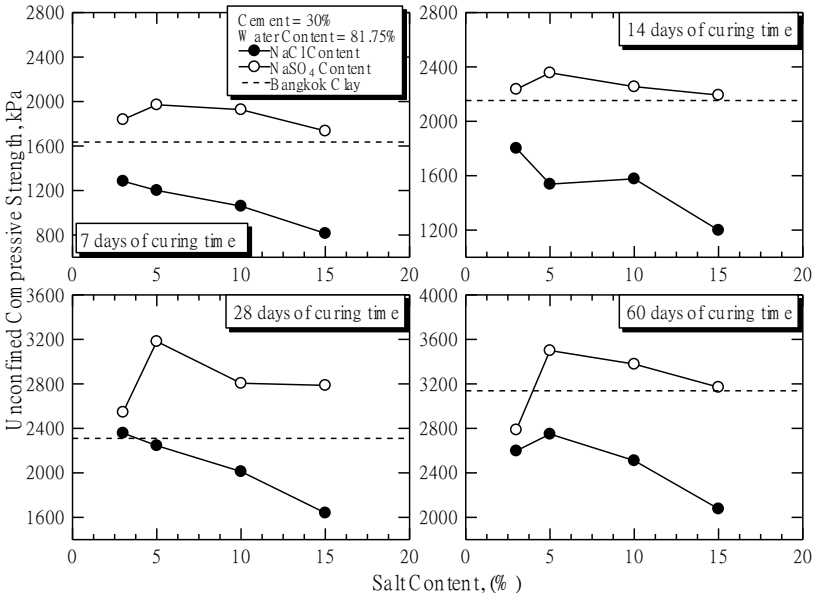

Fig.4 Influence of salt content on compressive strength of Bangkok clay (Cont.)

Compressive strength development on soft clay admixed cement

Figure 5 shows the types of salt influence on unconfined compressive strength of soft clay admixed cement at varying salt contents and varying curing times using cement content at 10%, 20%, and 30% by weight of soil. From the test results, it was found that the unconfined compressive strength increases accordingly with the increase of curing time for all mixing ratios; however, the compressive strength of soil cement mixed $NaSO_4$ resulted to a higher compressive strength than mixing with NaCl at all curing times and varying salt contents.

CONCLUSION

The increase of salinity in soil sample causes diffusion double layer to decrease leading the liquid limit (LL), plastic limit (PL), and plasticity index (PI) decrease**.** At a particular moisture content, cement content, and curing time, the unconfined compressive strength of saline (sodium chloride and sodium sulphate) soft clay admixed cement decreases in accordance with the increase of salt content because sodium chloride (NaCl) influences the soil particles disperse (specific surface becomes larger), whereas sodium sulphate ($NaSO_4$) causes to have a kind of crystal called Ettringite**.** This kind of crystal causes soil to disperse larger when hydration reaction happens**.** However, at the same level of salinity, the soil admixed cement mixed with sodium sulphate ($NaSO_4$) provides the unconfined compressive strength higher than soil admixed cement mixed with sodium chloride (NaCl) for all mixing ratios and curing times, and also higher than the unconfined compressive strength of natural clay admixed cement**.**

ABSTRACT

This paper demonstrates the influence of slope geometry and scale of the joint networks on the stability and the failure mechanisms in discontinues rock masses. These analyses based on finite element method (FEM) to calculate the factor of safety (FOS) and to simulate the explicit discontinuities deformations for different scales of rock masses. The study was carried out through examples of regular jointed models having different slope heights and an irregular jointed slope. The result shows that the slope stability decreases with increased scale and that the irregular columnar joints are more unfavorable to the slope stability than the regular ones. Furthermore, the failure mechanism appears shifting from structurally controlled for the 50m slope towards a step-like failure path for the 100m and 200m slopes.

Keywords: Rock slopes Stability, Failure mechanisms, Finite Element Method, Shear strength reduction factor

INTRODUCTION

In rock mechanics of both natural and engineering slopes, many studies have provided the influence of geological structures on slope stability. These discontinuities respond significantly to any change of stresses and loadings applied to rock masses (Brady and Brown, 2004; Bandis et al., 1983). This response changes the distribution of stresses to extend further to the next areas of the rock masses and other discrete pre-existing structures. These residual stresses could allow shear/tensile through intact rock and shear along discontinuities to create new fractures or initiate failures.

In geotechnical investigations of rock failures, many mechanisms primarily depend on the geometry of geological structure and change in slope scale. It has also been long observed from slope and other failures that the influence of discontinuities is not the same at different scales of excavations (Hamma et al., 2009). With increased slope angle or depth, comes an increased risk of slope failure (Sjoberg, 1999). Usually, at smaller slope scales, discontinuities may exert greater influence on behavior than rock properties. In small slopes, failure mechanisms such as planar wedges, which are controlled by joints, are common. In large scale slopes the pre-existing structures and the new fractures created by redistribution of stresses in slope surface probably congregate to develop a circular failure, combined failure or unidentified failure mechanisms.

Many failures of rock slopes appear to occur by sliding along major individual discontinuities such as fault planes and bedding planes, or along combinations of these planes (Stacy, 2006). As the scale increases, more complex mechanisms such as step-path failures and rotational shear failure, which combine failure along discontinuities with shearing through intact rock bridges, begin to occur (Eberhardt et al., 2004). These complex mechanisms can follow overall curved paths that can be similar to those encountered in soils. Toppling and columnar flexural bending or buckling are other failure mechanisms that can occur with increasing slope scale.

Rock discontinuities include joints, bedding planes, dykes, fractures, faults, shear zones, cleavages, foliations, stratums contacts and other geological structures, whose strength is lower than the intact rock. Most discontinuities increase the permeability of rocks, resulting in even lower strength. Thus, rock discontinuities are typically governing the overall behaviour of the rock masses (Zhao, 2004). Sjoberg (1996) indicated that pre-existing fractures in the rock mass and their characteristics were the most important factors contributing to potential slope failures, along with the hydrologic conditions at the mine. A recent study with more details (Xu et al. 2013) emphasised that the failure of rock slope depended on the size of discontinuities, and showed that both tensile and shear damages at the weakest element were the trigger for the failure surface initiation in the rock slope.

This paper inspects the effect of the geometry of slope on its stability. In open cut mine, the geometry of slope could be defined by height, width, bench face, interramp and slope angles. The rock masses of slope include the geological structure and intact rock. The geological structure in rock masses may vary in different scales, ranging from micro cracks having length of a few millimeters to many kilometers, such as the Paroo fault which strikes in south George Fisher and south-west of Handlebar Hill open cut mines at Mt. Isa (Long, 2010). From the study, it is found that the geometry of slope controls the behaviour of rock slope at different scales associated with the critical mechanism of rock failure. Paper size is 210mm×297mm of A4 paper. Please save to MS Word templates directory. Use 10 point Times New Roman font throughout the paper including text inside figures and tables. Single line spacing is mandatory. Try to avoid Underline or Bold within texts.

The top margin is 30mm while the left, right, and bottom margins are 25 mm. Headings should be left justified and without number. Leave one line between headings and the first paragraph and no space before succeeding paragraphs. Indent the first line of the paragraph by 5mm. All text should be left and right justified. Footnotes and underlines are not allowed.

THE SLOPE STABILITY ANALYSIS METHOD IMPLEMENTED IN THIS STUDY

The numerical models in this investigation are two dimensional finite element stress analysis using Rocscience/Phase2 program. Application of the finite element method (FEM) to problems of blocky rock masses as explicit modelling of the behaviour of individual joints can be used for practical engineering in blocky rock masses (Hamma et al., 2009). Geotechnical engineers have used different failure criteria for rock slopes. One of the techniques is the shear strength reduction (SSR) approach. SSR is simple in concept, which systematically reduces the shear strength envelope of material by a factor of safety, until deformations are unacceptably large or solutions do not converge (Hamma et al., 2005).

The SSR technique for slope stability analysis can be used to verify the stress reduction factor (SRF). The critical SRF is the one that brings the slope to failure, namely the factor of safety. The shear strength parameters of all slope materials will be reduced until the critical SRF is found. Use at most three levels of headings that correspond to chapters, sections and subsections. The first level headings for chapter titles should be in 10pt, bold, justified, and upper case font. Leave one blank line before and after the first level headings, respectively.

Finite Element Analyses for Models at Different Scales

The effect of slope scale on its stability was numerically experimented through five models. The change in safety factor and the failure mode of rock masses were verified in these samples when slope dimension increased. The strength parameters required to define the material properties dialog for discontinuities and intact rock are explained in Table 1. Shear strength reduction factor (SRF) was established within a tolerance of 0.001 for initial estimate of SRF =1 when setting the shear reduction dialog of the project.

The rock mass is assumed to be homogenous and rock slopes are dry. For all five models, the same discrete joint sets networks are used as shown in Table 1. One joint set dips at an angle of 36o (clockwise from the horizontal axis), while the other dips at 80o. The spacing of each joint set was assumed to follow a normal distribution with a mean of 4m and standard deviation of 1.0m. Both joint sets having infinite lengths that can form discrete elements through the rock block. The slope angle is 76o and the heights are 10m, 20m, 50m, 100m and 200m, respectively, for the five models. The FEM meshes for the five slopes are shown in Fig. 1.

The factor of safety was calculated during the numerical simulation and the failure mechanism was analysed for each of the models. Table 2 is the factors of safety obtained for each slope with the same infinite two joint sets and rock mass parameters.

Failure Mechanisms of Slopes with Regular Joints

Phase2 program was run to predict the behaviour of intact rock and fracture developments in these models. Figs. 2a to 2e are the modelling results of FEM-SSR.

The distributions of shear strains obtained from the numerical simulations are shown in Figs. 2a through 2e. Contours of shear strains in discontinuous rock mass in Fig. 2a indicate a highest shear strain zone above the toe at the intersection of the two joint sets, namely largest shear deformation in this zone for the 10m slope. Fig. 2b reveals the high shear strain zone at the toe controlled by two parallel 36o joints near the toe and an 80 o joint at the toe. At Fig. 2c for the 50m slope, the contours indicate large blocks shearing extending up through the intact rock and controlled by the joints. While in Figs. 2d and 2e, there are indications of more shearing through intact rocks and a step-wise shear strain contour at the bottom of the high strain band that is parallel to the 36° joints and the steps are

parallel to the 80o joints, suggesting a step failure coupled with intact rock shearing. The band in Fig. 2d expands much larger than in Fig. 2e.

It was found that the shear strain level formed above the toe is much higher, suggesting higher shear stress levels in those locations. Thus, unstable zones would be progressively initiated there. At lower slope heights, the slopes are stable (Figs. 2a and 2b), refer to Table 2.

When the slope is higher, the deformation expands till exceeding the limit, or slope failure as in the case of Fig. 2c. It may be concluded that the slope scale and joint sets control the development of unstable rock zone. While the high shear strain contours in Figs. 2d and 2e are in more structural rock masses (joint sets) and the dislocations have acquired approximate step path of failure

Table. 1 Mechanical properties of intact rock and joints used in Phase2 models

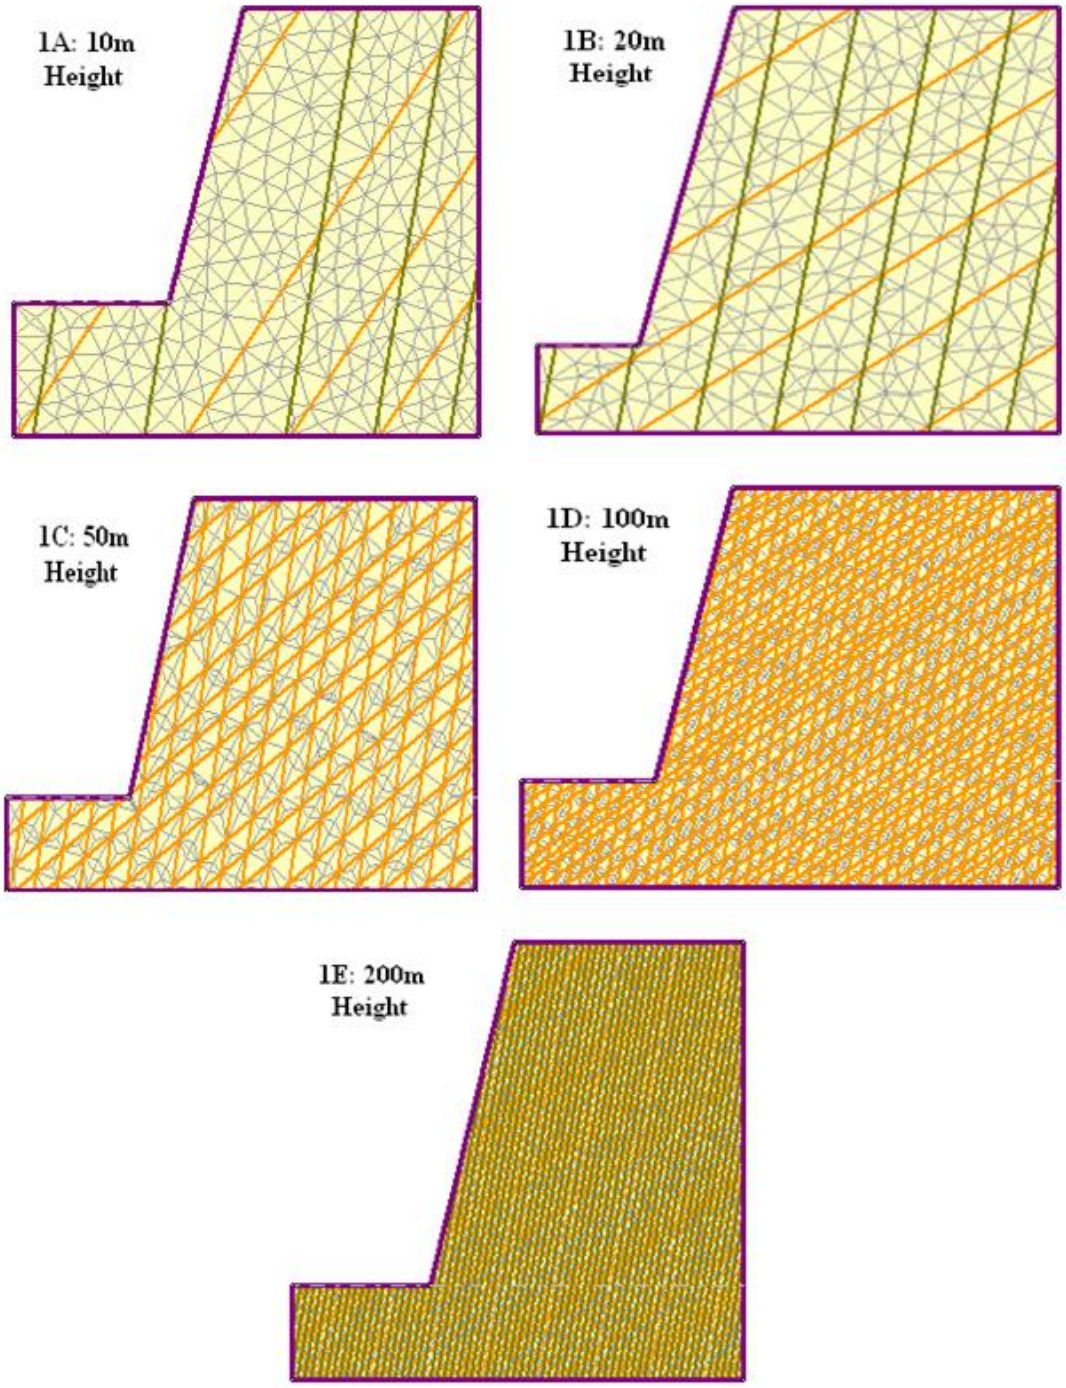

Fig. 1 Models of different scales used in this study

When the slope is higher, the deformation expands till exceeding the limit, or slope failure as in the case of Fig. 2c. It may be concluded that the slope scale and joint sets control the development of unstable rock zone. While the high shear strain contours in Figs. 2d and 2e are in more structural rock masses (joint sets) and the dislocations have acquired approximate step path of failure.

The mechanical properties of the rock mass is obviously influenced by the presence of joint sets and, more joint sets provide more possibilities of potential slide planes for rock blocks to slide and fall (Zhao, 2004). Initiations and progression of shear strain along joints were followed by block movements and the involvements of further development of more shearing through intact rock.

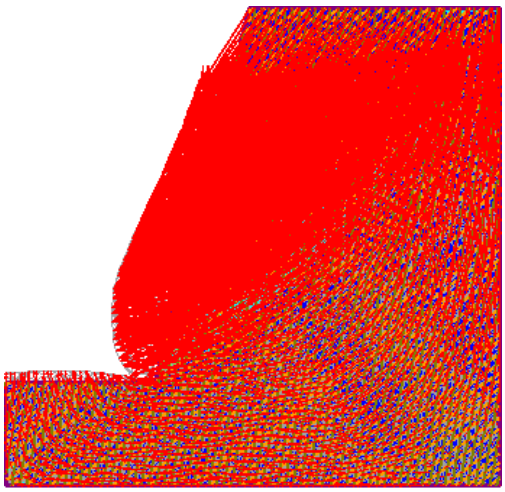

Fig. 3e Displacement and joints slip direction of 200m slope

Failure Mechanisms of Slopes with Irregular Joints

In this section, an irregular columnar joints voronoi network is introduced to obtain the influence of irregular joint patterns on slope stability. The same material properties composed the slope of 200m height and 76o slope angle (Case E in Fig. 1), is adapted to analyse the behaviour of irregular discontinuity. The numerical analysis result shows a FOS of 0.36 for the irregularly jointed slope. Fig. 4 (a) is the shear strain where the green legend represents largest shear strain and (b) is the total displacements.

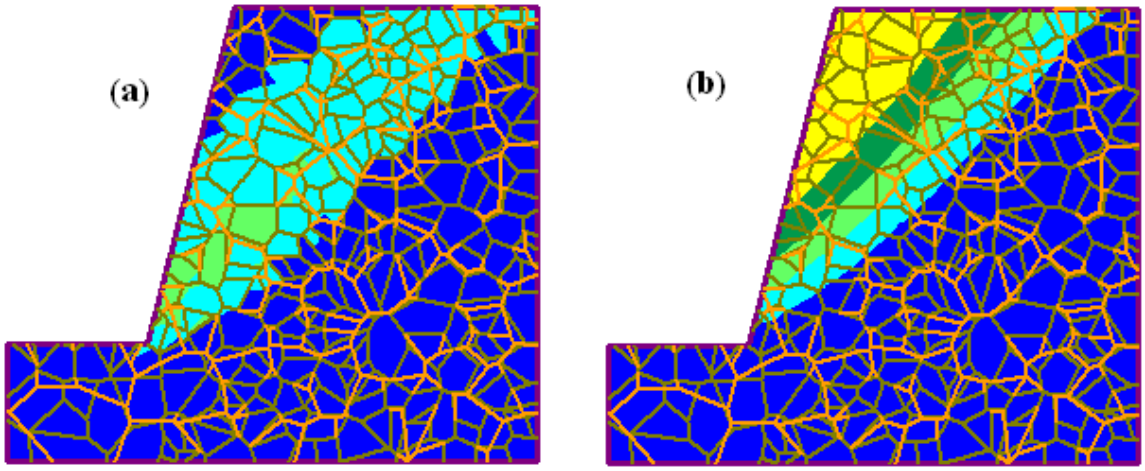

Fig. 4 Visualised slope with irregular voronoi- joints, slope angle 76o, slope height 200m and FOS is 0.36 (a) maximum shear strain, (b) total displacement.

DISCUSSION AND CONCLUSION

The factor of safety values in Table 2 clarify that when slope height increases, factor of safety reduces, and the mechanisms of failures (Cases C to E, refer to Figs. 2c-2d and Figs. 3c-3d.) have been varied with the slope scales. The finite element analysis using SSR method has demonstrated the influence of slope scales and joint patterns on the slope stability.

For the examples used in this study, the slope of 10 m height, the simulated results indicates that the area above the toe has the highest shear strain along a joint. Consequently, this area of the 10m slope is most critical. For the 20 m height slope in Fig. 2b, the simulation reveals a high shear strain zone controlled by joints near the toe. More recently, Xu et al., (2013), however, suggested that shear stress level and normal stress level might have significant effect on the long term behavior of rock mass with discontinuities of low strength.

As the height increases in Fig. 2c, further blocks are involved in the sliding and the critical failure surface developed from the initial local shear failure along the joint and near the toe. The contours of maximum shear strain indicate a rock failure mechanism involving structural movements and failure through intact rock. With further increasing the slope height, a composite failure surfaces become visible through the toe as illustrated in Fig. 2d. Fig. 2e shows maximum strain contours for the slope of 200 m height, suggesting a step failure coupled with intact rock shearing.

In the process of rock slope investigation for failure modes, it can be shown that these mechanisms depend on change in the scale of slope and geological structure. The stability of the minor slopes is controlled by small-medium geological structures, for example, joints control the slope failure mechanisms in wedge and planner slips along the intersection line of two structural features. In large scale slopes, failure occurs may involve in two or more interacted failure modes, such as step failure coupled with the intact rock shearing founded in this model study. Previously, Sjoberg (1996) stated that rotational shear failure in large scale slope, would probably primarily involve failure along pre-existing discontinuities with perhaps some portion of the failure surface going through intact rock. Recently, Ma et al., (2013) simulated numerical models for the progressive failure of rock slopes involving a complex non-linear evolution from initiation, through propagation to crack.

This study indicates that the scale of the slope remarkably influences the factor of safety, the higher the slope is, the less stable it becomes as shown in

Fig. 5. Moreover, the existence of the regular joint sets in the rock mass can significantly affect the mechanical behavior of rock slope and degrade the factor of safety (FOS). While the irregular joints further increase the slope instability and reduce the factor of safety (FOS) as shown in Fig. 6.

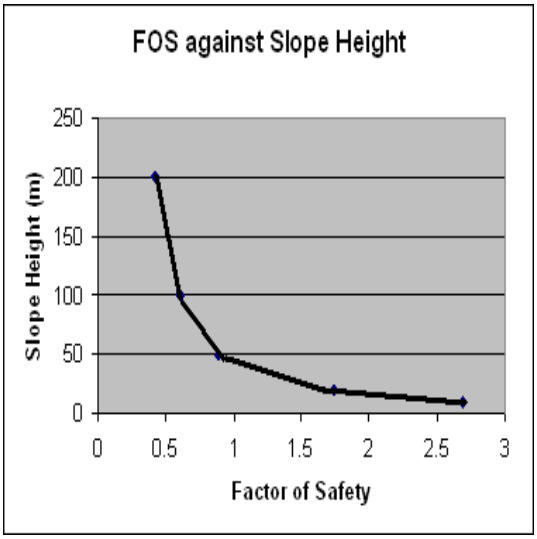

Fig. 5 Shows factor of safety against slope heights.

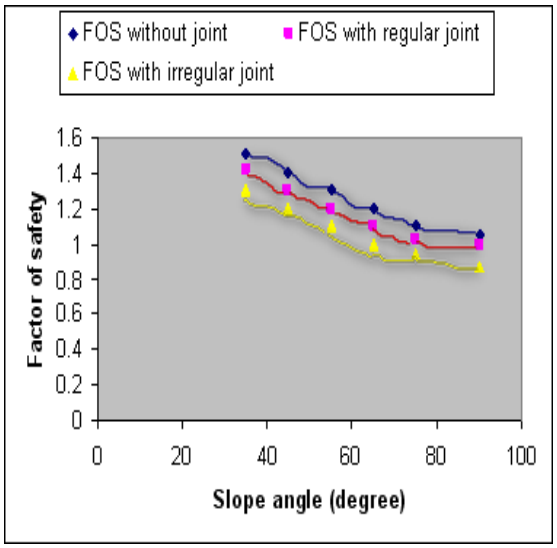

Fig. 6 Shows factor of safety of intact, regular and irregular jointed slopes.

PIV ANALYSIS OF THE SANDY SOIL TRANSPORTATION INDUCED OCEAN WAVE ON WAVE FLUME EXPERIMENT

Tatsuya Matsuda[1], Kinya Miura[1], Keita Anai[1] and Rintaro Takayanagi[1]
[1]Department of Architecture and Civil Engineering, Toyohashi University of Technology, Japan

ABSTRACT

Sandy soil transportation in seabed induced ocean wave is caused by complex interactions between shear stress and effective stress change due to seepage force. This study investigated the soil movement phenomena under various soil density condition that focused on the influence of the Shields number and the excess pore water pressure ratio using the wave flume experiment device. Particle Image Velocimetry (PIV) analysis was also done to quantitatively evaluate soil movement. In the case of the loose density of soil, liquefaction occurred with the phase difference of the pore water pressure fluctuation and the accumulation by residual pore water pressure. The soil particles showed the elliptical movement similar to water particles. On the other hand, in the case of medium-dense soil, the soil was moved to the offshore direction due to flow velocity in the ground surface when the effective stress decreased near the surface layer due to the phase difference of the pore water pressure fluctuation. Especially, the ground surface layer was moved in a body. As PIV analysis result, the upward velocity of soil particles is suggested as near as its a seepage flow velocity of the geomaterial.

Keywords: Wave flume experiment, Sedimental transportation, Shear stress, excess pore water pressure, PIV

INTRODUCTION

The Sediment transportation induced by ocean wave is an important problem for disaster prevention and the environment in the coastal area. In past studies on the scour and erosion, many researchers thought the application of a tractive force about the prediction of topographical changes due to water flow [1]. The geotechnical researchers have focused on the stress change in seabed induced by wave [2]–[5]. However, Flow movement of soil, sediment induced by sea wave is caused by a complex interaction between traction force and seepage force.

The authors have conducted a series of wave flume experiment with movable bed focusing on the influence of the traction and seepage forces for soil movement phenomena [6]. The experimental results for stress change induced by wave were validated with the exact solution which was derived by means of u-p formulation of the seabed as a two-phase material consisting of solid and fluid.

This study has investigated the soil movement phenomena under various soil density condition that focused on the influence of the Shields parameter and the excess pore water pressure ratio. Particle Image Velocimetry (PIV) analysis was also done to quantitatively evaluate soil movement.

OUTLINE OF EXPERIMENT

Experimental device and Measurement tools

Figure 1 shows the schematic diagram of wave flume channel. This channel has 25 m length, 0.6 m width and 1.0 m height. The movable bed area was installed in the channel. The length is 2.5 m and the depth is 0.2 m. The Hydraulic condition was taken into consideration Froude's similarity law. Similarity rate was set $\lambda_L = 1/25$.

During the experiment, the wave propagation was measured above the sediment area by using a capacity type wave gauge and an electromagnetic velocity meter. The pore water pressure in the ground was also measured using pore water pressure sensors. The measurement point of pore water pressure was shown by points in Figure 1. The experiments were recorded using a high-speed camera and a video camera to observe sediment transportation.

Selection of seabed material

It has a limit to applying the geometry scale of the geomaterial according to the Froude's similarity law: For example, geomaterial in model sediment is classified as silt ($D_{50}|m$ = 0.008 mm) when the prototype is fine sand ($D_{50}|p$ = 0.2 mm). Therefore, this study used Dean Number to select of the geomaterial [7]. Dean Number is a dimensionless fall speed parameter, given as the follows Eq. (1);

$$\left\{w/(H/T)\right\}_p = \left\{w/(H/T)\right\}_m \quad (1)$$

where, w, H, and T are vertical fall speed of soil

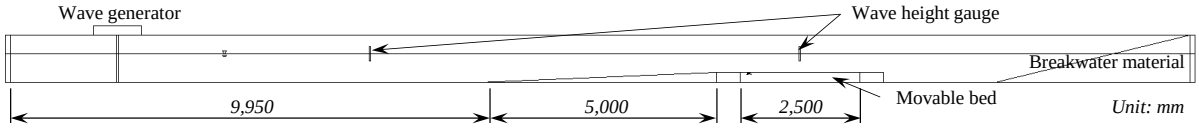

Fig. 1 Schematic diagram of the wave flume device.

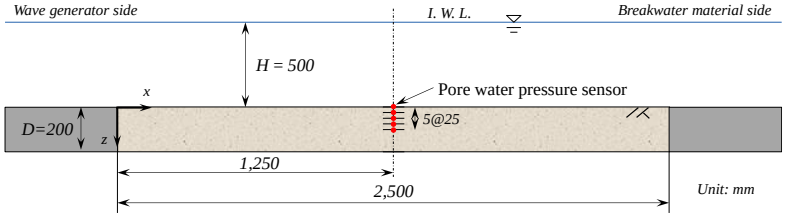

Fig. 2 Schematic diagram of movable bed.

particle in the fluid, wave height and wave period, respectively. The subscript of *p* and *m* means prototype and model. The vertical fall speed of sediment can be calculated using Hallermeier's Relationship as follows Eq. (2);

$$w = \frac{\left[\left(\rho_s - \rho_w\right)\cdot g\right]^{\frac{7}{10}}\left(D_{50}\right)^{\frac{11}{10}}}{6\left(\nu\right)^{\frac{2}{5}}} \quad (2)$$

there, ρ_s, ρ_w, ν and g are soil particle density, water density, the coefficient of kinematic viscosity (= 1.0×10^{-6} m^2/s) and gravitational acceleration, respectively. The geomaterial in the model which is applied to the Dean Number is classified as fine sand ($D_{50}|m$ = 0.075 mm) when the prototype is fine sand ($D_{50}|p$ = 0.2 mm). The characteristic of geomaterial is same between prototype and model.

Experimental condition

Table 1 shows the physical parameters of the geomaterial of sediment. In this experiment, the silica sand No.8 which is applied to Dean Number used. The movable bed was constructed to control the relative density D_r about 55%: Case1 and 67 %: Case2 with a saturated condition.

Table 2 shows the wave conditions. The wave condition is referenced by the book that was discussed liquefaction in seabed induced by the ocean wave, which is published from JSCE [8]. The regular wave was generated for 20 minutes and its acting the movable bed.

Data arrangement with the wave phase angle

Fourier transform was used in the frequency analysis of the time history data obtained from the

Table 1 Physical parameter of silica sand No.8

	Silica sand No.8
Mean diameter, D_{50} (mm)	0.090

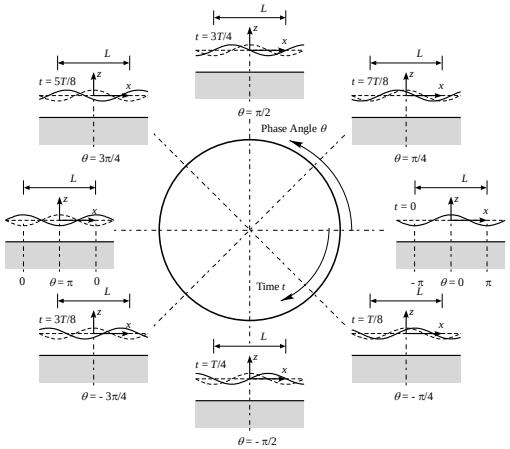

Fig. 3 Definitions of the water level using the phase angle.

experimental results and the data were arranged using a wave phase angle based on the wave duration. These procedures enabled the generalization of the results. Phase angle was defined on the basis of water level, which was

defined. Fig. 3 presents a conceptual diagram of the water level. Experimental data that from 60 to 120 s from the start of the experiment was used because the data became stable.

EXPERIMENTAL DATA ANALYSIS

Calculation of excess pore water pressure ratio

The excess pore water pressure ratio was calculated as follows a formula:

$$\Delta u_e / \sigma_0' = \left(p_n - p_{surface} \right) / \sigma_0' \quad (3)$$

where Δu is an excess pore water pressure and σ_0' is initial effective stress.

The excess pore water pressure ratio is showing the change in the effective stress state of the ground. The excess pore water pressure ratio equal to 1.0 mean that the sediment becomes liquefaction state. The excess pore water pressure was calculated as the pore water pressure at each point on the ground: p_n minus pore water pressure in the ground surface: $p_{surface}$.

Calculation of bed shear stress

The waves interact with the seabed sediment mainly through the bed shear stress. The bed shear stress was suggested by Jonsson [9] as follows Eq. (4);

$$\tau = \frac{1}{2} \rho_w f_w u_b^{\ 2} \quad (4)$$

where f_w is a wave friction factor and u_b is an amplitude of near-bed wave-orbital velocity.

A different measure of the balance between driving and stabilizing forces on sand grains at the bed was suggested by Madsen and Grant [10] as follows Eq. (5);

$$\psi = \frac{\tau}{\left(\rho_s / \rho_w - 1 \right) gd} \quad (5)$$

where, ψ is known the Sields parameter.

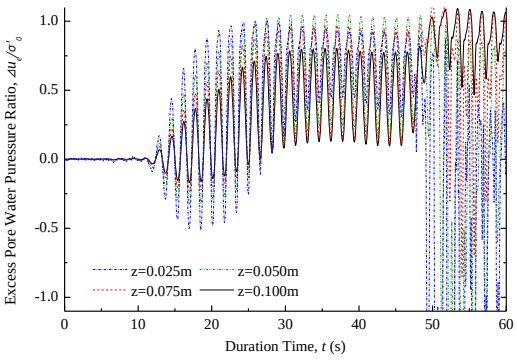
Eq. (4) and q. (5) give Eq. (6);

$$\psi = \frac{1}{2} \frac{f_w u_b^{\ 2}}{\left(\rho_s - 1 \right) gd} \times Sign\left(u_b \right) \quad (6)$$

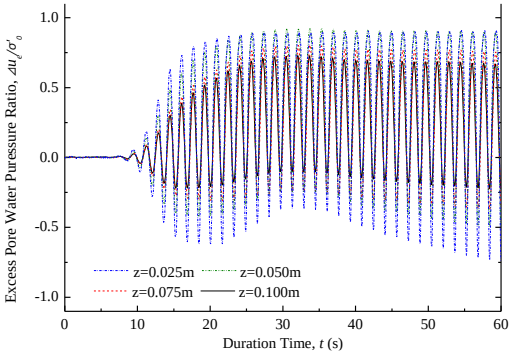
EXPERIMENTAL RESULT AND DISCUSSION

Excess pore water pressure ratio change

Fig. 4 shows the change in the excess pore water pressure ratio. In the Case1, liquefaction has occurred at t = 49 s with the phase difference of the pore water pressure fluctuation and the accumulation by residual pore water pressure. On the other hands in Case2, Accumulation of residual excess pore pressure was observed before t = 30 s. After then, the stabilized amplitude of excess pore water pressure was observed. Hereafter, this paper shows the analyzed result in detail of Case2.



(a) Case1, D_r = 55 %



(b) Case2, D_r = 67 %

Fig. 4 The change in the excess pore water pressure ratio from 0 to 60 s.

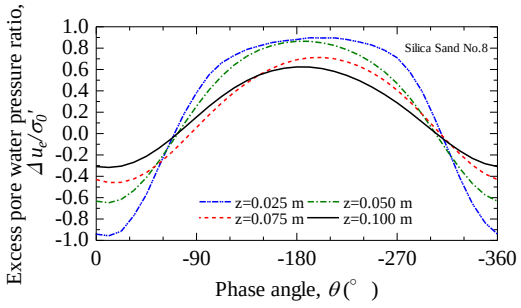


Fig. 5 The change in the excess pore water pressure ratio that is analyzed from one minute after 60 to 120 s.

Fig. 5 shows the change in the excess pore water pressure ratio that is analyzed of data that during one minute after 60 to 120 s from the start of the experiment. The excess pore water pressure ratio became maximum when the wave level became minimum at the phase angle θ = -180 degree. The reason for generating the excess pore water pressure that a difference of the phase angle of water pressure propagation was generated between the surface and the internal of the seabed. The effective stress was decreasing induced by wave action. The maximum excess pore water pressure ratio generated about 0.896 at z = 0.025 m.

Shields parameter and Excess pore water pressure ratio

Fig. 6 shows the relationship between the Shields parameter and excess pore water pressure ratio in Case2. The critical Shields parameter of fine sand is ± 0.05. The positive value is showing the wave flow in an inshore direction.

The excess pore water pressure ratio rising, and the near-seabed flow velocity is generated in the offshore direction opposite to the traveling direction of the wave at the timing of temporary instability in the ground surface.

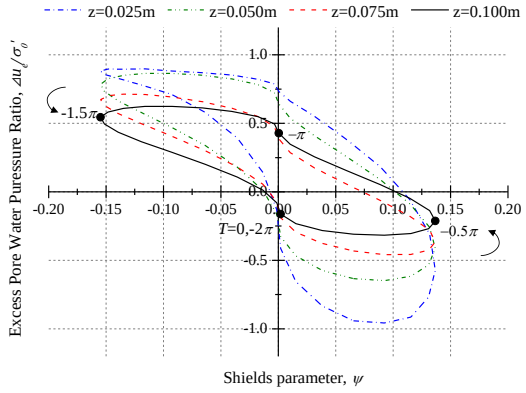

Fig. 6 The relationship between the Shields parameter and the excess pore water pressure ratio in Case2.

Observed sediment movement by PIV analysis

For the observation of sediment motion, PIV analysis was done. PIV analysis is an image analyzed method based on inferring in what direction and in what amount a part of an image has moved between two successive instants. The sediment transportation was recorded by a high-speed camera load a telephoto lens. The analysis was performed with soil particles as the target.

Fig. 7 shows the motion velocity vector of sediment that is calculated by PIV analysis. Color contour shows the velocity value; Maximum velocity as 0.3 m/s (red color), Minimum velocity as 0.0 m/s (blue color).

As a result of PIV analysis, the sediment surface was moved uniformly due to wave motion. The velocity vector is upward at the phase angle where the excess pore water pressure ratio increases. On the other hand, when the excess pore water pressure decreases, the velocity vector turns downward.

The movement velocity of the sediment is evaluated quantitatively. Fig. 8 shows the data extraction area. The velocity data were averaged in 1 mm steps from the ground surface, with the range of the center of the photograph, which is less affected by lens distortion.

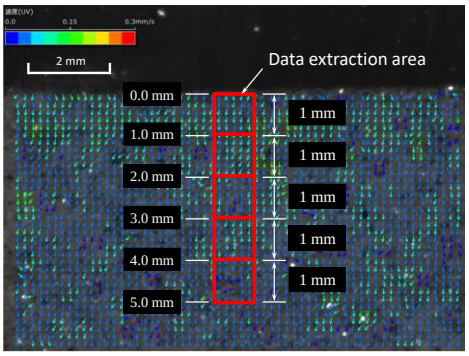

Fig. 8 PIV analysis result; The upper right figure shows a zoomed view of the dotted line position in the center of the whole.

Fig. 9 shows the movement velocity of the sediment in the horizontal direction, and Fig. 10 shows the movement velocity of the sediment in the vertical direction. Fig. 11 shows the relationship between the movement velocity of the sediment in the horizontal and in the vertical direction.

The maximum upward velocity became about 0.06 m/s when θ = -135 degree. Then, the horizontal velocity in the offshore direction was generating about 0.02 m/s. On the other hands, the downward velocity in a vertical direction was generated when the excess pore water pressure ratio decreases. The maximum downward velocity became about -0.12 m/s when θ = -315 degree. Then, the horizontal velocity in the inshore direction was generating about 0.04 m/s.

The surface-bed was transporting with influences of the bed shear stress, and seepage force with the excess pore water pressure change. The upward velocity of soil particles is suggested as near as its a seepage flow velocity of the geomaterial.

CONCLUSIONS

Sandy soil transportation in seabed induced ocean wave is caused by complex interactions between shear stress and effective stress change due to seepage force.

This study investigated the soil movement phenomena under various soil density condition that focused on the influence of the Shields number and the excess pore water pressure ratio using the wave flume experiment device. PIV analysis was also done to quantitatively evaluate soil movement. The results obtained indicate as follows;

- In the case of medium-dense soil, the bed shear stress on the ground was acting in an offshore direction when the effective stress decreased with excess pore water pressure increase near the surface layer due to the phase difference of the pore water pressure fluctuation.
- As PIV analysis results, the surface-bed was transporting with influences of the bed shear stress, and seepage force with the excess pore water pressure change. The upward velocity of soil particles is suggested as near as its a seepage flow velocity of the geomaterial.

ABSTRACT

Nailed-slab System is not a soil improvement method, but rather as an alternative method to improve the performance of rigid pavement on soft soils. The end of the slab of this system is the critical structural element. The void under the end of slab is to be potential to develop because of vehicle wheel paths. If the void is developed under the end of slab, the performance of Nailed-slab Pavement System may be decreased. This research is aimed to learn the effects of the void under the end of the slab due to the soil stress. The numerical analysis will be conducted to investigate the performance of the system. The soil and structural properties of Nailed-slab is based on the previous research on the soft clay. The dimension of the void will be varied in the direction of wide and depth of the void. A standard wheel load 40 kN is set on the end of the slab as a distributed load in 30 cm diameter. Soil stress will be investigated and discussed. Results show that significant effects occur in the soil stress due to the increase of void dimension. Void causes tension stress in the soil. Hence, the void under the slab affects the distributed load stresses to be dominantly resisted by the slab.

Keywords: *rigid pavement, void under slab, soil stress*

INTRODUCTION

The soil under the pavement slab is an important thing in bearing the stress due to traffic loads. Compacted soil tends to transfer the stress relatively uniform in the soil. Voids could occur under the pavement slab of the Nailed-slab System. In case there is a void under the slab, the stress will distribute in non-uniformly in the soil. Concentrated stress will cause maximum stress in the soil. Otherwise, the void can cause decreasing contact area between slab and soils. Hence, the soil bearing will decrease and the slab deflection will increase.

Previous researchers concerned only in normal soil condition under the pavement slab with no voids ([1] - [10]). Soil stress under the Nailed-slab System can be done by a finite element method ([10], [11], [12]).

The critical structural element of the Nailed-slab System is the end of the slab [3]. The void under the end of the slab tends to be more potential developed rather than in the other area. It is important to know what the effects of the void under the slab due to the soil. This research is aimed to investigate the effects of the void under the pavement slab of the Nailed-slab System due to the soil stress. The considered load will be a compression load on the edge of the slab.

METHODOLOGY

This research used soil and a one pile row Nailed-slab structural data from Puri [10]. There was the dense sand layer below the soft clay. The considered load 40 kN was an edge load on the pavement slab. The boundary condition of the soil is shown in Figure 1.

The dimension of Nailed-slab model is 6.0 m x 1.2 m and 0.15 m slab thickness. The slab is supported by 5 piles in a row. Pile diameter was 0.20 m. Pile spacing was 1.20 m. The pile-slab connections were monolithically. The pile length was 1.50 m. The models were analyzed by 2D finite element method. In 2D FEM plain strain analysis, the soft clay was modeled by Mohr-Coulomb in un-drained condition. All structural elements were modeled by plate element in linear-elastic behavior. Lean concrete was modeled by soil with the linear-elastic non-porous material. Soil parameters and idealization of structural elements are presented in Table 1 and 2 respectively.

The void was set under the end of edge slab (actually under the lean concrete). The dimension of voids were varied in 4 variations by depth, h vs. width, w (5 cm x 10 cm; 10 cm x 15 cm; 25 cm x 30 cm; 50 cm x 55 cm). Figure 2 shows the types of void shape and dimension.

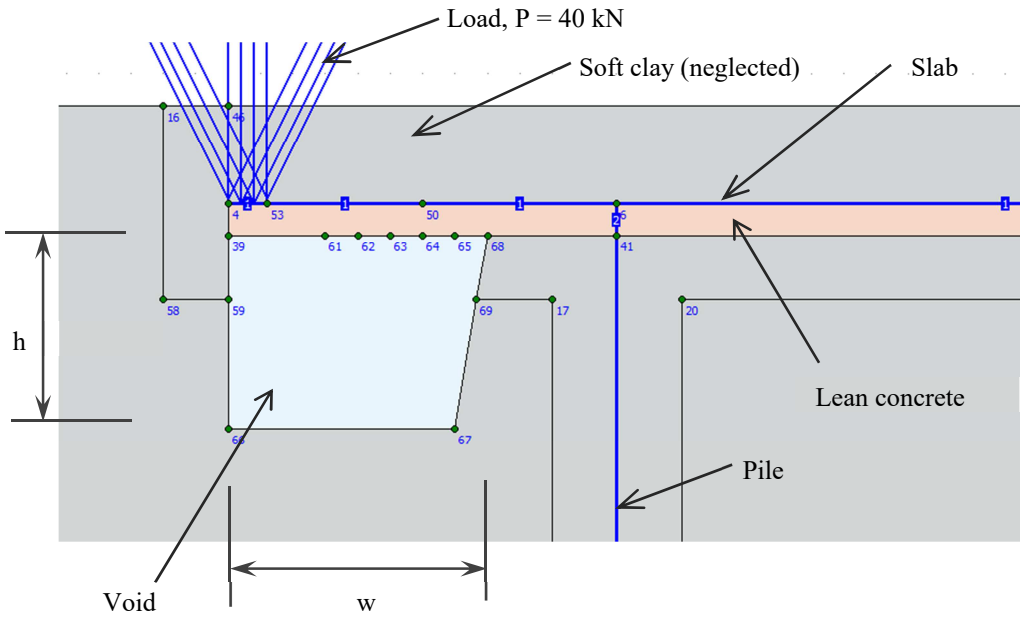

Fig. 2 Typical model of void shape and dimension under the end of edge slab.

RESULTS AND DISCUSSIONS

Figure 3 shows the effective stress of soil in the base of the void. In the normal condition (0 x 0 void), there was the effective stress in compression condition. Otherwise, in case there was a void under the slab, the effective stresses were changed to be in tension condition. This is not beneficial for the soil because soil cannot bear the tension stress. It is evident that the void causes negative effects the soil stress. Soil can easily fail in tension stress condition. Effective stress of soils tends to be relatively constant by increasing the void dimension. Hence, the distributed load stresses to be dominantly resisted by the slab.

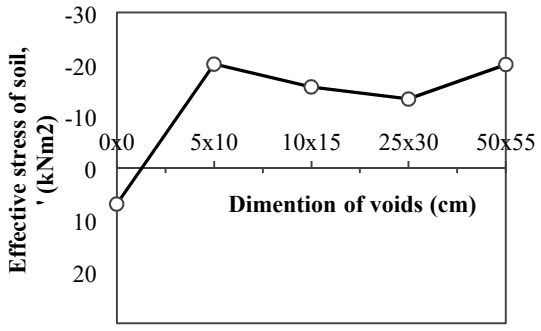

Fig. 3 Effective stress of soil vs. dimension of the void.

Figure 4 shows the effective stress distribution of soil around the void 10 cm x 15 cm. Tension stress condition occurred around the end of the slab and in the right base of the void. The other void dimensions had similar behavior.

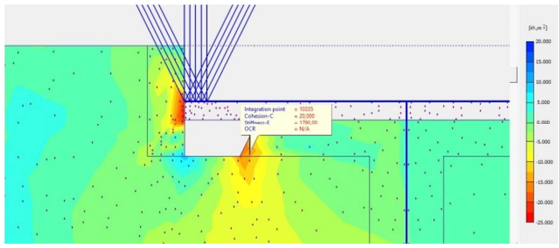

Fig. 4 Effective stress distribution of soil around the void 10 cm x 15 cm.

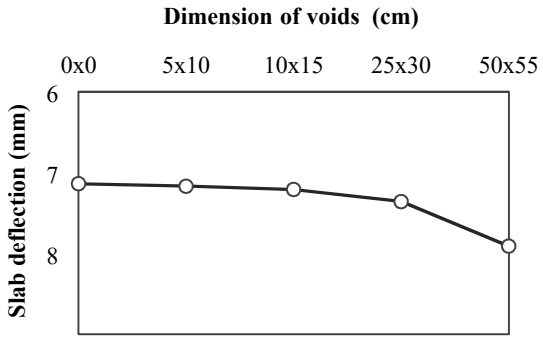

Figure 5. The relation between slab deflection and voids dimensions.

Figure 5 shows the relation between slab deflection and voids dimensions. Because of the distributed load stresses was dominantly resisted by the slab, the slab deflection tends to increase the void dimension. Changing the effective stress of soil around the void affects the increasing slab deflection insignificantly. Loading stresses were distributed dominantly in the slab through bending moments. Hence, the slab dominates to resist this bending moment by its resistance moment. Since the bigger void dimension under the slab, the distributed stress load was dominantly bear by the slab.

CONCLUSIONS

The void under the slab can change the effective stresses of soil in compression to be in tension condition. It is not beneficial for the soil because soil cannot bear the tension stress. It is evident that the void causes negative effects on soil stress. Effective stress of soils tends to be relatively constant by increasing the void dimension. Hence, the void under the slab affects the distributed load stresses to be dominantly resisted by the slab. Further research should be done to investigate the inner forces of structural elements.

A DETERMINISTIC APPROACH OF GENERATING EARTHQUAKE LIQUEFACTION SEVERITY MAP OF MINDORO, PHILIPPINES

John Guinto[1], Mariz Espinoza[1], Joey Grimaldo[1], Daniel Juan[1], Michael Mapacpac[1], and Nolan Concha[1]
[1]FEU-Institute of Technology, Philippines

ABSTRACT

An essential component in decision making for site planners is the availability of risk maps to various geological hazards. Liquefaction in particular can be devastating and impose disastrous damage to existing structures built in earthquake prone areas like the province of Mindoro. Through the aid of in situ data, a simplified method of evaluating earthquake induced liquefaction potential was carried out in this study. This is to address the difficulty and high cost necessary to carry out the development of a liquefaction risk map. Borehole data were collected from different locations in Mindoro and the earthquake liquefaction severity index in each location were calculated using deterministic approach. Results showed that different levels of liquefaction severity were obtained in various areas of Mindoro. There were locations exhibiting manifestations of surface liquefaction due to 7.1 Mw earthquake with a peak ground acceleration of 0.4g. The generated liquefaction severity maps can be utilized as baseline information in selecting appropriate geotechnical intervention for soil improvement and stabilization. Further, the indices can be used as additional dimension of evaluating the holistic reliability of existing engineering structures.

Keywords: Borehole, Liquefaction, Liquefaction Severity Index, Risk Map

INTRODUCTION

The Philippine Archipelago is located within the Pacific Ring of Fire. For this reason, the country is vulnerable to two natural hazards characteristic of this region that are significant to this study – earthquakes and soil liquefaction. Earthquakes, which is the shaking of the earth's surface due to the sudden release of energy in the lithosphere, often causes soil liquefaction. Soil liquefaction takes place when ground movements or earthquakes cause an increase in water pressure that turns the solid ground into a liquid-like state. The shaking of the ground disrupts the soil by increasing the spaces between grains, which in turn lessens soil cohesion, making the soil lose its bearing capacity or strength [1]. These disturbances in the ground lead to a significant problem for areas at risk for soil liquefaction - multi-story buildings and other infrastructures experience the sudden loss of support of the soil underneath it that may cause buildings to collapse. Owing to the Philippines' location in the Pacific Ring of Fire, a record number of earthquakes occurs almost every day in parts of the Philippines, but most are imperceptible tremors that people are entirely unaware of. Because of this, the impact and risks brought upon by soil liquefaction often have devastating results due to people being unaware that they are in risk zones.

There are a number of measures that can be done to lessen the impact and risk that this hazard can incur to a community. This phenomenon can be mitigated, through soil stabilization and a number of ground improvement techniques. Such as accelerating the dissipation of pore water pressure by inducing radial drainage through sand or stone columns, inducing cohesion into the soils or jet-grouting which also increases the density and strength, injection of chemical additives, and liquefaction mapping through hazard indexing. There are several approaches on how to develop liquefaction map by means of: First, Probability of Liquefaction by Chen and Juang [2], Iwasaki et-al. Liquefaction Potential Index [3], Liquefaction severity index by Sonmez and Gokceoglu [4]. In this study, the approach of liquefaction severity index proposed by Sonmez and Gokceoglu [4] will be used for probability and severity mapping. This introduces the probability of liquefaction equation based on the factor of safety to the liquefaction potential index concept. Rearranging the classification of liquefaction severity was done by considering Chen and Juang's probability of liquefaction classes based on P_L values. For this research, the Mindoro province were evaluated for generation of the liquefaction severity map by considering earthquake scenario of Mw=7.1 based from the destructive 1994 Mindoro earthquake.

Mindoro in particular is the seventh largest island in the Philippines by land area with a total of 10,571 square kilometers and is prone to Earthquakes [5]. However, no disaster mitigating methods due to earthquake liquefaction was carried out in the province. The absence of a liquefaction map might

impose devastating impact on built environment resulting to damage to structures and intangible losses.

To address this, this study aims to develop earthquake liquefaction severity map to identify liquefaction prone areas and measure the severity of liquefaction when an earthquake of various magnitudes occurs in the province. The generated map can be utilized as baseline information to develop appropriate mitigation techniques to lessen the risk of earthquake liquefaction. A rapid and inexpensive assessment of the degree of liquefaction can be carried out in a timely and convenient approach with the aid of the generated maps.

EXPERIMENTAL PROGRAM

This presents the procedures that the researchers have undergone to achieve the objectives of this study. The data gathered from the geotechnical reports were used for the calculation of the factor of safety against liquefaction (F_L) to the calculation of the probability of liquefaction (P_L) and the liquefaction severity index (LSI) as shown in Fig. 1. These will be used to determine if the soil in the Province of Occidental Mindoro is liquefiable or not liquefiable using earthquake magnitude 7.1 and to determine the severity of liquefaction in each location.

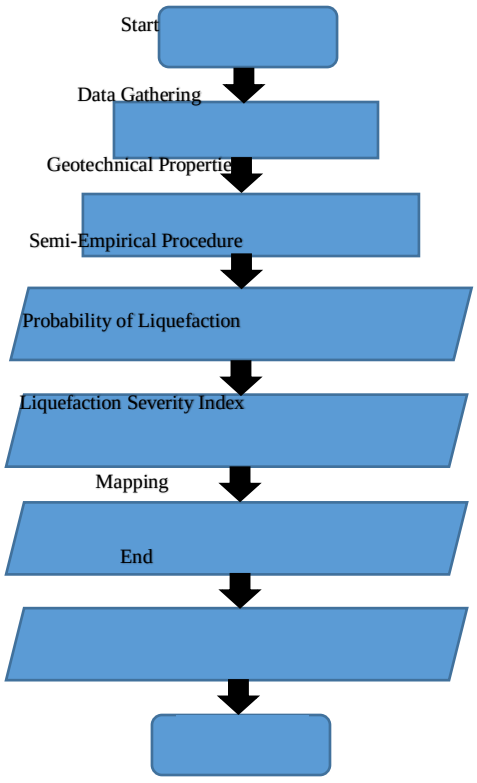

Fig. 1 Liquefaction Mapping Generation

A quantitative research that focused on computational techniques for the investigation with regards to liquefaction is used in this study. The geotechnical properties gathered from geotechnical reports was tabulated in Microsoft Excel to obtain the vertical pressure, pore water pressure, effective pressure, and the factor of safety against liquefaction at every 1.5 m layer. The susceptibility of liquefaction was based on the factor of safety against liquefaction by Idriss and Boulanger [6]. The Probability of Liquefaction (P_L) and the Severity of Liquefaction at each location was based on the Liquefaction Severity Index by Sonmez and Gokceoglu [4] which uses P_L values by Chen and Juang.

The Probability of Liquefaction by Chen and Juang based on $\mathbf{P_L}$ values were considered in rearranging the classification of liquefaction severity. An equation proposed by Juang et al. [2] was introduced by Sonmez and Gokceoglu to overcome the use of linear relation for impact of the factor of safety on liquefaction potential [4]. Table 1 shows the classification of the severity index.

Table 1 Classification of Liquefaction Severity Index

Liquefaction Severity Index	Classification
$L_s = 0$	Non-Liquefiable
$0 < L_s < 15$	Very Low Liquefaction Severity
$15 < L_s < 35$	Low Liquefaction Severity
$35 < L_s < 65$	Medium Liquefaction Severity
$65 < L_s < 85$	High Liquefaction Severity
$85 < L_s < 100$	Very High Liquefaction Severity

$$\mathbf{FS} = \frac{\mathbf{CRR_m}}{\mathbf{CSR}} \quad (1)$$

$$\mathbf{L_S} = \int_0^{20} \mathbf{P_L(z)W(z)dz} \quad (2)$$

$$\mathbf{P_L(z)} = \frac{1}{1+\left(\frac{F_L}{0.96}\right)^{4.5}} \text{ for } \mathbf{F_L \leq 1.411} \quad (3)$$

$$\mathbf{P_L(z) = 0} \text{ for } \mathbf{F_L > 1.411} \quad (4)$$

$$\mathbf{W(z) = 10 - 0.5z} \text{ for } \mathbf{z < 20m} \quad (5)$$

$$\mathbf{W(z) = 0} \text{ for } \mathbf{z > 20m} \quad (6)$$

RESULTS AND DISCUSSION

Geotechnical Assessment

Considering the geotechnical properties of Occidental, Mindoro, this study analyzes the factors of safety against liquefaction (F_L), the probability of liquefaction (P_L) and corresponding liquefaction severity indices for an earthquake having magnitude 7.1. The number of borehole logs on each municipalities of Occidental Mindoro are shown in Fig. 2.

Fig. 2 Map of Occidental Mindoro.

The data gathered from the Province of Occidental Mindoro was evaluated based from the water content, number of blows, N-values, and the depth of soil. The number of blows is the most dominant geotechnical characteristic because it affects the whole computation for Cyclic Resistance Ratio (CRR). The water content, specific gravity of soil and the depth of soil is important for computing the Vertical Pressure, Pore Water Pressure, and Effective Pressure which will contribute to the computation of the Cyclic Shear Ratio (CSR). The CSR and CRR values will help us obtain the factor of safety for each 1.5 m layer. Considering different factors needed in this study, a total of 73 boreholes were used as shown in Table 2.

Table 2 Borehole Distribution in Occidental, Mindoro

List of Municipalities	No. of Boreholes
Abra de Ilog	11
Calintaan	4
Magsaysay	9
Mamburao	12
Paluan	9
Rizal	1
Sablayan	13
San Jose	8
Sta. Cruz	6
Total No. of Boreholes	73

Based from the geotechnical report, the water content and n-values were used to solve the vertical pressure, pore water pressure, and effective pressure as shown in Table 3.

Table 3 Geotechnical Properties

DEPTH	WATER CONTENT	N-VALUE	VERTICAL PRESSURE	PORE WATER PRESSURE	EFFECTIVE PRESSURE
1.5	100	22	14.07	4.41	9.65
3	100	18	35.54	19.13	16.41
4.5	98	28	57.12	33.84	23.27
6	100	11	78.59	48.56	30.03
7.5	100	11	100.07	63.27	36.79
9	100	7	121.55	77.99	43.56
10.5	100	6	143.02	92.70	50.32

Semi-Empirical Procedure

A Semi-Empirical Procedure based on Idriss and Boulanger was used in this study to calculate the safety factor against liquefaction refer to Eq. (1). In determining the Factor of Safety, the values of the reduction factor (r_d), Magnitude Scaling Factor (MSF), equivalent clean sand standard penetration resistance value ($N_{1(60)CS}$), cyclic shear stress ratio (CSR), and cyclic resistance ratio (CRR) will be obtained as shown in Table 4. The soil is susceptible to liquefaction if $FS \leq 1$ or otherwise, it is not susceptible to liquefaction if $FS > 1$.

Table 4 Result of Factor of Safety at Magnitude 7.1

DEPTH	CSR	CRRm	FS
1.5	2.51	1.41	0.56
3	3.73	0.27	0.07
4.5	4.23	0.49	0.12
6	4.51	0.13	0.03
7.5	4.68	0.12	0.03
9	4.80	0.10	0.02
10.5	4.89	0.09	0.02

The table above shows the result of the factor of safety at magnitude 7.1. This table shows that with an increasing depth the reduction factor decreases and as CSR is greater than that of CRRm, the value of the factor of safety against liquefaction is less than 1 and is identified as a liquefiable layer, or otherwise, a non-liquefiable layer.

Liquefaction Severity Index

The factor of safety against liquefaction can be used to calculate the probability of liquefaction and the liquefaction severity index refer to Eq. (2), (3), (4), (5), (6) and as shown in Table 6.

Table 6 Computation of LSI for GPA 0.4g corresponding to Mw=7.1

DEPTH	Z	H	w(z)	$P_L(z)$	LSI
1.5	0.75	1.50	9.63	0.13	1.81
3	2.25	1.50	8.88	0.73	9.65
4.5	3.75	1.50	8.13	0.60	7.31
6	5.25	1.50	7.38	0.87	9.66
7.5	6.75	1.50	6.63	0.88	8.79
9	8.25	1.50	5.88	0.91	8.02
10.5	9.75	1.50	5.13	0.92	7.05
				∑LSI =	52.29

Level of Liquefaction Severity: MODERATE

Mapping

The probability of the soil to liquefy and the severity of liquefaction for each location was obtained in terms of LSI values of 9 municipalities having 73 boreholes around Occidental Mindoro. The maps of LSI values were generated for the province to show the distribution of the probability and severity of liquefaction as shown in Fig. 3 and Fig. 4. The probability map and the severity map will help identify liquefaction prone areas and measure the severity of liquefaction when an earthquake of various magnitudes occurs in the province.

The maps of LSI generated for the Province of Occidental Mindoro representing the probability of liquefaction and the levels of severity of liquefaction for an earthquake magnitude of Mw=7.1. The levels of severity as shown in Table 1. Abra De Ilog has 70-78% probability of liquefaction though the severity level varies from low to medium, Calintaan has 0-2.575% probability of liquefaction and the severity level varies from very low to low, Magsaysay has 0-66.15% probability of liquefaction and the severity level varies from very low to medium, Mamburao has 0-85.75% probability of liquefaction and the severity level varies from low to medium, Paluan has 0-41% probability of liquefaction and the severity level varies from very low to medium, Rizal has 11.25% probability of liquefaction and the severity level is low, Sablayan has 0-91.71% probability of liquefaction and the severity level varies from very low, low, and medium, Sta. Cruz has 0-83.20% probability of liquefaction and the severity level varies from low to medium, San Jose has 0-73.59% probability of liquefaction and the severity level varies from very low, low, and medium. Based on the analysis, Abra De Ilog, Magsaysay, Mamburao, Sablayan, Sta. Cruz, and San Jose has high probability of liquefaction while Calintaan, Paluan, and Rizal has low probability of liquefaction. Sablayan has the highest probability of liquefaction due to a smallest value of FS and as observed from the data, the least number of blows results to a smaller value of FS. Also, the effective pressure and depth of the soil affects the probability of liquefaction. The deeper the depth, the larger the pressure and at the same time has the least number of blows results to a higher probability of liquefaction as observed in the data. The factors that contributed to the level of liquefaction severity is the LSI value at every 1.5 m layer. The summation of all LSI values at each location results to the level of liquefaction severity.

As a result, the category of high to very high liquefaction severity were not observed for the earthquake scenario Mw=7.1. The factors that affects the severity of liquefaction are the depth of the midpoint of the soil layers, the thickness of the soil layer, and the probability of liquefaction. The higher the probability of liquefaction at a certain layer and the nearer it is to the ground results to a higher chance of having larger LSI values. Majority of the studied areas in the province are in moderate liquefaction severity as described by the LSI values. Furthermore, the severity of liquefaction in Occidental Mindoro ranges from very low to medium liquefaction severity although it is susceptible to liquefaction. Municipalities with low chance of liquefaction is because of the not existing ground water table at a depth of 10.5 m which means a dry soil in that certain depth and a shallow ground water table has very high chance to liquefy. It can be

observed in the probability map that a high chance of liquefaction would likely to occur in some of the areas in Occidental Mindoro while it can be observed in the severity map that most of the areas is not that severe when liquefaction would occur during seismic events.

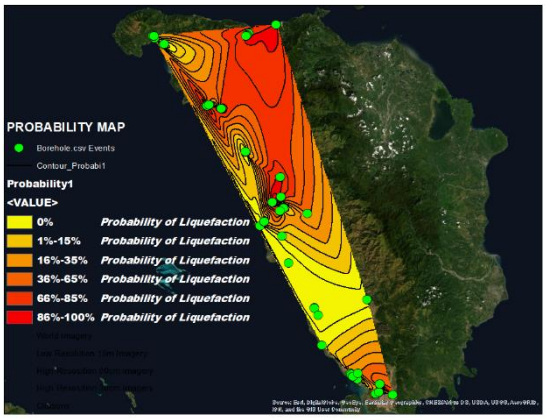

Fig. 3 Liquefaction Probability Map of Occidental Mindoro at EQ Magnitude 7.1

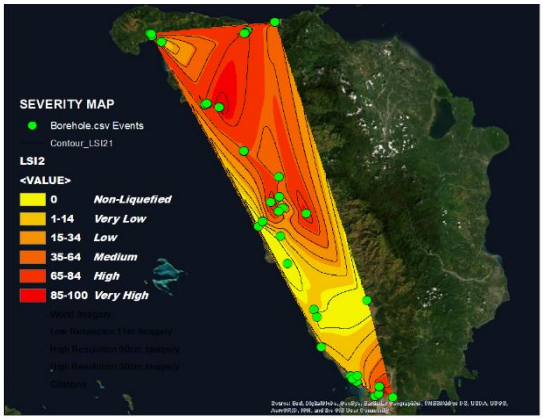

Fig. 4 Liquefaction Severity Map of Occidental Mindoro at EQ Magnitude 7.1

CONCLUSION

The soil properties were investigated in the Province of Occidental Mindoro to show manifestation of soil liquefaction during seismic events. It was observed that majority of the municipalities have high degree to liquefaction as described by P_L values, and the severity of liquefaction is not that severe in a 7.1 earthquake magnitude as described by LSI values. The Probability and Severity Map were able to provide a rapid and inexpensive assessment of the degree of liquefaction in a timely and convenient approach, which are essential to structural engineers in improving the safety matters of any structures to be built and developed in the Province of Occidental Mindoro.

ACKNOWLEDGMENTS

Special thanks to DPWH Occidental Mindoro who provided necessary geotechnical data needed in order to support our study.

THE INCREASING OF UNDRAINED SHEAR STRENGTH AND SHEAR MODULUS OF SOFT BANGKOK CLAY BY SILICA POWDER USING UNCONFINED COMPRESSION TEST WITH BENDER ELEMENT

Pithan Pairojn[1]
[1] Faculty of Science, Chandrakasem Rajabhat University, Thailand

ABSTRACT

The present study aims to increase the undrained shear strength and shear modulus of soft Bangkok Clay soil by silica powder when they were subject to unconfined compression test with the bender element. The shear wave velocity was measured using a pair of bender elements installed at the top cap and pedestal of the unconfined cell. The undrained shear strength was conducted step by step so that the variation of shear modulus could be determined. The undrained shear strength was carried out at the strain rate of 1% per minute during which the shear modulus was continuously recorded. The result found that when the soil was mixed with silica powder an increased rate, the undrained shear strength and shear modulus were increased but the strain was decreased. Therefore, the improvement of soil quality using silica powder can be increased the efficiency of the construction such as embankment and road construction.

Keywords: Undrained shear strength, Shear modulus, Bangkok Clay, Silica powder, Bender element

INTRODUCTION

At present, the construction in the central region of Thailand, such as road construction, slope construction, etc., has been damaged due to soil foundations that are soft clay (Bangkok soil), especially roads along the canal (Fig. 1). Therefore, requires the design and construction of roads to be appropriate according to the engineering principles which cause the collapse of roads along the irrigation canal caused by

1. Infrastructure construction and buildings in soft clay areas where soft clay layers are characterized by varying depth.
2. The rapid drop of water level in the irrigation canal (Sudden drawdown) from normal use with water supplying into the canal or during the extreme drought that farmers will accelerate pumping water into the garden or farmland area (Fig. 2) or in the late rainy season, early in the winter, the water in the canal will be drained faster, which will give the opportunity to the collapse of the riverbank slope in this regard. The behavior of river bank collapse due to the rapid decrease of water level, especially the clay bank soil slopes so that water and pressure caused water to flow out. If the water pressure is high enough, it will cause the river bank slopes and roads along the canal to collapse.
3. Longer summer months as a result of global climate change directly affect the collapse of river bank slopes and roads along the irrigated canal due to lack of water in the canal that will help push or support the bank slopes to stabilize.

This research focuses on improving soft soils by using additional mixtures, which the researcher uses silica powder because it is cheap, easily available, can fill the gap between soil mass and can increase the undrained shear strength and shear modulus of soft soil. The silica powder is not very expensive compared to other additive mixtures. Therefore, the construction of roads or roads along the canal can use clay mixed with silica powder for the efficiency, the investment value and the reduction of soil collapse [1]-[4].

METHODOLOGY

Use at most three levels of headings that correspond to chapters, sections and subsections. The first level headings for chapter titles should be in 10pt, bold, justified, and upper case font. Leave one blank line before and after the first level headings, respectively.

Unconfined Compression Test with Bender Element

The researcher developed the unconfined compression test with bender element (UCTwBE) by using the unconfined compression test of ELE International to install the axial force transducer and axial displacement transducer of Kyowa (Fig. 3).

Fig. 3 Unconfined compression test with bender element.

Bender Element

Install the bender element to measure small strain modulus. The Bender element converts the Eletro-mechanical system by converting mechanical energy (Vibration) into electrical energy. On the other hand, it converts electrical energy into mechanical energy. The bender element is characterized by two piezo ceramic plates attached together, can be both a transmitter and receiver (Fig. 4). Since the bender element is a material that resists electricity, therefore, the use must be careful about short-circuiting, the need to have electrical insulation because of moisture by using epoxy coating around the bender element (Fig. 5).

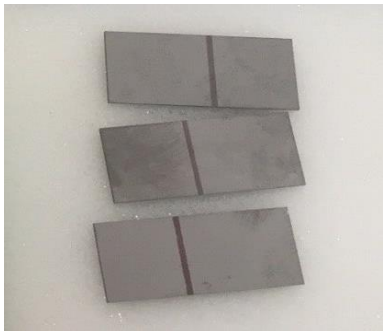

Fig. 4 Sample of bender element T226.

Fig. 5 Connecting the power cable to the bender element.

Signaling and Recording Equipment

Install the equipment for wave signal transmission using NI CompactDAQ Set (Fig. 6), which is installed with NI9237, NI9215, NI9263, NI9915, Function generator, Amplified voltage and DC supply 24V 5A for control and recording with CRU-Bender Recorder from LabView program (Fig. 7).

Fig. 6 NI CompactDAQ Set.

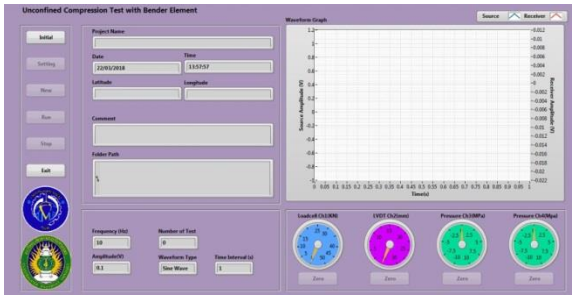

Fig. 7 CRU-Bender Recorder program.

Soil Properties Testing

Collect soil samples for testing as clay at Bang Khen in Bangkok, Thailand at a depth of 0-5 meters (13° 53’ 03" N, 100° 36’ 19" E) with engineering Properties as shown in Table 1.

Table 1 Engineering properties of clay samples

Property	Standard	Value
Water content, W_c (%)	ASTM D4959-00	20-21
Total unit weight, γ_t (t/m^3)	ASTM D4253-00	1.95
Liquid limit, LL (%)	ASTM D4318	53
Plastic limit, PL (%)	ASTM D4318	28
Plasticity index, PI (%)	ASTM D4318	25
Specific gravity, G_s	ASTM D854-00	2.56

Mixing Clay with Silica Powder

Compaction of clay as standard ASTM D698-12e2 standard test methods for soil using standard effort [5] by mixing normal water and mixing silica powder by 5% to 50% of water weight, respectively. Silica powder in Thailand is easy to find because Thailand has a lot of paddy so it can be synthesized into silica powder. Mix together (Figs. 8 and 9) and cut samples according to ASTM D2166-00 standard test method for unconfined compressive strength of cohesive soil [7] as shown in Fig. 10, installed with the UCTwBE to find undrained shear strength and shear modulus values.

Fig. 8 Mixing silica powder.

Fig. 9 Standard compaction test.

Fig. 10 Soil sample cutting.

Determination of Undrained Shear Strength

When cutting samples obtained from soil compaction tests Installed with the unconfined compression test with bender element (Fig. 11). The undrained shear strength can be obtained from Eq. (1) according to the standard ASTM D2166-00 Standard Test Method for Unconfined Compressive Strength of Cohesive Soil [6].

$$S_u = q_u / 2 \quad (1)$$

Where S_u = Undrained shear strength (kPa), q_u = Unconfined compressive strength (kPa).

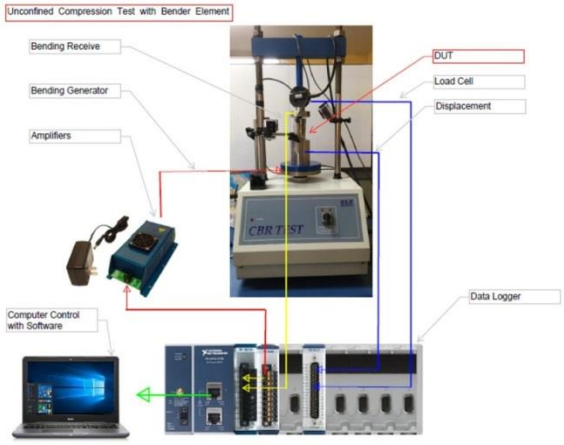

Fig. 11 The system of unconfined compression test with bender element.

Determination of Shear Wave Velocity and Shear Modulus

Shear Wave Velocity

During the testing of soil compression (Fig. 12), the sine waveform is generated and transmitted by a 20V pp 1 kHz frequency signal from the function generator and sent via the transmitter at the base through the soil sample to the receiver at the top cap when the shear wave travels through the soil sample. The shear wave velocity can calculate as Eq. (2) [7]-[8].

$$V_s = L / t \quad (2)$$

Where V_s = Shear wave velocity (m/s), L = Distance between transmitter and receiver (m), t = The travels time of wave between transmitter and receiver peak-peak (s).

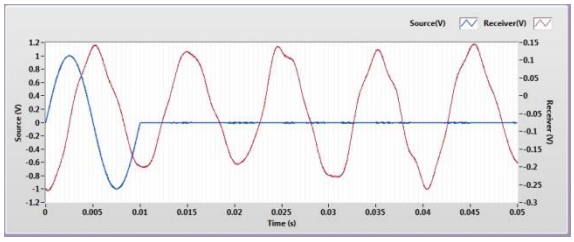

Fig. 12 Shear wave from the test of mixing silica powder by 30%.

Shear Modulus

When the shear wave velocity is obtained, then the small-strain shear modulus can be obtained from Eq. (3).

$$G_{max} = \rho V_s^2 \quad (3)$$

Where G_{max} = Shear modulus (MPa), ρ = Soil density (kN/m^3), V_s = Shear wave velocity (m/s).

RESULTS AND DISCUSSION

Result of Undrained Shear Strength

Figure 13 showed that the undrained shear strength of the soil mixed with silica 50% of water weight was the highest about 69.25 kPa. Which is greater than the soil mixed with water about 30.34 kPa, which is about 2 times at optimum moisture content (OMC).

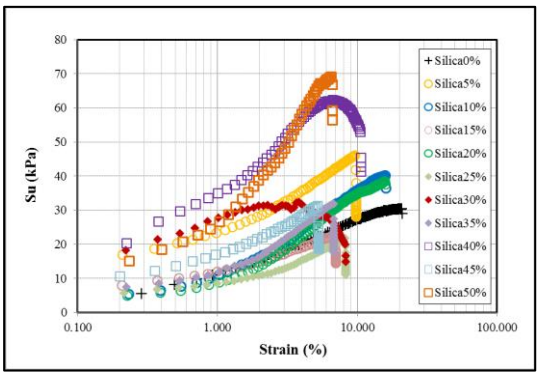

Fig. 13 Undrained shear strength of soil.

Figure 14 showed that the shear wave velocity of the soil mixed with silica 5% of water weight was the highest about 436.58 m/s. Which is greater than the soil mixed with water about 211.39 m/s, which is about 2 times at optimum moisture content (OMC).

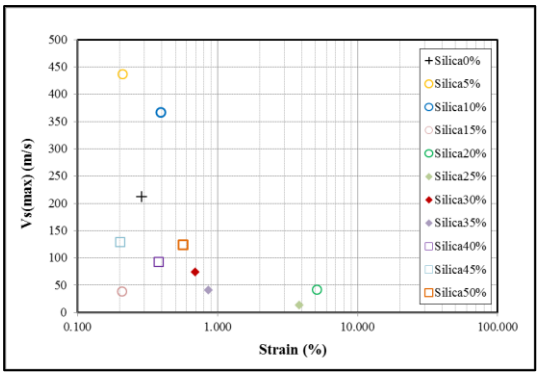

Fig. 14 Shear wave velocity of soil.

Figure 15 showed that the shear modulus of the soil mixed with silica 5% of water weight was the highest about 4,117.09 MPa. Which is greater than the soil mixed with water about 933.91 MPa, which is about 4 times at optimum moisture content (OMC).

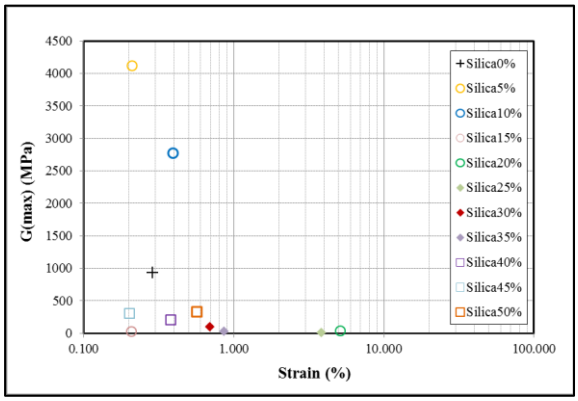

Fig. 15 Shear modulus of soil.

CONCLUSION

The results of the research concluded that improvement of soil quality by using silica powder approximately 5-10% of water weight as an additive during soil compaction in construction can increase the efficiency of the pavement to have undrained shear strength and shear modulus rather than soil mixed with water. Therefore, silica powder can be used to improve soil quality by mixing it as an additive during soil compaction. The unconfined compression test with bender element developed by the researcher can be used to determine the undrained shear strength and shear modulus. Thus, reducing time and cost savings in soil testing. It can be used to solve problems during construction, so it is an innovation that is suitable for engineers, designers, field engineers and supervisors. In future research, the researcher will conduct on the modification of soil chemical structure by mixing silica powder.

EVALUATION OF GROUNDWATER FLOW CHARACTERISTICS BY VOLTAGE DIFFERENCE METHOD ELECTRICAL PROSPECTING

Shuichi MIYAJI[1], Hisayuki NAKANE[1], Itsuo KAWASAKI[2], Yoshihiro NAGANO[2], Shuichi HASEGAWA[3] and Minoru YAMANAKA[3]
[1] Chiken Inc. Ltd., Japan; [2] Japan Crust Research co., ltd, Japan; [3] Faculty of Eng., Kagawa University, Japan

ABSTRACT

Evaluation of groundwater flow channel is very important for utilization and conservation of groundwater resources, safety and economical construction work, and protection of soil and groundwater against pollution. Although electric prospecting has long been used to evaluate the groundwater flow path, its interpretation is comparatively hard, because resistivity depends on groundwater as well as soils and bedrock.

The voltage difference method is an electrical prospecting method that obtains the resistivity change rate in addition to the normal resistivity, and by promoting forced polarization, it is possible to improve the estimation accuracy of the distribution and properties of the groundwater flow path. In this study, the relationship between resistivity change rate and groundwater flow and the relationship between the groundwater yield by observation holes was verified at the site where the groundwater survey such as electrical prospecting, boring survey and pumping test was conducted. As a result, the following was found. (1) The estimation interpretation of groundwater flow area is improved by resistivity change rate rather than resistivity. (2) The resistivity change rate and the yield may have a positive correlation.

This paper reports the effectiveness of the voltage difference method confirmed from the verification results of the research.

Keywords: groundwater flow, voltage difference method, electrical prospecting, resistivity, resistivity change rate

INTRODUCTION

No clear definition is given for the groundwater flow layer, so-called "water path", but it is qualitatively considered as "a place where groundwater is concentrated and flowing in the aquifer" [1]. Groundwater is divided into soil water that exists in the interstices of soil particles and fissure water that exists in the fissures of bedrock. When the fissure is large and continuity is good, it forms “water flow” [2].

Excessive groundwater use and inadequate construction work in the aquifer will cause various groundwater troubles such as depletion of groundwater resources, land subsidence, and diffusion of soil and groundwater contamination. Therefore, proper evaluation of the groundwater flow layer is very important for the appropriate development, utilization and maintenance of groundwater resources, safe and economical construction work, and environmental protection.

Electrical prospecting is used as a method to spatially understand the distribution and properties of the groundwater flow layer. Electrical prospecting is a physical exploration that applies a direct current to the ground and analyzes the resistivity characteristic of the ground from the potential formed. The ground has different resistivity depending on the types of minerals that make up sediments and rocks, and the ion concentration and amount of water that fills the pores between mineral particles, and the underground structure can be approximately estimated from the resistivity distribution [3]. Electrical exploration was introduced to Japan in the 1920s and used for groundwater surveys. Later, with the advancement of computer technology and simulation technology in the 1970's, complex underground structure analysis has become possible [4].

The normal electrical prospecting evaluates that the low resistivity zone is groundwater area. However, in general, the cohesive soil layer also has a low resistivity zone, and it is difficult to estimate the location and range of the groundwater flow layer from the resistivity distribution. The voltage difference method is a method to emphasize the forced polarization phenomenon, and in addition to the resistivity, the rate of resistivity change can also be obtained. As a result, it is possible to improve the estimation accuracy of the distribution and properties of the groundwater flow layer.

This paper indicate that the voltage difference method is effective for the appropriate evaluation of the groundwater flow layer from the case study.

VOLTAGE DIFFERENCE METHOD

Voltage difference method electrical prospecting is one of the forced polarization methods (IP method:

Induced Polarization Method) of electrical prospecting. This method can promote the forced polarization phenomenon by the same survey line and make the groundwater flow range clearer.

Principle

Induced polarization phenomenon

When an electric current is applied to rocks and ores, the electrical phenomenon observed as lagging response potential is called forced polarization. When groundwater flows in the fissures in rocks and pores in sediments below the ground, electrical interaction occurs at the boundary between minerals and groundwater. Normal water is electrically neutral, but when anions are left on the mineral surface, the water flow carries many cations, causing a bias in the distribution of cations and anions in the pore water (Fig.1) [5].

Voltage difference method

The voltage difference method carries out exploration twice on the same survey line and promotes forced polarization of the groundwater flow layer. The apparent resistivity value (ρ_a) of the ground by the electrical survey is not limited to the electrode arrangement, but as shown in the Eq. (1), linear relationship is established between the load current (I) and the measured potential (V) ($V_1 / I_1 = V_2 / I_2$).

$$\rho_a = \alpha \frac{V}{I} = \alpha k \qquad (1)$$

Here, ρ_a : apparent resistivity, V : measured potential, I : load current, α : proportional constant, k : constant

Since the ground acts as a dielectric, it is also known that a forced polarization phenomenon occurs due to the load current (I) ($V_1 / I_1 > V_2 / I_2$) [6]. If there is a groundwater flow layer, the potential of Eq. (2) is generated around "Groundwater flow", and the measurement V decreases due to this effect.

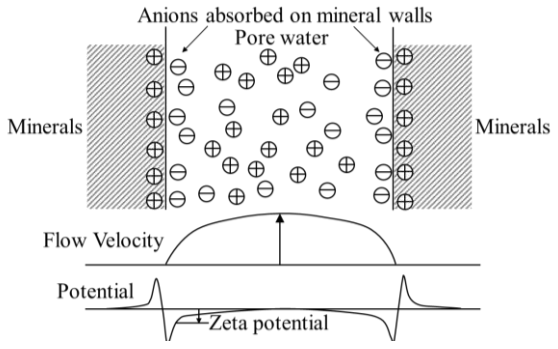

Fig. 1 Model for adsorption of ions in water to mineral surfaces

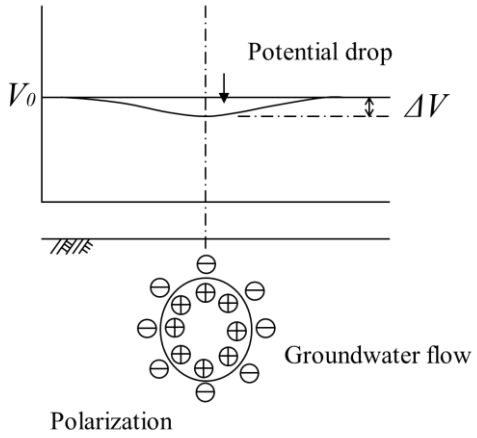

Fig. 2 Potential drop model in groundwater flow

$$E(\Delta V) = \frac{\Delta P \cdot D \cdot \zeta \cdot \rho_w}{4\pi \cdot \eta} \alpha \Delta P \qquad (2)$$

Here, E : flow potential, ΔP : water pressure, D : dielectric constant of the fluid, ζ : zeta potential, ρ_w : specific resistivity of groundwater, η : viscosity coefficient of groundwater

If laminar flow exists in the ground, it is considered that the generated polarization is released with the water flow, then a new charge starts, and the amount of current is absorbed continuously (Fig.2). On the other hand, if there is no water flow even in saturated ground, the polarization is put in a steady state is kept, and no voltage drop occurs. Therefore, the more pronounced the groundwater flow, the more the forced polarization phenomenon is emphasized, and the estimation accuracy of the water movement range in the ground improves.

Difference between conventional IP method and the voltage difference method

In the conventional IP measurement, the load voltage is returned to 0 after boosting to point A (V_1). At this time, if there is a dielectric (groundwater fluidized bed) on the ground, a dielectric potential is generated as a result, current I_0 (point C) at load voltage V = 0 is measured, and corresponding V_0 (measured voltage) is measured. The result is $\rho_a = \alpha (V_0 / I_0)$ (Fig.3).

The voltage difference method measures the measured current (I_2) by reducing the pressure to point B (V_2) immediately after point A (V_1) of the conventional IP method measurement. At this time, the pressure reduction path AB in the presence of the dielectric follows a path different from the pressure rising path OA, and it is considered that the following $\Delta\rho_a$ occurs (Eq. (3) (4)).

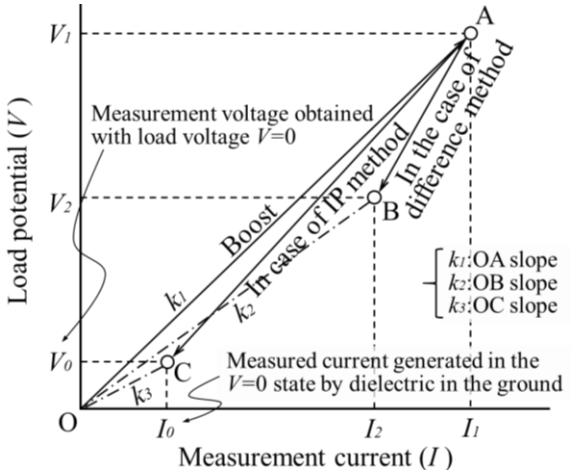

Fig. 3 Measurement principle of the voltage difference method

$$\left(k_1 = \frac{V_1}{I_1}\right) \neq \left(k_2 = \frac{V_2}{I_2}\right) \quad (3)$$

$$\Delta\rho_a = \rho_2 - \rho_1 = \alpha(k_2 - k_1) < 0 \quad (4)$$

In the case of voltage drop due to groundwater flow, even if the measurement is $V_1 = V_2$. It is assumed that $I_1 < I_2$ ($V_1 / I_1 > V_2 / I_2$), and the resistivity change rate can be taken out. Therefore, reducing the pressure from V_1 to V_2 has the effect of amplifying the specific resistance difference value.

Exploration method

The exploration is performed according to the following procedure, and the exploration are performed twice on the same survey line. The electrode arrangement in measurement uses Wenner method, which has high horizontal sensitivity, and Ertran method which has high vertical sensitivity. In addition, electrode spacing and survey line length should be set with a margin for accurate analysis of exploration depth and exploration target range. The exploration cross section image and the survey instrument are shown below (Fig. 4, Table 1).

1) Set a survey line to a predetermined route
2) Electrode placement
3) Cable attachment and wiring, and grounding resistance check
4) Initial measurement
5) Difference measurement (The search condition is the same as 4))
6) After data check, equipment removal

Analytical method

The normal resistivity cross section is analyzed from the initial measurement, and the resistivity change rate cross section is analyzed from the initial measurement and the differential measurement.

Manufacturing	NICHIDO DENKO Co., Ltd.
Size	ϕ 10mm, L=600mm

Resistivity cross section

In the analysis, apparent resistivity values are calculated from measured values of Wenner and Ertran method, and then apparent resistivity cross sections of both arrays are analyzed. Cross-sectional

analysis is performed from the apparent resistivity values of both arrays. For cross-sectional analysis, two-dimensional inverse analysis consisting of finite element method and nonlinear least squares method is conducted [7] [8].

Resistivity change rate cross section

The resistivity change rate ($\Delta\Omega$) is taken from the difference ($\Delta\rho$) of the resistivity values obtained by difference measurement (Eq. (5) (6)). If rate of change would become higher, the possibility of pressurization in the groundwater would be higher as a result it is judged that there is a confined groundwater or groundwater flow layer.

$$\Delta\rho = \rho_1 - \rho_0 \quad (5)$$

$$\Delta\Omega = -(\Delta\rho / \rho_0) \times 100 \quad (6)$$

Here, ρ_0 : resistivity at initial measurement, ρ_1 : resistivity at difference measurement, $\Delta\rho$: resistivity difference, $\Delta\Omega$: resistivity change rate (%)

CASE STUDY

The voltage difference electrical prospecting was applied to shallow terraces of surface rock, and the relationship between the survey results and groundwater flow characteristics was verified.

Geological setting

The site is located on a river terrace about 230 m above sea level. Bedrocks are interjected sandstone and mudstone and are covered by terrace soil layers of cohesive soil to gravel with a thickness of about 3-5m (Fig.5).

The mainly groundwater consists of free groundwater distributed around GL-3 to 5m. From the drilling conditions, the aquifer is presumed to be a gravel layer at the base of the terrace sediments or in fissures in weathered bedrocks (Fig.6).

Survey methods

Electrical prospecting overview

The exploration method was as described above. The survey lines were arranged in two lines so that they almost coincide with the previous boring points (Table.2, Fig.5).

Boring survey

All-core boring of φ 66 mm was conducted at two locations where groundwater flow can be expected in the electrical prospecting (Table. 3, Fig. 5). After the investigation, the hole was expanded to φ 116 mm and used as a test hole for the pumping test described later.

Pumping test

Pumping tests were conducted in accordance with JGS 1315-2012, and pumping and water level observation were conducted with a single hole. In the test, a 100 mm diameter perforated pipe with an aperture rate of 10% was inserted to carry out stepwise pumping up to the estimated critical pumping capacity. The critical pumping capacity was estimated from the relationship between stable water level and pumping capacity.

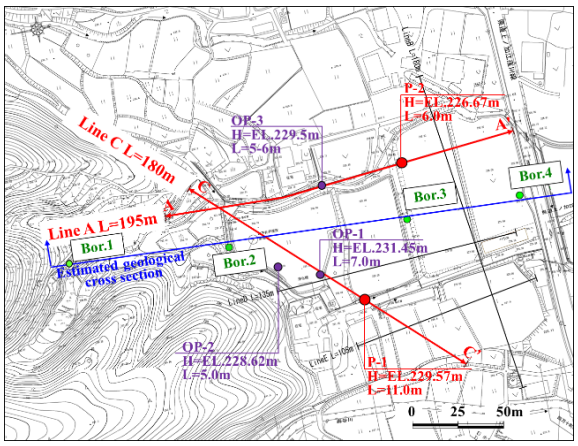

Fig. 5 Survey line and boring survey position

Table. 2 Exploration specifications

Line name	Line length	Electrode spacing	Number of electrodes
A	195 m	3 m	66 points
C	180 m	3 m	61 points

Table. 3 Boring survey specifications

Point name	Hole height (EL.m)	Depth (m)	Hole diameter (mm)
P-1	229.57	11.00	66
P-2	226.67	6.00	66

Result

Exploration result and interpretation section

The exploration result was colored the resistivity distribution by the initial measurement and was overlaid to the resistivity change rate of 10% or more with a contour, and the geologic interpretation was added to it. In both the A and C survey lines, the surface layer of 3 to 4 m has a resistivity of 50 to 700 Ωm, and the depth of more than 4 m has a resistivity of 50 to 2000 Ωm (Fig. 7). The bedrock shallower than GL-10-15m has a low resistivity band with a resistivity of 50-200 Ωm. The resistivity change rate is distributed in the relatively high range of about 10 to 20% on the electrode No. 10 to 45 of Line A and No. 0 to 10, 30 to 40 of line C. Geological interpretation was comprehensively judged based on existing geological data.

Electrical prospecting result of the boring point

In addition to the boring points of P-1 and P-2 investigated this time, data of three boring surveys of OP-1 to 3 exist near the survey line in the survey site. The resistivity change rate is the same at 50 to 300 Ωm at all points, but the resistivity change rate is as high as 10-20% at P-1 and about 10% of P-2, others less than 10% (Table. 4).

Table. 4 Exploration result of survey hole point

Point name	Hole height (EL.m)	Depth (m)	Resistivity (Ωm)	Resistivity change rate (%)
P-1	229.57	11.00	100-300	10-20
P-2	226.67	6.00	25-300	10
OP-1	231.45	7.00	100-200	10<
OP-2	228.62	5.00	100-200	10<
OP-3	229.5	5-6	50-150	10<

Note: The depth of OP-3 is estimated by listening.

P-1 and P-2 were the only points where groundwater could be pumped at the survey point. In addition, as a standard which can carry out a pumping test, it was set as the state where the stable groundwater level was maintained by the yield of several L / min.

Relationship between core properties and yield and resistivity change rate

P-1 is a softly gravel mixed silt with a low water content throughout the 5.0 m of the surface layer. It is a weathered mudstone in the form of rock fragments and angular gravel between 5.0 and 10.0 m in depth and becomes weakly weathered rock from 10.0 m or less in depth (Fig. 8). The surface 1.5 m of P-2 is a silty sand between. Between the depth 1.5 to 6.0 m is a weathered sandstone and a weathering mudstone

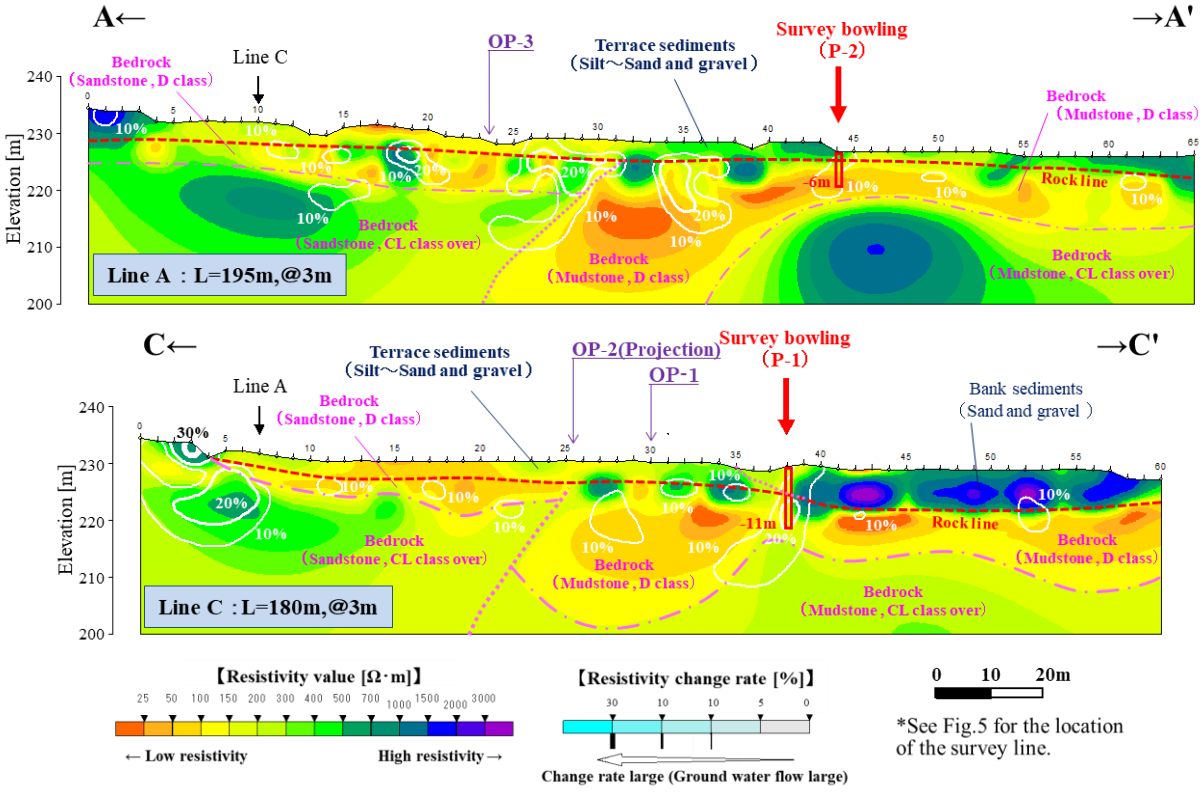

Fig. 7 Resistivity and resistivity change rate distribution and interpretation

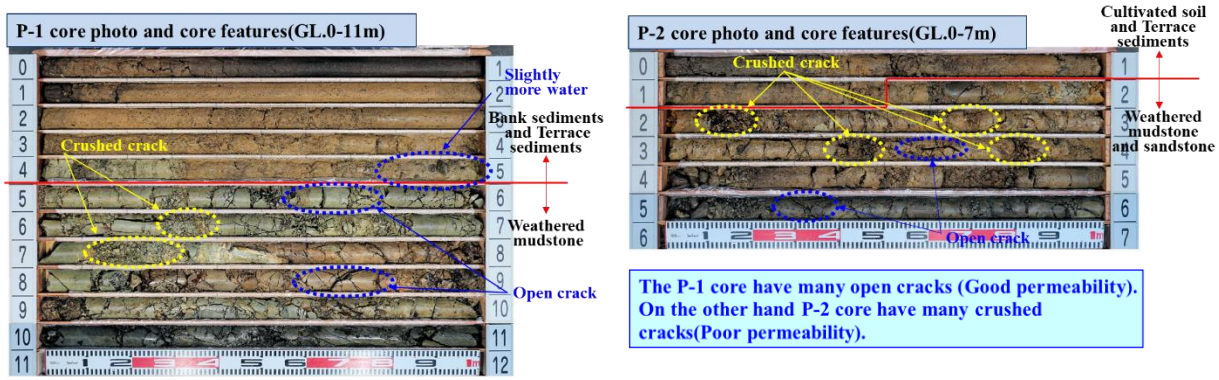

Fig. 8 Core properties of P-1 and P-2

from a rock fragment to angular gravel. As for rock fractures, P-1 tends to have many open cracks and P-2 tends to have few open cracks. At the time of the survey, the water level in the borehole was located near GL-5m for P-1 and 1.5m for P-2 and both were in the bedrock.

The critical yield of P-1 was as high as 8.35 L/min, and P-2 was as small as 3.05 L / min. The resistivity change rate of P-1 is mostly 20% or more in the bedrock, but P-2 is only 10%.

CONSIDERATION

The resistivity change rate distribution can be roughly compared with the groundwater flow range, and it is inferred that there is correlation between the magnitude of the change rate and the yield.

1) P-1 and P-2 had a resistivity change rate in the range of 10 to 20%, therefore it is a high possibility that the groundwater flow layer exists. While OP-1, OP-2 and OP-3 do not show clear change in resistivity change rate, and it is assumed that groundwater flowability is low.
2) The resistivity change rate may be positively correlated with the magnitude of the yield under almost the same weather conditions. Therefore, it is considered possible to estimate the permeability of the ground and the amount of yield water by the resistivity change rate at the point.

SUMMARY

The comparison with other groundwater survey indicates that the voltage difference method electrical prospecting is effective as an evaluation tool of groundwater flow characteristics.

1) The ordinary electrical prospecting is a limit to estimating the groundwater flow range and flow path, but it is considered that the estimation accuracy is improved by analyzing the resistivity change rate of the voltage difference method.
2) The resistivity change rate of the voltage difference method may be correlated with the yield. Therefore, it may be a quantitative evaluation index of groundwater fluidity.

ACKNOWLEDGMENTS

The authors are very grateful to the local people and related party for supporting the present work.

ABSTRACT

This study determined the effects of pulverized mussel shell on the properties of expansive soil. The expansive soil was collected from the vicinity of Taytay, Rizal. The mussel shell pulverized into different stages and passed the #200 sieve were used in the experimentation. The index properties and physical properties of the soil, determined as Plastic Limit, Liquid Limit, Plasticity Index, Shrinkage limit, Specific Gravity and Shear Strength, classified the soil to be SC Soil and were obtained in accordance with American Standard for Testing and Materials (ASTM). The Expansive soil was mixed with the pulverized mussel shell at different percentages (3%, 6% and 9%) by weight of the expansive soil. Index Properties test were conducted on the expansive soil alone, and with pulverized mussel shell to determine the changes to be dealt with the index properties of soil. Unconsolidated Undrained Triaxial Test was conducted on the expansive soil alone and with pulverized mussel shell to determine its shear strength. The test results of the study showed that with increasing amount of pulverized mussel shell, the expansive soil's moisture content decreased, specific gravity of expansive soil increased, Liquid Limit decreased, Plastic Limit increased, Plasticity Index decreased, Shrinkage Limit increased and the shear strength of the soil increased.

Keywords: Mussel, Triaxial, Expansive Soil, Shear Strength

INTRODUCTION

Several problems are encountered during the early stages of Construction whether it is vertical or horizontal. A major dilemma revolves about the type of soil present on the site. Structures built on soils that possess weak engineering properties are generally prone to foundation problems, for instance, the clayey soil which is not a good scenario in any construction works. Structure built under this condition experiences failure in the foundation due to low bearing capacity and shear strength. [1-3]

Clay mineral such as Smectite which is composed of Montmorillonite and Bentonite, makes the soil shrink or swell making it an expansive soil. When this type of soil is subjected to an increase in moisture content, swells, and shrinks when water escaped from it. [3-4] This soil is considered problematic because it tends to lose its strength when there is a significant change in its moisture content. When such soil expand, cracks on structures such as building foundations, roadways, and bridges that was built on it may occur, as well as pipes buried within it may be misaligned, causing leaks and adverse effect to series of pipe systems. [5]

In order to improve the properties of expansive soil, stabilizing the soil is necessary; this can be done through Chemical Stabilization. The most common Chemical Stabilizer is lime. Application of this material to expansive soil is proven to reduce the swelling and shrinkage capacity of soil, thus improving the properties of the soil. Commercially available lime is mostly made up of Calcium Carbonate and as the world continues to seek for a more economical soil stabilizer, Mussel Shell, which is composed of 95-99% Calcium Carbonate, arises as a possible soil stabilizer. [6].

METHODOLOGY

Researh Design

This study takes on the experimental method in determining the effects of pulverized mussel shell in the properties of expansive soil. The foresighted method according to key is suitable in a research study that intends to maintain control over all factors that may affect the result of an experiment. By adapting this method, the researchers determined what factors are to be controlled and what are to be manipulated in this study and attempt to determine what may occur. The problems in this research study were answered by depending largely on the collection of data from the series of laboratory test through which were measures of the effects of pulverized mussel shell in the properties of expansive soil.

Materials

Mussel Shell

The Mussel Shells were collected from a mussel shell product supplier from Bacoor, Cavite and were pulverized to obtain a particle size of not greater than the no. 200 sieve (0.075-mm opening).

Expansive Soil

The expansive soil was mapped out through the aid of soil map and soil survey from the Bureau of Soil and the soil was collected from Taytay, Rizal. A depth of 0.5 meter from the natural grade line was excavated before gathering the soil sample.

Preparation of Raw Materials

The Mussel Shell was collected from mussel shell product supplier from Bacoor, Cavite. It was cleaned to remove any organic matter from the shell. It was also washed with water and detergent to remove any unpleasant smell from the mussel flesh. The mussel shell was then air-dried and prepared for crushing. Safety equipment was used by the researchers such as safety goggles, mask, gloves, etc. in crushing the mussel shell.

The obtained pulverized mussel shell undergoes 2 stages of crushing. On the first stage, the shell was crushed by the use of roller compactor in order to obtain small particles sizes. The gathered crushed particles proceeded to the second stage of crushing with the use of willey-mill to produce a smaller particle sizes that passed through the #200 sieve. Shells that passed through sieve no. 200 (0.075-mm opening) were used in the study. After pulverizing the mussel shell, it was then incorporated to the soil, 0%, 3%, 6%, and 9% by weight and laboratory tests were performed.

Laboratory Tests

Physical Properties

To determine the physical properties of the soil samples laboratory tests for Moisture Content; ASTM D2216 – 10 Standard Test Method for Laboratory Determination of Water (Moisture) Content of Soil and Rock by Mass, Particle Size; ASTM D422 – 63 (Reapproved 2007) Standard Test Method for Particle-Size Analysis of Soils and Specific Gravity; ASTM D854-10 Standard Test Methods for Specific Gravity of Soil Solids by Water and Soil Classification; ASTM D2487 Practice for Classification of Soils for Engineering Purposes (Unified Soil Classification System) were conducted.

Index Properties

To determine the index properties of the soil samples laboratory tests for Plastic and Liquid Limit; ASTM D4318 – 00 Standard Test Method for Liquid Limit, Plastic Limit and Plasticity Index of Soils and Shrinkage Limit; ASTM D4943-02- Standard Test Method for Shrinkage Factors of Soils by the Wax Method were conducted.

Mechanical Properties

To determine the mechanical property of the soil samples laboratory tests for Shear Strength; ASTM D2850 – 03a Standard Test Method for Unconsolidated – Undrained Triaxial Compression Test on Cohesive Soil was conducted.

DATA AND RESULTS

Physical Properties

Soil Classification

In the Classification of Soils, the values of $D_{60,}$ $D_{30,}$ $D_{10,}$ Cu and Cc were computed. The values of liquid limit, plastic limit and plasticity index of the control soil are used to classify the soil. The coarse fraction is 78.158% which is greater than 50 % which means the soil is coarse grained. The gravel fraction is 1.354% which is lesser than 50 % which means the soil is sand. The A line is computed to be 40.384 so the plasticity index plots above the A line. Based from the Unified Soil Classification System, the soil sample is classified with a group name of Clayey Sand with a group symbol of SC. With the value of plasticity index and percent finer of 0.02 mm, the clay activity which was computed to be 6.025 this falls under the smectite category. The clay minerals composed in the soil is mostly smectite which is either montmorillonite or bentonite which are expansive clay minerals.

Particle Size Distribution

Table 1 presents the result of the particle size distribution for coarse grain soils. A total of 798.59 g of soil was tested. The sieve numbers used were 4, 10, 40 and 200 with sieve openings of 4.75 mm, 2.00 mm, 0.425 mm, and 0.075 mm respectively. The percent passing in #4 sieve is 98.646 %, 83.429 % in #10 sieve, 47.457% in #40 sieve and 15.078% in #200 sieve. The highest amount of soil was retained in sieve #40. From this test, the soil is mainly sand.

Table 1. Results of Mechanical Sieve Analysis

Sieve number	Mass of soil (g)	Cumulative mass of soil passing (g)	Cumulative mass of soil retained (g)	Percent passing (%)
4	10.81	787.78	10.81	98.646
10	118.33	669.45	129.14	83.829
40	296.77	372.68	425.91	46.667
200	198.25	174.43	624.16	21.842
PAN	174.43	0	798.59	0
Total	798.59			

Table 2 shows the result of hydrometer analysis for the clay particles contained in the expansive soil. A total of 50 g of soil that passed #200 sieve was tested. The hydrometer is read at 2 minutes, 5 minutes, 15 minutes, 30 minutes, 60 minutes, 250 minutes and 1440 minutes. The hydrometer readings are 355, 33, 31, 29, 27, 24 and 22 respectively.

Table 2. Results of Hydrometer Analysis

Time (min)	R	L (cm)	D (m)	P (%)	P' (%)
2	35	10.595	0.03116	13.741	62.912
5	33	10.921	0.02001	12.852	58.840
15	31	11.247	0.01172	11.962	54.768
30	29	11.573	0.00841	11.073	50.696
60	27	11.899	0.00603	10.184	46.624
250	24	12.388	0.00301	8.863	40.576
1440	22	12.714	0.00127	7.96	36.444

From table 2, The diameter of soil particles at every time are computed and they are 0.03116 mm, 0.02001 mm, 0.01172 mm, 0.00841 mm, 0.00603 mm, 0.00301 mm and 0.00127 mm respectively. The percent passing with respect to every diameter is 62.912 %, 58.840%, 54.768%, 50.696%, 46.624%, 40.576% and 36.444%. The percent passing with respect to the percent of #200 sieve are 13.741%, 12.852%, 11.962%, 11.073%, 10.184%, 8.863% and 7.96% respectively. By interpolation, the percent finer than 0.002 mm is 8.338%.

Moisture Content

The control specimen obtained the highest moisture content of 53.438% while the soil with 9% pulverized mussel shell has the lowest moisture content of 50.049%. With these, the moisture content of the soil decreases as the amount of pulverized mussel shell increases. When a stabilizer is added, flocculation-agglomeration causes the clay particles to clump together to form large particles resulting to decrease in the surface area which leads to the decrease in the moisture content.

Specific Gravity

In Figure 1 the results showed that the soil alone (control sample – serves as a basis for comparison) gained lower specific gravity than of those with pulverized mussel shell. The control sample has 2.56 specific gravity while the specific gravity of soil solids with 3%, 6%, and 9% ranges from 2.6 to 2.67. Both values of Control and Variable samples fall under the category of clay soils. The increase in specific gravity upon the addition of pulverized mussel shell means a decrease in organic content. According to (Huang,P., et.al), soils with high organic content have a specific gravity ranging from 1.0 to 2.0, and soils with high mineral content have a specific gravity of greater than 2.0. From the results obtained, both Control and Variable Soils have specific gravity of greater than 2.0, which means they have high mineral content.

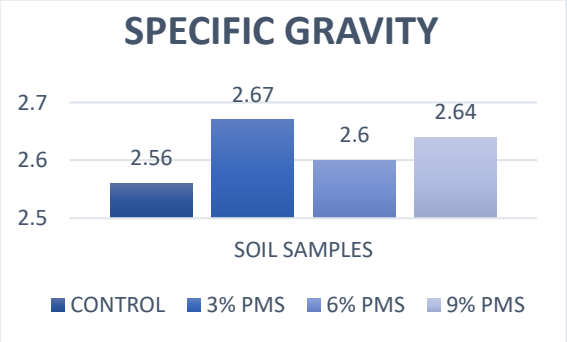

Figure 1. Specific Gravities of Soil Samples

Index Properties

Table 3 presents the summary of results for the Liquid Limit, Plastic Limit, Plasticity Index and Shrinkage Limit for the control sample, the 3%, 6% and 9% pulverized mussel shell

Table 3. Summary of Results of Liquid Limit, Plastic Limit, Plasticity Index, Shrinkage Limit

Index Property	Control Soil	3%	6%	9%
Liquid Limit (%)	75.32	64.17	59.29	53.31
Plastic Limit (%)	25.08	36.97	37.52	38.77
Plasticity Index (%)	50.24	27.2	21.77	14.54
Shrinkage Limit (%)	11.4	15.08	22.45	24
Plasticity	Very High	High	High	Medium

Based on Table 3, the results showed that the control soil has a higher value of liquid limit than those of soil with additional mussel shell and further addition of mussel shell results to a decrease in the value of the liquid limit. The highest liquid limit value was obtained from the control soil and the lowest liquid limit value was obtained from the soil with 9%

pulverized mussel shell. Soils with liquid limit higher than 50 usually have higher inherent swelling capacity and all soil samples fall under this condition.

Addition of mussel shell on the soil gave a higher value of plastic limit than of the control. As the pulverized mussel shell increase, the obtained value of plastic limit increased as well. The highest plastic limit was obtained upon the addition of 9% pulverized mussel shell to the soil with 38.77% plastic limit and the lowest value was obtained on the control soil with 25.08% plastic limit. The plastic limit of soil with 3%, 6%, and 9% have almost the same values as of each other.

The plasticity index of the soil alone has the highest value of plasticity index among the soil with pulverized mussel shell. The plasticity index decreased as the pulverized mussel shell was increased. The value of control soil with 50.24% plasticity index falls under soil with very high plasticity, and upon the addition of 3% and 6% pulverized mussel shell, the soil falls under the category of high plasticity. The addition of 9% pulverized mussel shell made the soil to fall under the category of medium plasticity.

The control soil has the lowest shrinkage limit while the soil with 9% pulverized mussel shell has the highest shrinkage limit. Based from the results, the shrinkage limit of the soil increases when the amount of the pulverized mussel shell increases. Flocculation-agglomeration produces a change in texture of clay soils. The clay particles tend to clump together to form a larger particles, thereby decreasing in liquid limit, increasing the plastic limit, decreasing the plasticity index and increasing the shrinkage limit of soils.

Mechanical Property

Figure 2 presents the undrained shear strength of the soil with 3%, 6%, and 9% pulverized mussel.

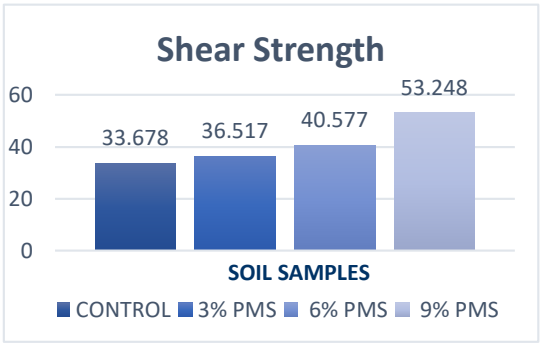

Figure 2. Undrained Shear Strength of Soil

The undrained shear strengths of the soil samples were computed to be 33.678 kpa, 36.517 kpa, 40.577 kpa and 53.248 kpa respectively. The results showed that addition of Pulverized mussel shell to the expansive soil increased its shear strength.

Resulting Undrained shear strength can be used used to calculate the unconfined compression strength which is used to classify the consistency of the soil. Table 4 shows the equivalent values of Unconfined Compression Strength of the obtained Unconsolidated Undrained Strength. Based from table 4, the expansive soil alone with 67.356 Kpa has a consistency of medium. Addition of 3% and 6% of pulverized mussel shell, with corresponding values of 73.034 Kpa and 81.154 Kpa, produced a consistency same as the expansive soil alone which is medium. On the other hand, addition of 9% pulverized mussel shell to the expansive soil improved its consistency from medium to stiff, with a value of 106.496 Kpa.

Table 4. Unconfined Compression Strength Value of Soil

Sample	c_u (KN/m^2)	q_u (KN/m^2)	Consistency
Control	33.678	67.356	Medium
3% PMS	36.517	73.034	Medium
6% PMS	40.577	81.154	Medium
9% PMS	53.248	106.496	Stiff

CONCLUSIONS

The study found out the effects of pulverized mussel shell on the properties of expansive soil. Based on the findings, it can be concluded that the moisture content of the soil decreased as the amount of pulverized mussel shell increased. It can be deduced that the specific gravity of expansive soil increased upon the addition of pulverized mussel shell. After the addition of pulverized mussel shell, the soil's specific gravity still falls under the average range of values of specific gravities for soils.

When pulverized mussel shell is mixed with the expansive soil, the liquid limit decreases while the plastic limit increases which results to the decrease in plasticity index. The plasticity index of expansive soil alone is classified to be very high plasticity and the addition of 9% pulverized mussel shell improved its plasticity index to medium plasticity.

It can be concluded that the shrinkage limit of the expansive soil increased upon the addition of pulverized mussel shell therefore, decreasing the shrink swell capacity of the expansive soil.

The addition of pulverized mussel shell improved the shear strength of the soil and the addition of 9% pulverized mussel shell yielded the most significant change. By the addition of 9% pulverized mussel shell, the shear strength of the expansive soil increased by 58.109%. The expansive soil's consistency improved from medium to stiff with the addition of 9% pulverized mussel shell.

RECOMMENDATIONS

From the results and experiences gained in this study, the following recommendations are drawn:

1. Unconsolidated Undrained Test is the only test that is used. It is recommended to conduct another test like unconfined compression test for further details of the strength capability of pulverized mussel shell as an additive for soil stabilization.

2. The percentages by weight of pulverized mussel shell used were 3%, 6% and 9%. The shear strength's trend up to 9% is still increasing. It is recommended to test another samples with pulverized mussel shell greater than 9% to determine whether the 9% addition is the percentage of pulverized mussel shell that yields the optimum increase in shear strength of the expansive soil.

ACKNOWLEDGMENTS

The researchers would like to acknowledge the support of the people who made this research possible.

They would like to express their deepest gratitude to their academic advisers, Engr. Crispin S. Lictaoa, and Dr. Ma. Cecilia M. Marcos, for their patience, vast knowledge, and commitment in helping them throughout the course of the research study.

They would also like to express their sincere gratitude to Mr. Mar Mercado for his time, patience, guidance and dedication in helping the researchers in their series of tests

Above all, they would like to express their sincerest gratitude to God, the Father, who provided the things and people that they were thankful for. For with Him, all things are possible.

ABSTRACT

In the deep mixing improvement method, soil-cement columns are installed in to an invisible ground, therefore it is impossible to visually confirm the circumstance of the constructions process. As the results, the inadequacy of construction data management and quality control of the constructed soil-cement columns may happen following re-construction of the columns, and structures failures/damages in some cases. By incorporating the information and communication technology (ICT), authors have invented and developed a system to visualize the construction process of the deep mixing work in real-time, namely "3D Pile Viewer". This system consists of two functions that are the positioning guidance and the visualization of the construction information. The former has been developed by using the combination of the global navigation satellite system (GNSS) or the total station (TS), and the tilt sensor. The latter is to create three-dimensional model of all information during construction such as depth, electrical current value, amount of slurry, rotation speeds, etc., then sharing via internet. By introducing the newly developed system to various actual construction sites Japan and oversea, the practical performance of the system and its advantages have been confirmed.

Keywords: Deep mixing method, Soil-cement column, Information communication technology, Construction information modelling, 3D Pile Viewer.

INTRODUCTION

Developing new infrastructure on a soft ground often faces many difficulties. To ensure the stability of the structure, reduce the large settlement, and mitigate liquefaction, the soft ground is normally required to strengthen. Among numerous soft ground improvement methods have been developed and applied worldwide, the cement deep mixing method that is a deep in-situ soil stabilization technique using cement as a binder is one of the most effective method. This method was mainly developed and practiced in Japan and Nordic countries until the end of the 1980s, but became very popular over the world recently [1].

Generally, the method consists of a deep mixing machine and a binder plant. The deep mixing machine is composed of one or several mixing shafts with a motor and gear box are installed at the top, and a set of mixing blades are mounted at the bottom. As for supplying cement slurry, a swivel joint is installed at the top of the shaft(s) for slurry supply and set of outlets is made at the bottom for binder injection. A mixing execution procedure ordinarily includes penetration of the mixing blades into the ground while rotating the mixing shaft(s) until designated depth, and then withdrawal of the mixing blades to the ground surface, the slurry could be injected to the ground during the penetration stage or withdrawal stage, or both. After one execution, a column shaped of treated soil-cement is constructed in the invisible ground. When implementing the construction work, the stabilized soil-cement columns must be installed to satisfy both geometric plan including location, depth, verticality, and the quality specified in the design. In order to ensure that operational parameters such as penetration and withdrawal speeds, rotational speed, amount of slurry and current value must be monitored and displayed continuously in control room and cabinet of machine during soil-cement installation [1]. However, those quality control parameters could be evaluated only after finishing working day and limited inside the construction area. If the construction parameters are properly recognized, displayed, shared, and evaluated in real time among related parties, then get the feedback immediately, the failure of column installation could be early fixed and prevented from repetition. Furthermore, a great amount of labor is required to collect the necessary information from a huge amount of numerical data to properly evaluate the construction process and then make the daily report.

On the other hand, the application of information and communication technology (ICT) become very popular recently in the construction industry. There are techniques to input the design data into the construction machines, then using these data for guidance or controlling the machines have been developed and applied in the practices [2], [3]. Additionally, the Japanese Ministry of Land, Infrastructure, Transportation and Tourism (MLIT)

has been positioned "1st for the productivity revolution" from 2016 onward, and has begun efforts to promote "i-Construction" to improve the productivity by incorporating ICT into all processes of construction including investigation, survey, design, construction, inspection, maintenance and so on [4]. In which, the ground improvement work by the deep mixing method is not out of the scope.

Based on the above-mentioned background, we have invented and developed a system called "3D Pile Viewer" [5] that is able to visualize all operational control parameters in three dimensions and shares real-time information among related parties even during the execution. This paper will introduce this system and its practical application on construction sites.

CONSTRUCTION INFORMATION VISUALIZATION SYSTEM (3D PILE VIEWER)

As shown in figure 1, the system has two main functions that are (1) positioning guidance function and the (2) data visualization function.

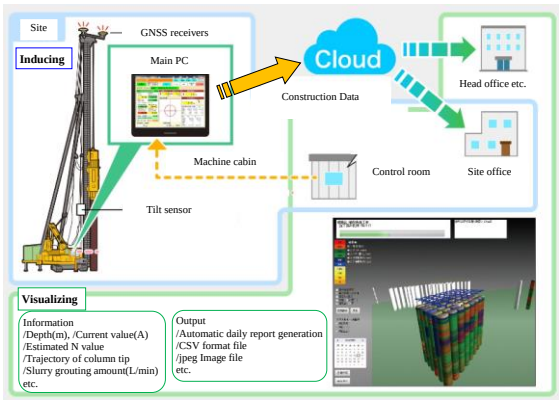

Fig. 1 Configuration of the system

Positioning guidance function

The function is configured by using global navigation satellite system (GNSS) or total station (TS), and tilt sensor measurement data to ensure the soil-cement columns are installed correctly as per the geometric plan as in the design. At first, three-dimensional designed data of the columns are registered into the system, then positioning work of every column is guided by GNSS or TS, and its verticality is controlled by tilt sensor during the construction process. Fig.2 shows the deep mixing machine attached with the instruments, two GNSS receivers are installed at the top and one tilt sensor (2 axes) is set at the bottom of the leader, and one computer and data communication antenna are mounted in cabin. In the computer monitor, the current position of casing rod(s) or mixing shaft(s) is displayed in comparison with the pre-registered designated position, and the other operational parameters are also presented (Fig. 3). The positioning guidance function allows to avoid geometric miss-installation of the treated soil-cement columns often caused by human errors. Moreover, the verticality of the column also is monitored instantaneously by obtaining measure data of the tilt sensor.

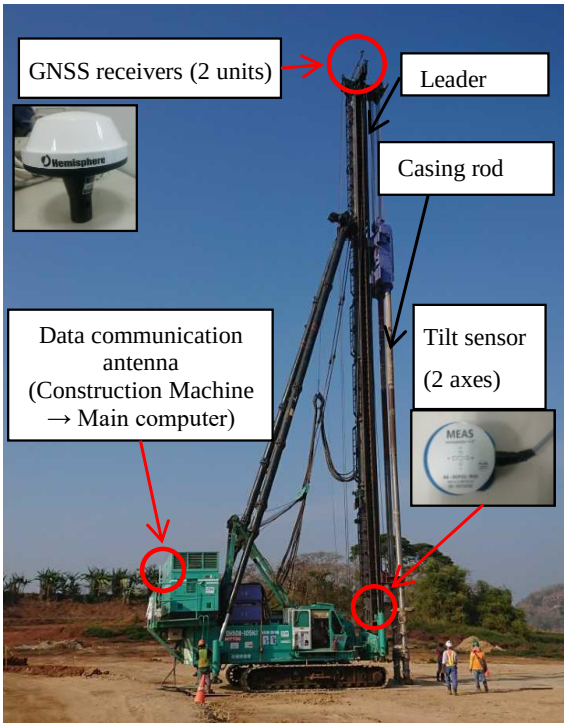

Fig. 2 Construction machine with attached instruments

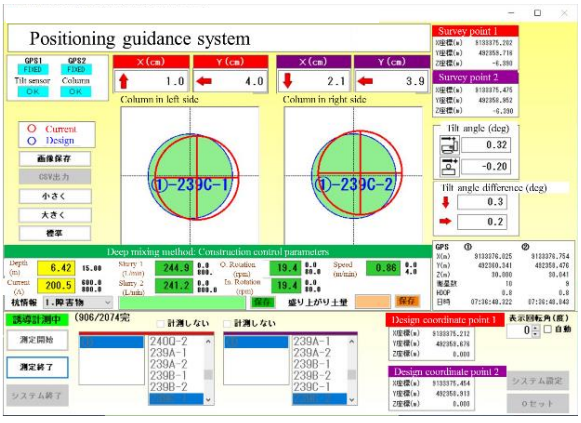

Fig. 3 Monitor screen in the machine cabin

Information visualization function

The second function of the system allows three-dimensional visualization and immediately evaluation by seeing the kinetic measurement

construction management data such as penetration/withdrawal depth, velocity, discharge amount of slurry, rotation speed of mixing blades, current value generating in the motor, ground properties, etc. In the meantime, the information is uploaded in to a Cloud from the main computer set up in the control room via internet. Consequently, all the construction measuring information are shared in real time among the parties related to the project. An example of the visualization screen is shown in figure 4, in which, the soil-cement columns are displayed in three-dimension on the left side. All the columns have been geometrically arranged conforming to the designed layout, the measured information of the columns have been constructed and the done part of the ongoing column are categorized and represented in a range of color. The columns and a part of column that are in white color have not been constructed. On the right side, all the distribution with depth of the recorded data of any target column are plotted in corresponding graph. By incorporating the ICT such as the Cloud and internet services, the construction situation and the changing of the ground properties are clearly visualized and evaluated in real-time; therefore, it is able to provide instruction then obtain feedback instantly during the construction process.

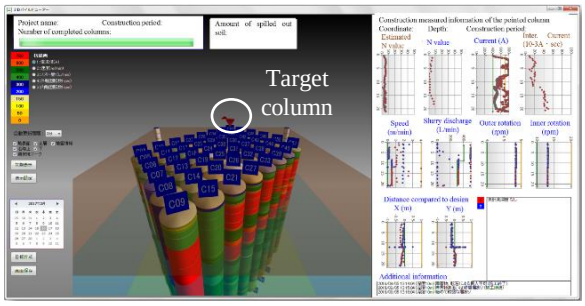

Fig. 4 The screen representing the visualization function of the system

APPLICATION AT THE CONSTRUCTION SITES

The above construction information visualization system has been introduced in several real construction projects in Japan, and oversea. The practical performance of the system is discussed here.

Katagishi high coastal embankment

As a restoration work after the Great East Japan Earthquake and Tsunami in 2011, an embankment of 800m long and 14.5m high (figure 5) is being built in Katagishi coastal zone in Iwate prefecture to prevent from the similar level of tsunami in the future [6]. A soft ground consisting of lose sand, and soft to medium silty clay is existing underneath the embankment.

Fig. 5 Location of the embankment

In figure 6, a complex ground improvement work including sand drain method and cement deep mixing method have been illustrated. The sand drain used at the center part to accelerate the consolidation settlement. The cement deep mixing method is performed at the embankment edges to increase stability, against liquefaction and to reduce settlement amount. In the design, the soil-cement columns with diameter of 2.0m are installed until maximum of 33.6m below the ground surface. The designed strength of the treatment soil-cement columns is different between sea side and land side. Moreover, the soil-cement columns were divided in to three patterns, the 1st pattern is a wall block type of soil column arrangement with 20cm overlapping up to the end of the upper lose sand layer as for liquefaction countermeasure, the 2nd pattern containing the columns are installed until the end of the upper silty clay layer against instability, and the tip of columns belonging to the 3rd pattern is set to reach the bearing layer to reduce settlement. Fig. 7 illustrates the geometric arrangement of soil-cement columns.

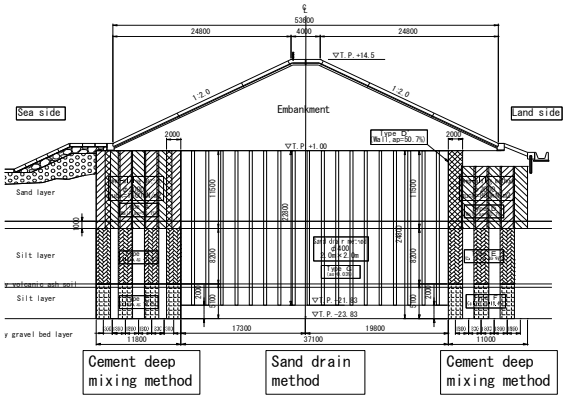

Fig. 6 Typical cross-section of embankment

To conform to the above-mentioned design specification, Deep Cement Stabilization method (DCS) has been selected. The DCS method has advantages in construction of large diameter and

extreme depth, as well as suitable for the ground containing sand and gravel layers [6].

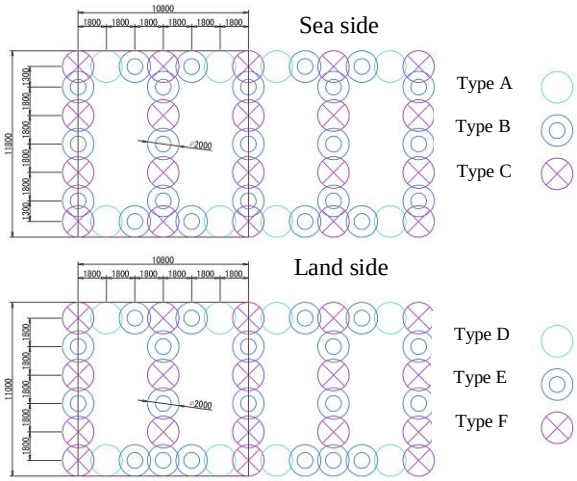

Fig. 7 Layout of soil-cement columns

As previously mentioned, the deep mixing work is quite complicated in this project. It is a challenge for controlling the quality during construction, therefore, the newly developed construction information visualization system has been introduced. Fig. 8 shows the captured screen of the system presenting the construction information of deep mixing work in this project. Since the designed layout and depth of all soil-columns were registered into the system in advance, so it is easy to guide the soil-cement columns to install correctly, and to be ensure overlapping between the columns have been made. Besides that, the soil-cement columns have been constructed in high quality without any mistake relating to the designed strength because all construction parameters are monitored in real-time allowing the engineers to control, evaluate, and give further instruction instantly during construction stage.

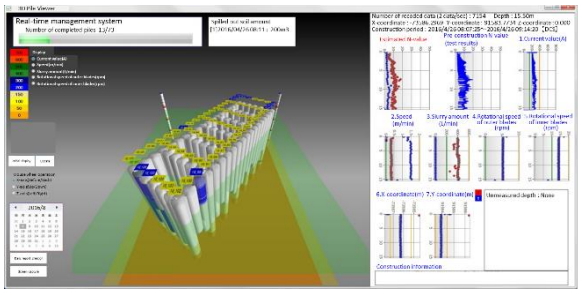

Fig. 8 The screen of visualization system applied in the Katagishi embankment.

Yokokan Minani-Sakae Interchange and Junction

This is a construction project of substructures of Yokokan Minani-Sakae Interchange (IC) and Junction (JCT) on the National Route No. 468 (figure 9). As showing in figure 10, the structure foundation is placed on a very soft ground containing a high-water content peaty soil with N-value of 0 from the ground surface to 7.0m depth, under that layer is the soft silt layer up to 18.0m depth with N-value range from 0 to 2, and below that is mudstone with N-value lager than 50 considering as the bearing stratum.

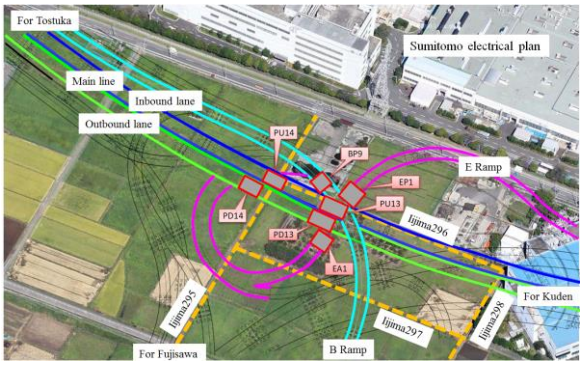

Fig. 9 Plan view of the project.

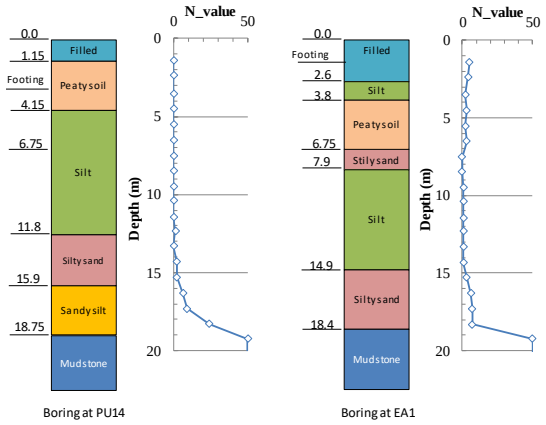

Fig. 10 Boring investigation results

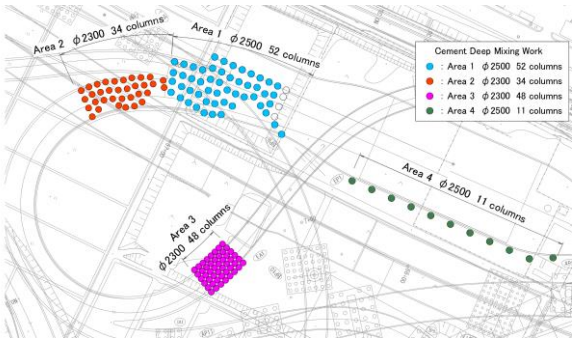

Fig. 11 The ground improvement plan

In order to increase the stability and reduce the consolidation settlement of the ground under the embankment of the IC and ramp sections, the ground

improvement by cement deep mixing (DCS method) was adopted. As showing in figure 11 and table 1, the cement deep mixing work was designed to perform in four areas with different geometric arrangement, diameter, design strength, length, and number of soil-cement columns. And the overlap among the columns was particularly designed in the area 3. In the design, the soil-columns are required to install to the designate depth or approach the Mudstone stratum. The penetration depth where the current value of motor is over 700A, or speed of the penetration is 10cm/minute is judged as the bearing stratum.

Table 1 Quantity and specification of soil-columns

Location	Diameter (mm)	Design strength (kN/m^2)	Length (m)	No. of columns
Area 1	2500	600	18.5	52
Area 2	2300	600	17.7	34
Area 3	2300	1000	18.7	48
Area 4	2500	600	19.5	11
Total				145

To comply with the design and the judgment specification, it would be not easy and takes time and effort to manage quality during construction process when applying the conventional construction management method, because the construction process is required to control uninterruptedly with high accuracy. For this reason, the new development construction information visualization system was introduced to overcome the difficulty as well as enhance the construction control more reliably and efficiently. The application of the system, for instance, is presented in figure 12. It is clearly seen that the deep mixing work had finished in the area 3, is ongoing in the area 4, and have not started in the area 2 and 1 yet. In addition, when the measurement current value data is chosen to illustrate in the three-dimensional screen, the parts having current value larger than 700A occur not only at the bottom but also in the upper parts of many columns. According to the specification, the construction of those columns might be ended shallowly. However, when that abnormal high current value was shown in the construction information visualization system the previous soil investigation data and others related information are checked immediately. After that, the inhomogeneous ground strata were confirmed, then resulted in continuation of the improvement works in those columns until the designed depth.

In conjunction with visualization of the construction information, a formula converts current value measured during construction to the N-value was included in the system to instantaneously estimate the N-value of the ground at the point where the soil-cement column installation was implemented. The conversion formula is established by doing statistical analysis on the soil investigation boring data and the construction information of the test column near the boring location. The conversion formula has been validated for the ground consisting of peaty, clayey, and silty soil [5], [7].

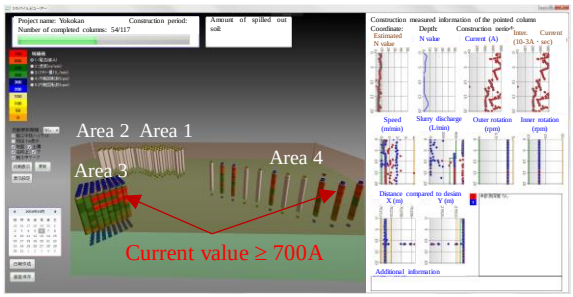

Fig. 12 The application of the visualization system in Yokokan Minani-Sakae.

Through this project, the accuracy of the system was confirmed by comparison with the conventional management method, the geometrical installation deviation due to human error could be prevented, and the construction process could be smoothly carried out providing that all the quality control information is visible in real-time. On the other hand, for the 1st time it came into notice that the data communication did not operate normally due to orientation of the construction machine and the antenna. The shortcoming was addressed properly confirming the alignment in the setting manual.

Wonogiri Multi-Purpose Dam

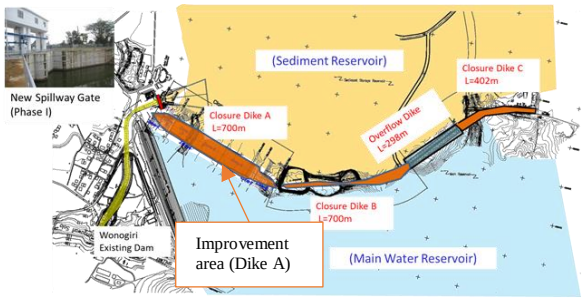

Fig. 13 Outline of closure dikes in Wonogiri dam.

Recently, the construction of closure dikes is being implemented in Wonogiri multi-purpose dam in Center Java, Indonesia with the aim of reducing sedimentation that are dramatically increasing every year and might cause serious effects on the intake. The outline of the project is presented in figure 13, the closure dikes are constructed to prevent sediments inflow from the Kudwan River into the Wonogiri dam reservoir and to discharge the sediment to the downstream side via the new flushing spillway. The top elevation and the height of closure dikes are

EL+140.0m and approximately 7.0m, respectively. Since the foundation of the closure dike A mainly consists of very soft to soft clay, silty clay sediment deposited in the dam reservoir, the ground improvement by the cement deep mixing method (CDM) is applied to secure stability against sliding and consolidation settlement. The cement deep mixing machine for on-land works having two mixing shafts is adopted in this project.

The layout of the soil-cement columns and longitudinal profile of closure dike A are shown in figure 14. The improvement ratio of 32.0% was required resulting in more than 5000 soil-cement columns are necessary to be installed. Because the depth of soft clay layer varies from 0.0 m to 24.0m in longitudinal section, the largest depth of soft clay layer is at the center of the closure dike A, and it reduces toward both left and right sides. Therefore, the improvement depth was designed from 6.0m to 24.0m corresponding to the changing of the soil profile. The typical cross-section of the deep mixing soil improvement is shown in figure 15.

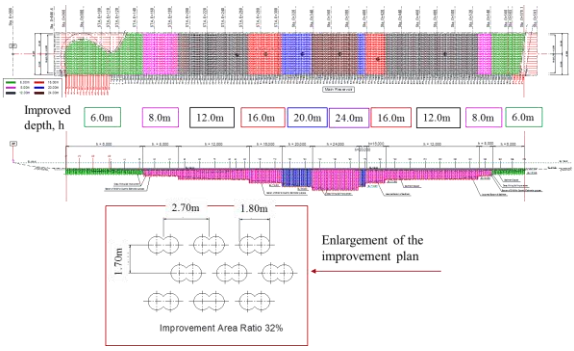

Fig. 14 Plan view and longitudinal profile of the soil improvement work in closure dike A.

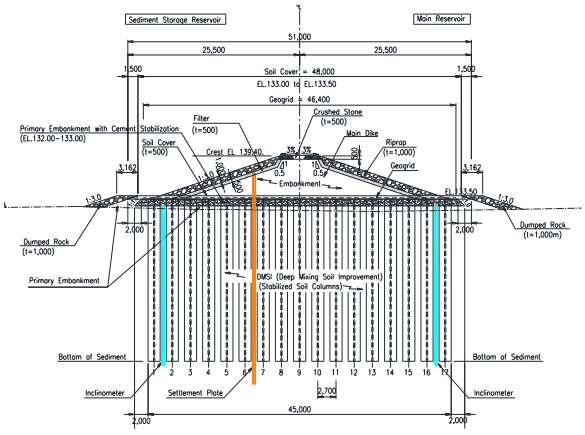

Fig. 15 Typical cross-section of closure dike A

In addition to the ordinary operational parameters, the soil-cement column finished depth that is embedded 0.5m into the bearing layer must be strictly controlled in the construction. Generally, the bearing layer is specified when the current value is larger than 300A continuously for at least one minute. To deal with that high criterion, the newly developed three-dimensional construction information visualization system is introduced. Fig. 16 is an example of the capture screen of the system applied in the project, in which, only the soil-cement columns belonging to the section 267 are chosen to display on the screen. Although all the columns in the section were designed to stop at the same depth, the different finished depth of each column was constructed actually in reality is clearly recorded and presented. Moreover, abnormal increasing of electrical current value at middle of 10 columns in the right side was recognized while it did not occur in the left. If the construction visualization system had not been adopted, those columns in the right would have been judged to end at the middle. However, similar to the Yokokan Minami-Sakae IC and JTC, the inhomogeneous geological condition was evaluated immediately, and then the construction process continued until reaching the real bearing stratum. The additional two borings positioned in each side were carried out instantly to clarify the abnormality. The boring data as illustrated in figure 17 indicates that there is a thin layer of dense silty sand to gravely sand with N-value of 30 exists at 5.0 to 7.0m deep.

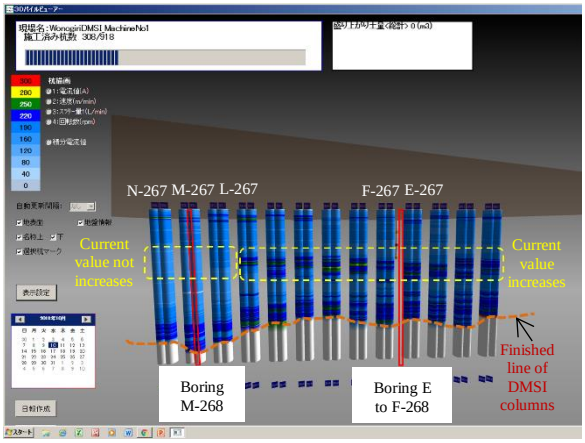

Fig. 16 The screen capture of the visualization system

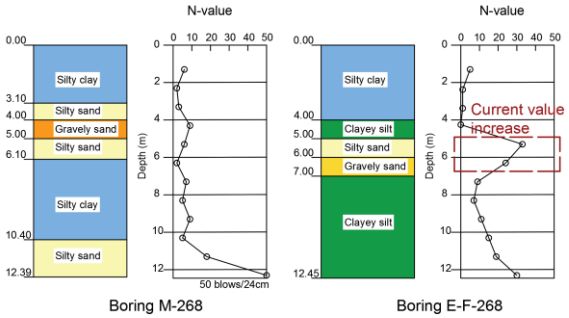

Fig. 17 Boring data at the section 267~268

The advantage of the construction information visualization system incorporating ICT could be confirmed successfully through this project. The construction progress and change in bearing layer depth were easy visualized and shared among the involved parties in real-time via internet and Cloud service. On the contrary, the issue in the operation of the system and downloading data due to huge number of soil-cement columns and the internet environment is not fast enough as in Japan was understood. Additionally, it is barrier to local staffs operating the system because only Japanese language is available at the current state.

CONCLUSIONS

By actively introducing ICT to develope the three dimensional visualization system for the deep mixing method, then applying in the real construction sites, the following advantages can be acquired.

1. The quality magament parameters/information obtaining during the construction process is visually displayed in three dimension and sharing in real time making it more easy to understand the construction situation and the alteration of the original ground condition to compare with conventional magament method.

2. It is expected that accurancy and efficiency of the construction management will improve. The human errors can be minimized and amount of labor for making daily report has been reduced drastically.

3. It raises the awareness of the contractor regarding the quality control and management, results in providing highly reliable products.

However, some shortcomings still remains in the application at the actual construction sites. For example, the system needs to improve to operate smoothly when large amount of treated columns are registered, and operating in the weak internet enviroment. Futhermore, the location of the tip of the column is calculated using measurment data of the tilt sensors attaching on the leader with the assumption that the leader and the mixing shaft(s) are integrated based on the position leader on the ground surface. In reality, there is a certain play between the two, and as the depth increases, there is a possibility that the deviation from the measured value increases.

ABSTRACT

The embankment is settled by different reasons. But the settlement hardly occurs in structures supported by pile foundation such as an abutment, culvert. Such a settlement difference causes a cavity in the lower part of the bottom of the structure. In order to prevent problems caused by cavity under the structure supported by pile foundation, soil flow protector (briefly called 'FLP'), which can be easily installed on the side of a structure, was developed. In this study, a laboratory model tests were carried out to analyze the reduction effect of settlement with stiffness of the FLP. As a results of the behavior in the ground showed that the installation of the FLP reduced the settlement of the lateral ground and prevented the leakage of lateral ground soil into the cavity. The results of the laboratory model test showed that the settlement depending on the stiffness of the FLP was reduced by average 28.4 % in flexible and average 50.0 % in stiffness compared with non-reinforcement, indicating that the higher the stiffness of FLP, the more effective for settlement reduction. And the results of the photo-analysis of deformation due to stiffness showed that if the stiffness of the FLP is high enough, the passive earth pressure area is generated in the upper part, which will be advantageous for the stability.

Keywords: Cavity, Settlement, Soil flow protector, Stiffness, Laboratory model test

INTRODUCTION

The embankment is settled by a consolidated settlement over time, drying shrinkage due to soil drying, poor compaction during construction, soil compression due to overburden load. But the settlement hardly occurs in structures supported by pile foundation such as an abutment, culvert. Such a settlement difference causes a cavity in the lower part of the bottom of the structure. As a result, groundwater and soil are inflowed by the cavity generated in the lower part of the structure. And soil discharged from the lateral ground to the cavity accelerates the settlement of the lateral ground of the structure, resulting in a larger settlement.

For these problems, [1] confirmed that cavity occurred under the bottom of the structure due to poor compaction of the backfill material and also settlement of ground caused by compression, corrosion of the head of the pile foundation. They also indicated that the penetrated groundwater into the cavity is the reason of erosion of the ground. Furthermore, [2], [3] summarized the main causes and ranking of the each step. They mentioned that cavity is occurred due to the compressive embankment, short connection slab, defective backfill material. Additionally, it has been reported that the lateral expansion due to horizontal earth pressure [4], cavities created at the bottom of connecting slabs [5], and soil erosion incurred by water infiltration may lead to further issues.

In addition, [6] and [7] pointed to the consolidated settlement of the ground as a major cause of the differential movement of the bridge connection. And [8] observed the tendency of road surface settlement after opening the highway and analyzed that the small settlement difference in the connection section of the structure also causes inconvenience to the driving of the driver.

Until now, however, there are no measures to prevent problems caused by cavities in the lower part of the structure when designing and constructing at home and abroad. Therefore, after the occurrence of the problem, there is no clear solution except for temporary measures such as filling (grouting) or continuous paving overlay.

Therefore, in order to prevent problems caused by a cavity under the structure supported by the pile foundation, FLP, which can be easily installed on the side of a structure, was developed. The FLP is designed to produce similar downward movement as the settlement of the ground. Therefore, the stability against the lateral earth pressure is maintained even after the cavity occurred.

In this study, the laboratory model test was carried out to compare and analyze the settlement behavior according to FLP thickness, installation length. And analysis of the results showed that the reduction effect of the settlement was affected by the change of the stiffness of the FLP.

COUNTERMEASURES METHOD WITH CAVITY GENERATION

Case of cavity and differential movement

As shown in Fig. 1, groundwater is gathered and the head of the pile is damaged by the cavity in the lower part of the box structure. In addition, settlement of the lateral side of the structure and the difference in settlement of the connecting part pavement cause the differential movement. Such differential movement causes settlement and cracking of the pavement.

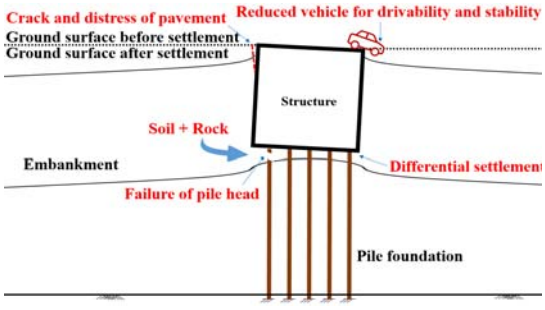
(a) Cavity generation

(b) Failure with cavity generation

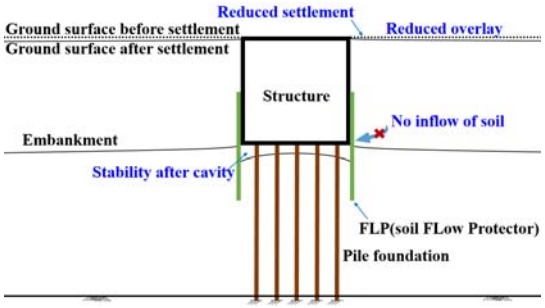
(c) Differential movement

Fig.1 Cavity generation and problems

Features of FLP



(a) Problems with cavity generation



(b) Countermeasures for cavity generation

Fig.2 A schematic diagram of problems and countermeasures method with cavity generation [9]

As shown in Fig. 2 (a), the problems caused by the cavity in the lower part of the structure include reduced vehicle drivability and stability due to cracks and damage of the pavement, damage of the pile head due to the inflow of soil into the lateral ground, and the differential settlement of the structure. As shown in Fig. 2 (b), the countermeasure against this is to reduce the settlement of the lateral ground even after the cavity occurs by installing FLP on the side of the structure and to secure the stability by preventing damage of the pile head caused by the soil introduced into the cavity.

LABORATORY INDOOR MODEL TEST

Equipment of tests

Plane strain model soil-tank

The plane strain soil box applied in this study is shown in Fig. 3. In order to satisfy the plane strain condition, a wall of the plane strain model soil-tank was formed with transparent acrylic with a thickness of 30 mm, and the device was constructed to prevent deformation by further reinforcing 280 mm x 380 mm spacing in width and height, respectively. A vibration motor capable of generating vibrations was installed in the lower part of the plane strain model soil-tank, and spring was installed to facilitate transmission of the generated vibration.

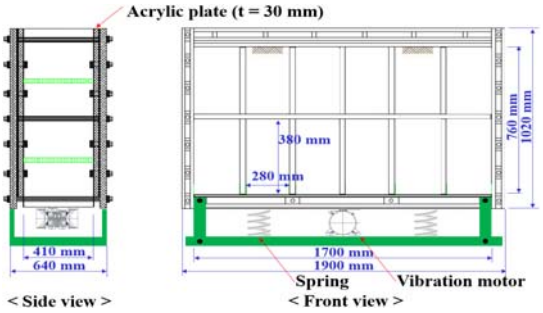


Fig.3 Side view and front view of plain strain soil tank

Dimension of model

As shown in Fig. 4, the dimensions of the box structure model are made of transparent acrylic with a thickness of 20 mm and its width x length x height are 408 mm x 350 mm x 340 mm, respectively. The actual structure is supported on a solid ground by pile foundation. In this study, however, it is fixed to the upper frame of the soil box to prevent settlement of the box structure by vibration. As shown in Fig. 5, an acrylic plate with a thickness of 3 mm (flexible) and 10 mm (stiff) were used for the FLP model and the horizontal length is 408 mm, 1 mm shorter on both sides to avoid friction with the width of the soil box (410 mm).

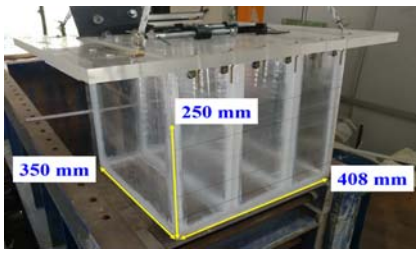

Fig.4 Test model of box structure

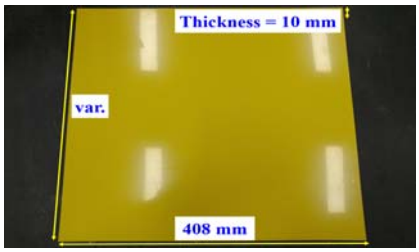
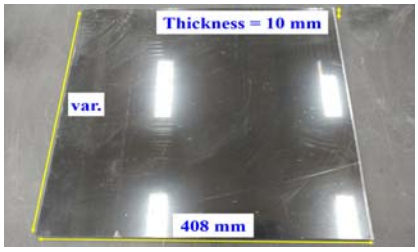


(a) Flexible



(b) Stiff

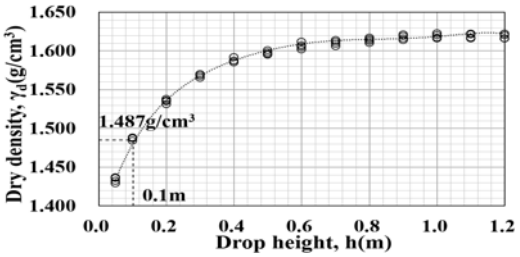
Fig.5 Test model of flexible and stiff FLP

Ground material

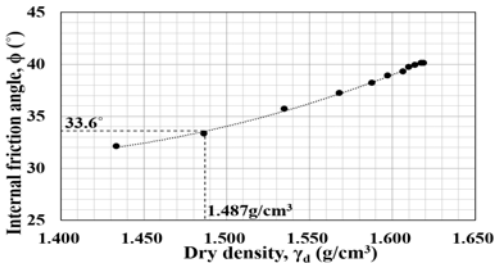
The ground material used when creating the ground is Jumun-jin standard sand and physical properties are shown in Table 1. Sandy soil such as Jumun-jin standard sand varies in density depending on the height of falling (Fig. 6(a)), and the mechanical properties also vary as the density changes (Fig. 6(b)), so the ground should be formed by keeping the density constant during the test. In this study, we used a sanding device to create with the ground with constant density with river sand method [10], [11], [12] at the falling height of 0.1 m, and the dry density at this time is 1.487 g / cm^3 on average.

Table 1 Physical characteristics of Jumun-jin standard sand

Description	Index	Property
Specific gravity	G_s	2.65
Water content	w_n (%)	0.9
Average particle size	D_{50}	0.580
Effective particle size	D_{10}	0.448
Uniformity coefficient	C_u	1.370
Coefficient of curvature	C_g	0.960



(a) Dry density relative to drop height



(b) Internal friction angle relative to dry density

Fig.6 Mechanical properties of Jumun-jin standard sand relative to drop height

Method of model tests

Considering the location where the box structure is installed, sand was installed up to the height where the bottom of the FLP was installed, then the FLP was installed and grease was applied between the wall of the soil box wall and the FLP. After that, sand was installed up to the height of the bottom of the box structure so that there is no difference in the earth pressure between the back surface and the front surface of the FLP, and then grease was applied in advance to the contact surface of the box structure and the soil inflow cut off, and a box structure was installed in order to prevent the penetration of sand and minimize friction.

In order to analyze the behavior of FLP due to the

settlement of the ground, the settlement was generated by force using a vibration motor. After the vibration occurred at each time, the settlement at regular intervals from the box structure was measured and averaged at the front, back and middle of the wall of the soil box. The experiment was terminated based on when the settlement due to vibration was almost converged. And Fig. 7 shows the installation of the box structure and FLP and the completion of ground creation.

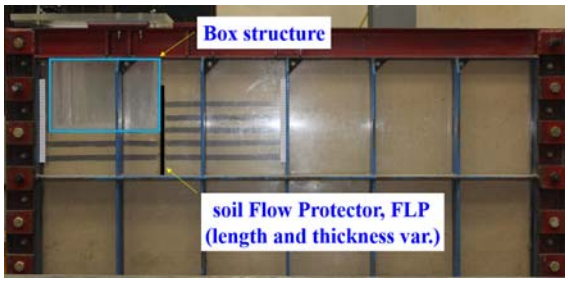


Fig.7 Front view of box structure and FLP after ground construction

Types of test

The tests were conducted under different installation conditions in order to check the effect of the FLP. The thickness of the FLP was divided into 3 mm, 10 mm and the installation length of the FLP was divided into 100 mm, 300 mm and 500 mm in order to analyze the behavior of the ground depending on the stiffness. Table 2 shows the types of model tests.

Table 2 Types of model test

Contents	Stiffness of FLP	Thickness of FLP (mm)	Length of FLP (mm)
Non	Non-reinforcement	-	-
S_100	Stiff	10	100
S_300			300
S_500			500
F_100	Flexible	3	100
F_300			300
F_500			500

Results of test

Fig. 8 shows the settlement of the lateral ground depending on 60 s, 120 s, 180 s, 360 s, 720 s and 1440 s, vibration time for each types of model test. The results show that the settlement tends to converge after 1440 s of vibration time, and the ground behavior was compared and analyzed based on the vibration time of 1440 s.

The settlement results for each types of model test are shown in Fig. 9.

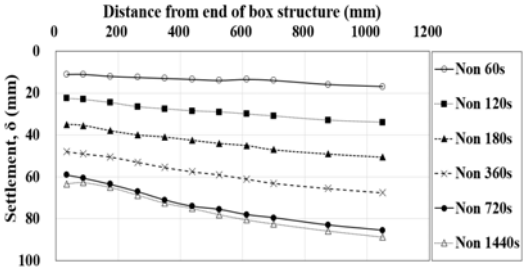

Fig.8 Settlement by vibration times

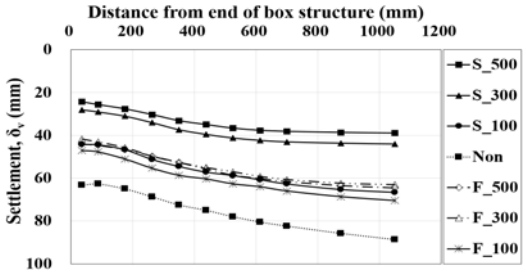

Fig.9 Settlement by types of model test (after 1440 s of vibration time)

ANALYSIS OF RESULTS

Ground behavior with installation

Table 3 Settlement with installation of FLP

Distance from end of box structure (mm)	Settlement		Ratio of Settlement S_300 / Non
	Non	S_300	
35.0	63.3	28.0	0.442
87.5	62.7	29.0	0.463
175.0	65.0	31.0	0.477
262.5	68.7	34.0	0.495
350.0	72.5	37.3	0.515
437.5	75.0	39.5	0.527
525.0	78.0	41.2	0.528

700.0	82.4	43.0	0.522
875.0	85.8	43.6	0.508
1050.0	88.7	44.0	0.496

In order to analyze the behavior of the ground according to the FLP installation, the settlement when the FLP is not installed (Non) and the FLP length is 300 mm (S_300) was shown in Table 3. The results show that, when the FLP is installed, the settlement was analyzed to be reduced by 44.2 ~ 52.8 % (50.0 % on average). As shown in Fig. 10(a), in the case of non-reinforcement, the inflow of soil into the cavity occurs as the ground sinks. Therefore, the installation of the FLP reduces the settlement of the lateral ground and prevents the leakage of lateral ground soil into the cavity.

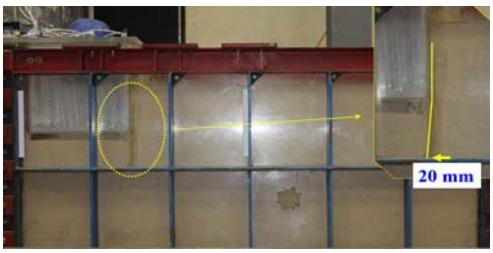
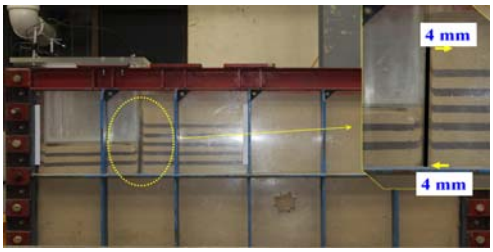
1050.0	88.7	63.1	44.0	0.711	0.496

In order to analyze the ground behavior according to the stiffness of the FLP, the thickness of the FLP was divided into 3 mm (F_300) and 10 mm (S_300) as shown in Table 4. As a result, the settlement was reduced by average 28.4 % in flexible and average 50.0 % in stiffness compared with non-reinforcement, indicating that the higher the stiffness of FLP, the more effective for settlement reduction. Fig. 11 shows the deformation after final settlement according to the stiffness of the FLP. It was found that the FLP displacement in a flexible case did not occur in the upper part, and displacement of about 20.0 mm occurred in the lower part. In the case of stiff, however, a displacement of about 4.0 mm occurred towards the back and the structure at the same time in the upper part and lower part of the FLP, respectively. Therefore, if the stiffness of the FLP is high enough, the passive earth pressure area is generated in the upper part, which is considered to be advantageous for the stability.



(a) F_300 (flexible)



(b) S_300 (stiff)

Fig.11 Deformation shape with stiffness of the FLP

Ground behavior with stiffness change by length

In order to analyze the ground behavior according to the difference of stiffness with the change of length of the FLP, the length of the FLP was divided into 100 mm, 300 mm and 500 mm with the stiffness, the results are shown in Table 5. In this case, if the length is changed, the flexural rigidity also changes. As a result, the settlement is decreased by average 25.7 %, average 50.0 % and average 55.6 % in the stiffness as the length is increased, and it is effective to decrease the settlement as the length increases. However, in ductility, average 20.9 %, average 28.4 % and average 27.0 % decrease in length is not effective in decreasing the settlement because the stiffness decreases with increasing length. Therefore, in order to reduce the settlement effectively, it is necessary to sufficiently secure the flexural rigidity according to the length.

CONCLUSION

In this study, a laboratory model tests were carried out to analyze the reduction effect of the settlement with the stiffness of the FLP. The results are as follow:

The results of the laboratory model test showed that the installation of the FLP reduced the settlement by 50.0 %. The results of the photo analysis of the behavior in the ground showed that the installation of

Table 5 Ratio of settlement with stiffness change by length

ABSTRACT

The Palu earthquake magnitude 7.4 on the 28th September 2018 has impacted a liquefaction process in several areas in Central Sulawesi. One of the areas affected by the disaster was Sibalaya, Sigi District. Liquefaction phenomena as an earthquake-induced effect in loose saturated soils is considered very dangerous for structures founded over such materials. The common practice for liquefaction potential assessment recommends geological survey and field testing such as more cost-effective method is the use of geophysical methods which are not destructive and faster. Regional geological mapping was carried out with a direct survey of the Sibalaya area affected by liquefaction. One of the geophysical methods that can find out the subsurface profile is resistivity method. This study aims to describe the soil resistivity in the Sibalaya area. The resistivity method used is 1D as many as 4 points in the direction of the direction of land shift. Mapping on the surface using UAV photogrammetry to determine the distance of shifting of the land. The resistivity method results found that the dominant lithology was sand with gravel and grit to a depth of 30 meters with average resistivity values ranging from 1.38 Ωm-6246 Ωm. Where the resistivity value of 1.38 Ωm-11.5 Ωm is categorized as silty clay layer and 11.5 Ωm-6246 Ωm is a layer of sand with a mixture of various materials such as gravel or silt. The difference in the initial ground level with the land that has collapsed ranges from 10 m with the results of the situation mapping.

Keywords: Liquefaction, Lithology, Resistivity, UAV photogrametry

INTRODUCTION

The earthquake that shocked Palu and Donggala which occurred on September 28, 2018 with an epicenter location 26 km north of Donggala, Central Sulawesi, magnitude 7.4 with OT 17:02:45 WIB which occurred at a depth of 11 km was a shallow earthquake due to the Palu Koro fault activity. The active fault of Palu-Koro extends with the north-east direction splitting the area of Palu City [1]. This fault is inside one system with North Sulawesi subduction lanes in part north and Matano fault in the south .

The earthquake has caused infrastructure damage in the form of buildings, roads, river and bridges that are quite severe and triggered a collapse / landslide slope , and resulted in a tsunami in the coastal area of the Palu bay [2] and resulted in liquefaction in the Petobo, Balaroa, Jono Oge and Sibalaya areas [3].

Liquefaction phenomena as an earthquake-induced effect in loose saturated soils is considered very dangerous for structures founded over such materials. Liquefaction occurs when the soil's shear strength plummets due to an increase in pore water pressure induced by dynamic loading . This event is problematic in geotechnics since it can cause failure in structures founded on liquefiable soils. One of the affected areas of liquefaction which will be discussed in this paper is the Sibalaya area, located in Sigi Regency, within ± 30 km south of Palu City.

Electrical resistivity tests are being used for geophysical characterization but the electrical properties of soils can also describe the subsurface lithology of each layer of soil. Soil physical properties relevant for studying electrical resistivity may be controlled by the compaction process because soil structure [4]. Geophysical method is field testing which more cost-effective, not destructive and faster. The use of this technique for *in situ* prospection allows characterizing wide open areas and large depths. Measurements were made namely 1D (dimension) electrical resistivity using 4 iron electrodes to induce electricity flow to the subsurface. Configuration measurements made are wenner with the characteristic distance of each electrode that is plugged in the same length

LOCAL GEOLOGY OF SIBALAYA

Investigation of local geology in the affected areas of Sibalaya liquefaction is carried out by conducting a visual investigation of the type of soil or rocks scattered in that location, by determining the direction and position of rock layers and also identifying the geological structure occurring in the investigation area, especially after the earthquake in the area. Donggala. Fig 1 is a result of gological investigation in affected area of Sibalaya

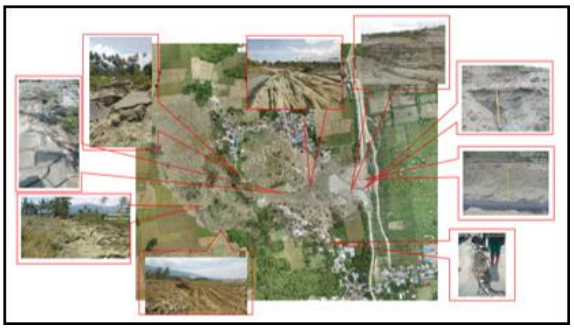

Fig 1. Results of local geological investigations in the Sibalaya area

Based on morphology, the location of Sibalaya is located in a depressed area and forms a pattern of trellis river flow, where there is only one main river (Palu river) with the presence of small rivers whose flow leads to the Palu river. The pattern of trellis river flow generally occurs in areas that have complex geological structure processes.

The main geological structure formed in the Sibalaya area is the presence of horizontal drift faults located on the right and left side of the Palu river, so that the Sibalaya area is located in the area of decline or the Depression which is increasingly narrowing towards the south. The fault was characterized by the presence of triangular facet which is a macro characteristic of Fault in the western part of Sibalaya, and mountains with steep slopes formed in the eastern part of the Sibalaya location that shows ini Fig 2.

Fig. 2 The existence of a triangular facet

Based on the results of the local geological investigation of the Sibalaya area it was found that the Sibalaya location was dominated by sand material with the presence of mixed deposited conglomerates and in some locations this conglomerate was deposited relatively at the bottom of the sand, with sand thickness varying between 1.8 - 2.4 m. The sand material is very loose / decomposed so that it makes the material vulnerable to the liquefaction process.

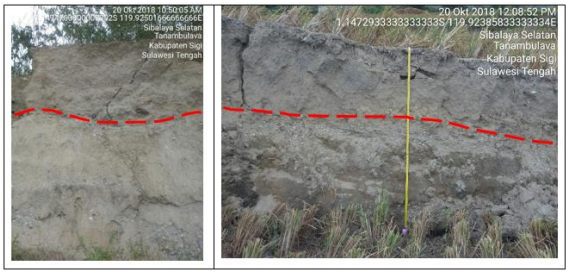

Fig. 3 The existence of sand and conglomerates

At the location of the investigation it was also found the emergence of mud material consisting of clay and silt that appeared around the cracks with the condition of the mud being wet due to the presence of water. The thickness of the mud that appears varies between 20 cm - 100 cm. The mud was identified in the upstream part of the Sibalaya liqueurfaction site on slope outcrops that experienced landslides, while in the lower reaches of Sibalaya it was found on the surface of lowland and in natural watersheds.

In making a local geological map a topographic map or detailed contour map with a scale ranging from 1: 1000-1: 2000 is needed. The contour map of the Sibalaya area is obtained based on the results of measurements using UAV planes with a map of the following:

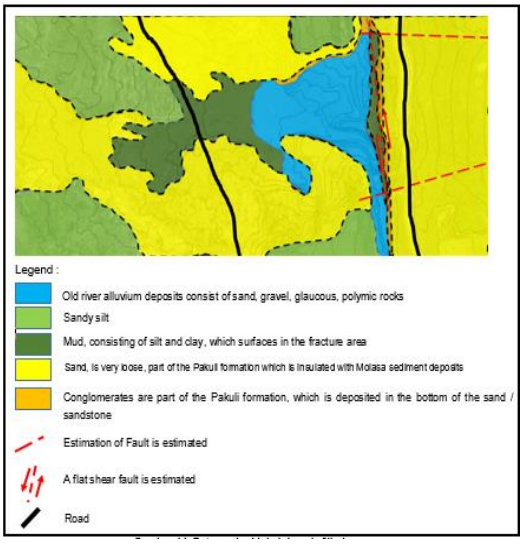

Fig. 4 Local geological map of the Sibalaya area

THEORETICAL FRAMEWORK

Liquefaction Potential Assessment

Liquefable soils according to [5] The first step in engineering assessment of the potential for "triggering" or initiation of soil liquefaction is the determination of whether or not soils of "potentially liquefiable nature" are present at a site. This, in turn,

raises the important question regarding which types of soils are potentially vulnerable to soil liquefaction.

It has long been recognized that relatively "clean" sandy soils, with few fines, are potentially vulnerable to seismically induced liquefaction. There has, however, been significant controversy and confusion regarding the liquefaction potential of silty soils (and silty/clayey soils), and also of coarser, gravelly soils and rockfills.

Coarser, gravelly soils are the easier of the two to discuss, so we will begin there. The cyclic behavior of coarse, gravelly soils differs little from that of "sandy" soils, as Nature has little or no respect for the arbitrary criteria established by the standard #4 sieve. Coarse, gravelly soils are potentially vulnerable to cyclic pore pressure generation and liquefaction. There are now a number of well-documented field cases of liquefaction of coarse, gravelly soils. These soils do, however, often differ in behavior from their finer, sandy brethren in two ways: (1) they can be much more pervious, and so can often rapidly dissipate cyclically generated pore pressures, and (2) due to the mass of their larger particles, the coarse gravelly soils are seldom deposited gently and so do not often occur in the very loose states more often encountered with finer sandy soils. Sandy soils can be very loose to very dense, while the very loose state is uncommon in gravelly deposits and coarser soils

Mass Movement

Mass movement eventually caused by a highly erosive precipitation as a climate variable to determine its type and magnitude [6]. But some mass movement likes liquefaction may occur during Earthquake [7], slope failure as a mass movement could be initiate by a trigger mechanism which is a discrete, identifiable event or influence its mass movement. A very effective trigger mechanism are tropical cyclones and earthquakes [8].

Sibalaya mass movement where its topography such as along ridges amplified ground acceleration of earthquake-triggered landslides, different with a landslides rainfall-triggered which occur lower on slopes, depends on groundwater discharge area [9]. Geotechnical investigations conducted to the landslide revealed that large volumes of highly sensitive clays (quick clays) known molase, were mobilized in the later stages of the landslide as mass movement [10]. Boreholes and static cone penetration tests conducted to assess the liquefaction susceptibility during earthquakes [11].

Photogrametry UAV

Unmanned Aerial Vehicles (UAVs) are increasingly used for surveying in widespread and operational for several applications [12], [13] rapidly across many civil application domains including real-time monitoring, providing wireless coverage, remote sensing, search and rescue, delivery of goods, security and surveillance, precision agriculture, civil infrastructure inspection [14], land rights[15] and hazard as well . it is very efficiency and flexibility for observing geological processes and acquiring data from different attached instruments, allowing especially wide application in the field of photogrammetry and remote sensing. Close range aerial photogrammetry, processed by modern computer vision approaches, allows the derivation of a digital elevation model at very high resolution [10].

Aerial photo survey activities are carried out to create topographic maps and situations from the results of the latest aerial photography by using a Unmanned Aerial Vehicle. The mapping location is in Sibalaya Village, Tanambulaya District, Sigi Regency, Central Sulawesi. The area to be surveyed is ± 580 Ha. The survey location is an area of settlements and rice fields. The aircraft used was Dadali X8 with a fixed wing/delta wing type autopilot control system.

The technical specifications of this work are as follows:

1) Fixed Wing Drone equipment with an autopilot and remote control navigation system,
2) Camera device, has a 20 MPixel sensor
3) The value of GSD (Ground sampling Distance) <10 cm / pixel
4) 70-80% Overlap and 50-60% Sidelap

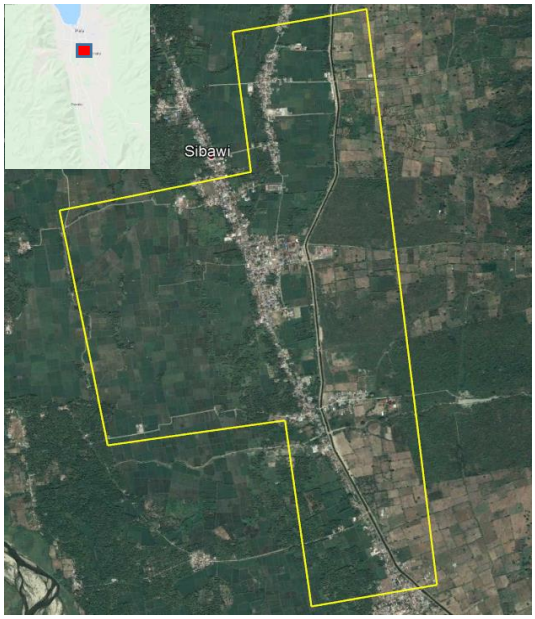

Fig. 5 Location of aerial photo surveys in Sibalaya.

GCP (Ground Control Point) are used to geo-referencing [16]. A pre-mark is installed as a GCP which becomes a reference / position controller in the Air Triangulation process. Ground control measurement using Geodetic GPS. Data acquisition

using Drones is carried out after all pre-marks are installed. Fig. 6 shows distribution of premark.

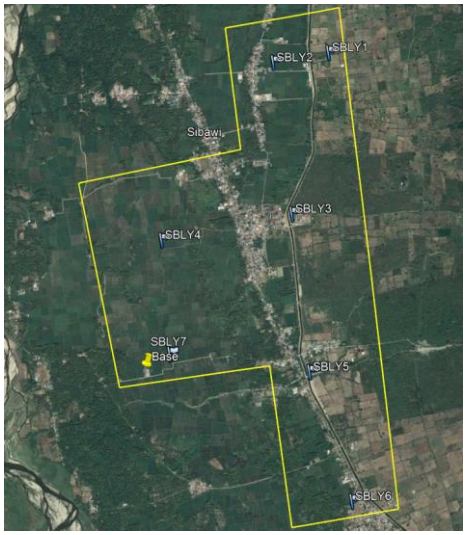

Fig. 6 The location of the pre-mark point in the Sibalaya.

Air triangulation, aerial photography is possible to calculate 3-dimensional coordinates for elements of each object. In the process several points are needed with known positions that appear on some photos. These points are the control points that are an important part of the air triangulation process. The process of implementing air triangulation is carried out automatically through the application program with the following stages and illustrations:

- Automatic identification of tie point points and ground control points based on image matching
- Perform a bundle leveling count that is equipped with a self-calibration count to obtain the optimal camera calibration value
- Look at the RMS value that shows the precision of the count and cannot be more than 3 x GSD

Digital Terrain Model (DTM) is 3-dimensional data that represents the surface state of the object covered. DTM is raster data with cell size of 1 mm on a map scale, which is obtained automatically with stereo matching techniques and continued with semi-automatic data editing.

Fig. 7 Plan for UAV flyways.

Fig. 7 is track as a plan for UAV flyways to make sure image can be captured follows the technical specification.

Electrical Resisitivity Method

Geophysical methods can provide information on subsurface conditions through measurements on the surface, including resistivity, electromagnetic induction, ground-penetrating radar, magnetometry, self-potential, seismic, gravity, radioactivity, nuclear magnetic resonance, induced polarization, etc [17].

Geological subsurface mapping is done by the type of resistivity method [18], measurements are made by energizing electric current (I = Ampere) to the earth and observing the potential difference (V = Volt), obtained by the value of rock resistance (Ohm) from equation :

$$V = I. R \quad (1)$$

Information:
V: measured potential difference (volts)
I : the amount of current sent (Amper)
R : rock resistance (Ohm)

The type of resistance value ($\boldsymbol{\rho}$a) is influenced by the relationship between the magnitude of the value of rock resistance (R) and the measured depth (a) and geometric. Material type resistance is defined as:

$$\boldsymbol{\rho} = R. A / L \quad (2)$$

Where:
$\boldsymbol{\rho}$: material type resistance (Ohm-m)
R: measured electrical resistance (Ohm)
L: length (m)
A: cross-sectional area (m^2)

The Wenner electrode arrangement, the geometric correction factor is 2 $\boldsymbol{\pi}$ a and the resistivity value of the type is obtained from the formula:

$$\boldsymbol{\rho} a = 2. \boldsymbol{\pi} a. R \quad (3)$$

Where:
$\boldsymbol{\rho}$a : pseudo-type resistance value (Ohm-m)
2 $\boldsymbol{\pi}$ a : geometric correction factor (m)
a :the electrode spacing (m)
R :rock resistance (Ohm)

This resistivity method uses a Wenner configuration. The Wenner four-pin method is the most commonly used technique for soil resistivity measurements [19]. The distance between electrodes, which is considered recommendable for various depth. The distance of each electrode in the Wenner configuration is always the same for each displacement. The farther the distance between the electrodes the deeper the depth will be. The

illustration of the Wenner configuration is shown in Figure 8

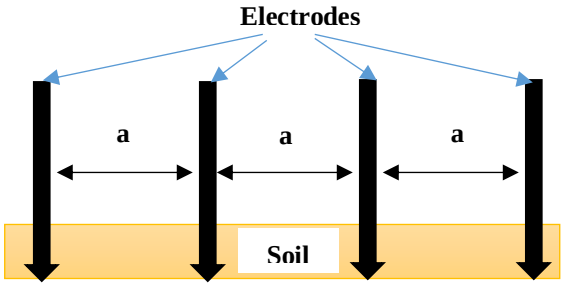

Fig 8. Ilustration of Wenner configuration

Concept of measuring the geoelectric resistance type (resistivity) [20], among others:

1) Resistance-mapping
   a. Measurements to obtain information about variations in lateral resistivity.
   b. Measurement at several points with fixed electrode spacing
   c. The electrode spacing is changed to obtain lateral variations at different depths

2) Resistivity-sounding or VES (Vertical Electrical Sounding) estimation
   a. Measurements to obtain information about resistivity variations vertically
   b. Measurement at one fixed point (sounding point) with varying electrode spacing
   c. Pseudo-type resistance data as an electrode space function
   d. VES data plots a pseudo-type resistance log (a) with a log spacing the current electrode (a)
   e. VES curve describes type resistance as a function of depth at the point of measurement (sounding)
   f. Modeling 1 D

Based on the value of the type of resistance carried out subsurface geological interpretation to be able to estimate the thickness, type of rock and its spread. The type of resistivity values measured on the tool, mapped and depicted two-dimensional resistivity contours (2 D) with the direction of the horizontal axis X and Z depth using IP2WIN software for VES measurements. In this paper rockworks version 15 software is used to better describe the subsurface section with an interpolation system for each resistivity value at the subsurface.

RESEARCH METHODOLOGY

The measurement location is shown in Figure 9, where resistivity testing is carried out in 4 points. The reason is done in that place because it can still be reached, it is considered safe if measurements are taken and it is considered sufficient to determine the objectives to be obtained. The length of the stretch reaches 150 meters to find up to 50 meters below the surface, so a wide and straight surface is needed.

Fig. 9 Location of acquisition resistivity method

RESULT AND DISCUSSION

Photogrametry UAV

GCP coordinates are determined from the processing of GPS observation data with BM Reference 'Base' points located in the location of Sibalaya Village. Result of GCP measurement can be found at table 1. This result is used for georeferencing

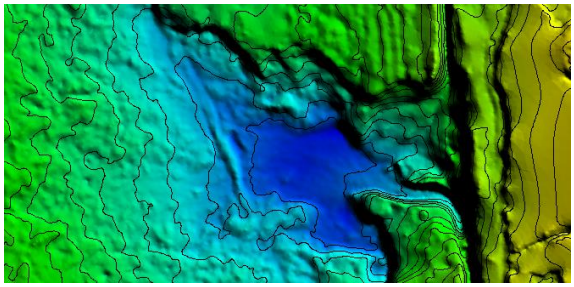

Fig.12 DEM of soil surface as a result of classification

Electrical Resistivity Method

The results of the geological mapping in which the majority of lithology that forms the Sibalaya area is sand with several other forming lithologies found in the area such as conglomerates, gravels, and other molasses sediments found in the Pakuli formation. So that the resulting resistivity value will be of great value because the main lithology of the location is sand. The results of processing using IPI2WIN are in table 1 where there is a column of depth and resistivity, while the lithology column is the result of interpretation.

Where the resistivity value of 1.38 Ωm-11.5 Ωm is categorized as silty clay layer and 11.5 Ωm-6246 Ωm is a layer of sand with a mixture of various materials such as gravel or silt. At GL-0 point the interpretation results are in table 2 with the largest resistivity value of 3718 Ωm which is included in mixed sand lithology and the resistivity value of 1.38 Ωm is interpreted as silty clay lithology

Table 2 The results of the interpretation at GL-0

Hole	Depth (m)	Rho (Ohm.m)	Lithology	Description
GL-0	0	293	Mixed Sand	Sand with a mixture of various materials such as gravel or silt
GL-0	0.224	183		
GL-0	0.668	3718		
GL-0	1.73	196	Silty Clay	Silty Clay
GL-0	50	1.38		

The depth of 0.224 -0.668 meters still considered one layer with a resistivity value of 293 29m and 183 Ωm which is thought to be soil and gravel in the area. After that at a depth of 0.668 meters up to 1.73 meters filled with a layer of molasses consisting of a mixture of sand lithology and conglomerates with poor gradations so that the value of the resistivity is 3718 Ωm. The next layer with a resistivity value of 193 µm at a depth of 1.73 meters - 33.9 meters is thought to be the lithology of a sandy silt where the resistivity value is not too large as sand and too small like silt. The sand contained in this layer can be caused by the layer above it in the form of a layer of molasses which is deposited on the lithology. Furthermore, with a resistivity value of 1.39 Ωm at a depth of 33.9 - 50 meters, it is assumed that the layer contains a lot of water content because the resistivity value is small compared to the others. The lithology that can be estimated for this layer is silt with a lot of water content which can also be called a aquifer zone.

In GL-1 the results of the interpretation are in table 3. The largest resistivity value of 5879 Ωm is interpreted as gravel found in the dominating sand layer, then the smallest resistivity value is 2.99 Ωm which is interpreted as a more conductive silty clay lithology. Fig. 13 Show the stratigraphic section of electrical resistivity from measurement.

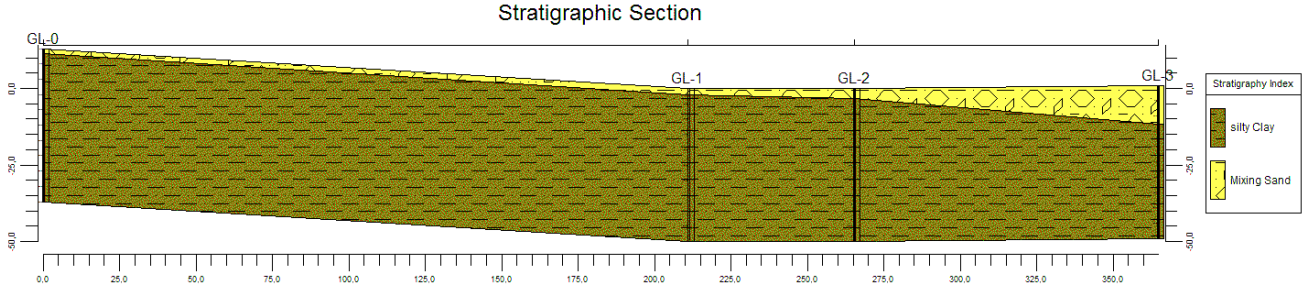

Fig.13 Stratigraphic section of electrical resistivity

Table 3 The results of the interpretation at GL-1

Hole	Depth (m)	Rho (Ohm.m)	Lithology	Description
GL-1	0	76.2	Mixed Sand	Sand with a mixture of various materials such as gravel or silt
GL-1	0.228	1936		
GL-1	0.554	46.7		
GL-1	2.21	5879		
GL-1	50	2.99	Silty Clay	Silty Clay

Resistivity values at depths of 0 - 0.554 meters are 76.2 Ωm and 1936 Ωm which is assumed that this layer is a pile of land which is buried beneath. Depth of 0.554 - 2.21 meters has a resistivity value of 46.7 Ωm which is assumed that in this layer there is silt with a little sand inside. The next layer with a resistivity value of 5879 Ωm at a depth of 2.21 - 5.82 meters is thought to be a layer of molasses with sand lithology with a conglomerate mixture so that the resistivity value is high. The depth of 5.82 - 50 meters with a resistivity value of 2.99 µm is thought to be a wet silt layer and contains a lot of water in it so that the resistivity value is small.

Table 4 The results of the interpretation at GL-2

Hole	Depth (m)	Rho (Ohm.m)	Lithology	Description
GL-2	0	335	Mixed Sand	Sand with a mixture of various materials such as gravel or silt
GL-2	0.24	5825		
GL-2	0.656	88.4		
GL-2	3.35	6246		
GL-2	50	11.5	Silty Clay	Silt Clay

Interpretation of results at the point of GL-2 contained in Table 4 with a resistivity value worth 6246 Ωm largest and the smallest is worth 11.5 Ωm. Resistivity values of 335 Ωm - 5825 Ωm are considered in one layer, namely the uppermost layer consisting of sand, gravel, and also conglomerate debris that can be seen from the surface and located at a depth of 0 - 0.656 meters. This measurement area is a landslide area so that a lot of material is carried from above to the middle area (GL-2). The value of resistivity 88.4 Ωm at a depth of 0.656 - 3.35 meters is thought to be a sand silt layer considering that from the GL-1 point there are also layers with almost the same resistivity value range. The next layer with a resistivity value of 6246 Ωm at a depth of 3.35 - 9.57 meters is thought to be a mixture of sand molasses and conglomerates with poor gradations so that the resistivity value is large. The last layer with a resistivity value of 11.5 Ωm from a depth of 9.57 - 50 meters is thought to be a silt layer.

Table 5 The results of the interpretation at GL-3

Hole	Depth (m)	Rho (Ohm.m)	Litologi	Deskripsi
GL-3	0	117	Mixed Sand	Sand with a mixture of various materials such as gravel or silt
GL-3	3.55	22.4		
GL-3	5.5	98.1		
GL-3	12.6	35.2		
GL-3	50	2.81	Silty Clay	Silt Clay

Table 5 describes the results of the GL-3 point interpretation. The resistivity value of GL-3 tends to be smaller than the previous geoelectric measurement because a day before the measurement takes place rain with high rainfall so that it can increase the amount of water below the surface which is more conductive. Depth 0 - 12.6 meters is considered to be the same layer with a resistivity value of 22.4 Ωm - 117 Ωm. The depth of 12.6 - 50 meters is considered to be the same layer only different from the water content contained in it where a small resistivity value has more water content than the others. The alleged lithology in this layer is silty clay or mud. Fig. 13 shows result of geotechnical borehole.

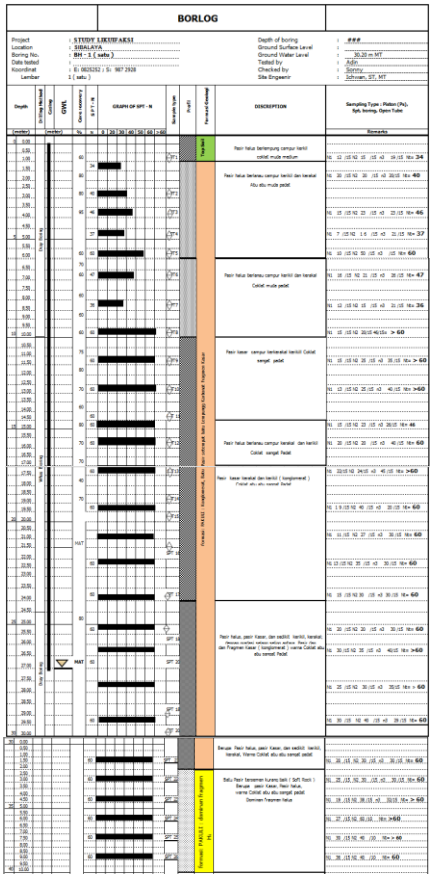

Fig. 13 Bore log Sibalaya Liquefaction

CONCLUSIONS

The dominant Sibalaya location is sand material that is loose/decomposed. There is a minor geological structure proven by the presence of line scratches and building shifts due to the presence of horizontal faults. There is a change in topography in the location area with a 10 meter decrease from the initial condition before the disaster occurs.

There are 3 main layers that make up the surface of the Sibalaya area. Aquifer zone (saturated layer of water) in the upper Sibalaya area (GL-1) at ± 30 meters depth while in the lower Sibalaya area (GL-4) around ± 6 meters. In general, the soil layer around the Sibalaya liquefaction zone consists of fine-grained to coarse material with loose properties (N-SPT 7-10), from rather dense to solid (N-SPT 16-47) and very dense (N-SPT> 50).

EFFECT OF CEMENT SOIL STABILIZATION ON THE PREVENTION OF SOIL OUTFLOW FROM BACK OF THE BRIDGE ABUTMENT

ABSTRACT

In recent years, heavy rains have frequently occurred in Japan, and a large amount of soil, rocks, and trees that were dislodged by landslides have flowed into rivers, causing damage to bridges. When a bridge is blocked by driftwood and boulders, the river water overflows onto and around the bridge abutment and the back face banking of the abutment is eroded, rendering the bridge impassable. We propose cement soil stabilization as a countermeasure to the erosion for the back of abutments. In this study, channel experiments on a 1:15 scale into the effect of cement soil stabilization were carried out. It was observed that erosion started from the downstream corner of the abutment when the overflow water returned to the river at the downstream point. In addition, when the back face banking of the abutment was strengthened with the minimum addition amount of concrete (set as 50 kg/m3) and cured for approximately two days, erosion was inhibited in both the reinforced back face banking and the unimproved levee.

Keywords: Overflow water, Erosion, Back of the abutment, Cement soil stabilization,

INTRODUCTION

In recent years, large-scale rainfall has increased in Japan due to the effects of climate change. It has been reported that trees and rocks have flowed into rivers from collapsed slopes due to heavy rainfall, causing damage to bridges. Driftwood and boulders accumulate between the bridge piers, that block the flow of the river and wash out the bridge or erode a levee and a back face banking of the bridge abutment. Bridges are vital parts of roads and railways; when they are damaged, traffic obstacles occur, which significantly affects evacuation, isolates villages, and hinders post-disaster recovery. As an example, the Yuyabashi Bridge over the Ohmata River in Kumano City, Mie Prefecture, was damaged by Typhoon Talas in 2011. Drifts were deposited on the bridge, and water overflowing from the upstream embankment eroded the ground. On the back face banking of the abutment, the ground was eroded by up to approximately 5.0 m, making the bridge impassable (Fig. 1).

In this study, we focus on the erosion of the back face banking of the abutment by overflow water. Abutments are generally constructed by excavating a space enclosed by inserted steel sheet piles, and space is then backfilled with on-site soil (Fig. 2). Because the enclosed working space is narrow and the abutment is a hindrance, backfill soil is difficult to compact and tends to be a weak spot. Therefore, we propose the use of cement soil stabilization for the shallow ground to improve the ground strength of the back face banking of the abutment, thereby preventing erosion. In this paper, we clarify the erosion process due to overflow water by a basic water channel model experiment, and also examine the erosion prevention effect of the ground improvement.

PREVIOUS STUDY

Various damage has occurred at the back face of abutments. Such as subsidence of embankment at the boundary between the different material characteristics of the structure (abutment) and the ground (back face banking of the abutment) caused by an earthquake, or the erosion of the embankment caused by tsunami or flood.

Ikemoto et al. devised a method of creating a column-like reinforced body using cement-based material as a measure to prevent the settling of the rear surface of the abutment during earthquakes and verified the effect by shaking table tests [1]. Their studies have been put to practical use in JR East as a method for preventing subsidence back face banking of abutments on railroad bridges, and show the effectiveness of ground improvement using cement-based materials. However, the effects of erosion are not discussed in their study. It is therefore necessary to separately consider the effectiveness of the ground surface erosion prevention which this study targets, the construction range of the improvement body, and the construction method.

There are few research cases on erosion and runoff of back face banking of the abutment and concrete measures. The development of effective measures with excellent workability and economy should be promoted. There are approximately 700,000 road bridges over two meters in length, and approximately 160,000 road bridges over 15 meters in length; half of them will have existed for 50 years or more by the mid-2020s [2]. Considering that there is a large number and age range of existing bridges, it is desirable to upgrade to a structure that is resistant to disasters as efficiently as possible while maintaining and managing them. In this study, when considering countermeasure works, we placed emphasis on three points: (1) low material cost; (2) low construction cost; and (3) the possibility of implementation at the same time as routine maintenance. The surface of the abutment approach section is often asphalt-paved, and the pavement is subjected to repair work such as replacement over a fixed period as it deteriorates. Therefore, the above three points may be satisfied by constructing the shallow ground in the lower part of the road body at the same time as the renovation of the pavement.

EXPERIMENTAL OUTLINE

Experiment model

The experiment simulated the upper part of the embankment in the cross-section of the river in order to investigate the influence of a rising water level and overflow on the erosion of the embankment, especially around the abutment. The open channel used for the experiment has a length of 13,000 mm, a width of 500 mm, a height of 350 mm, and a slope of 5°. Among them, a 1333 mm section (model scale: 1:15, actual scale: 20.0 m) was closed to simulate a bridge with a width of 333 mm (actual scale: 5.0 m) and the upper part of the left bank levee. The bridge model made combined the following four parts (Fig. 3): the wall of the inverted T-abutment modeled in a simple box shape; the bridge girder; the panel simulating a blockage between the bridge pier and abutment; and the floor board of the width of the channel. The bridge model was placed at the center of the experimental section in the extension direction and fixed to the bottom of the water channel. The part of the free board of the levee (the revetment top end to the levee top end) and the surface of the embankment was assumed to be bare ground, and the embankment surface was assumed to be horizontal. The image of the experimental model on the actual embankment is shown in Fig. 4, and the experimental model is shown in Fig. 5. Silica sand No. 7 was used as the embankment material, and it was designed so that the optimum water content ratio w = 10% and the compaction degree Dc = 85%. The thickness of one layer was 50 mm and layers were compacted to a predetermined volume.

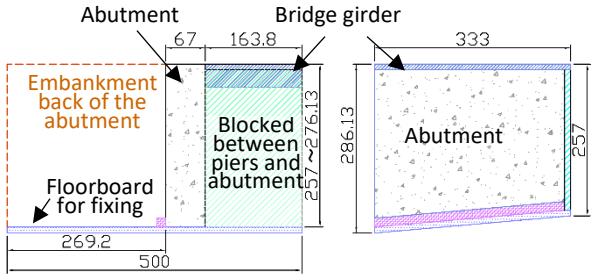

Fig. 3 Bridge model

Fig. 4 Revetment and Free board of a levee

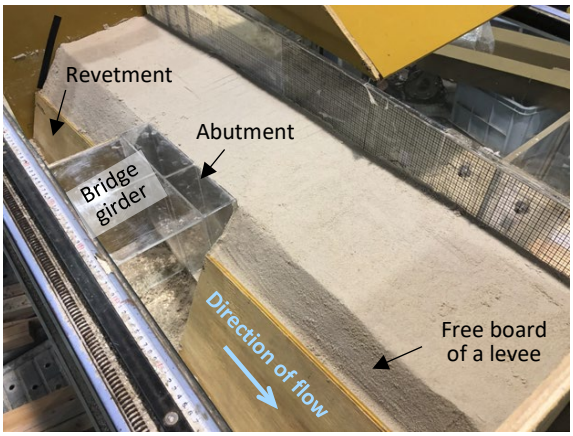

Fig.5 Experimental model （Case 1）

Experiment case

In this paper, we report four cases of experiments. The differences in the experimental conditions are shown in Table 1. In the experiments of Case-1 and Case-2, the effect of the countermeasure is considered from the difference of the erosion process depending on with or without the countermeasure with a similar flow rate. Additionally, in the experiments of Case-2, Case-3, and Case-4, the influence of the flow rate is considered from the difference of the erosion process of the same condition ground improvement part when the flow rate is different.

Table 1 The main difference between the four cases

	Soil stabilization	Curing period （ days）	Flow rate （ m^3/s）
CASE-1	Without	—	2.00×10^{-2}
CASE-2	With	2	1.77×10^{-2}
CASE-3	With	3	2.34×10^{-3}
CASE-4	With	3	2.18×10^{-4}

Blast furnace cement type B was used as the stabilizer for ground improvement, and the amount to be added was set to 50.0 kg/m3, which was considered the minimum additional amount necessary to be sure of an accurate mix of stabilizer and untreated soil [3]. The improvement range was the entire back face banking of the abutment, and the improvement depth was 80 mm (actual scale: 1.2 m). The usual method of mixing requires stabilizer to be spread onto the target ground and mixed with the ground material using a shovel-loader. However, in this experiment, the soil of the ground improvement target area was put into a bucket and mixed thoroughly with the stabilizer. Subsequently, the prescribed amount of improved soil was returned to the target area and compacted. If the cement setting time (approximately 2 hours) is exceeded, the cement stabilized soil loses its strength significantly. It is therefore desirable that the time from mixing to compression be within approximately one hour. Consequently, the ground improvement was carried out in a timely manner. Generally, it takes seven days for the strength development of the stabilizer to become stable; however, we set the curing time to between two and three days to impose a more severe condition in these experiments.

The flow velocity was targeted at approximately 3.0 m/s based on the references [4]. Based on equation (1), the flow amount was adjusted so that the overflow water depth around the bridge center was approximately 60 mm, and the design standard flow amount simulating a flood was 2.00 × 10-2 m3/s. In Case 3 and Case 4, the flow rate is changed. The pump used in these experiments caused an error in the flow setting depending on the water supply condition, so the flow rate during the experiment was measured every time.

$$v = \sqrt{gh} \tag{1}$$

$$\frac{h_m}{h_p} = L_r \tag{2}$$

in which v is the average flow velocity (m/s) , g is gravitational acceleration (m/s^2), and h is water depth (m), h_m is the water depth of the model (m), h_p is the water depth of the prototype (m), L_r is the model scale .

Measuring equipment

In order to quantitatively evaluate the amount of displacement of the embankment, inclinometers (PMP-S5HT) were installed at symmetrical positions on the upstream and the downstream sides, centering on the center of the abutment. The two-dimensional (2-D) diagram of the inclinometer installation position is shown in Fig. 6. These inclinometers detect inclination in one direction by the leaf spring pendulum method, to an effective inclination angle

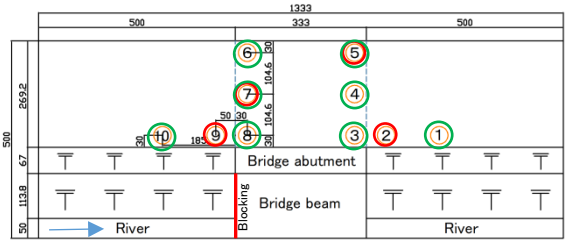

Fig. 6 Tilt sensor arrangement plan
（Case-1: ①②③④⑤⑥⑦⑧⑨⑩
Case-2 : ①②③④⑦⑧⑨⑩
Case-3 : ①②③⑤⑥⑧⑨⑩）

of ± 5°. They were installed with the condition that when they incline toward the downstream side, the output change is positive; their bases were embedded to a depth of 100 mm. The external dimensions [5] and the interpretation of the direction of inclination are shown in Fig. 7.

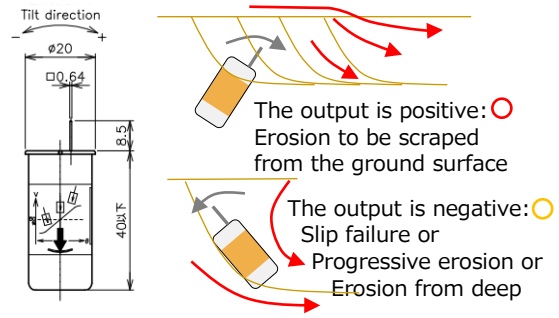

Fig. 7 Tilt direction and interpretation of results

RESULTS AND DISCUSSION

The results of Case-1

The state after the water flow is shown in Fig. 8, and the tilt fluctuation around each measurement point is shown in Fig. 9. The overflow water reached the end of the downstream embankment adjacent to the abutment 6 s after the onset of the overflow, and the erosion started approximately 1 s later (Fig. 8). The erosion area expanded from that position and the embankment at the installation position of the downstream inclinometer (2, 3, 4, 5) flowed out 17 s after the start of the overflow. Subsequently, the eroded area expanded downstream and upstream.

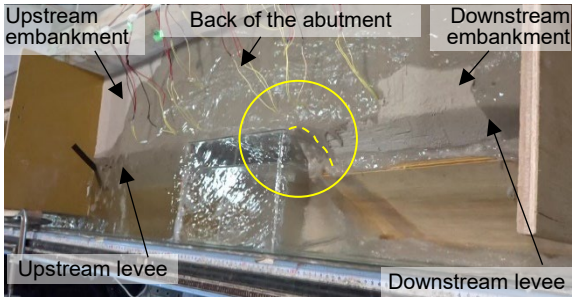

Fig. 8 Start of erosion (After overflow 6 s)

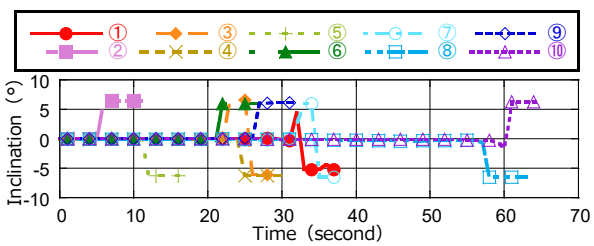

Fig. 9 Tilt fluctuation (Case 1)

The red circle in Fig. 7 shows that the upper part of the inclinometer fell towards the downstream side. The inclination direction of the inclinometer at each point was uneven, and the characteristic tendency was not found in the erosion direction.

The results of Case-2

The state after the water flow is shown in Figs. 10 and 11, and the tilt fluctuation around each measurement point is shown in Fig. 12. The erosion of the embankment started after The overflow water reached the end of the downstream embankment adjacent to the abutment as with Case 1. However, the subsequent erosion process was different from Case 1, and the erosion near the back face of the abutment did not progress rapidly.

The downstream levee was notably eroded by the surface flow, and the erosion progressed slowly at the boundary between the ground improvement part adjoining the abutment and the downstream embankment (Fig. 10). Furthermore, the erosion of the upstream embankment progressed (yellow in Fig. 11) and the embankment just under the improved part was washed away. However, the unified improved part showed resistance to erosion and remained in its former position by the frictional resistance of the abutment and the water channel wall. Inclinometers 3, 4, 5, and 6 (red in Fig. 11) of the improved part started to gradually incline at approximately 2 min and 40 s from the start of overflowing, and they greatly inclined downstream all at once after 3 min and 27 s. Because the four inclinometers showed the same behavior at the same time, it is clear that the ground improvement part became integrated (Fig. 12). Inclinometer 8 (blue in Fig. 11) in the upstream embankment part continues to incline gently from approximately 2 minutes and 27 s to the end of the experiment. Comparing with Case 1, in which the same position embankment was washed away 60 s after the start of overflow, this result shows the unimproved embankment on the upstream side increased its resistance for erosion.

The direction of inclination of the inclinometers is analyzed in order to consider the state of erosion. The green circle in Fig. 7 shows that the upper part of the inclinometer fell towards the downstream side when the inclinometer started to move. With only inclinometers 2 and 7, close to the improved part, did the lower part of the inclinometer fall towards the downstream side. It is inferred that it moved along with the sliding soil due to the strong flow from upstream to downstream. With the other inclinometers, their upper parts fell towards the downstream side. It is inferred that deep progressive

erosion was suppressed and the influence of erosion from the ground surface was larger.

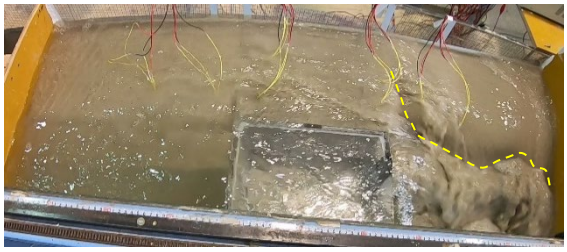

Fig. 10 Erosion at the boundary of the downstream

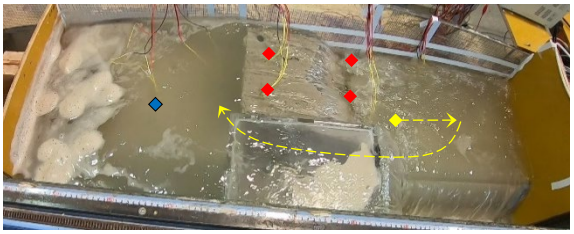

Fig. 11 Broken ground improvement part and process of displacement (After overflow 3 min 40 s)

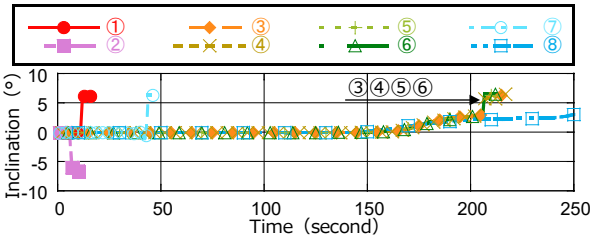

Fig. 12 Tilt fluctuation (Case 2)

Effectiveness of ground improvement

Case 2 was carried out with the conditions of the minimum amount of cement addition and two days of curing. From the results of Case 2, it was confirmed that the ground improvement was integrated, and the erosion was suppressed more than in Case 1, which was without improvement. Although the improved part settled and inclined because the foundation ground supporting the improved ground had been lost, if the foundation ground remained, there is a fair possibility that it would maintain its function as a road on the embankment adjoining the abutment. There is room for consideration of the improvement ground range, such as the downstream embankment adjacent to the abutment, because erosion proceeds from weak areas such as the boundary between the abutment and the embankment, or the boundary between the improved part and the unimproved embankment.

In addition, the result from improving the ground of the embankment adjoining the abutment, the unimproved embankment became more resistant to erosion. It was considered that the cause of this phenomenon was affected by the following: the resistance to erosion of the improved part increased compared to the case without improvement; and the penetration of the improved part was suppressed. Moreover, because the improved part was not eroded, the flow of the overflow water and the progress of erosion became reduced compared with the unimproved case.

The results of Case-3 and Case-4

In both Case 3 and Case 4, significant time passed before the water level rose and overflow occurred because of the low rate of flow, with the result that penetration and erosion of the upstream levee preceded other areas of erosion (Fig. 13). It is thought that the erosion was accelerated because the formwork moved by compaction energy at the time of formation of the levee and the ground adjoining the revetment loosened. After the erosion area approached the bottom of the upstream levee, the unimproved ground immediately below the improved ground adjoining the abutment was eroded in the downstream direction, and a water flow analogous to a tunnel penetrated underneath the improved part (Fig. 14). The erosion gradually progressed at the boundary between the improved part and the levee on the downstream side until approximately 1 min and 20 s (in Case 3), and 2 min and 30 s (in Case 4), after the start of overflow. Subsequently, the erosion area did not expand because the water flowed through the tunnel in Case 3, and the downstream embankment was completely washed away by the water flow in Case 4, so the experiment was ended.

Fig. 13 Scour-like erosion and flow at the upstream side (Case 3)

Fig. 14 Improved soil after the experiment (Case 4)

In both cases, inclinometers 3, 4, and 5 in the improved part were not displaced (Figs. 15-16). The cause of displacement of inclinometer 6 in the improved part close to the upstream revetment in Case 3 is that the base of the improved part was slightly eroded by the water flow.

The results show when the flow volume is low (the flow velocity is low), the embankment erosion by the penetration on the upstream side is notable, and the erosion progresses in the riverbed direction. In addition, because the amount of overflow water is small, the amount of erosion at the downstream embankment is small. Erosion was observed at the boundary with the improved part and the unimproved embankment, however, the improved part adjoining the abutment almost became integrated with the structure and remained consolidated.

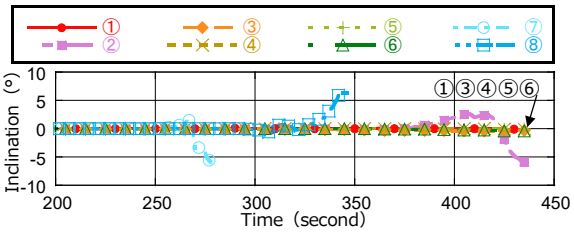

Fig. 15 Tilt fluctuation (Case 3)

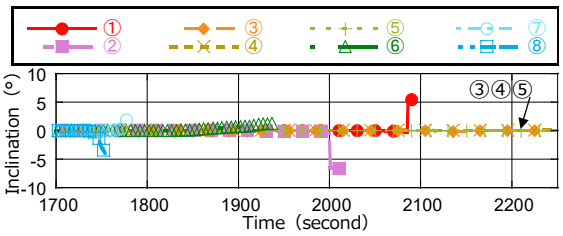

Fig. 16 Tilt fluctuation (Case 4)

CONCLUSIONS

In this study, four experiments were conducted to examine the resistance to erosion of soil stabilized by a cement-based solidifying material. Under the conditions of this experiment, it was found that to carry out ground improvement of the embankment adjoining the abutment, erosion can be suppressed, the ability to maintain function as a road is improved, and the suppression effect can be expected also against the erosion of the surroundings of the abutment.

Progression of erosion at the boundary between the ground improvement section and the embankment was confirmed. The overflow water from the river embankment due to the blockage of the bridge significantly eroded the downstream embankment, especially near the abutment. If the flow rate is small, the risk of seepage failure on the levee increases on the upstream side. Therefore, countermeasures for the upstream and downstream levee near the abutment are also desirable.

In the future, under the condition that the foundation ground does not run off, it is necessary to consider the amount of cement to be added, curing conditions, and ground improvement range, to resist against larger flow rates and longer overflow times.

ABSTRACT

In the event of flooding, the road infrastructure especially the subgrade will be affected in terms of its capacity to support the pavement. It is well known that subgrade deterioration will eventually cause pavement failure. However, little is known on how the subgrade reacts to different flooding conditions especially in terms of the depth and duration of the floods. The aims of this study are to evaluate the moisture content variation and strength of the subgrade using the flood simulation model. The pavement loading characteristics are referred to the Manual on Flexible Pavement Design published by the Malaysian Public Works Department (ATJ 5/85 Rev. 2013). The flood parameters used for this experimental model are based on actual data of flooding events from 1991 to 2014. It includes the parameters of flood water level, flood duration and repeated flooding. The samples were exposed to flooding for a duration of 3, 24 and 48 hours for unrepeated flooding and 2, 5, and 24 hours for repeated flooding. Flood water levels were set to 0.3 m, 0.6 m and 1 m. This study shows that there is a strong relationship between moisture content and subgrade strength. The increase in the duration of the flooding affected the performance of the subgrade due to the increasing moisture content. The study also revealed that the rate of deterioration in subgrade strength for second flooding events is 30% less than for first flooding events. The result of this experiment will be used to develop the basis for including flooding characteristics in the modified California Bearing Ratio test for soils in flood prone areas.

Keywords: Moisture content, Flooding, road subgrade, California Bearing Ratio

1. INTRODUCTION

The economic development of a country can be assessed by the connectivity of its different regions by means of roads and railways. Thus, the construction of road infrastructure is one of the important civil engineering works undertaken for interconnecting the different places in a country [1]. For a developing country like Malaysia damage to road infrastructure due to natural disasters such as flooding commonly result in a huge expenditure for rehabilitation and road works [2]. The foundation soil supporting the pavement is called the subgrade. In the design of flexible pavements, the CBR test is the most widely performed method to estimate the strength values of the road subgrade and sub-base. These CBR values enable the design of a suitable thickness for the base and pavement layers. As the performance of a constructed road essentially depends on the various parameters e.g. subgrade material, materials used in different layers of the pavement and the traffic loading, the selection of appropriate subgrade materials with better quality is very important for getting a superior performance [3]. The destructive effect of moisture on pavement performance is an important consideration especially as the monsoon season is an annual occurrence. Furthermore, it affects the long-term performance of granular or stabilized base and sub-base, and of the sub-grade [4]. When the road is inundated for an extended time, the materials in each layer of the pavement become saturated, and then as the floodwaters drain, the subgrade soils begin to shrink and subside. [2]. A study by Ismail et al. [5] on flood depths and duration found that the average flash flood occurs in less than 6 hours in most locations in Malaysia, but flash floods duration may exceed 6 hours with the flood water level above 1.0 m due to heavy rain and high tidal level. In contrast, the average monsoon flood duration is two days with an average flood water level of 1.0 m, depending on rainfall conditions. In addition, repeat flooding frequently happens within a month of the first flooding event. There are several studies by previous researchers on the effect to the soil subgrade due to the duration and flooding depth. According to Alam and Zakaria [6], the period of inundation by floodwater affects the strength of pavement layers significantly and in the case of surface layers the strength also reduces substantially. Other researchers like Fairweather and Yeaman [7] concluded that the effect of flood on the road pavement structure

deterioration shows a good relationship between strain and moisture in the subgrade layer and poor relationship between surface layer strain and moisture. This manuscript presents a general overview on the following issues regarding road infrastructure especially how the subgrade will be affected in terms of its capacity to support the pavement. It is well known that subgrade deterioration will eventually cause pavement failure. However, little is known about how the subgrade reacts to the different flooding conditions, especially the depth and duration of the floods. The focus is determine the moisture content and strength of the subgrade from actual flood events using a flood simulation model. At the end, this experiment will be used to develop the basis for including flooding characteristics in the modified California Bearing Ratio Figure 1 is a typical road inundation during a monsoon flood.

2. EXPERIMENTAL SET UP

An experimental program was planned to study the effect of flood events on subgrade soil performance on a reduced scale in the laboratory. The first phase was specimen and test preparations and the second phase was the preparation of an experimental model section. The proposed test is called a Flood Simulation Model (FSM). The samples of sub-grade soil were taken from quarries that supply soil which is usually used as the embankment soil in road works. The soil samples were approved according to the Standard Specification for Road Works - Section 2: Earthworks by the Public Work Department (PWD), Malaysia. The properties of the soil samples are shown in Table 1 and the physical and mechanical properties of the soil samples were determined according to the Unified Soil Classification System (ASTM D2487). The tested soils were found and can be classified in the group of "Well-graded sand''.

Table 1: Basic Properties of soil Sample

Soil properties	Value
Specific Gravity	2.65
Moisture content	12%
Adjustment moisture content	14.5 %
Maximum dry density	1.92
Ph value	5.04
Organic Content	1.69%
Liquid limit	45%
Plastic limit	Non-Plastic
Plasticity index	Non-Plastic
Grading	SW

2.1 Specimen and Test Preparation

Initially, experiments such as the Atterberg limit, sieve analysis and index properties were conducted to determine the properties of the soil. Soil with a total mass of 4956g with an optimum moisture content at 12% was compressed in the mould using Static Compression with Tamping [8] for unflooded and unrepeated flood sample. For repeated flood events a soil sample with total mass of 5067 g with adjustment optimum moisture content at 14.5% was used. 80 specimens were prepared in total, and the specimens were intended for control, unrepeated flood and repeated flood.

2.2 Flood Simulation Model (FSM)

The flood parameters used in this experimental model were based on actual data of flooding events from 1991 to 2014. The data on flood statistics were obtained from an annual flood report issued by for the Department of Irrigation and Drainage Malaysia. Only complete information was considered in the study. It includes the parameters of flood water level; flood duration and repeated flooding were identified based on the high frequency of flood cases. The samples were exposed to flooding for a duration of 3, 24 and 48 hours for unrepeated flooding and 2, 5, and 24 hours for repeated flooding. Table 2 which shows the flooding characteristics of the flood simulation model. The percentages of adjustment moisture content were determine based on the duration estimated within a day-10 using an outdoor moisture content test (refer Figure 6). The purpose of the outdoor moisture content test is to determine the reduction of moisture content after the soil sample was submerged. In this test, the soil sample is submerged for 24 hours and then placed in an outdoor area for an estimated reduction of the moisture content in one month (refer to Figure 2).

Table 2: Flooding characteristics of FSM

Types of flooding	Duration flooding (Hours)	Water level (Meter)	Duration repeated flooding (Days)
Unrepeated flooding	3,24 and 48	0.3,0.6, and 1.0	_
First repeated flooding	2,5 and 24	0.3,0.6, and 1.0	2 days
Second repeated flooding	2,5 and 24	0.3,0.6, and 1.0	2 days

(a) (b)

Fig 2: (a) Specimen under water to simulate flood and (b) placed in outdoor area

To clarify the methodology of the research, this study focuses only on one type of conventional flexible pavement: granular base. Table 3 shows the loading characteristics of the flood simulation model for the purpose of calculating the loading characteristics to simulate the load of the pavement structure on the subgrade layer to represent the actual flooding event. These calculations have been designed based on typical conditions for roads and highways in Malaysia as referred to the Manual for Flexible Pavement Design published by the Malaysian Public Works Department. Pavement structure has slightly different characteristics due to unknown variables and several factors such as environmental and weather conditions. The design of actual pavement structures depends on the types of local material and the design approval from local authorities.[9]. Figure 3 shows the layout of the apparatus for FSM. All specimens will be tested referring to a modified soaking procedure from Malaysian Standard MS 1056: 2005 (Confirmed:2013), Soils for Civil Engineering purposes, Part 4. After that, the California Bearing Ratio (CBR) test was carried out to determine the strength of the subgrade soil [8].

Table 3: Loading characteristics of FSM

Level	Pavement structure (kg)	Flood water level (kg)	Total weight (kg)
0.3 m	17.6 kg	5.4 kg	23 kg
0.6 m	17.6 kg	10.8 kg	28.4 kg
1m	17.6 kg	18 kg	35.6 kg

(b)

Fig. 3. Set up of the flood simulation model configuration: (a) diagram model (b) photograph

In this study, regression models were established to show the relationship between dependent variables and independent variables. Correlation equations are developed by performing single linear and multi linear regression analysis using Microsoft Excel tool pack analysis. Firstly, simple linear regression analysis (SLRA) was carried out by considering the moisture content as the independent variable (IV) and CBR values as dependent variables (DV). Secondly, a multiple linear regression analysis (MLRA), was determined by considering first and second repeated events as independent variables (IV) and CBR values as dependent variables (DV). The scatter diagrams are presented in Figures 5 and 9.

3. RESULT AND DISCUSSION

3.1 Unrepeated Flood

The results of CBR strength and moisture content values presented in Figure 4 illustrate the comparison between unflooded and flooded conditions. The soil samples were flooded for 3, 24 and 48 hours for unrepeated floods. From the combo chart, the vertical left and right axes represent the CBR value and moisture content (MC). It shows the CBR value for unflooded condition is relatively higher than the CBR value for flooded condition due to the saturated duration for flooded soil. Obviously, the presence of water when the soil was flooded for 3, 24 and 48 hours contributes to the decreasing of soil strength and performance. The soil had been losing strength starting in the 2-hour flood when it is compared to the unflooded condition. In addition, in the 48 hours of flooded condition at flood level 1.0 m, the value of CBR was reduced from 20% to 18%.

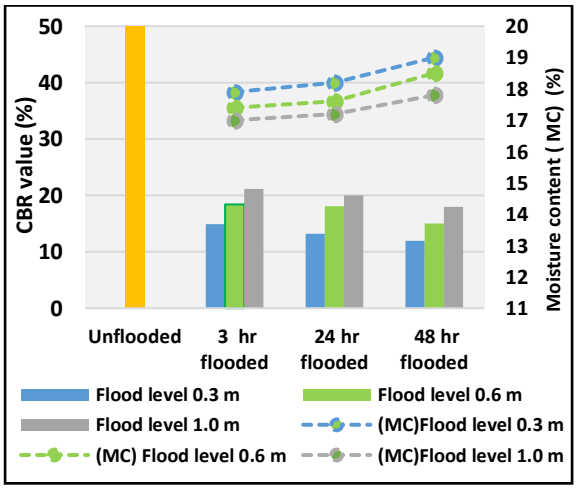

Fig. 4: Comparison of CBR value and water content of unrepeated flood samples.

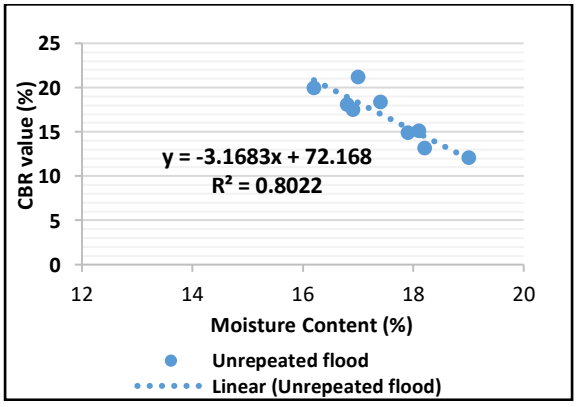

Fig 5: Relation between moisture with CBR value of unrepeated flood

Figure 5 presents the model developed for CBR values where the coefficient of correlation R^2 was found to be 0.82. Thus, moisture content has a high influence on the CBR value and the linear regression equation for unrepeated flood is CBR value (inundation) = -3.1683(MC) + 72.168

3.2 Repeated Flood

The outdoor moisture content test is a process by which soils decrease the moisture content in the specified volume. In this test, the focus is on observing the reduced effect water content from the outdoor condition for the soil sample. Figure 6 shows the result of the outdoor moisture content test for one month and the figures are given as percentages of the moisture content. It can be seen that the percentage of moisture content slightly increased to 20.2 % after a 24 hour soaking. Otherwise, there was a minimal decrease in the percentage of moisture content in the day-1 to day-30 tested samples and the average percentage reduction in water content is 0.4 % per day. However, this is dependent on the weather factor and the outdoor environment. The typical weather condition in Malaysia is uniform temperature and high humidity which is the one major factor contributing to the fluctuation in the rate of the soil moisture content. In a general overview, it shows that the moisture content will return to its original rate of 12% on day-16. Therefore, it can be concluded that the repeated flood after day-16 can be categorised as unrepeated flood. The moisture in the soil will return to its original value.

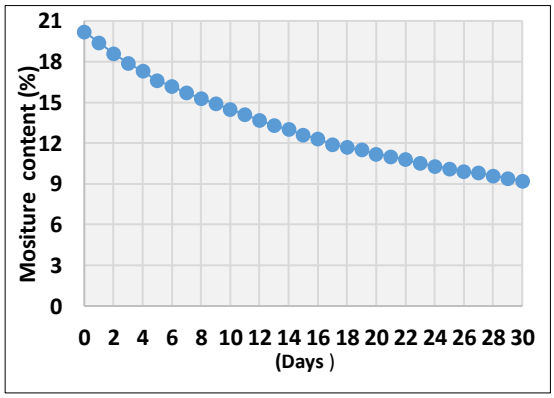

Fig. 6: Percentages moisture content of outdoor test

The result of CBR strength and moisture content presented in Figure 7 illustrates the comparison between unflooded and flooded condition. From the combo chart, the vertical left and right axes represent the CBR value and moisture content (MC). The soil samples were flooded for 2, 5 and 24 hours for the first repeated flooding condition. It shows that the CBR value for unflooded condition was 41% and in the first repeated flood for 2 hours at

flood water levels 0.3 m, 0.6 m and 1.0 m, the CBR values were 15.4%, 17% and 18% respectively. In addition, at 5 hours on flood water levels 0.3 m, 0.6 m and 1.0 m, the CBR values were 16%, 17% and 19% respectively. The unflooded samples mostly showed better performance in their strength and the CBR strength probably can be increased with suitable compaction of the soil tested. However, for 24 hours flooding at flood levels 0.3 m, 0.6 m and 1.0 m the CBR values were 17.9%, 16.5% and 22% respectively. The average CBR strength was reduced in 2 hours flooding to 24% and subsequently the CBR value also reduced in the 5 to 24-hour floods compared to the unflooded sample. The CBR strength increased by 2.9% after flooding for 2 hours at flood level 1.0 m. The moisture content values in the combo chart show the fluctuation pattern of the result.

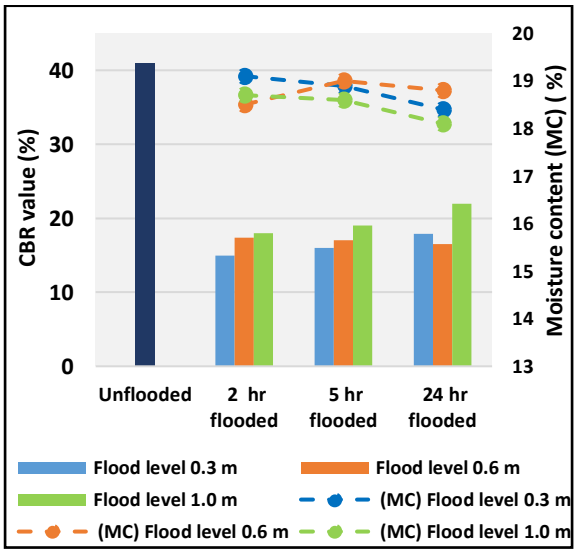

Fig 7: Comparison of CBR value and water content of first repeated flood samples.

In contrast, the combo chart in Figure 8 shows the second repeated flood condition is seen differently compared to the unflooded and flooded conditions. From the combo chart, the vertical left and right axes represent the CBR value and moisture content (MC). The soil samples were similar with the first repeated flood in which the soil samples were flooded for 2, 5 and 24 hours. It shows that the CBR value for unflooded condition was 41% and in the first repeated flood for 2 hours at flood water levels of 0.3 m, 0.6 m and 1.0 m, the CBR values were 11.9%, 12.6% and 14% respectively. It follows that, for 5 hours at flood water levels of 0.3 m, 0.6 m and 1.0 m the CBR values were 12.3%, 13% and 14.3% respectively. However, for 24 hours at flood levels 0.3 m, 0.6 m and 1.0 m the CBR values were 14.3%, 15.4% and 17% respectively. In the second repeated flood case, the moisture content increased in the 5 hour flood at flood levels 0.3 m and 0.6 m, to 20.7% and 20% respectively. This condition may be due to the subgrade of the soil becoming saturated because of the number of floods and the loads used during the FSM in the soil sample affecting the absorption of moisture content.

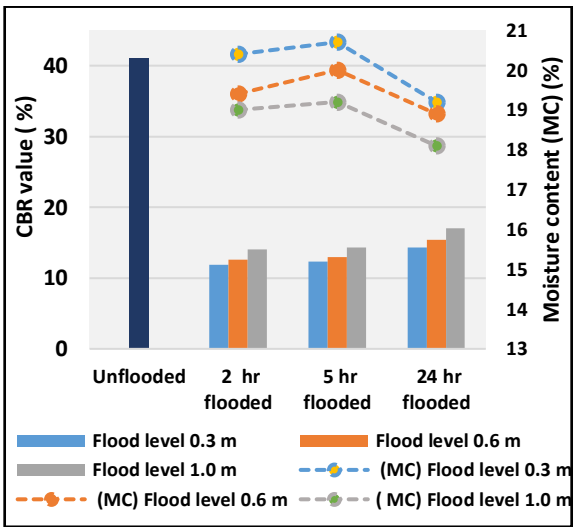

Fig 8: Comparison of CBR value and water content of second repeated flood samples.

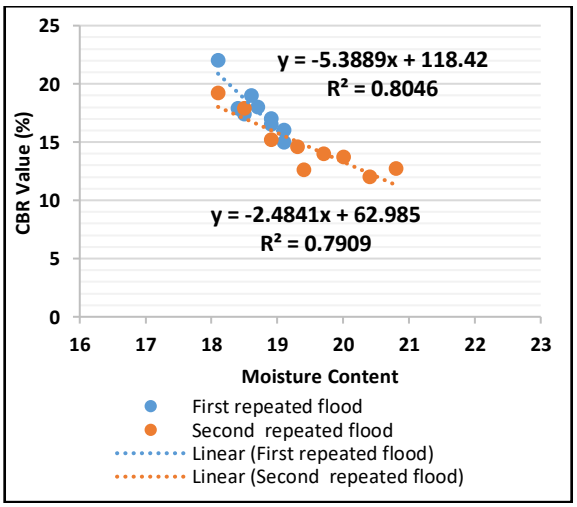

Fig 9: Relation of CBR value and water content of repeated flood.

From Figure 9 it is observed that there is a multi linear relationship between the moisture content and CBR value in repeated flood events. In general, as moisture content increases the subgrade strength decreases, indicating a linear relationship exists between these two parameters. From linear regression the coefficient of correlation R^2 for these two parameters in first and second repeated floods were found to be 0.80 and 0.79 respectively.

5. CONCLUSION

This study was carried out to evaluate the moisture content variation and strength of the subgrade using the FSM. It can be concluded that:

i) Based on experimental results and linear regression this study shows that there is a good relationship between moisture content and subgrade strength. A linear relationship exists between moisture content and subgrade strength with a coefficient of correlation on unrepeated flood, first and second flood events, R^2 = 0.80, 0.80 and 0.79 respectively. It illustrates that the increase in the duration of the flooding affects the performance of the subgrade due to the increasing moisture content.

ii) The study also revealed that the rate of deterioration in subgrade strength for the second flood is 30% less than for the first repeated flood.

As described, the selection of the type of soil in this study is relevant as the impacts of flood depths or water flow under hydraulic gradient is significant. Furthermore, clayey soils of low hydraulic conductivity will require extended time for soil moisture content to change. The decease of CBR value and shear strength does not happen immediately. It's due to shear force generated by the friction and adhesion between particles of soil. In addition, pore water pressure dissipation is also corresponded to time factor.

For future works, this study will continue to investigate the effect of the period for inundated roads and recurring inundation and how these could affect the whole road structural systems in different localities and sub-grade properties.

ABSTRACT

Coastal areas have been used as a settling ground for human population as they provided abundant fisheries and marine resources and possibilities for business sectors. Coastal hazards cause loss of life and the degradation of coastal environment. It defined as physical phenomena that expose a coastal area to risk of property damage. Coastal areas are frequently changing, in which natural hazards such as tsunamis is one of the sources. The management of coastal hazard currently has become an important aspect for coastal planning in order to improve the resilience of society to coastal hazards. Coastal disaster management can be done based on the risk analysis using several vulnerability and risk parameters. The current research tried to analyze the potential risk area due to tsunami hazard using the parameter of vulnerability in the coastal area of East Java Indonesia. Risk map produced from the geospatial database analysis in the concept of the geographical information system (GIS). Risk assessment combines the outputs of vulnerability assessments and the hazard, in which the topography elevation, type of building, land cover, coastal vegetation density, and the type of coastline build the vulnerability map. Historical data of some tsunami events indicates that some of the damage caused by the coastal elevation as one of the physical parameters of tsunami vulnerability, as well as social parameters. The study describes an important result related to multi-criteria processing in predicting the tsunami risk area. GIS plays as important approaches in combining the geospatial database of each parameter and displays it in geographical perspective.

Keywords: Geographical information system, hazard, tsunami, risk, vulnerability

INTRODUCTION

The development of coastal areas today is more focused on the consideration of environmental degradation. Various kinds of hazard threats to the coastal environment, such as natural disasters and other natural phenomena, are also considered in the management of coastal areas. Coastal areas are one of the areas that are susceptible to environmental damage, both caused by the pressure of human activities and the consequences of natural disasters.

Coastal hazards can be defined as physical phenomenon that exposes a coastal area to risk of property damage, loss of life and environmental degradation. In the term of coastal zone management, coastal hazard management has become an increasingly important aspect. This is important to improve the resilience of society to coastal hazards. Possible management options include the design of coastal structures, application of natural coastal green for coastal protection, various accommodation approaches as well as a managed infrastructure in the area close to the coastline. For overcoming coastal hazards, it is also important to have early warning systems and emergency management plans in order to be able to address sudden and potential disastrous hazards i.e. major flooding events, tsunami, or hurricane. Events as the 2004 Indian Ocean earthquake and tsunami, the Hurricane Katrina affecting the southern USA in 2005, the cyclone Nargis affecting Myanmar in 2008, the 2011 Tohoku, Japan earthquake and tsunami, and also the 2018 Sulawesi, Indonesia earthquake and tsunami provides clear examples of the importance of timely coastal hazard management.

The purpose of mitigation is not only to minimize the loss of property damage but also minimize the damages of environmental due to development. Disaster mitigation program also important approaches in order to avoid impacts by not taking actions, to reduce impacts by rehabilitation the affected environments or constructing long-term maintenance operations, and compensating for impacts by providing substitute environments for resources.

Through human history, developing technology has increased the range of adaptation options in the face of coastal hazards, and there has been a move from retreat and accommodation to hard protection and active seaward advance via land claim as exemplified by the Netherlands [1].

in general coastal hazards can be grouped into five main impacts, usually with several contributing

processes causing cumulative harm; (1) coastal erosion and coastline stability (including the area of river mouths, tidal inlets and cliffs) from waves, storm tide, changes in sediment budgets, river floods, coastal structures, storm water, and sea-level rise; (2) coastal flooding cause from storm tide, river floods, tsunami, and sea-level rise; (3) the level of groundwater in the coastal area due to storm tide, intense rainfall, sea-level rise, and salinization; (4) recreational activities together with hazards arising from surf zone conditions (e.g. rips, wave conditions, long-wave surges); (5) oceanic activities together with marine navigation hazards arising from wave conditions, storm tide, strong winds, long-wave surges and also tsunami.[2].

The application of Geographical Information System (GIS) for disaster research provides an important integrated contribution in order to assess the risk of the coastal area due to the natural disaster [3]. The development of satellite remote sensing technology and its applications enable the use of satellite imagery for mapping the distribution of an area damaged by a disaster. Satellite images have the advantage of being able to deliver simultaneous images of wide areas [4]-[5]-[6]. In addition, with the aid of the GIS, spatial multi criteria analysis helps prioritize the decision-making process using spatial database. Spatial multi criteria analysis is vastly different from conventional Multi Criteria Decision Making (MCDM) techniques, due to the inclusion of an explicit geographic element.

GIS mapping of tsunami vulnerability has also applied using the Shuttle Radar Topography Mission (SRTM) to obtain the topographic data of the study area [7]-[8]. Another geospatial analysis approach has applied soil type, urban form and social type system for the potential natural hazard mapping [9] and has assessed the tsunami vulnerable area by comparing building damage map with the physical topography data includes elevation, land use, and the distance from the coast [10]. Mapping of the 2011 Tohoku earthquake tsunami inundation and run-up by in-situ survey also has been published in order to develop create appropriate disaster mitigation concepts [11].

This study tried to apply several physical topography data for analyzing coastal hazard and its affected areas, especially caused by the tsunami disaster using GIS approach.

METHOD

Study Area

The analysis was applied in three different case study areas around the coastal area of Indonesia in order to know the different result of applying physical topographic dataset. The area includes the coastal area of Java Island and divided into the western part of Java which is represented by Banten Regency areas, the eastern part of Java Island which represent by Banyuwangi Regency, and also Malang regency area which represents the area that directly faces to the Indian Ocean. The study area as describe on Fig. 1.

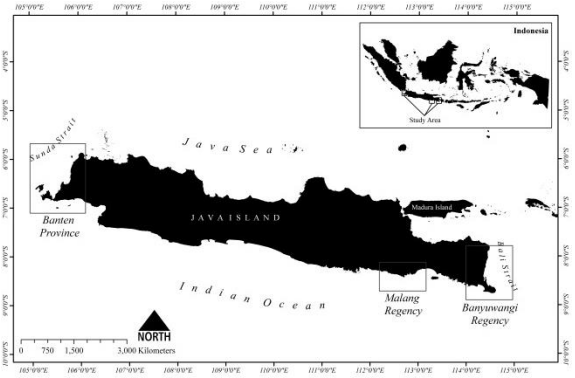

Fig. 1 Study area

Dataset

Physical data set for assessing the affected area of tsunami disaster in all coastal areas of case study was collected. This dataset includes topography elevation, slope, building area, coastal proximity and coastal type, and also population density as well. For providing the physical topographic parameters, the dataset of The ASTER Global Digital Elevation Model (ASTER GDEM) version 2 was collected from *https://gdex.cr.usgs.gov/gdex/*. This data are available from the Land Processes Distributed Active Archive Center (LP DAAC). Moreover, The NASA Shuttle Radar Topographic Mission (SRTM) also collected for preparing topographic elevation dataset. SRTM has provided digital elevation data (DEMs) for over 80% of the globe and distributed by USGS and is available for download from the National Map Seamless Data Distribution System, or the USGS ftp site. The SRTM data is available as 3 arc second and downloaded from *http://srtm.csi.cgiar.org/srtmdata/*.

In addition to provide land use map that describe also the building areas, Sentinel 2 satellite image was applied. Sentinel-2 is a European wide-swath, high-resolution, and multi-spectral imaging mission. The full mission specification of the twin satellites flying in the same orbit but phased at 180°, is designed to give a high revisit frequency of 5 days at the Equator. Sentinel-2 carries an optical instrument payload that samples 13 spectral bands: four bands at 10 m, six bands at 20 m and three bands at 60 m spatial resolution. The orbital swath width is 290 km [12]. This data was collected from *https://scihub.copernicus.eu/dhus/#/home.*

The type of coastal, distance from coastline to hinterland (coastal proximity), and other land use

feature were created from vector data of base map. This data was collected from Indonesia Geospatial Information Agency. Dataset that used in the analysis as described in Table 1, Table 2, and Table 3.

Data Analysis

As one of the potential natural disasters that affect to the dynamic of coastal area, the affected area due to tsunami could be assess through the analysis of risk and vulnerability. In order to analyse this assessment, all parameters will be analyzed using GIS. GIS helps in the integration of all dataset geographically.

DEM dataset collected will be calculated for producing topographic elevation data and slope. This elevation and slope data will then be analyzed spatially based on the risk standard and vulnerability of these two parameters to produce a map of coastal area vulnerability to tsunami hazards. DEM data will be visualized using surface analysis in GIS as well as the slope was created from the DEM data. DEM data will be visualized using surface analysis in GIS as well as the slope was created from this DEM data.

The distance from coastline to the hinterland (coastal proximity) and the radius zone from river was calculated and created using vector base map of the study area and analyzed through multi-ring buffer of proximity analysis in GIS. In order to set the radius number of coastal proximity for assessing the risk area due to tsunami, Eq. (1) was applied.

$$log X_{max} = log 1400 + {}^{4}/_{3}\, log\left({}^{Y_0}/_{10}\right) \quad (1)$$

In which, X_{max} is represent the maximum reach of the tsunami over land, and Y_0 is the height of the tsunami at the coast. For applying this algorithm, a set of tsunami historical data which describe the information of maximum run-up in the area of study was collected. The class number of this coastal proximity was different for three research areas. Type of coastline was created also using vector base map of the study area by digitizing polyline data of the coastline and categorized it based on the coastal morphology type.

For preparing the land use data and build area of the study area, Sentinel-2 satellite image was analyzed using image classification process. The satellite image processing starts with the computation of TOA (Top of Atmosphere) Reflectance. The numeric digital counts (CN) of each pixel image (*i*,*j*) and each spectral band (*k*) are converted in TOA reflectance (ρ). This conversion takes into account the equivalent extra-terrestrial solar spectrum (*Es*), the incoming solar direction defined by its zenith angle (θs) for each pixel of the image and the absolute calibration (*Ak*) of the

Multispectral Instrument (MSI). As explained in Sentinel-2 technical guides [13], The TOA conversion equation as described in Eq. (2).

$$\boldsymbol{\rho_k(i,j)} = \frac{\boldsymbol{\pi \times CN_{k.NTDI}(i,j)}}{\boldsymbol{A_{k.NTDI} \times E_S \times d(t) \times \cos(\theta_s(i,j))}} \qquad (2)$$

where:
$CN_{k.NTDI}$ is the equalized numeric digital count of the pixel (*i,j*) with NTDI, the number of Sentinel-2 TDI lines. E_s is the equivalent extra-terrestrial solar spectrum and depends on the spectral response of the Sentinel-2 bands. The component *d(t)* is the correction for the sun-Earth distance variation (as described in Eq. (3)). It utilises the inverse square law of irradiance, under which, the intensity (or irradiance) of light radiating from a point source is inversely proportional to the square of the distance from the source [13].

$$\boldsymbol{d(t)} = \frac{\boldsymbol{1}}{\boldsymbol{(1-0.01673 \times \cos(0.0172 \times (t-2)))^2}} \qquad (3)$$

Where :
t is the Julian Day corresponding to the acquisition date. 0.01673 is the Earth orbit eccentricity. 0.0172 is the Earth angular velocity (radians/day). The parameters *Ak* and *Es* are provided by the GIPP and are also included in the ancillary data of the Level-1 products. The sun zenith angles are determined at this level too. A sun angle grid is computed by regularly down-sampling the target geometry (Level-1C tile). The cosine of the zenith angle *θs* is defined at each point of the grid using the ground coordinates and the datation of the corresponding pixel acquisition.

Reflectance value, often between 0 and 1, is converted into integer values, in order to preserve the dynamic range of the data by applying a fixed coefficient (1000 by default). This reflectance value was used as standard value in image classification process in which the supervised classification method was applied using several training area.

All geospatial databases will be analyzed through a spatial overlay process, where all parameters were in the form of a raster data base and processed based on the standard value of each parameter, as illustrated in Table 4 and Table 5. Analysis carried out through GIS with a pixel-based weighted overlay process. The weights of the parameter were constructing using pair-wise comparison matrix of Analytical Hierarchy Process (AHP) method.

Table 1 The physical vulnerability value range for elevation, slope, and landuse

Vulnerability class	Elevation (m)[1]	Slope (%)[2]	Landuse[3]
High	<5	0-2	Urban
Slightly high	5-10	2-6	Agriculture
Moderate	10-15	6-13	Bare soil
Slightly low	15-20	13-20	Water
Low	>20	>20	Forest

RESULT AND DISCUSSION

This study was one of the approaches in the integrated coastal hazard assessment, in which the analysis for describing the affected area caused by tsunami wave was studied. Analysis of all disaster risk parameters in this study obtained thematic maps of each parameter. This map illustrates the potential areas affected by the tsunami disaster. To get a conclusion of the risk area based on a combination of all parameters, a spatial overlay process for all parameters was carried out, with the multiplication concept of each pixel of parameter with its weight. The weight of each parameter was obtained from expert judgment and calculated based on the AHP approach. The conclusion of this calculation is the form of pair-wise comparison matrix with the required consistency ratio of less than 10% (2.9%), as explained in Fig. 2. The result of AHP calculation through pair-wise comparison matrix described that the elevation was parameters with the highest weight that affect the creating of risk maps. In contrast, the parameter of river distance was the lowest. In the future analysis, the different type of landcover would be important to be separated. The area with a high density of vegetation would be included in the low class of tsunami risk compare with the bare land.

In the application of parameter's weight for creating risk area map, a research on tsunami vulnerability in Alexandria was applied all parameter in equal weight due to the limitation of knowledge regarding to the study area [14]. The use of pair-wise comparison matrix in weight calculation also applied in the tsunami vulnerability mapping along coastal area of Miyagi Prefecture, Japan and. illustrated a similar pattern of tsunami vulnerability

area to the real tsunami inundation area during the 2011 Tōhoku's tsunami [15].

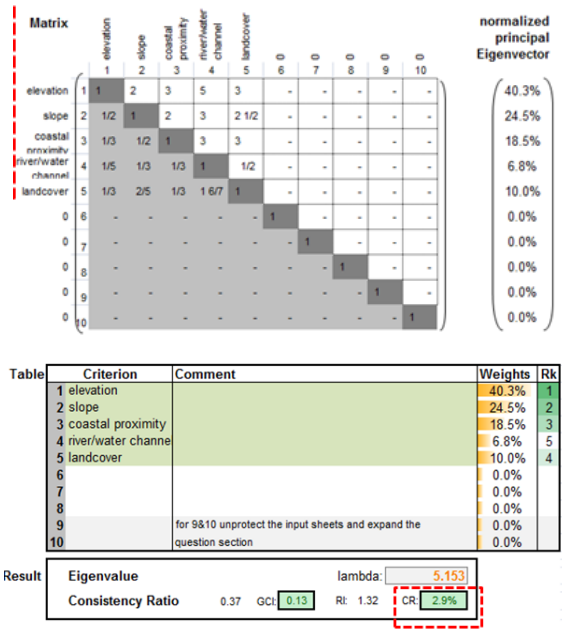

Fig. 2 Pair-wise comparison matrix and normalized principal eigenvector

The result of the analysis as describe on Fig. 3, Fig. 4, and Fig. 5. The map shows that in general the high risk areas were mostly found in the coastal area with the sloping coast type. Elevation and slope play an important role in determining the stability of the terrain in the coastal [16]. The research of tsunami vulnerability along coastal area of Bali, Indonesia described that the distribution of vulnerability is not uniform and physically it is highly influenced by the distance from coastline to the hinterland, topography elevation, and also slope [17]. The most risk area due to tsunami disaster in depends on the direction of tsunami source or the epicentre of the earthquake.

The results of this study illustrate that areas with low vegetation density, high distribution of build area, flat areas, and areas close to large rivers will have greater disaster risk. The existence of rivers in the coastal area will enable it to act as the successor to the tsunami wave that comes and takes it far towards the land until it reaches a certain elevation.

The outputs of the tsunami hazard analysis are very much dependent on data availability and the application of methods. The approaches range from simple empirical methods to sophisticated numerical simulations. Empirical methods use simplified formulas to derive tsunami hazard maps. In general, information on the elevation and the distances from coastline are applied in combination with empirical formulas to estimate the inundated areas on coastal areas [18].

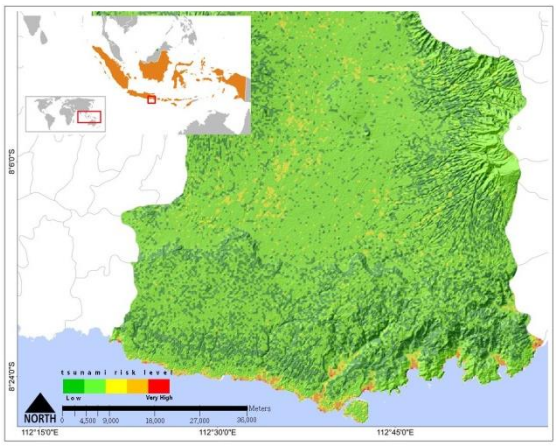

Fig. 4 Tsunami risk area in the coastal area of Malang, Indonesia

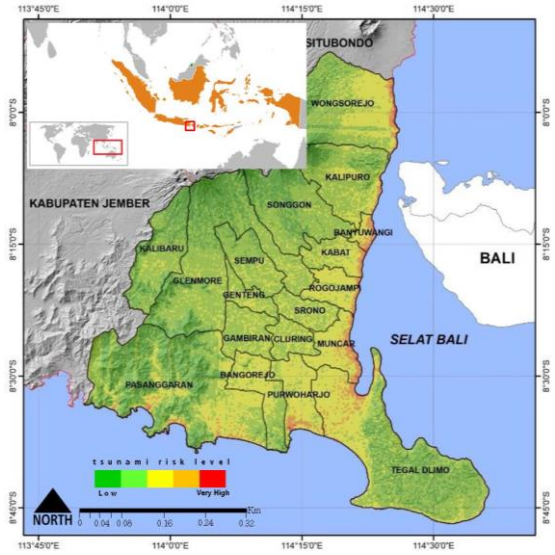

Fig. 5 Tsunami risk area in the coastal area of Banyuwangi, Indonesia

CONCLUSIONS

Risk and vulnerability assessment is one of the important steps in contributing the information regarding to the coastal hazard analysis. The concept and methods have been applied to compare the importance of using risk parameters by testing them in three different coastal regions. From the analyses key parameters are derived and integrated for assessing the risk and vulnerability map. The result will be act an important role for effective early warning system. In the future work, the social and ecological parameter will be an important parameter for analysis.

DIAPHRAGM WALL DISPLACEMENT WITH UPLIFT CONSIDERATION FOR VERY DEEP BASEMENT EXCAVATION IN SOFT BANGKOK CLAY

Wanchai Teparaksa[1], Jirat Teparaksa[2] and Mike Sinkinson[3]
[1]Faculty of Engineering, Chulalongkorn University, Thailand; [2] Strategia Engineering Consultant Co., Ltd., Thailand; [3]Thai Bauer Co., Ltd., Thailand

ABSTRACT

High-rise condominium is being constructed in Bangkok city center, Thailand. It consists of six underground basement floors (B1-B6) planned to be underground automated car park as this system provides much more parking spaces than the conventional which requires many ramps to access to basement floors. To provide space for automatic car park system, basement floors number B2, B3 and B5 were taken out of the design leaving only B1 (-3.20 m), B4 (-10.85 m) and B6 (-16.50 m). The maximum depth of excavation is -21.00 m which is desired for lift pit while the normal depth of excavation is -19.50 m. Diaphragm wall of 0.80 m and 1.20 thick were used as a soil retaining structure with five layers of temporary bracing strut. At the center strip of the basement floors in the longitudinal side, it is a void space throughout six basement slab causing weaker system of diaphragm wall. Therefore, the thickness of diaphragm wall was revised to be 1.20 m with band beams as a strengthener to resist the lateral earth pressure. Since the depth of excavation was deep, the effect of uplift pressure was also considered. The Finite Element Method (FEM) was conducted to predict the behavior and displacement of the diaphragm wall with the Mohr-Coulomb soil modeling as a failure criteria. During the construction, the displacement of the diaphragm wall was recorded and was compared with the FEM result. The predicted value by FEM agreed well with the field performance.

Keywords: Diaphragm wall, basement construction, finite element method, wall displacement, deep excavation

INTRODUCTION

High-rise residential building with six floors of substructure is being constructed in Bangkok city center. Basement floor of this building is desired to be an underground automatic carpark. This system maximize parking space by eliminating driving path and ramps. In order to provide space for automated car park system, basement floor number B2, B3 and B5 were taken out of the design leaving only B1 (-3.20 m), B4 (-10.85 m) and B6 (-16.50 m). General depth of excavation is -19.50 m while the maximum depth of excavation is -21.00 m in lift pit area. Diaphragm wall (D-Wall) of 0.80 m and 1.20 m thick were employed as a soil retaining structure. The former was intended for the general excavation area while the latter was designed for lift pit area due to higher induced bending moment. The tip of D-Wall is penetrated in the hard clay layer at -35.00 m. There were five temporary bracing strut layers at – 2.00, -5.50, -9.00, -12.50 and -15.80 m.

Typical sections of bracing system and basement structure are presented in Fig 1 and Fig 2. In this project, car lift was located closed to diaphargm wall leaving the opening (6.40 x 7.60 m) at every basement floor as can be seen in Fig 2. Special band beam was designed to transferr axial force from the retaining structure to the basement slab.

The research work for study the behavior and performance of diaphragm wall for basement construction in Bangkok subsoil with various conditions was presented by Teparaksa[1],[2],[3].

This paper presents the performance and behavior of the diaphragm wall. The lateral displacement of diaphragm wall is predicted by FEM analysis by simulating the construction sequence in the analysis. The lateral wall displacement was monitored during excavation and casting the basement floor. The FEM prediction was compared and discussed with the field performance.

SOIL AND GROUND WATER CONDITIONS

Two boredholes of 70 m deep were carried out to investigate soil condition for underground structural design. It consists of a 11.5 m thick very soft Bangkok clay layer followed by soft clay layer to -15.0 m deep. The medium stiff clay and very stiff clay are encountered from -14.0 to -17.0 and -17.0 to -20.5 m, respectively. From -20.5 m to -24.0, a 3.5-m-thick very stiff clay layer was found. The first dense sand layer was at -24.0 to -28.0 m while the second sand layer was at -30.0 to -34.0. After the second dense sand layer, it was a hard clay layer where the tip of diaphragm wall is penetrated into. Fig 3 shows illustration of soil profile and engineering properties.

Groundwater condition of Bangkok soft clay is hydrostatic strating from -1.0 m. The deep well pumping in the past had promoted under drainage of the soft and the first stiff clay. The piezometric level of Bangkok aquifer was reduced and was constant at -23.0 m [1] causing advantages to geotechincal engineers such as higher effective stress and dry condition during underground construction. However, 20 years ago, Thailand's government prohibited deep well pumping to solve the problem of land subsidence promoting an increase in piezometric level up to -13.0 m as presented in Fig 4 [4].

ANALYSIS OF DIAPHRAGM WALL BEHAVIOR BY FINITE ELEMENT METHOD

Design Criteria of Diaphragm Wall

The behavior of diaphragm wall can be predicted by numerical analysis by means of Finite Element Method (FEM). The result of FEM analysis of diaphragm wall behavior is presented in term of bending moment and shear force induced in the diaphragm wall as well as lateral displacement. The soil modeling is one of the main parameters for FEM analysis. The step of soil excavation, bracing installation, as well as preloading in the strut system are simulated in the FEM analysis. The casting of base slab, basement floor and the step of removal of strut system are also have to be designed and combined in the FEM analysis of diaphragm wall. In this project, the PLAXIS 2D [5] program wa used as the FEM program analysis to predict the diaphragm wall behavior. In this regards, the bending moment, shear force and lateral displacement can be determined at all construction steps.

The Mohr-Coulomb soil modeling was emloyed. The Undrained Young's modulus (Eu) of each clay layer was correlated with undrained shear strength (Su) while in the sand layer, the drained modulus (E') was correlated with the Standard Penetration Test (SPT) N-value.

The correlation of Eu and Su as well as E' and N-value can be conducted as follows.

- For soft to medium clay layer, Undrained Young's modulus
  (EU) = 500 – 700 Su (Undrained Shear Strength)
- Stiff to very stiff silty clay layer
  Eu = 1000 Su
- Sand layer
  E' = 2000(N) SPT-N-Value (kN/m^2)

The above correlations between Eu-Su, and E'-N(value) are based on the back analysis from various basement excavation projects by means of FEM analysis compared with field measurement proposed by Teparaksa [6].

Surcharge on the diaphragm wall

The ground surface surcharge behind the diaphragm wall during construction was assumed at 10 kN/m^2 to simulate possible loads such as truck traffic and loading of materials. However, the surcharge value affects the diaphragm wall behavior in inducced bending moment, shear force and lateral displacement. The appropriate value have to be selected. In authors experience, 10 kN/m^2 is closed to real situation. This ground surface was applied during excavation, basement casting and completion of the basement work.

Groundwater table

The ground water in Bangkok subsoil condition is in the draw down condition due to deep well pumping. Recently, as the deep well pumping is not allow, the recent ground water table was at -13 m. below ground surface. The original design of D-Wall length was only 25 m deep. However, according to uplift calculation, the safety factor against uplift was too low. Therefore, length of D-Wall was lengthened to be penetrated in the hard clay layer at -35 m just before the construction of D-Wall.

FEM ANALYSIS RESULTS

All the construction sequences were taken into the account in FEM analysis using Mohr-Coulomb as a failure criteria. The first stage was first excavation just little below the first temporary bracing strut. The second was the first strut layer installation and excavation to litle below the second strut layer. The process continued until reaching the final depth. The deformed mesh at this stage is shown in Fig. 5. At final depth, the mat footing was casted followed by removal oftemporary bracing strut layer 5 and 4. respectively. The bracing layer 3 can be removed after casting of basement slab B4. The process continued until the ground floor slab was casted as shown in Fig. 6.

In FEM, all the basement floors were modelled. This was intended to determine the axial forces in basement for band beam design. The design and construction of band beam was complicated. Stirrup of band beam was casted with the D-wall during D-Wall construction and was then pulled out during basement construction to combine with the transverse reinforcement which would act against horizontal force. The band beam was 3 m high. Fig 7 and 8 show the photos of band beam construction. This project was one of the very first projects in Thailand with band beams as a force transfer structrure.

Fig 9 presents the envelop of bending moment diagram induced in the diaphragm wall with all excavation steps including soil excavation and bracing installation until casting the foundation. The upward construction including casting base slab, removing of bracing as well as basement casting are also included in the envelope.

Diaphargm wall reinforcement was designed based on this bending moment envelop. It can be seen that the capacity of reinforcement covers all the construction sequences.

DIAPHRAGM WALL DISPLACEMENT AND TRIGGER LEVEL AND SAFETY CONTROL

Inclinometers were installed in the diaphragm wall to monitor wall deflection. The safety control and monitoring criteria were proposed in terms of trigger level as shown in Table 1. During construction inclinomter data was recorded and compared with the analysis as shown in Fig 10. It can be observed that the performance of diaphargm wall agreed well with the FEM analysis. It should be noted that the latest reading was during the third bracing strut removal. The basement construction is not yet finished.

Fig. 8 Band beam during construction

Table 1 Trigger level and safety control

Trigger Level	Inclinometer Movement (mm)		Safety Crteria
	General Area	Lift Pit Area	
Alarm Level (70 % of DV)	37.65	31.39	Inform designer to review CS
Alert Level (80 % of DV)	43.02	35.87	Inform all parties to review CS
Action Level (90 % of DV)	48.40	40.36	Stop construction and revise the CS
Maximum	53.78	44.84	

Note: DV = Design Value, CS = construction sequence.

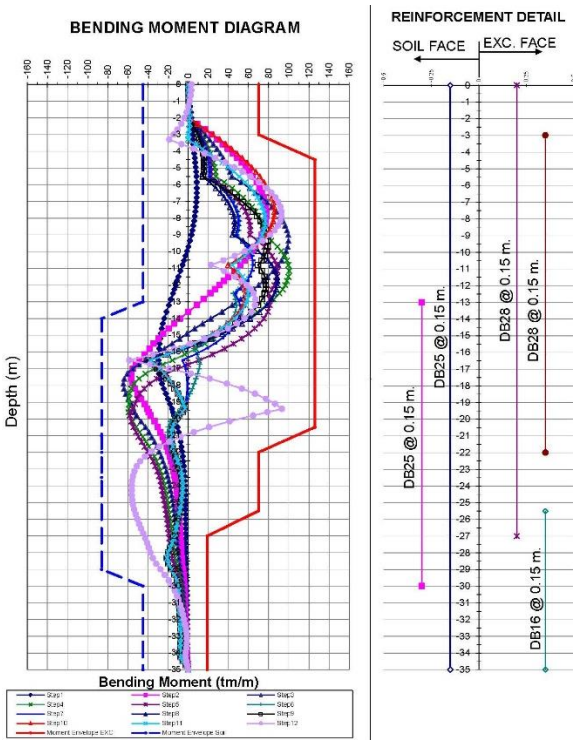

Fig. 9 Bending moment induced in diaphragm wall and reinforment

SAFETY AGAINST UPLIFT PRESSURE

The maximum depth of excavation of this project was -21 m. The illustration of sand layer where uplift pressure occurs is shown in Fig 11. The pressure occurs in sand layer at EL.-45.0 to EL.-47.0 m. Uplift pressure based on D-Wall tip of -35 m was estimated to be 320 kN/m^3 while the overburden stress of soil is 501.3 kN/m^3 and 473.2 kN/m^3 at general area and lift pit area, respectively. Thus, the safety factor against uplift is 1.57 and 1.47 which is higher than the required minimum value, 1.30.

The original design of D-Wall was only 25.0 m in length. The safety factor against uplift was too low. Thus, the d-wall tip was lengthened to -35.0 m to be penetrated in the hard clay layer. In addition, the groundwater of Bangkok keeps raising due to prohibition of deep well pumping. It is important to consider uplift issue for deep excavation in the future.

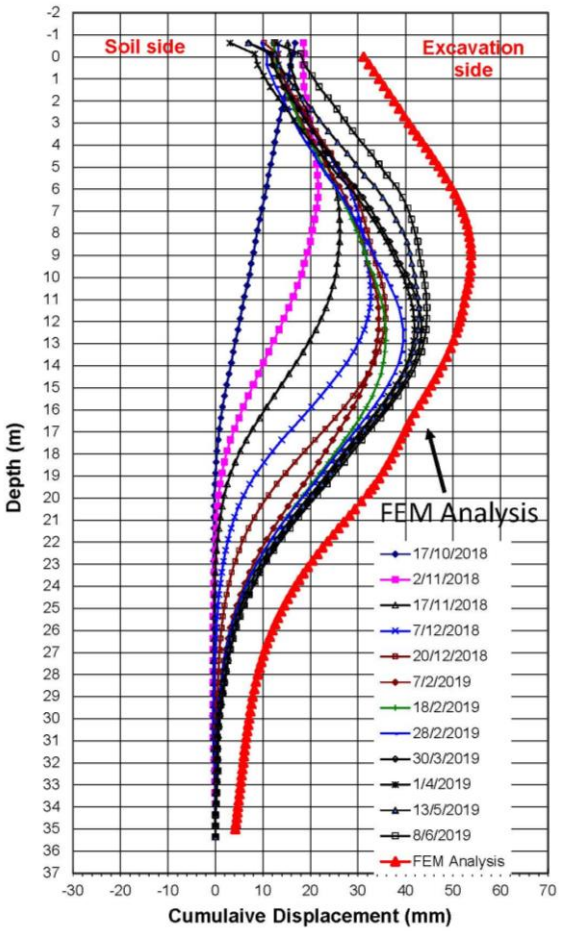

Fig. 10 Diaphragm wall displacement monitoring data and FEM analysis

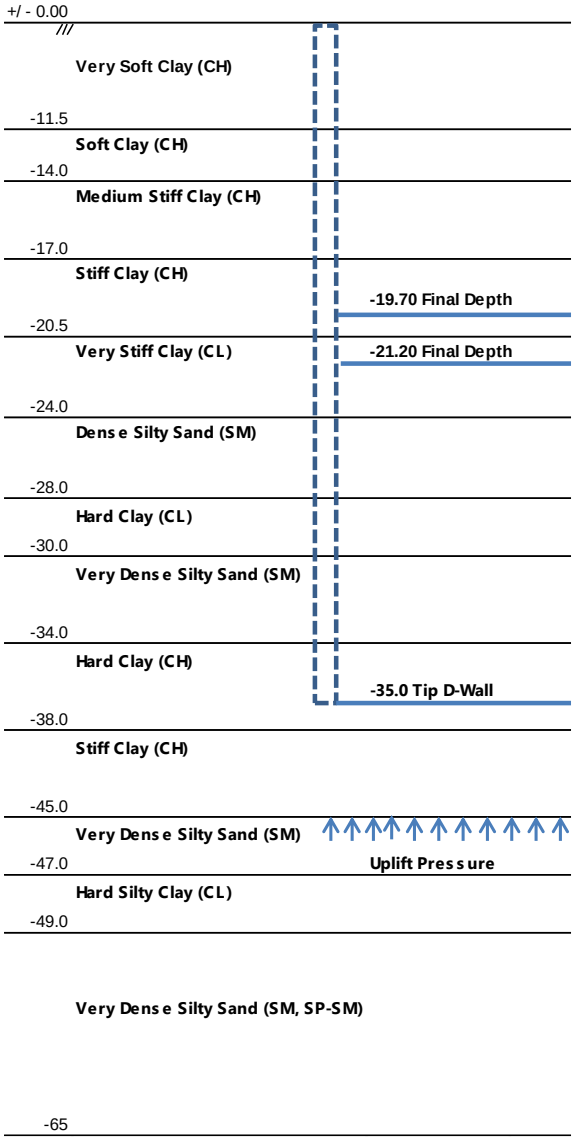

Fig. 11 Illustration of uplift pressure in sand layer

CONCLUSIONS

The underground basement construction was designed to be underground automatic carpark of the high-rise residential building. It consisted of six baseement floors using diaphragm wall as a soil retaining structure. However, to minimize space for automatic system, floor B2, B3 and B5 was cleared leaving only B1, B4 and B6. In addition, the car lift was located closed to the diaphargm wall promoting opening throught out the underground basement from B6 to ground floor. Band beam was designed to resist and transfer force to the basement slab. Safety against uplift was checked.

The behavior of diaphargm wall was predicted by means of FEM analysis with Mohr-Couloub failure criteria. All the construction sequences were simulated in the FEM. The diaphargm wall behavior and displacement were predicted and compared with the field monitoring data from inclinometer installed in the diaphragm wall. The FEM result agreed well with the field performance.

ABSTRACT

Expansive soil is considered as one of the most problematic soil in geotechnical engineering arena due to its swell-shrinkage behavior. In developing countries like Bangladesh, coal-based power plant is increasing day by day which leads to generate large amount of fly ash. Geopolymer stabilization is a suitable way to improve the properties of such soil which utilize the Fly Ash (FA) as a binder with some chemical additives. This research represents the laboratory investigation on expansive soil stabilized with fly ash based geopolymer. In this Consequence, synthesized expansive soils has been treated with FA treated geopolymer at different mix ratios and engineering properties of such treated soils are examined through laboratory investigation. Besides, swelling index, which is one of the major indicator for differentiating expansive soils are also experimentally determined. The significant increase of unconfined compressive strength and reduction of Modified free swell index is observed on geopolymer treated expansive soil compared to its original condition. To be specific, an optimum amount of 20% stabilizing agent is found to improve the swelling behavior of expansive soils.

Keywords: Fly ash, Expansive soil, Geopolymer Stabilization, Modified free swell index

INTRODUCTION

Foundations on problematic soils is always a concern in geotechnical engineering. Among several problematic soils, expansive soils is one of the most unreliable soils for safe foundation design due to its swell-shrink behavior. The Na^+ based clay minerals which expand in the presence of water exhibits huge swelling pressure. This swelling pressure is responsible for damage of foundations, roads, embankments etc. Considering the risk of failure of structures on expansive soils, researchers have been trying to found some efficient and economical remedial measures. To date, several approaches were developed and suitability of those methods have been validated by experimental and in-situ applications. Partial replacement of expansive soils with non-expansive soil is one way to stabilize the problematic soils. Concomitantly, treatment of expansive soils with stabilizing agent(s) is a clever approach in rational mitigation of the associated problem. Some common stabilizing agents are Ordinary Portland Cement (OPC), lime, Ground Granulated Blust Furnace Slag (GGBFS), Fly Ash (FA) etc. All the same, the stabilizing agent itself is not capable of improving the properties of soils owing to the lack of binding agent. With the current scenario, adding some additives with the stabilizing agent accelerate binding nature and expedite strength gain in many instances. OPC is so far the mostly available and viable stabilizing agent used to improve the soils. However, Use of OPC associated with some environmental issues, like the cement production discharge CO_2 around 5% of total CO_2 released into air [1]. Keeping the current scenario in mind, an alternative approach of using environmental friendly agent is suitable over the conventional approach. FA, which is the industrial by-product can be a good option considering no threat for environment and safe disposal. Chemical additives i.e. geopolymer based treatment is necessary to be added to the FA to make it active in the bonding. The chemical reactions of Geopolymerization process is entirely different from conventional Portland cement/lime type admixtures. Polymerization process includes a very first chemical reaction of Si-Al minerals in presence of alkali activators (Sodium/potassium hydroxide and sodium silicate), which results a 3D polymer ring and chain type structure having Si-O-Al-O bonds [2].

Expansive soil treatment by 9% of GGBFS and cement by-passes dust mix was found to reduce swelling index and pressure [3]. Cokca, Yazici & Ozaydin [4] found that 15% of Granulated blast furnace slag-cement (GBFSC) admixture is optimum for lowering swelling percentage up to 10 times of untreated expansive soil having high swelling potential. Yadu & Tripathi [5] used GGBFS to stabilize expansive soil and found 9% admixture as optimum which increase the UCS around 28% of untreated soil. the presence of

expansive clays are generally found in steppe climate zone where the precipitation is much less compared to evapotranspiration [6]. In Bangladesh presence of expansive soil was found in several locations named as Joydevpur, Savar, Lalmai Hills of Cumilla and some part of Rajshahi and Tangile [7].

Summarizing the above discussions, an attempt was made to check the effectiveness of fly ash based geopolymer for stabilizing a laboratory synthesized expansive soil. The performance of geopolymer binder was evaluated based on its improvement of strength and swelling properties. The subsequent sections describe in detail the outcomes of the current study.

MATERIALS

Expansive Soil

The expansive soil used for this study was synthesized artificially in laboratory. Firstly, a suitable clayey soil was collected near the coastline of Bangladesh and 5% of commercial grade Bentonite was blended with pulverized clay soil to generate expansive behavior. The nature of expansive soil was medium expansive as per IS: 1498-1970 [8]. The geotechnical properties of medium expansive soil are listed in table 1 and the particle size distribution is shown in Fig. 1.

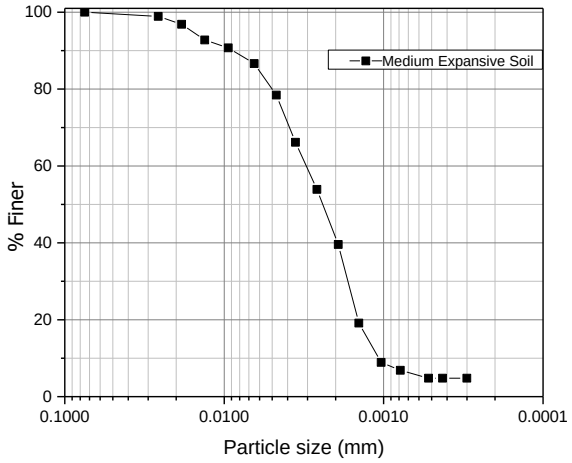

Fig. 1 particle size distribution of used soil.

Geopolymer

The main constituents of geopolymer used for soil stabilization is alkali activators and binder materials. The function of alkali activators is to stimulate the reaction of polymerization process. In present study, sodium silicate (Na_2SiO_3) solution and sodium hydroxide (NaOH) pallets were collected from local supplier to prepare alkali activator of geopolymer. Equal proportion of Sodium hydroxide and sodium silicate was mixed to prepare alkali activator solution prior to use and 10% of this solution was used in geopolymer. Class F fly ash was used as binder. Table 2 represents the properties of fly ash. A total of five mix ratios from 10% to 30% by weight of fly ash was replaced with natural soils, while the amount of alkali activator was kept fixed for all cases.

Table 2 Properties of Fly ash

Specific Gravity	Fineness (cm^2/g)	SiO_2 (%)	Fe_2O_3 (%)	Al_2O_3 (%)
2.22	2325	62.1	6.6	22.4

TEST PROGRAM

Series of experimental program was run on geopolymer treated and untreated synthesized expansive soil. In this study, dosage of geopolymer indicates the amount of fly ash present in geopolymer such as 10% geopolymer treated soil means the mixture have 10% fly ash, 10% alkali solution and 80% dry soil. where the 0% geopolymer denoted as the untreated soil.

firstly, required amount of fly ash and soil was mixed in dry condition through a mixture machine. Alkali activator solution was gradually applied thereafter and mixed until a homogeneous mixture is obtained.

Compaction test was performed maintaining standard effort (600 kN-m/m3) for each mix combination to find the optimum moisture content and maximum dry density. Figure 2 represents the compaction curve of different soil-geopolymer mix.

The samples for unconfined compressive strength (UCS) test were prepared in laboratory according to the standard procedure of ASTM D 1632 [9] maintaining the optimum moisture content and maximum dry density obtained from compaction curve. Three identical samples were tested under compression loading for each case and the average value was taken. The UCS test was performed on both untreated and treated soil samples immediately after preparation which is reported as 0 days strength.

In addition, the strength development with the time was also checked. For this, UCS samples were warped with thin cling film and preserved in desiccator to check the strength after 7days and 28 days.

Table 1 Geotechnical properties of used soil

Liquid Limit (%)	Plastic Limit (%)	Plasticity Index (%)	Swelling Pressure (kPa)	Specific Gravity	Clay (%)	Silt (%)	Sand (%)	USCS Classification
42	19	23	81	2.56	9.0	91	--	ML

The swelling parameter of expansive soil was determined in terms of modified free swell index (MFSI). To observe the effect of geopolymer stabilization, modified free swell index test was performed after 28 days curing age. The soils were oven dried, pulverized to pass through 425-micron sieve and 10 grams of soil was dispersed in distilled water and placed on a 100 ml graduated cylindrical jar. The MFSI is calculated as the ratio of equilibrium sediment volume (V_d) of dispersed soil to its dry weight [10].

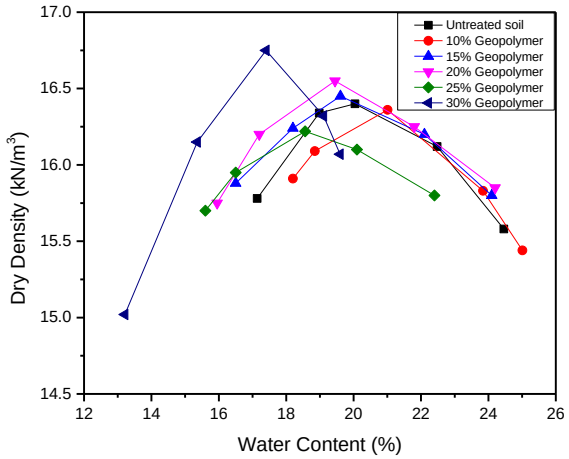

Fig. 2 Compaction curve of different soil-geopolymer mix.

RESULTS AND DISCUSSION

The influence of various geopolymer dosage on artificial expansive soil was evaluated in terms of UCS and MFSI. The general trend of compaction test is not clear, though increased dry density was seen with the increment of geopolymar content. Concurrently, moisture content shows slight decreasing trend with the variation of geopolymer content. The variation of strength and swelling behavior of geopolymer stabilized expansive soil are explained separately as following:

Effect of Stabilization on Unconfined Compressive Strength

The UCS of untreated expansive soil was found 88 kPa and remain constant with curing time. The effect of geopolymar was compared by normalizing its strength with the untreated soils. Figure 3 represents the variation of normalized compressive strength of geopolymer treated soil at different curing age.

The strength gaining rate of geopolymer treated expansive soil is observed to very low at 0 days curing. At any particular geopolymer dosage UCS increase continuously with curing age which indicates that, the curing time have significant effect on strength development. For 20% geopolymer stabilized soil UCS is only found 1.7 which increased up to 2.8 and 4.2 times after 7 and 28 days, respectively. The maximum normalized UCS was found as 4.2 at 28 days for 20% geopolymer content

The experimental results also show the decrement of normalized UCS after 20% of geopolymer content. Similar trend of unconfined compressive strength development was also reported for fly ash - lime treated expansive soil [11]. Cementation of soil particles happens in treated soil matrix due to stabilization with chemical additives up to a certain percentage of admixture.

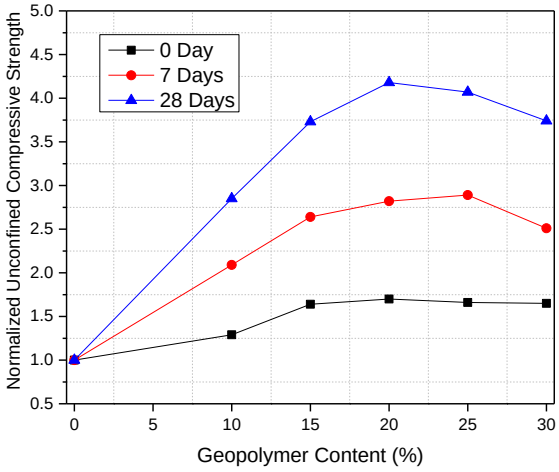

Fig. 3 Effect of Geopolymer content on Normalized UCS of expansive soil.

It was observed that during stabilization of expansive soil with increasing percentage of admixture, the soil particles become more granular in shape [12]. However, for higher percentage the above-mentioned process reach saturation level and excess additive remains unbonded that reduce overall strength level of soil [13].

Effect of Stabilization on Modified Free Swell Index

Figure 4 represents the variation of modified free

swell index with the variation of geopolymer content. The figure indicates that as the percentage of geopolymer increases the modified free swell index of soil decreases.

The MFSI of untreated expansive soil is found 1.75 and that of treated soil is observed to vary from 1.55 to 1.2 due to variation of geopolymer content from 10 to 30%. However, A steep reduction of modified free swell index has been noticed for geopolymer content up to 15% and the reduction rate becomes slower thereafter.

The fly ash provides multivalent cation to soil which results flocculation and reduce water affinity of expansive soil. When such non expansive admixture is added to soil, the swelling behavior of expansive soil decreases to some extent [11].

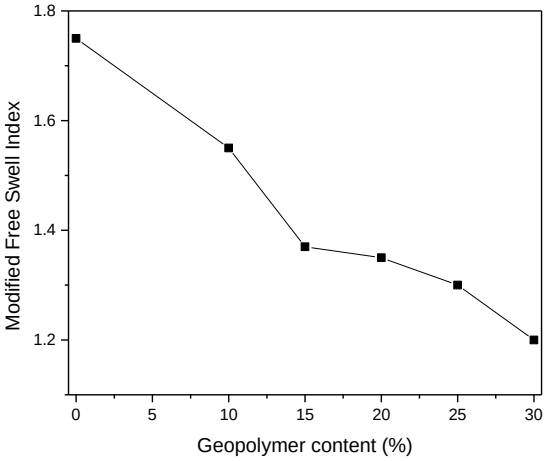

Fig. 4 Variation of modified free swell index with geopolymer content.

CONCLUSIONS

The Effect of various percentage of geopolymer on strength and swelling properties of expansive soil was investigated experimentally. The major conclusions are listed below:

1. Addition of geopolymer dosage increase the dry density of treated soil while the optimum moisture content decreases.
2. The swelling behavior of geopolymer treated soil reduced substantially with the increment of fly ash content in geopolymer.
3. Strength gaining of geopolymer treated expansive soil is time dependent. After 28 days curing the unconfined compressive strength is almost 4.2 times of instant strength.
4. The maximum unconfined compressive strength of treated expansive soil is found for observed for geopolymer having 20% fly ash content and 10% alkali activator solution.
5. Based on experimental study 20% geopolymer dosage can be taken as optimum dosage for stabilization of expansive soil.

RELATIONSHIP BETWEEN DRAINAGE DENSITY AND DEGREE OF DISSECTION OF LARGE-SCALE LANDSLIDES IN SHIKOKU, JAPAN

*Daisuke KANBARA[1], Shuichi HASEGAWA[2], Atsuko NONOMURA[2], Makoto YANAGIDA[3] and Matsuri KIMURA[1]
[1]Yonden Consultants Co., Inc, Japan, [2]Kagawa University, Japan; [3]Hanshin Consultants Co., Ltd, Japan

ABSTRACT

A geomorphic approach is essential for landslide investigation because it represents different topographies from the surrounding slopes. Yanagida and Hasegawa first proposed a relational expression between the formation age of landslides and the degree of dissection by using carbon-14 dating and volcanic ash to compare the age of formation. As a result, it became possible to estimate landslide age even for landslides whose formation age is unknown.

In this study, the relationship between the degree of dissection and drainage density, which are both indicators of landslide topography, by using digital elevation model (DEM) data. We determined the relationship between drainage density and degree of dissection for 17 landslides in Shikoku in Southwest Japan, where the degree of dissection was already known from previous studies. An approximate relationship between the drainage density (V_1, km^{-1}) and the degree of dissection (D, %) of landslide bodies can be expressed as $D = e^{0.72V_1}$.

Keywords: Landslide, DEM, Drainage density, Degree of dissection, Relative drainage density

INTRODUCTION

Landslide is defined as "A general term covering a wide variety of mass-movement landforms and processes involving the downslope transport, under gravitational influence, of soil and rock material en masse" [1], and landslides play a significant role in terrain formation in mountainous areas [2]. Most landslide topographies are inferred to have been formed by strong triggers. If a landslide has stabilized, dissection of the surface landslide topography and the landslide mass will begin [3]. The topographic development of a landslide is therefore important information when evaluating the stability of the landslide [4, 5].

In recent years, research on landslide analysis using digital elevation model (DEM) data acquired by aviation laser surveying has been ongoing [6]. The use of this type of data enables researchers to conduct topographic analyses over wide areas much faster than could be done manually. It has also become possible to extract drainage and inclination information with good reproducibility. Research and development has been generally been conducted to extract high risk area from surrounding slopes by using multiple parameters, including landslide micro topography. For example, the Slope Stability Evaluation (SSE) model using satellite data and geographical information has been developed [7].

The formative age of landslides is estimated by ^{14}C dating of wood fossils in landslide deposits and identification of volcanic ash that covers or is part of the landslide deposits [8, 9]. Yanagida and Hasegawa [10] focused on the erosion of the topography of a landslide similar to the terrace analyzed by Suzuki [11] and Ota and Ikura [12], and they estimated the correlation between the formation age of the landslide and the degree of dissection. In addition, Kanbara et al. [13] identified landslide ages by using volcanic ash and improved the accuracy of the relationship between topographical analysis and landslide age. Inagaki et al. [14] have reported that landslide topographies with older formative ages are more stable.

On the other hand, Tsukamoto et al. [15] and Tsukamoto and Noguchi [16] regard the collapse of mountains as valley development. I In other words, the development of valleys can be regarded as a slope dissection process. Landslides have been regarded as a rejuvenation of river systems in mountains [17], and landslide topographies have been considered as slopes with drainage density smaller than that of the surrounding area [18]. Hasegawa et al. [19] and Kinoshita et al. [20] developed a method for evaluating slope failure using drainage density and reported that the larger the drainage density, the larger the collapse density.

In this study, we focused on valley development (drainage density) and examined the relationship between the dissection rate of landslide topography and drainage density. The examinations were conducted by using a DEM in conjunction with available data to make determining the relationship between the degree of dissection and drainage density

as simple and easy as possible.

STUDY AREA

We have collected information on 17 landslides whose formative ages were inferred by using ^{14}C dating and volcanic ash in Shikoku, southwest Japan (Fig. 1).

On the 17 sites, landslides 1 to 13 were reported by Yanagida and Hasegawa [10], and 14 to 17 were reported by Kanbara et al. [13].

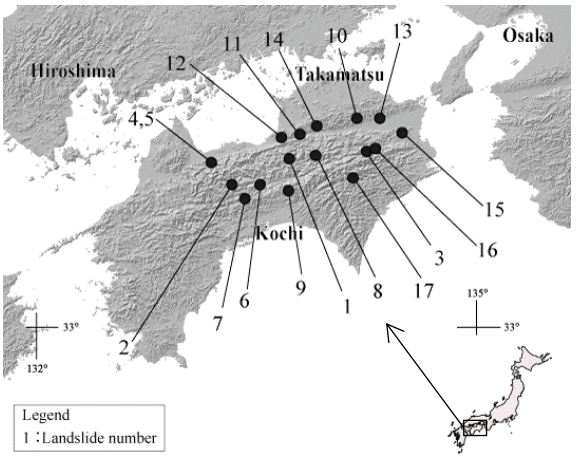

Fig. 1 Study area

METHODS

DEM Data and Analysis Software

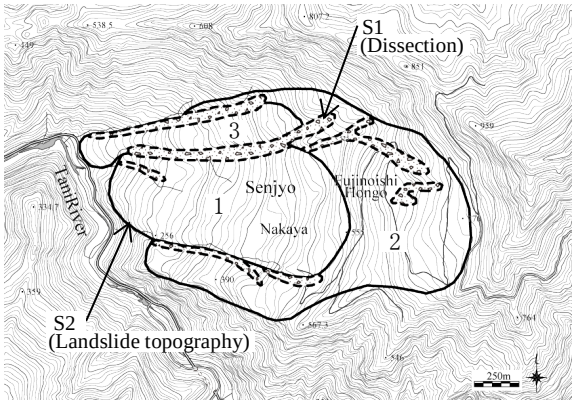
The 10-m resolution DEM data used for topographical analysis were acquired from the Geospatial Information Authority of Japan (https://fgd.gsi.go.jp/download/menu.php). ILWIS 3.3 Academic, a published source code, was used for the analysis of drainage density.

Degree of Dissection of Landslide

We have used the method described by Yanagida and Hasegawa [10]. The degree of dissection (D, %) as the ratio of the dissection surface area (S_1, km^2) to the landslide mass surface area (S_2, km^2) are defined as follows.

Degree of dissection*(D)* = Area of dissection *(S_1)* / Area of landslide topography *(S_2)* (1)

Figure 2 shows an example of the measurement method. First, we transcribed the landslide mass onto 25,000:1 topographical maps and obtained the surface area of landslide unit 1 (S_2=0.71km^2) using the Auto Cad LT (Auto Desk) surface area calculation function. Next, we have conducted photographic interpretations of dissections using 10,000:1 scale aerial photographs, transferred them to 25,000:1 topographic maps, and thereby obtained the dissection surface area of landslide unit 1 (S_1=0.04 km^2) with the Auto Cad LT (Auto Desk) surface area calculation function. The degree of dissection was then calculated as $D=S_1/S_2$=0.04/0.71 or about 6%.



Unit 1, D = 6%; unit 2, D = 12%; unit 3, D = 26%.
S_1, Area of dissection (km^2);
S_2, Area of landslide topography (km^2); and
D, Degree of dissection of the landslide topography (%) ($D = S_1 / S_2$).

Fig. 2 Method for evaluating the degree of dissection of a landslide

Drainage Density

Mean curvature

Mean curvature defined as the average of the maximum and minimum values of the curvature of all measurement lines passing through a point on a curved surface, is used as an indicator of topographic unevenness. We have extracted the valleys, which determined the mean curvature (H), by using the equation (2) [21].

$$H=\frac{h_{xx}\left(1+h_y^2\right)+h_{yy}\left(1+h_x^2\right)-2h_xh_yh_{xy}}{2\left(1+h_x^2+h_y^2\right)^{3/2}}, \quad (2)$$

where h is elevation and

$$h_x=\frac{\partial h}{\partial x},\ h_y=\frac{\partial h}{\partial y},\ h_{xx}=\frac{\partial^2 h}{\partial x^2},\ h_{yy}=\frac{\partial^2 h}{\partial y^2},\ \text{and}\ h_{xy}=\frac{\partial^2 h}{\partial x\partial y}.$$

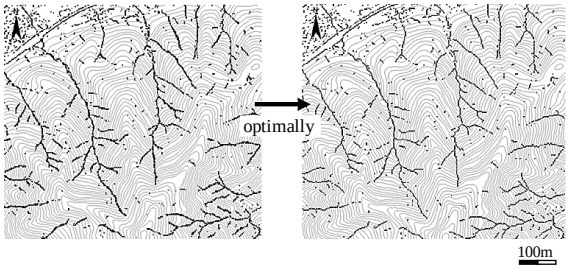
We set the mean curvature at H>0.10 following Nonomura et al. [22]. We optimized the line width to one pixel following Kinoshita et al. [20] (Fig. 3).

Calculation of drainage density

Drainage density represents the degree of development of the river drainage in an area, and

erosion becomes stronger as drainage density increases [23]. The valleys were evaluated by counting the number of pixels contained in the extracted valleys. Following equation (3) was used to determine of drainage density.

$$\text{Drainage density } (V_1)\ (\text{km}^{-1}) = \frac{\text{Total extension of the extracted valley(km)}}{\text{Basin area}\left(\text{km}^2\right)} = 100 \times \frac{\text{Total number of valley pixels contained in the extracted valleys}}{\text{Total number of basin area pixels}} \quad (3)$$



Before optimization After optimization

Fig. 3 Optimization of a valley

Degree of relative drainage density

The physical properties of the bedrock strongly influence the topography [24], and they are considered to control the development of the valley surface [25]. Therefore, in 17 landslides evaluated in this study, we decides to the relative drainage density with the surrounding slope (E) in order to reduce the influence of differences in bedrock (equation (4)).

Relative drainage density *(E)*
= drainage density of landslide bodies (V_1)
/ drainage density of surrounding slope (V_2) (4)

RESULTS

The surrounding slopes were chosen to examine the relative drainage densities of selected landslides (Fig. 4).

The drainage density and the degree of dissection of selected landslide topographies of the 17 landslides are shown in Table 1. The drainage networks determined by using the DEM were in agreement with the degree of dissection determined by using the aerial photographs. Scattered valleys were identified as undissected slopes in aerial photo interpretation.

DISCUSSION

Relationship between Drainage Density and Degree of Dissection

The relationship between drainage density and degree of dissection was examined for 17 landslides at some places in Shikoku, Southwest Japan. Figure 5 shows that the drainage densities increased according to the degree of dissection in landslides 1 to 17. In other words, after landslide formation, the drainage density is reset to almost zero.

Table 1 Measurement results of the degree of dissection (*D*), drainage density (V_1), and relative drainage density (*E*).

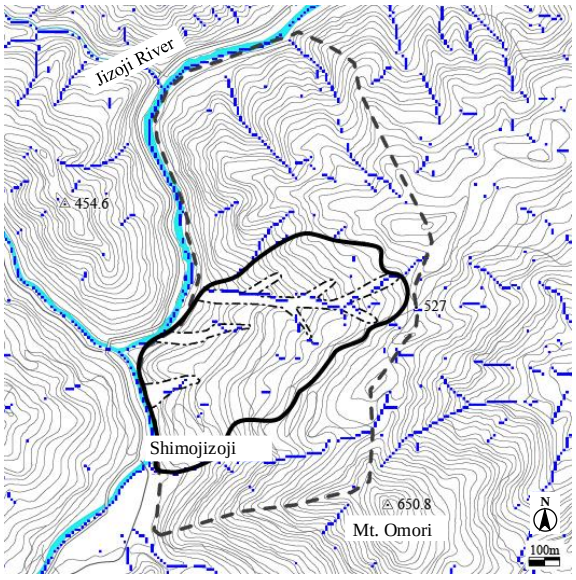
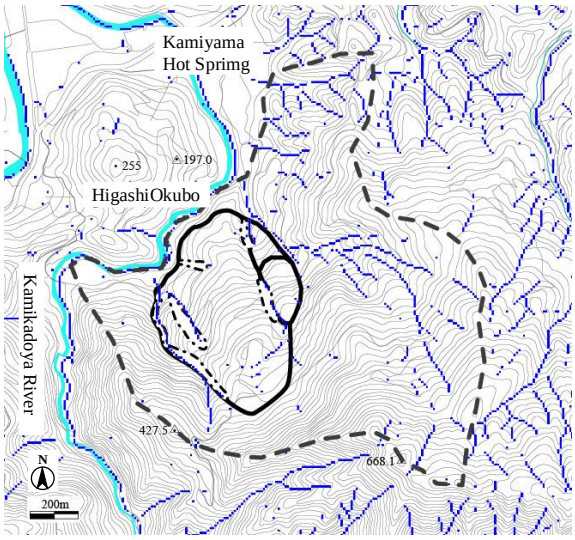
Relative drainage density = 1.6



No. 8 Shimojizoji
Degree of dissection = 17.0%,
Drainage density = 3.1%,
Relative drainage density = 1.0



No. 15 HigashiOkubo
Degree of dissection = 10.6%,
Drainage density = 2.3%,
Relative drainage density = 0.6

Fig. 4 Analysis results examples

It shows that the dissected valleys in landslide bodies then start to develop, and as a result, drainage density starts to increases. The exponential relationship shown in Figure 5 can be expressed as $D = e^{0.72V_1}$ and can be used to evaluate dissected landslides.

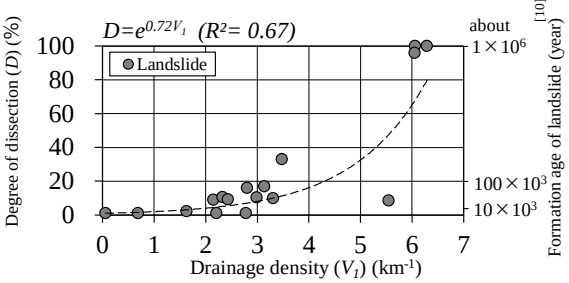


Fig. 5 Relationship between drainage density and degree of dissection (landslides 1-17)

Relationship between Relative drainage density and Degree of dissection

The relationship between relative drainage density and degree of dissection is shown in Figure 6. The degree of dissection increases as the relative drainage density increases, and the exponential relationship can be expressed as $D = e^{2.9E}$. The drainage density of most landslides selected in this study was less than 1. The relative drainage density of completely eroded landslides tended to be greater than 1, which was larger than the drainage density of the surrounding slopes.

We originally thought the drainage density and the relative drainage density would be different because the bedrocks in these landslides are different, but the graphs show a similar relationship (Figs. 5, 6). All the bedrock of the selected landslides are composed of Mesozoic and Paleogene hard bedrock.

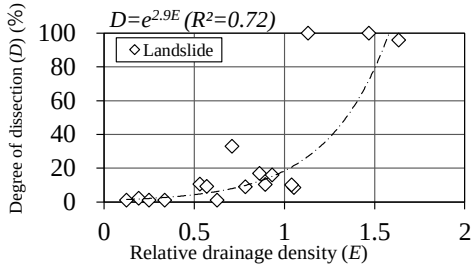

Fig. 6 Relationship between relative drainage density and degree of dissection (landslides 1-17)

CONCLUSION

We have examined the relationship between the degree of dissection and drainage density by using 10-m DEM data. The results are as follows:

1) The drainage density of landslide bodies gradually increased after the formation of landslide topographies. The older the landslide, the higher the drainage density.
2) The degree of dissection increased as the relative drainage density increased. The relative drainage density of completely eroded landslides tended to be greater than the drainage density of the surrounding slopes.
3) With this method, the relationship between drainage density and degree of dissection can be used as a guideline for landslide development in Shikoku, southwest Japan. Applicability of the method to other places is a research subject in the future.

EVALUATING HYDRAULIC AND MECHANICAL PROPERTIES OF NATURAL PREFABRICATED VERTICAL DRAIN (PVD) ON A LABORATORY SCALE

Dea Pertiwi[1] and Maulana Iqbal[1]
[1]Institute of Road Engineering (IRE), Bandung, Indonesia

ABSTRACT

Rapid development in urban areas requires reliable technology but still puts forward the environment issues. Synthetic Prefabricated Vertical Drain (PVD) commonly used in accelerating settlement over soft soils tend to not easily decomposed in soil after the service period has been exceeded, thus storing plastic waste under the ground. Local materials such as coconut fibers and jute woven fibers that can be cultivated in Indonesia are promising option because of its easily biodegradable characteristic. To check their performances, series of laboratory test of hydraulic and mechanical properties using geosynthetic testing apparatus were conducted. The test revealed that natural PVD tested with geosynthetic testing apparatus gives high tensile strength and permittivity. However, its laboratory discharge capacity is ten times lower than synthetic PVD if tested in horizontal condition using water flow (in-plane) capacity apparatus (EN ISO 12958). Considering the good performance of natural PVD in field in accelerating embankment settlement over soft soils especially due to its nature capillarity characteristic, specific laboratory test standards for natural PVD are needed, and the range of test results must be distinguished from synthetic PVD.

Keywords: PVD, Natural fibers, Hydraulic properties, Soft soils, Laboratory test

INTRODUCTION

Synthetic Prefabricated Vertical Drain (PVD) technology made from polymer has been widely recognized as one of soil improvement technologies with the main function of dealing with the problem of settlement over soft soil by accelerating the consolidation process. The demand for the use of PVD technology in Indonesia is very large because soft land areas in Indonesia estimated to cover some 20 million hectares or around 10% of Indonesia's land area [9]. Preloading with PVD is one of the technologies used, in addition to the use of other soil improvement technologies.

In addition to synthetic drains, natural-based drains often used outside Indonesia i.e. Japan, Korea, Bangladesh, India mainly due to consideration of environmental preservation. The advantages of drains made from natural materials are non-toxic, recyclable, high absorbency, the disintegration time in the soil is relatively fast due to biodegradable properties. Thus, in less than 1 year the drain material will be decayed in the soil. This advantage is very suitable for dense urban areas because the location of the former drain installation can be used for other underground constructions.

However, their application is still very limited because they are usually composed of individual fibers with large openings which allows fine soils trapped while discharging pore pressure, so that they are reducing the hydraulic conductivity of the drain [11].

Jute drains was first developed in 1994 and named Fiberdrain [2]. They were used in seaward runway construction in Singapore. Later, jute drains also developed in India and named PJVD or Prefabricated vertical Jute Drains and modified into braided sheath (filter) named as Brecodrain [3] which prioritizes the efficient manufacturing stage and withstand buckling very well [4], [7]. In Srilanka jute PVD named as VFD or Vertical Fiber Drain [8]. In Indonesia the development of jute drains began in 1990s and applied in reclamation, road and highway project.

Studies related to natural fibers was conducted on a laboratory scale to find the most suitable material for PVD by varying materials, geometry and configuration to obtain model with best technical performance.

METHODOLOGY

In this study, the parameters that determine the specifications of the natural drains are described. If referring to [5], then all tests refer to EN ISO standard of testing, although some of samples are also tested using ASTM standard. Fifteen drain models were evaluated using the variations shown in Table 1. The materials used are coconut fiber for core and jute sheath for filter, webbing density 5,6 and 7,8 weft thread per inch, number of filter layers are 1 and 3, numbers of coir rope are 3 and 6.

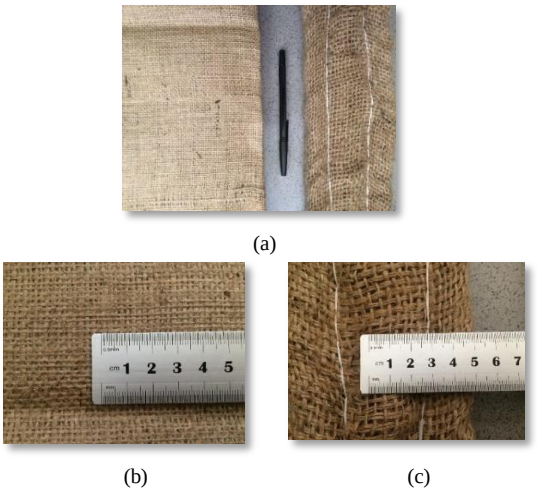
Drain width are 6 cm, 9 cm, 9,5 cm and 10 cm. Four last model variation (Model 6) were made from coconut coir core and recycled synthetic fibers to compare their performance.

Table 1. Drain models and testing standard

Property	Model name	Testing Standard
Drain composite		
Width	Model 1	EN ISO 9863-1
Thickness	Model 1-a	EN ISO 9863-1
Tensile strength in longitudinal direction	Model 1-b Model 1-c	EN ISO 10319
Elongation at maximum tensile force	Model 1-d Model 1-e Model 1-f	EN ISO 10319
Discharge capacity, straight	Model 1-g Model 1-h Model 3 Model 6	EN ISO 12958
Drain filter	Model 6a Model 6b	
Width	Model 6c	EN ISO 9863-1
Mass per unit area	Model 6d	EN ISO 9864
Pore size, O_{90}		EN ISO 12956
Velocity index (vh_{50})		EN ISO 11058
Tensile strength in longitudinal direction		EN ISO 10319
Tensile strength in cross direction		EN ISO 10319

Natural Drain Characteristic

At the beginning, materials tested for drain filter were woven jute fiber and woven hemp fiber, whilst material for drain core are coconut fiber and non woven jute. Visually, hemp fiber is finer and has higher density than jute. Hemp has pore opening size of ± 0.1 mm (Fig. 1b), while jute has larger pore opening size of ± 0.5 mm as presented in Figure 1c.



(a) (b) (c)

Fig. 1 Visualization of studied PVD: (a) comparisan between hemp (left) and jute (right) weaving; (b) density of hemp fiber ±0,1 mm; (c) density of jute fiber ±0,5 mm.

The opening size of hemp is more uniform than jute. Nevertheless, jute fibers are rougher, thicker and have higher tensile strength. Furthermore, only jute fibers were studied. Because coconut fiber raw material is easy to obtain while non-woven jute is not, then only coconut fiber is studied as PVD core material.

Drain Properties

Required testing parameters for synthetic PVD refers to European standards [5] are only tensile strength, seam strength, in-plane water flow capacity in straight and buckled conditions, opening size and elongation. Testing of tensile strength, grab strength, puncture strength and tear strength of drain filter are not required because they are not determinant of performance.

For natural PVD, as reviewed by [3] in [6] and by [10], the determinant parameters of performance are thickness at confining pressure of 20 kPa, mass per unit area, tensile strength and elongation, opening size, permeability, and drainage capacity. If referring to the EN ISO standard, testing the strength of the PVD filter (pull, grab, puncture, tear) are not required.

Study by [2] examined the components that need to be considered in testing natural drains, i.e. thickness, compressibity, tensile strength and durability. The measurement of thickness of coconut coir and jute filter revealed that thickness did not change after being tested for 30 seconds. Meanwhile, the thickness of non-woven coconut fiber and hemp filter showed no change after 60 seconds. By following ASTM D 5199-01 (2006) and/ or EN ISO 9863-1990, it is recommended to measure the thickness drains at the end of 60 seconds, after giving a normal load of 2 kPa.

Compressiblity

The results of the study from [2] shows that non-woven coconut coir has maximum compressibility, while woven coconut coirs have lower compressibility. The woven jute or hemp are more compressible than the woven coconut coir . However, it should be noticed that when testing woven fibers, compressibility can drop drastically to below 6 kPa.

Tensile Strength

From several related studies of tensile strength, it was summarized that for geotextiles made from woven natural fibers, width-length ratio of specimen does not affect the tensile strength. If the width is left constant and the length is changed, then strain will experience a linear variation.

The test speed between 2 mm/minute to 300 mm/minute does not have a significant effect on the strength and strain of natural fibers. While the test

speed below 2 mm/minute results decreasing in strength and strain. On the contrary at test speed above 300 mm/minute increases slightly. This makes the natural fibers different from synthetic.

For soaked test specimens, strength will decreases and strain increases.

Durability

Research by [1] on the durability of coconut coir and jute forms was carried out at controlled temperatures and humidity. The effects of variations in pH values, salt water, wet-dry processes, soil types (sand and clay), organic content in the soil, and installation in different climatic conditions were examined. The results revealed that design life of coconut coir is more than a year, while jute had two or three years. Durability test can be carried out by grab test, immersion in acid solution (pH = 3), alkaline solution (pH = 12) or kept in clay soil in a separate containers. Core and filter are tested separately.

RESULTS AND DISCUSSION

Development of Specification of Natural PVD

Studies are made for 15 natural PVD models with variation and testing standard explained in Table 1. As a comparison, the test results of more than 20 specimens of synthetic PVD were also evaluated. Synthetic PVDs are made of polypropylene material, polypropylene-polyethylene, polyolefin and high-density polyethylene (HDPE). Figure 2 and Figure 3 compares the characteristics of natural PVD with synthetic PVD when testing discharge capacity refers to EN ISO 12958 (Geotextiles and geotextile-related products - Determination of water flow capacity in their plane) measured at 20 kPa, 100 kPa, 250 kPa and 350 kPa confining pressure and hydraulic gradients of 0,1 and 1,0.

From the relationship between dicharge capacity and confining pressure during the test, it was known that discharge capacity of both type decreased as pressure increasing. Discharge capacity of synthetic PVD is 10 times greater than natural PVD. PVD with non woven jute core (Model 3) has the largest value because the core has greater capillary than coconut fiber.

Discharge capacity of natural PVD tested in i = 1,0 and 20 kPa (low confining pressure) ranged between 0,0568 to 0,3040 litre/m.sec, in 350 kPa confining pressure ranged between 0,0027 to 0,0242 litre/m.sec. Synthetic PVD tested in i = 1,0 and 350 kPa confining pressure ranged between 0,050 to 0,240 litre/m.sec.

As reviewed by [11] the difference between discharge capacity from different studies are understandable because of the varying drain models and testing apparatuses. However, in all case, discharge capacity tend to reduces significanly as the confining pressure increases.

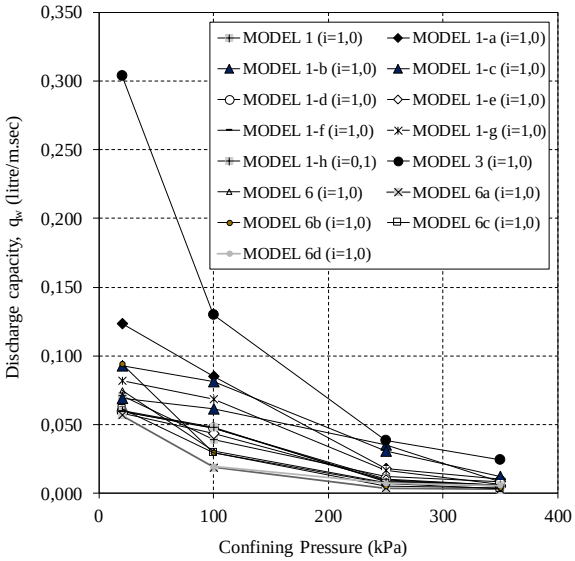


Fig. 2 Relationship between confining pressure and discharge capacity of natural PVD models tested in hydraulic gradients 1,0.

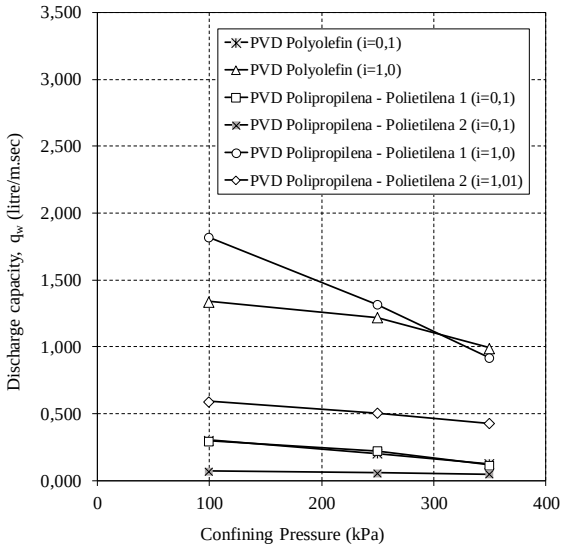

Fig. 3 Relationship between confining pressure and discharge capacity of synthetics PVD models tested in hydraulic gradients 1,0.

The low value of discharge capacity of natural drains analyzed due to sample placed horizontally, not vertically while tested which is against the ability of natural drain capillary forces. Natural fiber relies to its capillary, so testing a sample in a vertical position and confined with soil is recommended.

Tensile strength of PVD in machine direction and tensile strength of PVD filter in machine and cross-machine direction are three requirements for testing

synthetic PVD in the laboratory referring to EN ISO 10319. Figure 4 and Figure 5 shows relationship between discharge capacity and tensile strength of natural PVD and synthetic PVD.

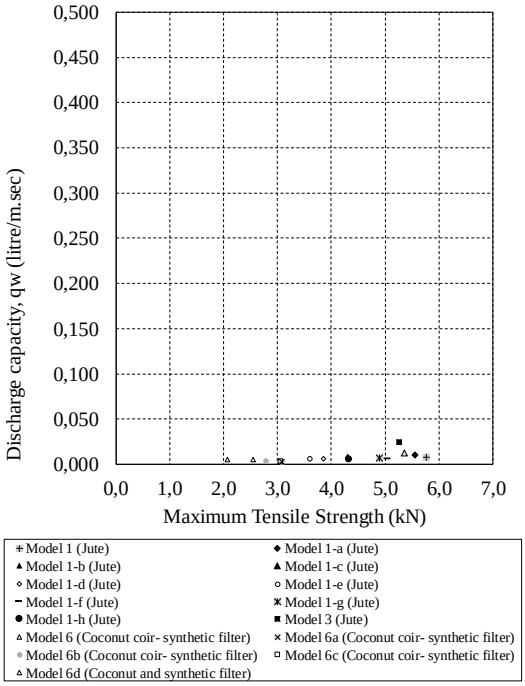

Fig. 4 Relationship between maximum tensile strength and discharge capacity of natural PVD models.

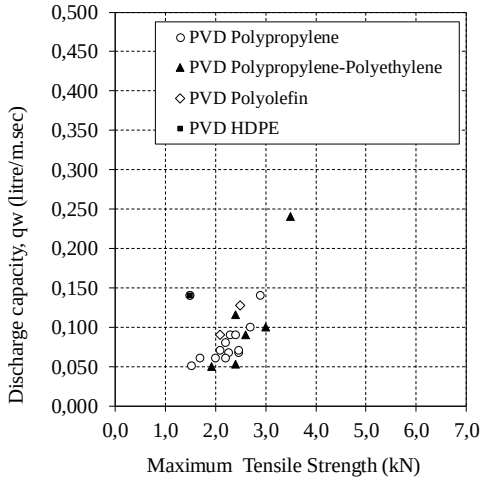

Fig. 5 Relationship between maximum tensile strength and discharge capacity of synthetic PVD models.

Required strength of synthetic PVD filters ≥ 3 kN/m, while for PVD installation depth > 25 m and in soft soils, required cross-machine direction strength is ≥ 6 kN / m [5]. Tensile strength of natural PVD ranged between 3,5 to 6,0 kN/m and the combination with synthetic filter ranged between 2,0 to 5,8 kN/m (requirements ≥ 1,5 kN/m), whilst synthetic PVD ranged between 1,5 to 3,5 kN/m. If correlated with field construction, jute PVD will have sufficient tensile strength to prevent the materials from damage during installation and during their design life.

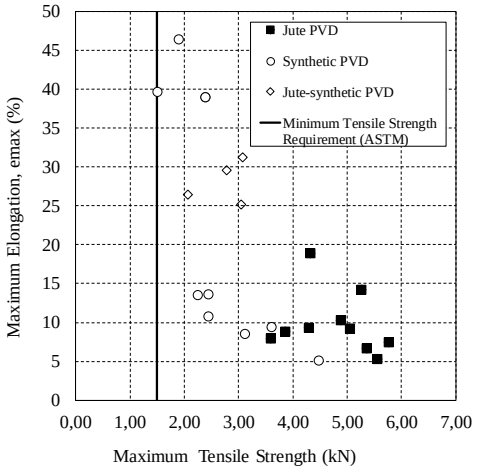

Fig. 6 Relationship between maximum tensile strength and maximum elongation of PVD.

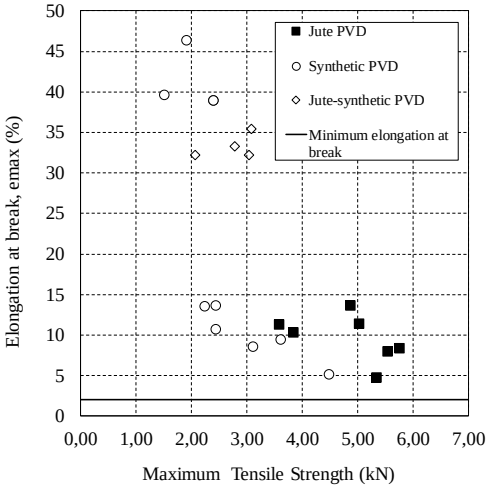

Fig. 7 Relationship between maximum tensile strength and elongation at break of PVD.

Maximum elongation and elongation at-break refers to EN ISO 10319 are presented in Figure 6 and Figure 7. Elongation at-break requirement for synthetic PVD is ≥ 2% on the weakest element and ≤ 10% in testing pressure of 0,5 kN. Minimum tensile strength required is > 1,5 kN on the weakest element and PVD structures are not allowed to break (BS EN 15237-2007).

From Figure 5, it was found that maximum elongation of natural PVD ranged between 3,5 to 5,5%, whilst natural PVD combined with synthetic filter ranged between 2,0 – 3,2%. Maximum elongation of synthetic PVD ranged between 1,5 to 4,5%, lower that natural PVD.

It can be concluded that in terms of mechanical

and hydraulic properties, natural PVD (jute PVD) has good tensile strength and elongation performace despite its lower disharge capacity value when tested with geosynthetics testing apparatus in the laboratory.

Thickness and mass per unit area refers to EN ISO 9863-1. The thicker and heavier filter material, the higher cost of preparing raw material. Figure 8 presents relationship between PVD thickness and amout of discharge capacity. To increase efficiency, it is recommended to use models that have moderate discharge capacity but less thick. the thickness ranged between 5 to 10 mm. Mass per unit area ranged between 150 to 350 gram/m'. Figure 9 presents the results.

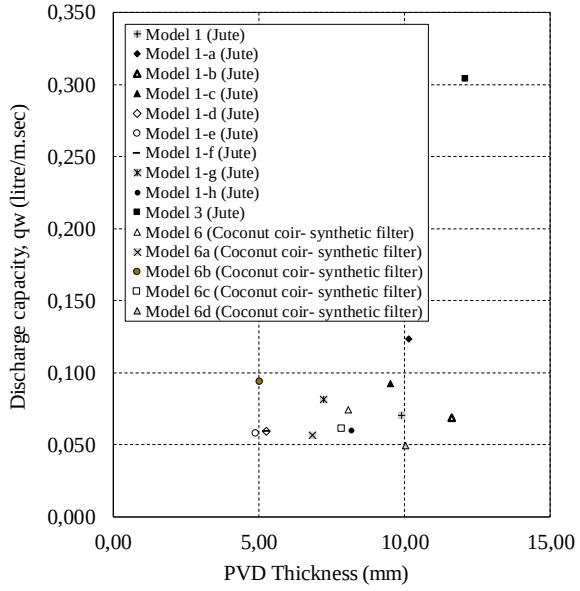

Fig. 8 Relationship between PVD thickness and discharge capacity.

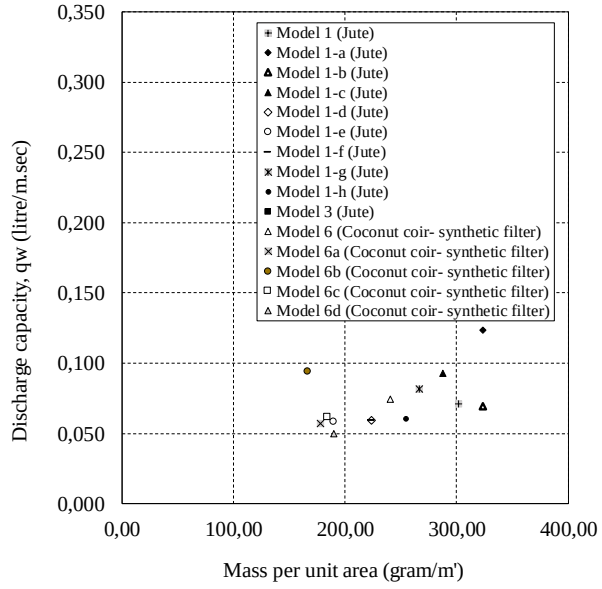

Fig. 9 Relationship between mass per unit area of PVD and discharge capacity.

Last parameter observed is velocity index, refers to EN ISO 11058 (Fig. 10). It was found that vh50 of natural PVD and PVD with recycled synthetic filter are ≥ 1 mm/sec. Value of vh50 ranged between 27 to 120 mm/sec. The greater filter pore size, the higher vh50. Table 2 summarized the overall results of the tested natural PVD compared with synthetic PVD specifications

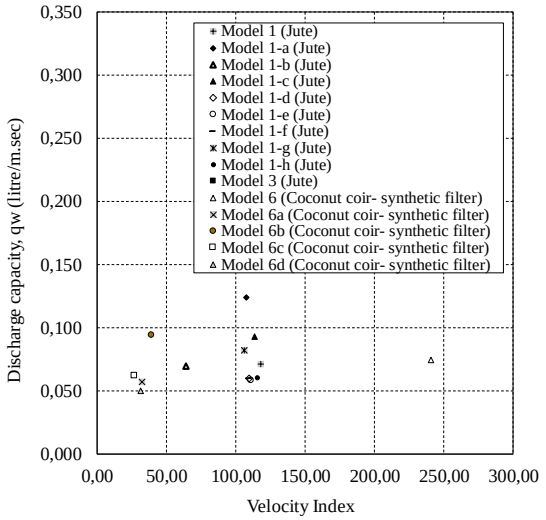

Fig. 10 Relationship between velocity index and discharge capacity.

CONCLUSION

Laboratory test results summarized that PVD model with the best performance is Model 1h with 1 layer of jute, 6 ropes of coconut fiber and filter webbing density of 5,6 feed / inch). The model gives high tensile strength and velocity index but lower mass per unit area an thickness so that it is still efficient. However discharge capacity of natural PVD is relatively lower than synthetic PVD, possibly due to placement of sample in testing apparatus is against capillarity force of natural fibers.

Testing of natural PVD needs to be accompanied by special procedures for sample preparation and initial conditioning (soaking the sample) before tested. If natural PVD is retested, the result will not similar with previous test because natural fibers are inhomogeneous.

Compared with specification for synthetic PVD, some values meet specifications, but some are differ from synthetic PVD, therefore the testing standard and minimum value of natural PVD should be made separately.

Testing in a large-scale radial consolidation apparatus in the laboratory which confined with soils, is highly recommended rather than tested in-plane water flow capacity apparatus.

Table 2. PVD Specifications

Testing properties	Specification of Synthetics PVD (ASTM)		Specification of Synthetics PVD (BS EN 15237, 2007)		Proposed specification (obtained from this study	
	Value	Test method	Value	Test method	Value	Test method
Composite						
Tensile strength	≥ 1500 N (≥ 1,5 ken)	ASTM D 4595	> 1,5 kN, longitudinal direction	EN ISO 10319	> 2,0 kN	EN ISO 10319
Tensile strength at elongation ≤10%	≥ 1300 N (≥ 1,3 kN)	ASTM D 4595	Not required	-	Not required	
Seam strength		-	≥ 1 kN/m	EN ISO 10321	Not required	
Type of polymer	PP / PET	-			Jute, Coconut Coir	
Width	100 ± 5 mm	ASTM D 3774	-	EN ISO 9863-1	60 – 100 mm	EN ISO 9863-1
Thickness	2,5 - 5,0 mm	ASTM D 5199	-	EN ISO 9863-1	7,0 – 17 mm	EN ISO 9863-1
In-plane water flow capacity, *straight*	≥ 1 x 10^{-6}	ASTM D 4716	As designed	EN ISO 12958	As designed	EN ISO 12958
In-plane water flow capacity in 200 kPa, *buckled*	-	-	As designed	EN ISO 12958	As designed	N/A
In-plane water flow capacity in100 kPa, *buckled*	-	-	-	-	As designed	N/A
Elongation at maximum tensile force (at-break)	-	-	≥ 2%	EN ISO 10319	≥ 3,5%	EN ISO 10319
Elongation at 0,5 kN	-	-	≤ 10 %	EN ISO 10319	≤ 10 %	EN ISO 10319
Filter						
Tensile strength	≥ 4 N	ASTM D4595			≥ 4 N	EN ISO 10319
Grab strength	≥ 330 N	ASTM D 4632	-	-		
Puncture strength	≥ 100 N	ASTM D 4833	-	-		
Tear strength	≥ 100 N	ASTM D 4533				
Opening size, O_{90}	-	-	80 μm	EN ISO 12956	> 300 μm	EN ISO 12956
Opening size, O_{95}	50 – 90 μm	ASTM D 4751	-	-		
Permeability	≥ 1 x 10^{-4} m/sec	ASTM D4491	-	-		
Tensile strength	-	-	3 kN/m*	EN ISO 10319	≥ 3 kN/m	EN ISO 10319
Velocity index (vh_{50})	-	-	1 mm/sec	EN ISO 11058	26,8 – 117,75 mm/sec	EN ISO 11058

For further development, the influence of soil clogging on the discharge capacity of natural PVD should be examined, due to jute filter opening size could not prevent soil penetrating into internal part of PVD at larger load increments.

EVALUATION OF ELASTIC AXIAL STIFFNESS REFERS TO TENSILE STRENGTH TESTING OF GEOGRIDS AND NON-WOVEN GEOTEXTILES

Dea Pertiwi[1] and Fahmi Aldiamar[1]
[1]Institute of Road Engineering (IRE), Bandung, Indonesia

ABSTRACT

Over the last several years geosynthetics are widely used for soil reinforcement in many cases of embankment over soft soil material or steep slope construction. Mechanisms of reinforcement that expected are lateral resistance through friction between geotextile and soil/aggregate and reducing the potential bearing surface failure plane to develop higher surface shear strength. In design phase, reinforced slopes are currently analyzed using modified limit equilibrium slope stability methods, while for complex cases numerical model is commonly used for determining required tensile strength within factor of safety assigned in the design requirements. In most cases, elastic axial stiffness (E.A.) as input parameter in finite element method is determined from typical strain distribution of geogrids or non-woven geotextiles in soil foundations, with the value less than 2%, which are provided by manufacturers and assumed to be linear elastic. To confirm those assumptions, several tensile strength test of geogrids and non-woven geotextiles are conducted according to ASTM D4595-17 procedures. Proposed elastic axial stiffness and typical strain distribution for numerical model described in this paper to guide the designer for selecting proper input design parameter.

Keywords: Non-woven geotextiles, Geogrids, Soil reinforcement, Elastic axial stiffness, Strain distribution

INTRODUCTION

Geosynthetics have been utilized in most of soil improvement techniques as a soil reinforcing systems to escalate the bearing capacity of the soil and reduce settlement. Geosynthetics are also commonly used as separator, filtration, drainage, erosion control and even shore protection. For separator purposes, requires high tensile strength geosynthetics whilst for erosion control requires high permeablity geosynthetics. Many types of geosynthetics are available in the engineering process (geogrid, geotextile, geocell, geomembrane, etc.).

Required tensile strength within factor of safety assigned in the design requirements are often analyzed using numerical models to simplify the complexity of calculations. Elastic axial stiffness (E.A.) as input parameter in finite element method is assumed from typical strain distribution of geogrids or non-woven geotextiles with the value less than 2% which are provided by manufacturers and assumed to be linear elastic [2]. For non-woven fabrics. However, generalization or assumption should not made for determining E.A. due to different properties of geosynthetics used in the design.

METHODOLOGY

Several studies showed that geosynthetics were applicable as reinforcement, particularly in embankment over soft soil. Most of them designed with numerical model using finite element method due to calculation complexity. However parameter that often used is ultimate tensile strength, whilst strain or elongation parameters rarely considered in the design or decided based on asumption, as mentioned in [1], [2], [4] and [10]. In Plaxis reference manual geotextile is introduced as a tensile element i.e. E.A [5]. To avoid using assumptions in determining the value of E.A a number of tensile strength data from laboratory Wide-Width Tensile Test (ASTM D 4595/ISO 10319) results of geosynthetic non woven and geogrid were collected and studied. By using a correlation between maximum tensile strength and elongation at break in machine (MD) and cross-machine direction (CMD), axial stiffness or E.A. can be calculated using Eq. (1) [5].

$$EA = \frac{F}{\Delta l / l} \qquad (1)$$

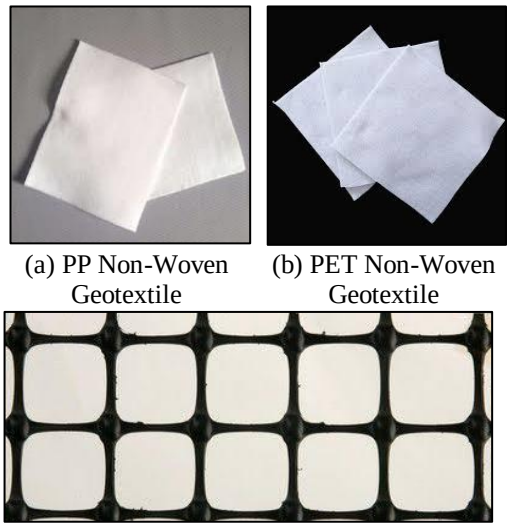
The axial stifness is the ratio of the axial force (F) per unit width and the axial strain ($\Delta l/l$). l is grip to grip separation at the start position of testing. Δl is the elongation, derived from the difference between length of sample after being pulled and l.

Then using a simple embankment model, finite element modeling was carried out with varied E.A. and tensile strength parameters of geogrid and non-woven geotextiles in order to provide guidance for designer to select proper input of E.A. parameter particularly in numerical analysis.

Geosynthetics Properties

Geogrids and non-woven geotextiles are flexible elements with a normal stiffness and no bending stiffness [5]. Maximum tensile strength (F_{max}) parameters from Wide-Width Tensile Test were used to calculate E.A. use Eq. (1). Geogrids are open grid-like materials of integrally connected polymers and are stronger than most geotextiles. Compared to geotextiles, geogrids have low strain. However, it can withstand heavy tension loads without much deformation [7]. Geogrids evaluated in this study were uniaxial and biaxial as shown in Fig. 1c.

Geotextiles are defined as permeable textile used with foundation soil, rock, earth, and any other. There are two types of geotextiles, i.e. woven and non woven geotextiles.Woven geotextiles are cloth-like fabrics, and tend to have high tensile strength but relatively low strain compared to non-woven geotextiles [6]. Non-woven geotextiles studied in this paper were PP (Polypropylene) as shown in Fig.1a and PET (Polyethylene) as shown in Fig. 1b that assemblied by mechanically-bonded, needle-punched or thermal-bonded methods.



(a) PP Non-Woven Geotextile (b) PET Non-Woven Geotextile

(c) Geogrid

Fig. 1 Types of geosynthetics used in study.

Figure 2 and Fig. 3 each shows the relationship between normal force and strain from a number of geogrids and non-woven geotextiles data from laboratory test results of Wide-Width Tensile Strength referring to [3] and [9]. The graphs informed that different types of geotextiles and geogrids yields different strain pattern and have different maximum strain. Therefore tensile strength for design should not obtained at ultimate (T_{max}) and at 2% strain as stated in [1], but also at maximum strain (ε_{max}). Although for non-woven geotextiles the axial stiffness is usually not considered since these elements typically served at separating layers [8], in this study, the parameters were evaluated and compared with geogrids.

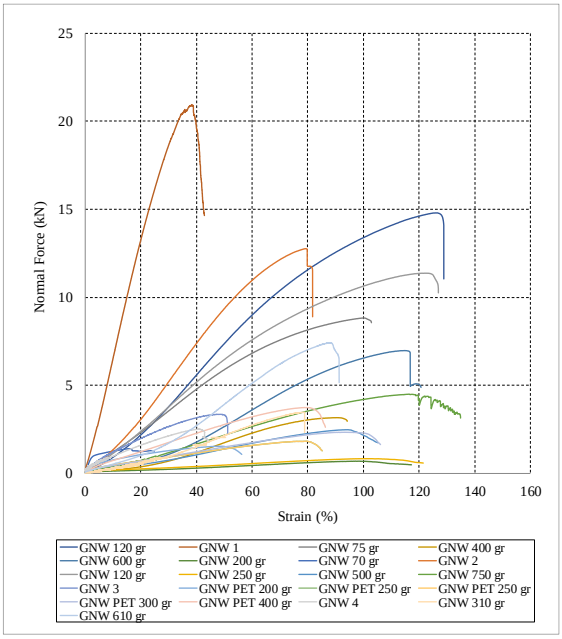


Fig. 2 Strain and force relationship of non-woven geosynthetics.

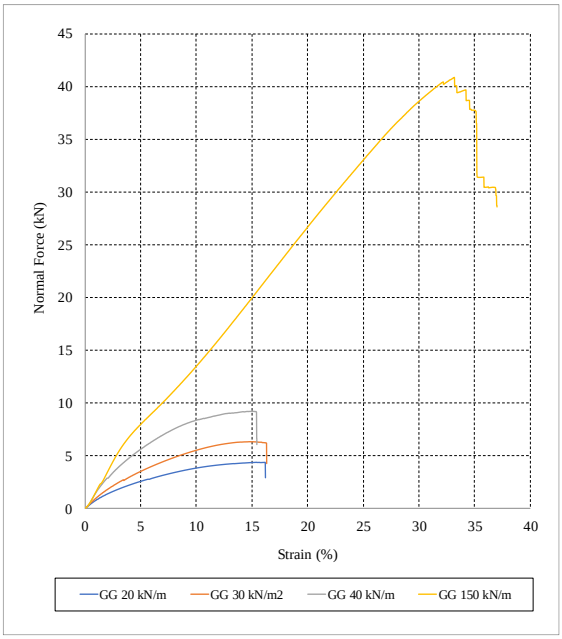

Fig. 3 Strain and force relationship of geogrids.

Finite Element Modelling

Geosynthetics modelling

Geogrids are used to model soil reinforcements, whilst non-woven geotextiles are used to model soil

separator or filtration. Both was modeled using elastoplastic constitutive model with the parameters elastic axial stiffness, E.A. and maximum axial force, N_p entered in units of force per unit width. N_p also is ultimate tensile strength of the geosynthetics.

Embankment modelling

The 2 m embankments with 1,5H : 1V slopes as presented in Fig. 4 was evaluated in this study. The water level was at 0,00 level (critical condition). A surcharge of 12 kN/m^2 has been used for modelling the traffic load. As the model is symmetric with respect to center line, half of the embankment is modeled in analysis. The numerical modeling using commercial Finite Element Method (FEM) package (PLAXIS version 9) is employed for performing the analyses.

In the first model safety factor of road embankment without geosynthetic placed between the base of embankment and overlaying clay layer evaluated. After that, placement of PP Non Woven Geotextile, PET Non Woven Geotextile and Geogrid at base of embankment (Fig. 4) conducted to evaluate increase of safety factor and also displacement on each of geosynthetic in horizontal and vertical direction.

The material properties used for the model are presented in the Table 1. Model material used is Mohr-Coloumb, since it has been considered as a first order approximation of real soil behavior and main focus of research are stability of embankment.

Table 1 Soil parameters of underlaying layer and embankment

Soil parameters	Underlaying layer	Embankment
γ dry (kN/m^3)	14	18
γ wet (kN/m^3)	16	20
Young's modulus, E_{ref} (kN/m^2)	2.000	10.000
Poisson's ratio, ν	0,3	0,3
Cohesion, c_{ref} (kN/m^2)	5	10
Friction angle, ϕ (°)	20	30
Dilatancy angle, Ψ (°)	0,0	0,0

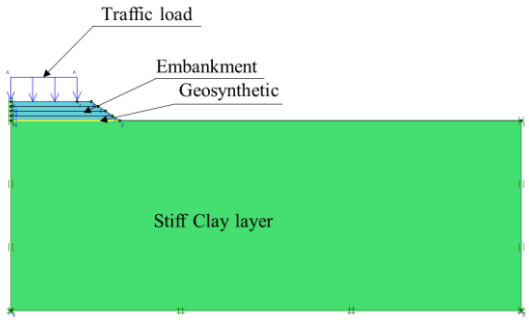

Fig. 4 Geometry model for evaluating effect of geotextiles and geogrid

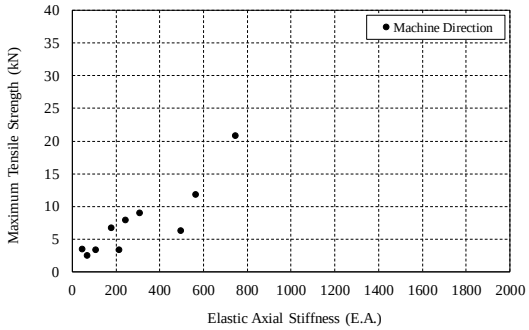
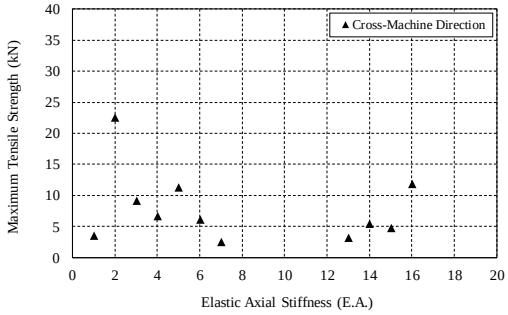
RESULTS AND DISCUSSION

Figure 5a shows the relationship between E.A., calculated using Eq.(1) and maximum tensile strength of PP non woven geotextiles tested in Machine Direction (MD). The graph showed that EA and maximum tensile strength are linearly distributed. For tensile strength 0-10 kN, E.A. ranges from 50 - 400 while for > 10 kN E.A. ranges from 400 - 800. So when designing geotextiles as separators, E.A. entered as input parameters should be less than 800.

Figure 5b shows the relationship between E.A., calculated using Eq.(1) and maximum tensile strength of PP non woven geotextiles tested in Cross-Machine Direction (CMD).

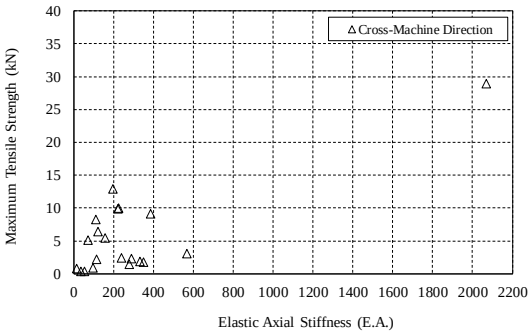


(a) Tested in Machine Direction

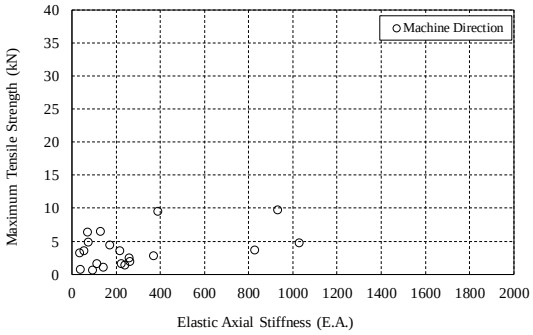


(b) Tested in Cross-Machine Direction

Fig. 5 Elastic axial stiffness (E.A.) and maximum tensile strength of PP non-woven geotextiles.



(a) Tested in Machine Direction



(b) Tested in Cross-Machine Direction

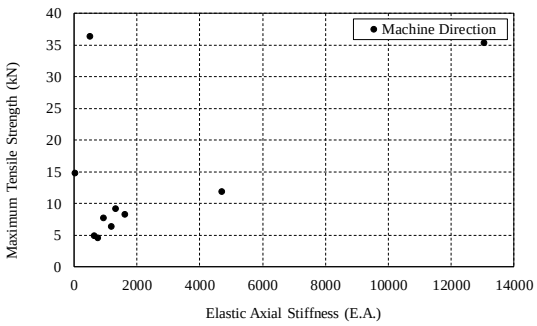
Fig. 6 Elastic axial stiffness (E.A.) and maximum tensile strength of PET non-woven geotextiles.

In contrast to the results of MD test, E.A. tend to have lower ranges i.e. 1 - 12 and uneven data distribution. Therefore it is recommended to use the results of the MD test for design, and because the installation of geotextiles in the field is at longitudinal direction.

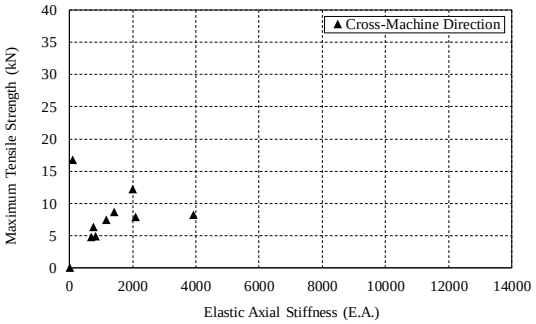
The relationship between E.A and the maximum tensile strength for PET non-woven geotextiles shown in Fig. 6 explains that E.A. in MD test is twice higher than in CMD (transverse direction) However, there is a maximum tensile strength of non woven geotextiles which has a greater tensile strength when tested in MD. Compared with PP geotextile, PET geotextile has higher E.A. up to 1000 for maximum tensile strength up to10 kN.

Although geogrid data are less than non-woven geotextile data, Fig. 7 summarized that the distribution of E.A. to the maximum tensile strength of the geogrid is also linearly distributed. Geogrids tested in MD (Fig. 7a) tend to give the same tensile strength and E.A. distribution with those tested in the CMD (Fig. 7b), except for some types of geogrids that have higher tensile characteristics than the general type of biaxial geogrid.

From the data studied here, it can be concluded that for maximum or ultimate tensile strength up to 10 kN, E.A. ranged from 600 – 1600 and for ultimate tensile strength 15 – 35 kN, E.A could reached until 13000.



(a) Tested in Machine Direction



(b) Tested in Cross-Machine Direction

Fig. 7 Elastic axial stiffness and maximum tensile strength of geogrid.

Figure 8 showed that the design with geogrid should enter the input value of E.A. which is quite high. Since the laboratory result for geogrids with high tensile strength (tensile strength > 20kN) are limited, E.A. value resulting a lower result than equation approach. This may lead to unrealistically E.A. value that could lead error result when using geogrid elastoplastic model.

Assesment the effect of geosynthetics layers

To assess the effect of geosynthetics layer on road embankment, 4 type of FEM condition namely road embankment without geosynthetic, using PP and PET non woven geotextile and also geogrids conducted using different elastic axial and ultimate tensile strength parameter as seen in Table 2. Each of FEM model resulting on increase of safety factor in accordance to increase of tensile strength used (Fig. 9). Increase of tensile strength also effectively reduce horizontal displacement acting on geosynthetics (Fig. 10).

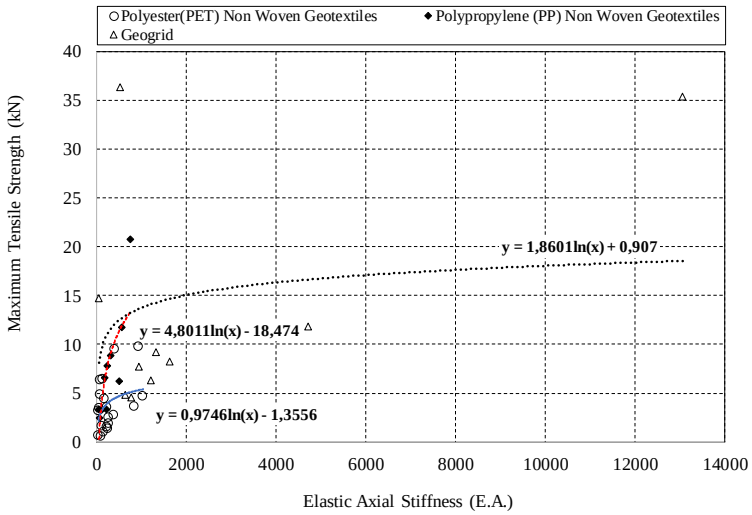


Figure 8. Equation approach for determining E.A. from laboratory tensile strength test of non-woven geotextiles and geogrids

PP and PET non woven geotextile for separator purpose had relatively small tensile strength (less than 20 kN) which resulting in small increase of safety factor and relatively large horizontal displacement, while geogrids using 25 kN and 35 kN resulting higher safety factor and smaller horizontal displacement (Table 2). Vertical displacement for each model resulting a similar result which mean that for this case, increase of tensile strength did not influence the vertical displacement of geosynthetics.

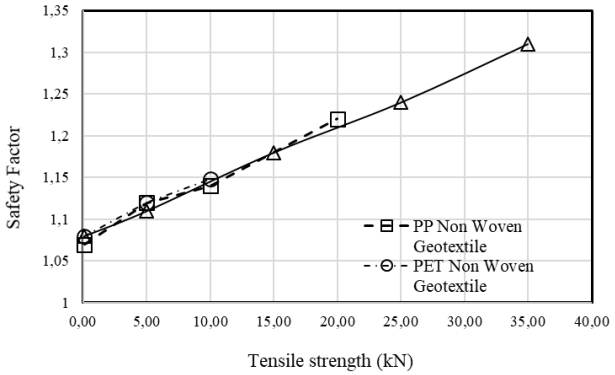

Fig. 9 Result of safety factor and increase of tensile strength

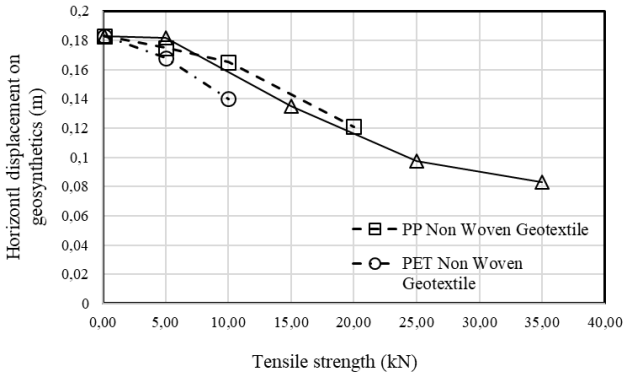

Fig. 10 Result of horizontal displacement on geosythetics and increase of tensile strength

Result of stability analysis (Fig. 11) showed a circular failure deformation mechanism and position of geosynthetic that placed between embankment and original ground are cut off the circular failure plane. Position of geosyntetic for embankment reinforcement is critical to be observe due to the misplaced of it could resulting in ineffective use of soil reinforcement.

CONCLUSIONS

Numerical model using FEM for several model of geosynthetic use for road embankment show a good result and increase of ultimate tensile strengh resulting increase of safety factor and also reduce horizontal displacement.

Proposed elastic axial stiffness and typical strain distribution for numerical model described in this paper are expected to guide the designer for selecting proper input design parameter. Hence, result gained from this research are basically customized for specific type of geogrid. Evaluation for non woven or geogrid material with different characteristics should be conducted to evaluate their behaviour.

ABSTRACT

This study focuses on the stability analysis of an existing roadside slope near Mirpur Cantonment area, Dhaka. Both numerical and analytical approach was adopted to examine the roadside slope against failure. For numerical analysis, Plaxis 2D was used [1][2]. Mohr-Coulomb failure criteria was adopted as the material model for various layers of the slope. Analytical studies were conducted following the limit equilibrium method [3] as stated by Bishop [4], Fellenius [5] and Janbu [6] using the GEO 5. To obtain the parameters undisturbed samples were collected with boring and triaxial drain tests, consolidation tests and other laboratory tests were conducted. To visualize the failure pattern and validate the numerical model and analytical study, a physical model test was carried out. The two layered physical model was constructed with a slope angle similar to the existing roadside slope using same soil of the site. It was observed from the numerical simulation and analytical analysis that slope starts to fail at an angle of 45^0. This phenomenon is also validated by the observation from mobilized section of the slope in the physical model in saturated condition.

Keywords: Slope stability, Mohr-Coulomb Failure criteria, Limit equilibrium analysis, Plaxis 2D, GEO 5, Physical model.

INTRODUCTION

From geological and geographical point of view, Bangladesh is intensely vulnerable for slope failure for many reasons. In present time, the country is facing problems regarding slope failure which has become a common phenomenon. This project work was based on the stability analysis of a connecting road which is vulnerable due to heavy vehicle movement and also for the landslide because the road is surrounded by a lake in both sides. So, this road is prone to failure because of the buoyancy effect due to the pore water pressure generated at the slope.

METHODOLOGY

Digital survey was carried out at the first stage to determine the existing soil profile. Soil samples were collected from selected road side slope area. A borehole was set at a depth of 48 feet and six samples were collected from the borehole at an interval of 8 feet. Various laboratory tests were conducted by the procedures specified in ASTM standard, such as Grain size analysis (ASTM D422-63), Atterberg limit (ASTM D 4318-00), specific gravity test by water pycnometer (ASTM D 854-02), Hydrometer analysis, triaxial test, consolidation test, direct shear. Sub-soil characteristics of the slope were determined based on these test results.

To observe the failure pattern and comparison between analytical and numerical analysis and also for evaluating the stability of the slope in terms of factor of safety, a small-scale physical model was constructed in two layers, the same as in existing slope in the site. It consists of silty sand layer at bottom and clayey silt layer at top. Tests were carried out with two slope angles of 30^0 and 45^0.

Figure1: Small scale physical model for 30° slope

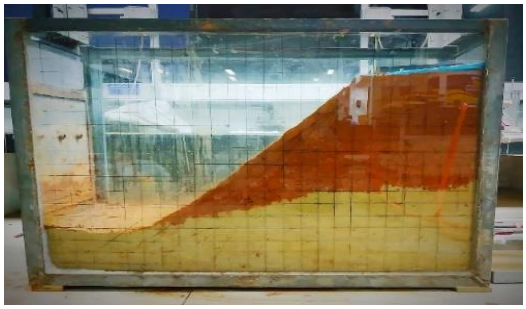

Figure 2: Small scale physical model for 45° slope

Experimental Procedures

Seepage water pressure

Two buckets were installed at a height of 2 m. The water flowed through the pipes into the soil at a low velocity, which were controlled by the valves. The water entered in the soil by seepage, and pore water pressure was created.

Figure 3: Set up for applying seepage water

Change in water level

Water level was changed at an interval of 30 minutes from bottom to mid height of the slope. this process was done to observe the watering and dewatering effects on the slope.

Figure 4: Initial height of water. Water was kept in this level in the first stage.

Figure 5: Dewatering process. Height of the water level was changed through this process.

Surcharge load

Surcharge loading was installed on the slope to observe the effect. Total loading of 120 kg was applied on the slope gradually. The loads were placed on a wooden plank to distribute the load uniformly over the slope.

Figure 6: Applied 120 kg surcharge load. The loads were balanced by placing them on wooden pieces, to keep them steadier.

Artificial rainfall

Artificial rainfall was introduced to the face of the slope to observe the impact of the rainfall. The grated bucket or sprinkler was used for application of rain fall. For 30-degree slope, 13.5 mm/min and for 45-degree slope, 11.11 mm/min water was applied at an interval of 1 hour for 5 times.

Figure 7: Application of artificial rainfall.

Limit equilibrium method

To model in GEO5, there are some components need to be considered. Initially the problem definition of geometry of the slope was inputted. As the soil layer was taken as multi material layer, the soil type was classified and their property was defined in the particular region in the model. Computing the load as worst condition surcharge load was applied on the upper portion of the slope which was indicated as stress applied on the road. As in the selected site, there

was a lake just beside the slope, water level is defined keeping a variation for observing the fluctuation of FOS in different condition.

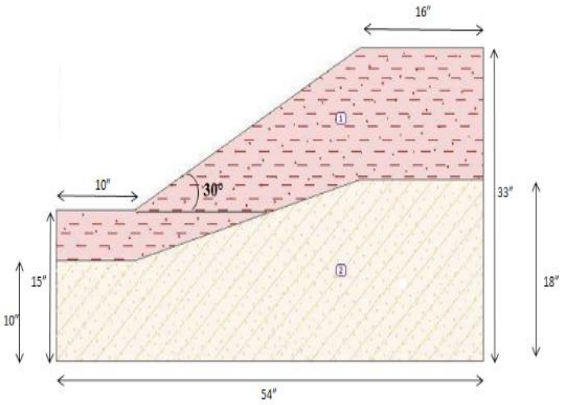

Figure 8: Geometry of the slope for 30^0 angles

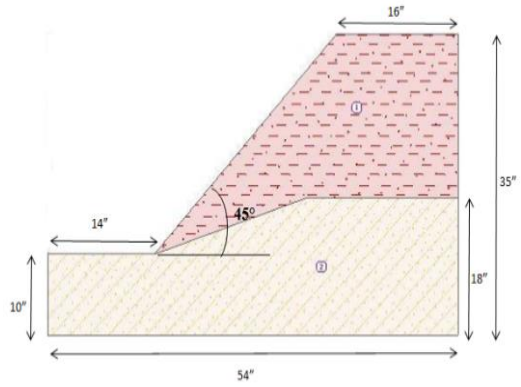

Figure 9: Geometry of the slope for 45^0 angles

Surcharge load

To keep similarity of stress with the selected site in the model 6 KPa is applied to consider it as a surcharge pressure and to compare the factor of safety at different water level for the same surcharge pressure. The value of surcharge pressure is taken as the worst condition.

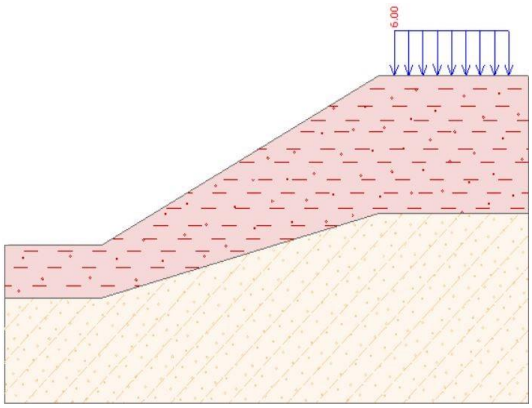

Figure10: Geometry of the slope (30°) with surcharge pressure

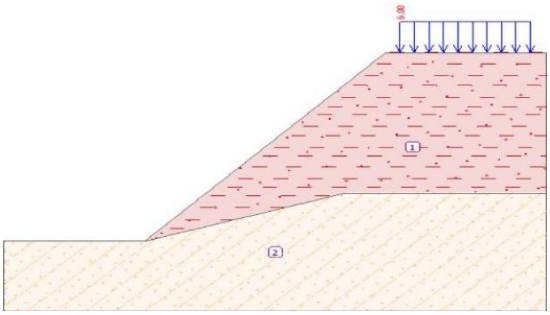

Figure11: Geometry of the slope (45°) with surcharge pressure

Water level variation

In this case water level variation was kept considering two seasonal occurrences. In dry season water level decreases with time and in rainy season water level increases. In this model three different condition is considered keeping the water level at bottom, mid top and top of the slope. Top of the slope is applied for the worst condition in rainy season. If flood occurs, comparing the fluctuation of factor of safety in the slope is the purpose of keeping water level at the top of the slope. The level of water in 30° & 45° slope is represented in table 1

Table1: Water level variation in $30^0$and 45^0 slopes

Water Level	30° slope	45° slope
Bottom		Mid Top		Top		
Finite Element Method

In this study, for determining the stability of the slope by numerical analysis method, PLAXIS 2D was used. PLAXIS version 8.2 has been used for numerical modeling. There are 2 different model for 30 degree and 45 degree. Height, distance, slope angle is same

as defined in GEO 5 and model type is Plain strain and 15 nodal. Since the study slope was not axisymmetric, plain strain type model was selected from the dropdown. Dimensions were in meters giving the real geometry of the considered in two different sections.

Material properties

To determine the failure criteria of the road side slope, the properties of the soil was determined by the lab tests**.**

Table 2: Parameters acquired from lab test for clayey silt

Parameters	Value
Unsaturated Unit weight (kN/m^3)	16

Boundary condition	Fixed at the bottom of the FE model
Restrains	Standard fixities
Applied external load	5 Kpa (calculated from surcharge load obtained from the axle load)
Meshing size	Very fine mesh
Level of ground water taken in to consideration	Three different level was considered. First one was at mid height of the slope, second one was at the toe of the slope (dry season) and third one was at the top of the slope (rainy season)
Calculation type chosen for phase-1	Consolidation; time:30 days for clayey silt layer.
Calculation type chosen for phase-2	Consolidation; time: 2 days for clay layer.
Calculation type chosen for phase-3	Plastic; load: -5kpa

RESULTS

Observations from small scale physical model

For30^0 slope

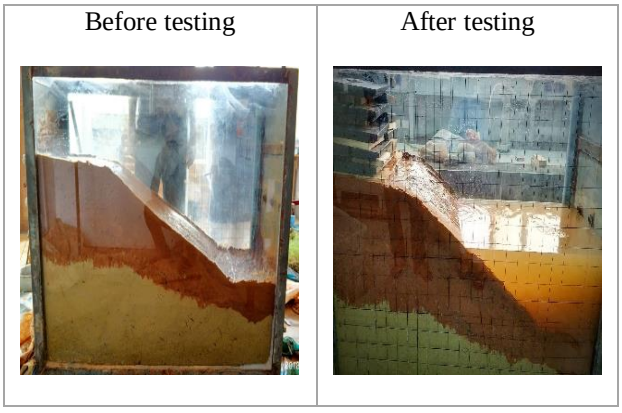

Figure12: Conditions of the 30^0 slope, before and after the testing. There were no changes after testing in the slope except for the surface erosion created by the artificial rainfall.

For 45^0 slope

All the test procedures were applied on the 45^0slope and after 48 hours, it was observed that, sand boiling was occurring at the downslope surface. the sand boiling leads to cracks on the lower soil surface of the slope. piping occurred inside the silty sand, which was observed. sand particles started entering into the clayey silt layer, and cracks were widening by time.

Figure13: Sand boiling at the lower soil surface.

Figure14: Piping action in the silty sand layer.

Figure15: Generation of cracks at the toe of the slope.

It was observed that the cracks lead to the top of the slope. The upper soil layer settled down at a visible rate, and the surcharge loads leaned towards the slope. Within 3 minutes, the top of the slope failed drastically, although the surcharge loads bumped on the slope and slightly restrained a chunk of clayey silt layer from failing. So, it can be said that, for slope angle of 45-degree failure occurs vulnerably.

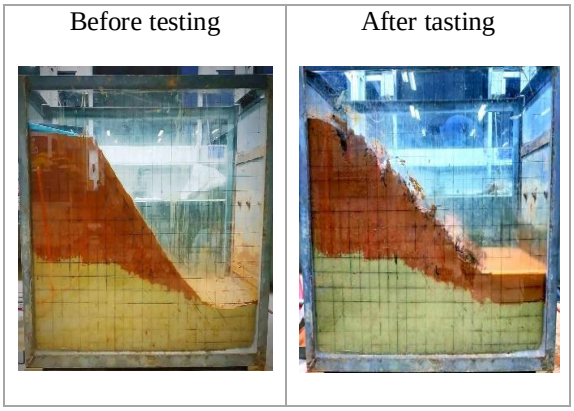

Figure16: Conditions of the 45^0 slope, before and after the testing.

Results from Limit Equilibrium Method

Table 5: factor of Safety was found for 30^0 slope

Methods	FOS	
	Bottom	Mid Top
Bishop	0.97	0.89
Janbu	0.97	0.88
Spencer	0.96	0.88
Morgenstern Price	0.97	0.88

Table 6: factor of Safety was found for 45^0 slope

Methods	FOS	
	Bottom	Mid Top
Bishop	2.00	1.76
Janbu	2.00	1.76
Spencer	1.99	1.75
Morgenstern Price	2.00	1.76

Results from Finite Element Method

Total displacements could be observed for water level at mid height and water level at lower height in both 30^0 and 45^0 slopes.

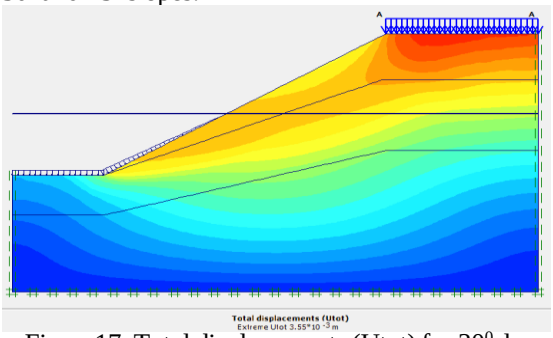

Figure17: Total displacements (Utot) for 30^0slope was found $3.55*10^{-3}$m for water level at mid height.

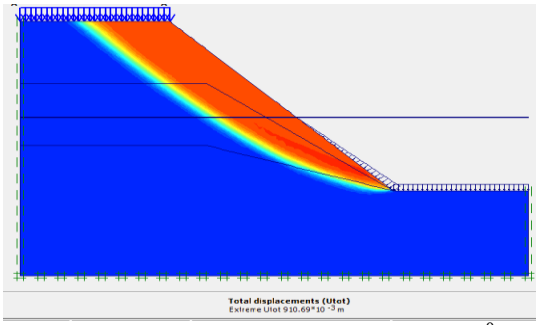

Figure18: Total displacements (Utot) for 45^0slope was found $910.69*10^{-3}$m for water level at mid height.

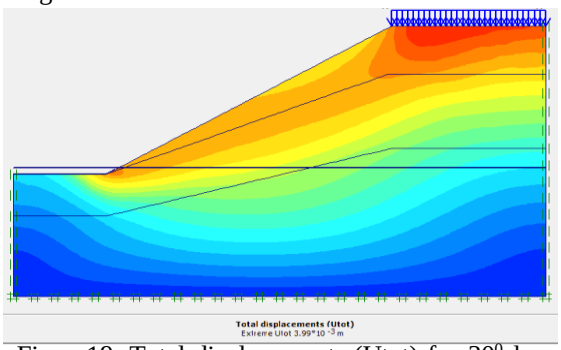

Figure19: Total displacements (Utot) for 30^0slope was found $3.99*10^{-3}$m for water level at lower height.

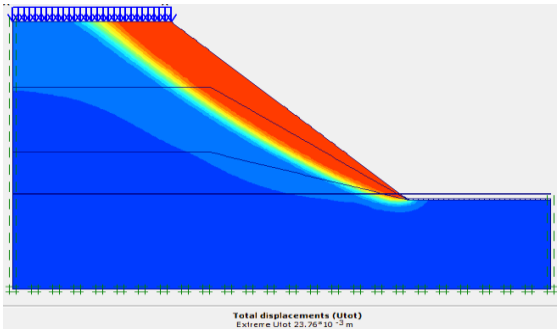

Figure20: Total displacements (Utot) for 45^0slope was found $23.76*10^{-3}$m for water level at lower height.

CONCLUSION

From the physical model, it was observed that when slope angle was 30º, settlement occurred in the ground, however, no visible failure pattern was observed. On the other hand, for the slope angle of 45º, a slope failure is seen and the pattern of slope was rotational non-circular failure. Depending on the slope angle, the deformation of the ground varied. Moreover, surface cracks, boiling of sand and formation of sinkholes behind the edge of the slope were also observed in the physical model tests.

The failure pattern and failure slope angle from physical model coincides with the analytical and numerical analysis. In the numerical analyses the failure pattern was also rotational non-circular when slope angle was 45º, but a negligible amount of settlement occurred when slope angle was 30ºthe same as the physical model tests.

In analytical analyses with different water levels, the factor of safety varied from 1.75 to 2.10, when slope angle was 30º. In contrast, for different water levels, the factor of safety varied from 0.88 to 1.05 when slope angle was 45º, which indicated the failure of the slope which coincides the results of the physical model tests.

ABSTRACT

Geotechnical issues have increased in the last two decades since sedimentary rocks material such as mudstone or shale has been widely used as embankment material. They, however, tend to be weathered once they are immersed in the water. This phenomenon is a kind of weathering processes known as slaking and may cause a reduction of stiffness and peak strength. This paper, in order to evaluate the slaking induced deformation, a number of one-dimensional compression slaking tests and scanning electron microscopy (SEM) tests to observe the physical morphology of mudstone were performed. These data confirm that slaking in crushed mudstone is accompanied by a variation in the particle size distribution during wetting and drying cycles, and a variation in grading results in an irreversible change in mechanical characteristics, such as the reference packing density. Since the particle size distribution was transformed under confined stress constant occurs without a change in the maximum particle size, it can be described by existing indexes of grading such as breakage parameter *Br*. Furthermore, to eliminate the deformation behavior of sedimentary rocks, changing the particle size distribution in the beginning by applying loading/unloading history before slaking cycle has exhibited the significant result. The compressibility during wetting and drying cycle decreases to 50% of conventional compression by applying this countermeasure method. In earth construction works, the process of roller compaction is necessary in order to encourage the particle crushing. Proper compaction can control the occurrence of slaking under wetting and drying cycle so that volumetric compression does not occur easily.

Keywords: mudstone, slaking, particle size distribution, one-dimensional compression, deformation

INTRODUCTION

Soft sedimentary soft rock such as mudstone or shale are highly susceptible to weathering. They have a tendency to slake and soften when immersed into the water and as a result their strength diminishes gradually with time. Due to this natural behavior, mudstone material has been mostly disposed as waste material. However, while dealing with economic considerations and environmental concerns, several earth constructions projects propose to utilize the crushed mudstones or shales as embankment materials. Since large embankment made of these materials was considered, long term stability problem may possibly occur to slaking [1] - [3]. One of these embankments located on the Tomei expressway in Makinohara district in Japan failed during the earthquake in 2009, with subsequent field investigation and analysis identifying the primary cause to be slaking of the mudstone [4]. The cross section of Tomei expressway after and before collapse is shown in Fig. 1. The slaking behavior of mudstone has been studied experimentally [5] - [7] through slake-durability tests and other similar tests, in which a number of wetting and drying cycles are applied to evaluate the weathering resistance of weak rocks such as shales, mudstones and siltstones. This has demonstrated that slaking cycles significantly affect the degradation process and evolution of particle size distribution in such rocks [8] – [10]. Particle size distribution characteristics such as the gradation of weak rock tend to transform in response to slaking induced by wetting and drying, and this will ultimately affect the mechanical behavior as the material after slaking is quite different from the original material [11], [12]. Weak rocks may lose their strength or stiffness through slaking, as this usually results in a gradation with small particle sizes.

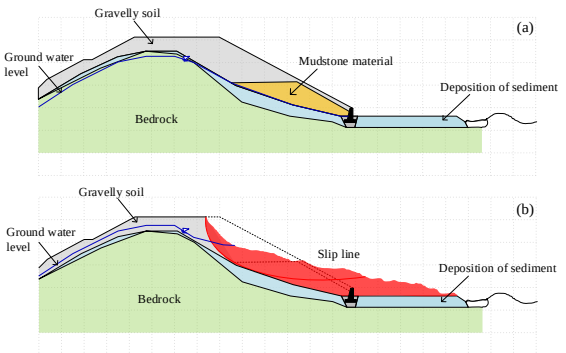

Fig. 1 Cross section of Tomei expressway fault after and before the earthquake in 2009

Such variation in mechanical characteristics during slaking can directly affect the deformation and failure behavior of the ground, but so far, most studies have only looked at the role of slaking in the evolution of the particle size distribution or the change in behavior of weak rocks. As there has been little discussion of the deformation behavior that is directly induced by slaking, this paper attempts to address the slaking-induced deformation based on the one-dimensional compression slaking tests and to propose a rational way to eliminate the issues of the granulated weak rocks in earth construction projects.

MATERIALS AND METHODS

Weak rock materials

The tested materials presented in this paper has originated from several embankments which caused deformation issues due to slaking phenomena. Kakegawa mudstone was derived from the embankment on Tomei expressway in Japan. Hattian Bala mudstone was obtained from a natural dam which was generated by Kashmir earthquake 2005 that locates at 3.5 km of Karli River in Pakistan. In addition, to investigate the rational countermeasures to the issues related with the weak rocks in embankments, loading histories (loading/unloading) were applied before the wetting and drying cycles. The test was carried out on Nou mudstone since the deformation issues in the field has occurred due to slaking. The particle size distribution of mudstone specimens at the initial state of the one-dimensional compression slaking test was a unit grading having a diameter of 0.85-2.00 mm (passed by sieve no. 10 and restrained by sieve no. 20 ASTM [14]). The physical surface morphology and general properties of the material are summarized in Fig. 2 and Table 1.

Several mechanisms of the slaking of weak rocks were attributed to the compression of air entrapped in the intra-granular pores of the particles [5]. Moreover, the size and the roughness of the pore boundaries have dominant effects on the resistance of particles against slaking. Therefore, it is necessary to explore the surface characteristics of the granulated weak rocks through SEM (Scanning Electron Microscopy) analysis using the same particle size distribution for one-dimensional compression slaking test.

Table 1 General properties of weak rocks materials

Properties	Kakegawa	Hattian Bala	Nou
Particle density (gr/cm^3)	2.65	2.75	2.69
Max. Void ratio (e_{max})	1.83	1.09	1.97
Min. Void ratio (e_{min})	1.29	0.79	1.40

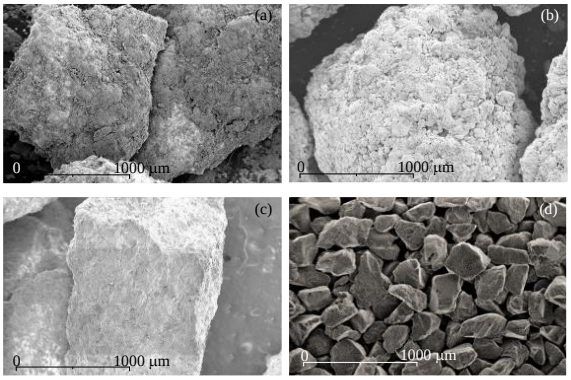

Fig. 2 Physical surface appearance of granulated mudstone magnified to 50 x: (a) Kakegawa; (b) Nou; (c) Hattian Bala and (d) Toyoura sand

Slaking under Confined Condition: One-Dimensional Compression Slaking Tests

In order to evaluate the slaking induced deformation on mudstone, a one-dimensional compression test that incorporates wetting and drying cycles [11] was modified. The schematic setup of testing apparatus is shown in Fig. 3, and consisted of: a measuring system (left), loading system (centre), and wetting and drying paths (right). The specimen container was a rigid steel cylinder with dimension of 60 mm in diameter and 40 mm high, with porous stones installed on the top and bottom loading plates, respectively. For testing, dried specimens were first installed in the steel cylinder, after which the load cell and contact-type displacement gauge were installed and initialized. The initial height of the specimen was measured to determine the initial void ratio, and then a vertical stress was applied in stages (9.8, 19.6, 39.2, 78.5, 157, 314, 628, 1256 kPa) by a pneumatic cylinder by way of a loading rod. The time for each loading was set to 30 min, as compression of the specimen immediately occurred and the volumetric behavior did not appear time dependent during the compression stage. After reaching a prescribed vertical stress, a wetting and drying cycle was carried out while keeping the vertical stress constant.

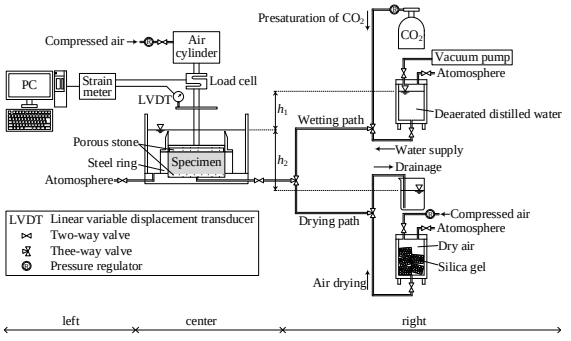

Fig. 3 The schematic of one dimensional compression slaking test

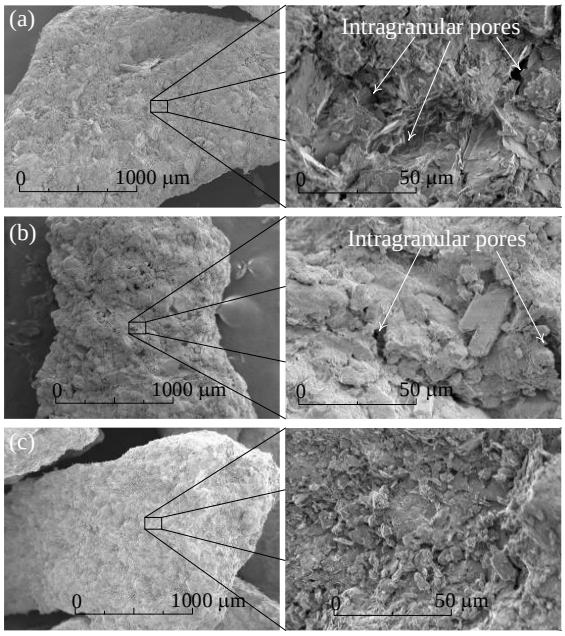

Fig. 4 SEM images of the weak rocks: (a) Kakegawa mudstone; (b) Nou mudstone and (c) Hattian Bala mudstone.

The wetting process started by permeating carbon dioxide slowly through the specimen without changing the void pressure for 30 min to remove any air, after which distilled water was permeated through the specimen by a slight difference in water level between the water tank and specimen container (h1) until the specimen was fully submerged. After leaving the specimen submerged for 6 h, the drying process was commenced by draining the void water from the specimen for 30 min through light difference (h2) in water level. Silica gel packs were then set around the steel cylinder of the specimen container, and dried air was slowly permeated through the specimen for 48 h to ensure it was completely dry. This cycle of wetting and drying was repeated three times, during which time the volumetric behavior was observed. Following the final drying process, the specimen was oven-dried and then sieved using only horizontal circular movements without any tapping impulse being added.

RESULTS AND DISCUSSIONS

Intra-granular pores

Several different mechanisms of the slaking of weak rocks have been pointed out in past studies. One of the slaking mechanisms is attributed to the compression of air entrapped in the intra-granular pores of the particles. The effect of the geometry of the intra-granular pores and revealed that the size of the pores and the roughness of the pore boundaries have dominant effects on the resistance of particles against slaking [5], [13]. The surface characteristics of the granulated mudstones were explored through SEM. The low-magnification images of each specimen on the left side in Fig. 4 clearly expose that clay-sized particles that produce a rough surface texture. It is note that the particles of the Kakegawa and Nou mudstone there is a particularly pronounced accumulation of tiny particles, with apparent intra-granular pores appearing to form within each bulk particle (the right side in Fig. 4.). In comparison, the surface texture of the Hattian Bala mudstone looks relatively smoother, but is still rougher than that of the Toyoura sand presented in Fig. 2.

Deformation on Weak rocks due to Slaking

The test result of one dimensional compression slaking for the crushed Kakegawa and Nou mudstones under a vertical effective stress σ_v' of 314 and 1256 kPa are shown in Figs. 9 and 10, respectively, whereas the results for the crushed Hattian Bala mudstone under a vertical effective stress σ_v' of 314 kPa are provided in Fig. 11. It is evident from this that the particle size distributions of the crushed Kakegawa was transformed after compression, and that mudstone types experience particle breakage during one-dimensional compression. It is also clear that there is a slightly greater change in particle size distribution at 1256 kPa, and so the evolution of grading due to particle breakage is related to an increase in the stress level. The effect that changes in grading due to slaking have on the mechanical characteristics were investigated by monitoring the maximum and minimum void ratios of the Kakegawa mudstones, Nou mudstone and Hattian Bala mudstone after each cycle of wetting and drying. As seen in Fig. 5 to Fig. 7, the maximum and minimum void ratios decrease by almost the same amount until the third cycle. For the Hattian bala mudstone, these ratios remain almost constant, while in the Kakegawa and Nou mudstone they slightly decrease. The crushed Hattian Bala mudstone, however, retains its original void ratios, and does not seem to exhibit any particle breakage under a stress of less than 314 kPa (Fig. 7).

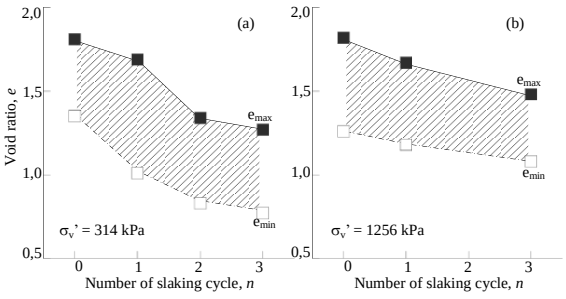

Fig. 5 Changes in void ratio (e) during slaking cycles (n) of Kakegawa mudstone

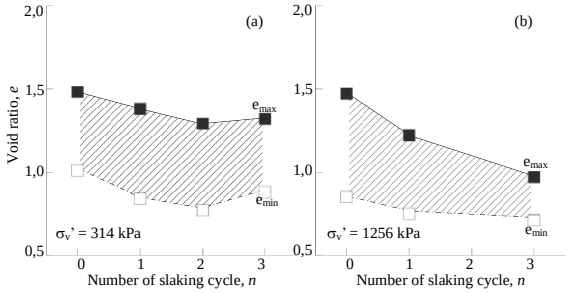

Fig. 6 Changes in void ratio (*e*) during slaking cycles (*n*) of Nou mudstone

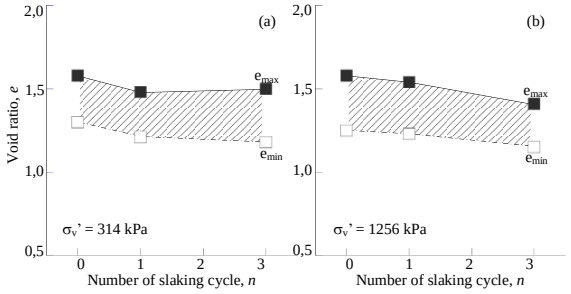

Fig. 7 Changes in void ratio (*e*) during slaking cycles (*n*) of Hattian Bala mudstone

Furthermore, the Hattian Bala mudstone particles did not contain any intra-granular pores (Fig. 4(c)), which would explain why there is so little change in particle size distribution during wetting and drying cycles shown by the breakage parameter (B_r) value. Figures 9, 10 and 11 exhibit the relationships between the vertical effective stress σ_v', number of wetting and drying cycles *n*, void ratio *e* and breakage parameter B_r for the all crushed mudstone, respectively. The upper figures ((a) and (b)) illustrate the behavior in compression, whereas the lower figures ((c) and (d)) show the variation in grading based on the B_r value. From the behavior of the Kakegawa mudstone shown in Fig. 9, it is clear that the value of B_r (Fig. 9(c)) increases to 0.12 at 314 kPa and to 0.19 at 1256 kPa, which is consistent with particle crushing theory. The compression line in the semi-logarithmic plot of *e* and log σ_v' also becomes steeper, which further confirms that particle crushing occurred [8]. After wetting and drying, the B_r value increased to 0.44 (Fig. 9(d)) and the specimen experienced significant compression, to the extent that the decrease in void ratio was greater than 0.6. For the crushed Nou mudstone, the results for which is summarized in Fig. 10, the B_r value increases from 0.21 to 0.25 at 314 kPa but decreases from 0.35 to 0.29 at 1256 kPa during wetting and drying. It was confirmed that particle breakage increases the proportion of fine particles to fill the void space between larger particles without considerably changing the maximum particle size.

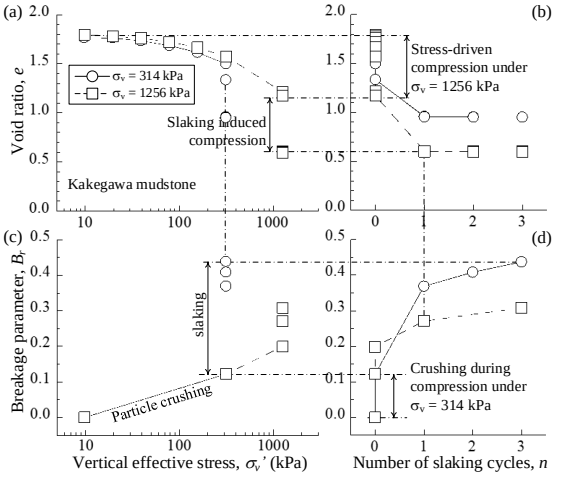

Fig. 8 Changes in the compressive properties and particle size of the Kakegawa mudstone

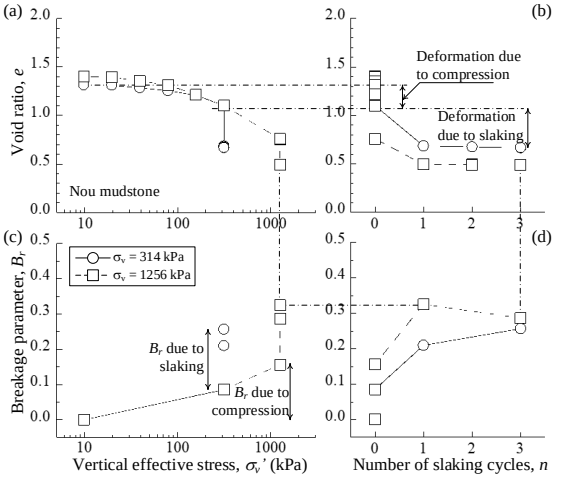

Fig. 9 Changes in the compressive properties and particle size of the Nou mudstone

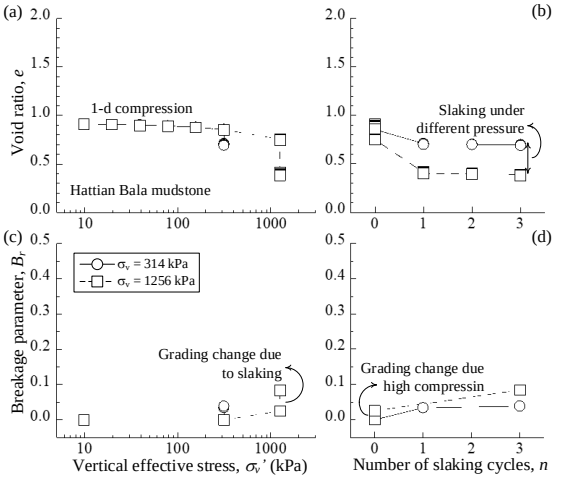

Fig. 10 Changes in the compressive properties and particle size of the Hattian Bala mudstone

The decrease in void ratio e (volumetric compression) were not significant, comparing to the Kakegawa mudstone. In contrast, the increase in Br of the crushed Hattian Bala mudstone (Fig.11) was almost zero during the compression stage at 314 kPa and slightly increase due to high compression at 1256 kPa. The compression line in the e-ln σ_v' plane was comparatively flat. This indicates that the variation in Br during wetting and drying is small. It can be inferred that slaking induced by wetting and drying cycle under a constant vertical effective stress causes substantial compression of geo-materials derived from mudstone.

An Effort to Eliminate the Deformation on Weak Rocks

A rational countermeasure technique is needed for reducing the deformation due to slaking on the earth construction project. A number of one-dimensional compression slaking test has been performed on Nou mudstone to get a better understanding related to these circumstances. The effect of loading/unloading compression history before wetting and drying cycle applied is one technique to consider. The procedure for the loading stage was similar with the previous one-dimensional compression slaking test already explained. Except for the effect of loading/unloading, after the high compression of 1256 kPa is applied for 30 min, then followed with the unloading process to 314 kPa for 30 min. Further, the wetting and drying cycles were applied as one cycle. The combination loading patterns in this section are summarized in Table 2. The particle size distribution (PSDs) changes of each case patterns of the test are shown in Fig. 12. It is significant that the PSD curve after loading history (case 7 and case 8) almost similar, despite the initial void ratios are different. It is inferred that the void ratio did not significantly affect to the grading changes. In spite of the high compression applied on the specimen, the final grading change (case 7 and case 8) almost similar with the test result of one-dimensional compression slaking under constant vertical effective stress at 314 kPa (case 3).

The total volume compression between case 3 and case 7 (Fig. 13(a)) also exhibit similar behavior, even though in case 7 the high compression stress has been applied in the beginning. It is pointed out that during the earth construction utilizing the geomaterial which has slaking properties, paying attention to roller compaction throughout the embanking work enhances the crushing of particles, controlling the occurrence of slaking under cyclic wetting and drying so that volumetric compression does not occur easily.

CONCLUSIONS

In order to investigate the deformation due to slaking behavior, a number of one-dimensional compression slaking tests has performed in this paper. The surface morphology of mudstone based on SEM result indicated the different slaking and deformation behavior caused by the intra-granular pores within particle. The transformation of particle size distribution due to slaking is influenced by the existences of intra-granular pores. As a result, it causes an irreversible change in the mechanical properties of weak rocks attributable to variation in

the density compaction. Moreover, the changes in particle size distribution as an evolution grading during compression can increase the compressibility of weak rocks, with wetting and drying cycles causing significant compression even if the effective stress remains constant. Since the evolution of particle size distribution under confined stress constant occurs without a change in the maximum particle size, it can be described by existing indexes of grading such as breakage parameter B_r. A countermeasures technique of the deformation behavior of weak rocks was performed in this study. Changing the particle size distribution in the beginning by applying loading/unloading history before wetting and drying cycle has exhibited the significant result. The compressibility during wetting and drying cycle decreases to 50% of conventional compression by applying this countermeasure method. In earth construction works, the process of roller compaction is necessary in order to encourage the crushing of particle. A proper compaction can control the occurrence of slaking under wetting and drying cycle so that volumetric compression does not occur easily.

ACKNOWLEDGMENTS

Finally, authors would like to extend their appreciation and thanks to the earthworks research section of the NEXCO Research Institute for providing mudstones specimens. The first author is grateful to the University of Lampung and Yokohama national University for supporting and research collaboration. This research is financially supported by JSPS KAKENHI Grant Numbers 24360192, 16H06099 provided to the second author.

ABSTRACT

Stability of onshore and offshore structures subjected to stormy ocean waves is influenced by the soundness of seabed foundation ground, as well as the intensity of wave pressure acting directly on the structures. The seabed soundness would be affected by the change of the seabed surface elevation caused by erosion and/or deposition of sediment. The fluctuating effective stress in the seabed ground, which is induced by sea wave loading, would cause the reduction in seabed stiffness, and then the sediment flow and related scouring of seabed must be also affected by the effective stress fluctuation. In the present study we propose a calculation method for sediment traction flow on seabed around cylindrical structures. The calculation method that we used comprises with linear wave theory, pore-linear-elasticity theory for seabed medium, and empirical sediment traction flow model regarding seawater flow velocity. Although the intensity of sediment traction flow is mainly a function of seawater flow velocity, the sediment traction flow must be also influenced by the soundness of seabed ground. In the present study we calculated sediment flow and associated erosion-deposition around upright cylindrical structures of several types. The characteristic behavior of sediment flow was clarified.

Keywords: Sediment flow, Erosion-deposition, Cylindrical structure, Reflected-diffracted wave, Effective stress

INTRODUCTION

When seabed surface is subjected to water pressure change induced by sea wave loading, the fluctuation of pore water pressure and related effective stress are propagated along depth through seabed ground, where the seabed behaves as multi-phase porous continuum. The fluctuation of effective stress causes the reduction of the seabed stiffness, and then liquefaction or fluidization of seabed material may occur under stormy wave conditions. Some damaged structures which were affected by the destabilization of seabed ground have been reported [1]. On the other hand the destabilization of seabed ground would have effects on the sediment flow, and related scouring.

We focus on the sediment flow that is mobilized by traction force from seawater flow; suspended sediment and sheet flow are out of scope of the present study. Although the sediment traction flow is mainly a function of seawater flow velocity, the sediment traction flow would be also influenced by the soundness of seabed ground even under the same seawater velocity on seabed; the sediment flow in a particular direction would be enhanced by the reduction of effective stress near surface. Miura, Morimasa, Otsuka, Yamazaki and Konami [2] explained the combined effect of seawater velocity and effective stress induced by variation of water pressure on sediment flow, and qualitatively examined the direction of sediment flow average per cycle. Tran, Miura, Matsuda and Yoshino [3] proposed an analytical method regarding the effective stress response of seabed for sediment traction flow, and the method was applied to the seabed subjected to travelling wave and stationary wave near line structures. They clarified the characteristics of erosion-deposition behavior of sediment flow quantitatively; the sediment was deposited near nodes, on the other hand seabed was eroded near loops near line structures. In the present study we modify the analytical method and apply it to the sediment traction flow behavior around cylindrical structures.

ANALYSIS METHOD

The analysis method used consists of three processes: a sea wave analysis, a response analysis of seabed ground to sea wave loading, and an evaluation of sediment flow on seabed.

Sea Wave Analysis

The behavior of sea wave was analyzed in the framework of linear theory for small amplitude waves.

Incident plane wave

The incident wave travelling along x-axis is expressed by seawater surface elevation η_i and

velocity potential ϕ_i; flow velocity vector v_i and water pressure p can be calculated as the derivatives of velocity potential ϕ_i;

$$\eta_i(x,y,t) = \frac{H}{2} e^{i(\lambda x - \omega t)} \quad \because \lambda = \frac{2\pi}{L}, \quad \omega = \frac{2\pi}{T} \tag{1a}$$

$$\phi_i(x,y,z,t) = i\frac{gH}{2\omega}\frac{\cosh\lambda(h+z)}{\cosh\lambda h} e^{i(\lambda x - \omega t)} \tag{1b}$$

$$v_i = -\phi_{i,i}, \quad p = \rho_w\left(\dot{\phi}_i - gz\right) \tag{2}$$

where H, λ, and ω are wave height, wave number, and angular frequency, respectively. And ρ_w is density of seawater, and g is gravity acceleration.

Travelling and stationary waves

The geometry of upright cylindrical structures is presented in Fig. 1 with an incident plane wave. Two extreme cases were considered for comparison. One is zero-radius (no-structure) case in Fig. 2(b): travelling wave simply appears without reflection or diffraction. The other is infinite radius (line structure) case in Fig. 2(c), where stationary wave appears without diffraction. The travelling wave is expressed by Eq. (1b), and the stationary wave is expressed by the following Eq. (3).

$$\begin{aligned}\phi &= \phi_i + \phi_s \\ &= i\frac{gH}{2\omega}\frac{\cosh\lambda(h+z)}{\cosh\lambda h}\left\{e^{i[\lambda(x-R_o)-\omega t]} + e^{i[\lambda(-x+R_o)-\omega t]}\right\} \\ &= i\frac{gH}{2\omega}\frac{\cosh\lambda(h+z)}{\cosh\lambda h}\cos\lambda(x-R_o)\cdot e^{-i\omega t}\end{aligned} \tag{3}$$

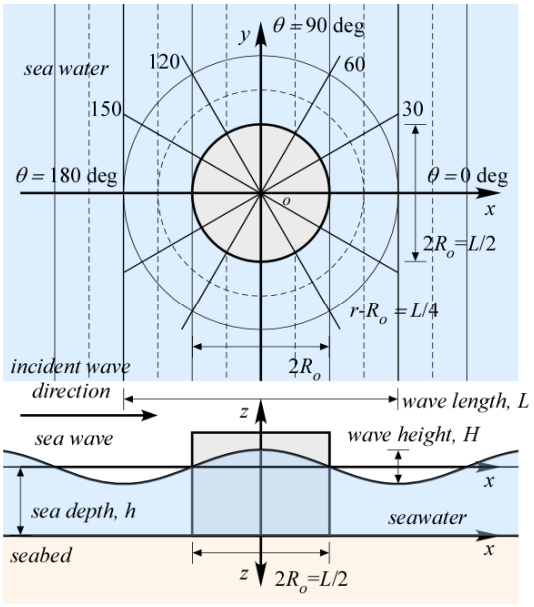

Fig. 1 Upright cylindrical structure

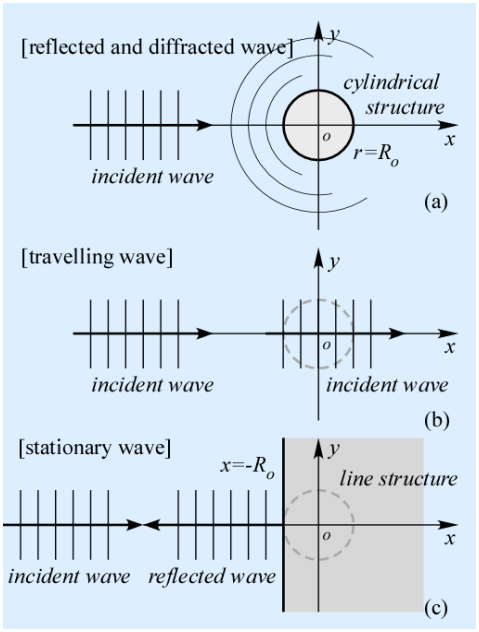

Fig. 2 (a) Reflected-diffracted waves for cylindrical structure, (b) Travelling, (c) Stationary wave for line structure

Reflected-diffracted wave for circular cylinder

For the cylindrical structure, the reflected-diffracted wave was generated as a response to the incident plane wave as shown in Fig. 2(a). For the upright cylinder of R_o in radius, MacCamy and Fuchs [4] succeeded in deriving velocity potential according to no-flow condition in radial direction on the side surface as follows

$$v_r = -\partial(\phi_i + \phi_{rdc})/\partial r = 0; \quad (r = R_o) \tag{4}$$

$$\begin{aligned}\phi_{rdc} = &-i\frac{gH}{2\omega}\frac{\cosh\lambda(h+z)}{\cosh\lambda h} \\ &\times\left[\sum_{k=-\infty}^{\infty}\frac{J_k'(\lambda R_0)}{H_k^{(1)\prime}(\lambda R_0)}H_k^{(1)}(\lambda r)\left(ie^{i\theta}\right)^k\right]e^{-i\omega t}\end{aligned} \tag{5}$$

where J_k is Bessel function of first order, and $H_k^{(1)}$ is Hankel function of first order.

In the present study, an ocean wave field with uniform depth of 20m was assumed, and an incident plane wave of wave height H of 10m, period T of 13m, and wave length L of 167.5m, was employed, regarding the sea wave condition set up for cooperative study by JSCE Committee [5].

Seabed Response Analysis

The effective stress response of seabed ground to sea wave loading on surface is analyzed with poroelastic continuum model within the framework of linear elastic theory [6]. In the model, seabed material is modeled as a binary phase material

consisting with solid phase and fluid phase (mixture of pore water and pore air), and the interaction between the two phases is combined as permeability. Miura, Asahara, Otsuka and Ueno [7] examined the applicability of the poroelastic continuum model and associated formulations under extensive conditions, according to that we employed the u-p formulation under quasi-dynamic, one-dimensional condition in the present study. For a uniform seabed layer with infinite thickness, the fluctuating pore water pressure Δp and associated vertical effective stress $\Delta\sigma_v$ can be calculated as follows.

$$\Delta p(z,t) = \Delta p_o \frac{1}{B_f + E_u}\left(B_f + E_u e^{-\zeta z}\right)e^{-i\omega t}$$
$$\sigma_v(z,t) = \Delta p_o \frac{E_u}{B_f + E_u}\left(1 - e^{-\zeta z}\right)e^{-i\omega t} + (\rho_t - \rho_f)z \qquad (6)$$
$$\because\ \Delta p_o e^{-i\omega t} = \rho_w \dot{\phi};\ z = -h \ \text{(on seabed surface)}$$
$$\zeta = \sqrt{i\omega h_v}$$

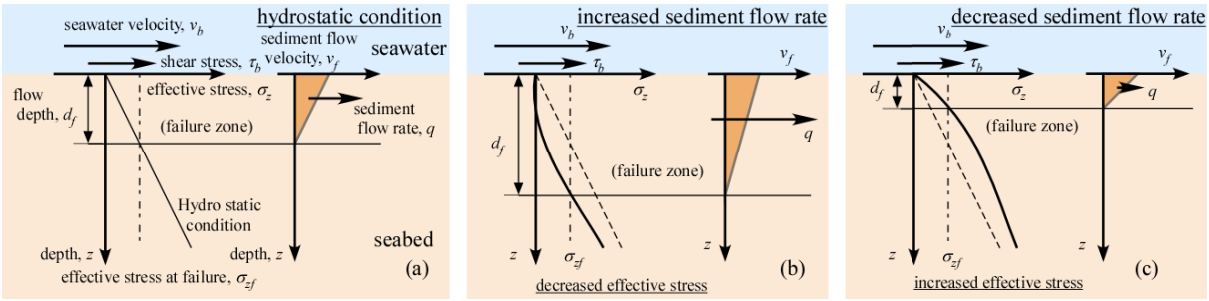

Fig. 3 Sediment flow intensity: (a) hydrostatic pressure condition, (b) decreased effective stress condition, (c) increased effective stress condition

Amount of sediment flow

The surface shear stress τ_b, that is traction force per specific seabed surface area, was assumed to be proportional to the seawater velocity v_b squared as expressed in Eq. (7), where dimensionless coefficient C_b of 1/40 was introduced.

$$\tau_b = C_b \rho_w v_b^{\,2} \qquad (7)$$

The sediment would be fluidized within the layer of d_f in thickness, where shear stress τ_b exceeds shear resistance τ_f which is calculated as a function of effective stress σ_z and internal friction angle ϕ_e as shown in Eq. (8). Finally the fluidization depth d_f can be determined.

$$\tau_f = \sigma_z(z,t)\cdot\tan\phi_e,\quad \tau_b = \tau_f$$
$$\therefore\ \sigma_z(d_f,t) = \tau_f / \tan\phi_e \qquad (8)$$

Then we assumed that the distribution of sediment flow velocity v_f within the fluidization layer was triangular along depth as shown in Fig. 3. Thus the amount of sediment flow vector per unit width q (m^2/s) can be calculated with Eq. (9), where the dimensionless coefficient C_q was introduced for the difference between seawater velocity v_b and sediment flow velocity v_f. The value of C_q was assumed to be 1/2.5.

$$q = \frac{1}{2} d_f v_f = \frac{1}{2} d_f C_q v_b \qquad (9)$$

As explained schematically in Fig. 3, the amount of sediment flow vector q would be rather dependent on effective stress distribution. Figure 3(a) shows the case of hydrostatic effective stress. If the effective stress decreases, the fluidized shear zone becomes thicker and thus q becomes larger as in Fig. 3(b). On the other hand, if the effective stress increases, the fluidized shear zone becomes thinner and thus q becomes smaller as in Fig. 3(c). It should be noted that even under the same seawater velocity

In the present study, it was assumed that for typical uniform loose sand, uniaxial stiffness of solid phase E_u is $1.40\text{x}10^5$kN/m^2, average stiffness of fluid phase B_f is $0.933\text{x}10^5$kN/m^2, and hydraulic consolidation coefficient H_v is $1.75\text{x}10^{-3}$ s/m^2 (see [5,7] for detailed explanation).

Evaluation of Sediment Flow on Seabed

The sediment flow and related variation of seabed surface elevation, that is erosion and/or deposition, was calculated in an empirical manner based on the concept of Shields Number, regarding the effective stress response in seabed ground (see Fig. 3).

v_b, sediment flow is dependent on effective stress.

Sediment storage rate: erosion-deposition

As shown in Fig. 4, the rate of sediment storage designated as Q (m/s) can be calculated from the total balance of inflow and outflow in both x- and y-directions to/from an infinitesimal rectangular area.

$$Q = -\frac{q_{x(x+\Delta x/2,y)} - q_{x(x-\Delta x/2,y)}}{\Delta x} - \frac{q_{y(x,y+\Delta y/2)} - q_{y(x,y-\Delta y/2)}}{\Delta y} \rightarrow -\left(\frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y}\right) \quad (\Delta x \rightarrow 0, \Delta y \rightarrow 0) \tag{10}$$

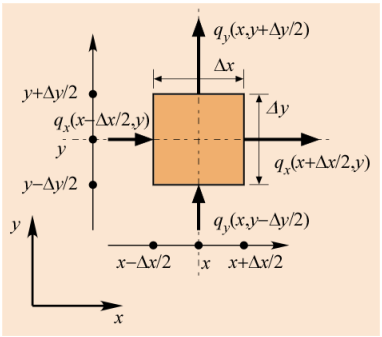

Fig. 4 Calculation of sediment storage from the balance of inflow and outflow to/from infinitesimal rectangular area

The positive and negative values of sediment storage rate Q correspond to deposition and erosion, respectively. The sediment flow velocity vector q and storage rate Q both can be integrated during a sea wave period T for evaluating the accumulated sediment flow behavior; the accumulated integrated values were designated as q_T (m^2) and Q_T (m), respectively.

EXAMINATION OF CALCULATED BEHAVIOR AND DISCUSSION

Sea Wave Behavior around Cylindrical Structure

Figure 5 shows sea wave behaviors along radial directions both in front and back of the cylindrical structure of R_o/L=1/4; the variation of seawater surface elevation along radial direction are drawn in 8 sections of wave period T. For comparative examinations, the travelling wave and the stationary wave are shown in front of the structure (Fig. 5(a): θ =180deg), and the travelling wave is shown in back of the structure (Fig. 5(b): θ =0deg). In the front of cylindrical structure, loop appears on the structure side surface, and node and loop are repeated along

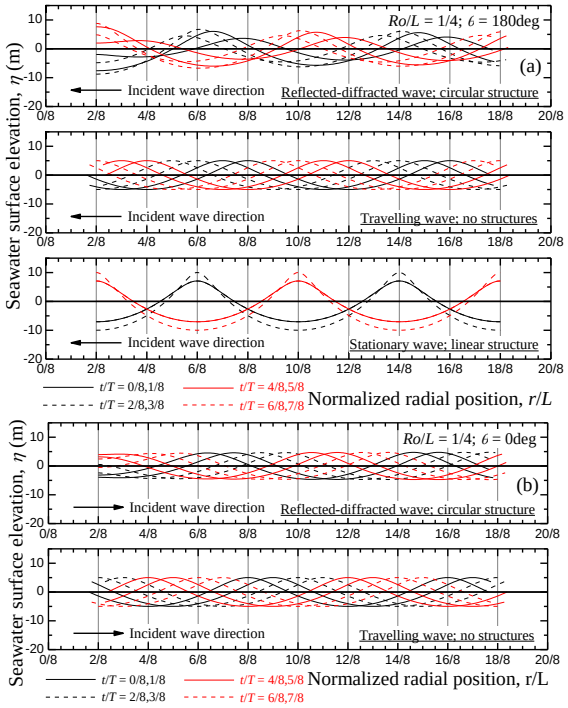

Fig. 5 Behavior of sea surface along radial direction: (a) front of structure, θ =180deg, (b) back of structure, θ =0deg

the radial direction. Though the loop and node are not clear compared with the stationary wave near line structure, characteristic behavior of stationary wave can be recognized in Fig. 5(a). In back of the structure, sea wave behavior is similar to that of travelling wave with somewhat smaller wave height and a phase lag of about T/4 compared with the travelling wave in Fig. 5(b).

Sediment Flow and Storage: Erosion and Deposition around Cylindrical Structure

Behavior in radial direction

Figure 6 shows sediment flow behaviors along radial direction both in front and back of a cylindrical structure of R_o/L=1/4; the variations of accumulated sediment flow vector q_T and sediment storage Q_T are shown in 8 sections of wave period T. For comparative examinations travelling wave and stationary wave are also shown in the figure. In structure front (θ=180deg) radial component of sediment flow vector q_{Tr} is fluctuating but consistently positive. This feature means that the sediment flows away from the structure, and the flow direction is in the opposite of the incident wave travelling direction. The behavior of sediment storage Q_T shows that the seabed is eroded on the side surface, and however, the sediment deposits around the node apart from the structure surface by L/4. The erosion and deposition are seen clearly in

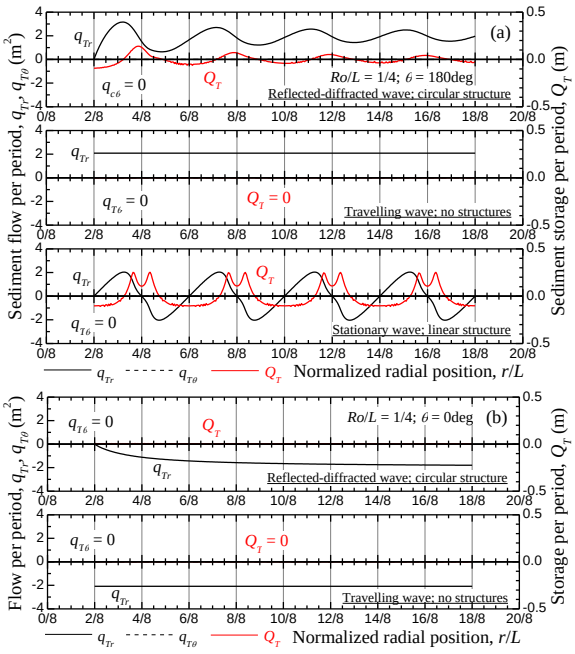

Fig. 6 Behavior of sediment flow on seabed along radial direction: (a) front of structure, θ=180deg, (b) back of structure, θ=0deg

the case of stationary wave, and the erosion and deposition are repeated along the radial line in front of the structure.

On the other hand, in back of cylindrical structure (θ=180deg), q_T is not fluctuating and consistently negative. This means that the sediment flows toward the structure in the opposite of the incident wave travelling direction. As Q_T is negligibly small, the erosion or deposition wouldn't occur in structure back.

Behavior in circumferential direction

Figure 7(a) shows the behavior of sediment flow and associated storage of sediment on the side wall of the cylindrical structures with different diameters. On the side wall (r=R_o) sediment flows only in circumferential direction. Although the sediment flow is somewhat influenced by the structure size, $q_{T\theta}$ is anti-symmetry and positive on the right hand side but negative on the left hand side in the top of Fig. 7(a). It is suggested that the sediment flows accumulatively for back to front on the structure side surface. The behavior of Q_T tells that notable erosion (Q_T<0) occurs near structure front (θ=180deg), its intensity is equivalent to that in the case of stationary wave.

Figure 7(b) shows the sediment flow behavior on the concentric circle apart from the structure side surface by a quarter of wavelength (r=R_o+L/4). The behavior of $q_{T\theta}$ shows the circumferential flow from structure back to front as similar to the case of on the side surface (r=R_o). The radial flow of sediment q_{Tr} is positive near structure front but negative near the perpendicular directions (θ=+90 or –90deg). On the concentric circle (r=R_o+L/4), notable deposition of sediment (Q_T>0) is recognized around structure front (θ=180deg).

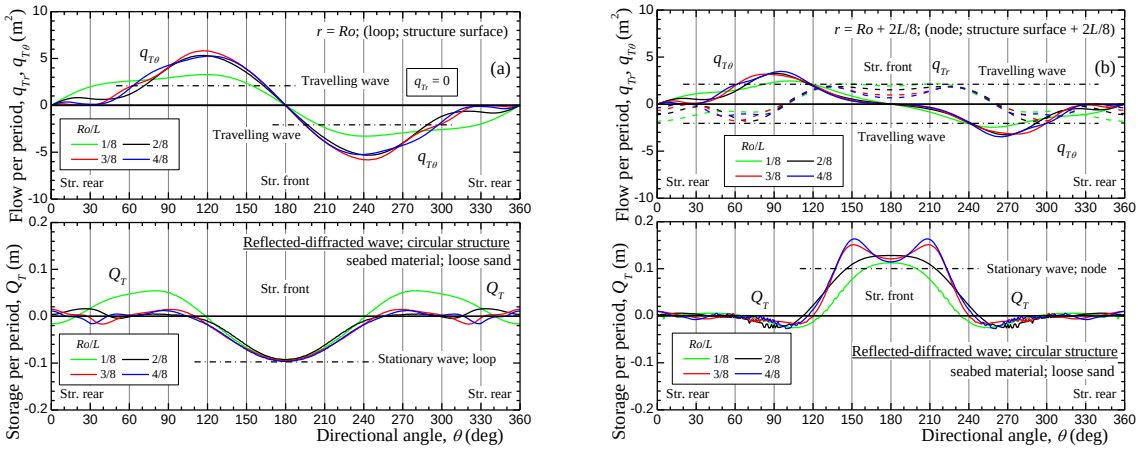

Fig. 7 Behavior of sediment flow along circumferential direction:
(a) (on structure side surface: loop) r=R_o, (b) (on concentric circle: node) r=R_o+2L/8

Plane view of the sediment flow

Figure 8 shows the plane view of sediment flow and associated storage of sediment near the cylindrical structure of R_o = L/4. The red vector indicates the direction and intensity of accumulated sediment flow q_T, and color gradation and contour lines indicate the intensity of sediment storage Q_T. Without structures, the incident wave and travelling wave generate uniform sediment flow with no-storage, in the opposite direction to the incident wave as shown in Figs. 7(a, b) (see [3]). As a result

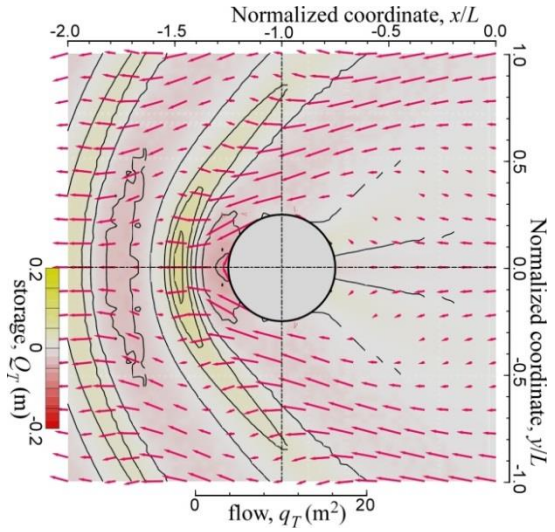

Fig. 8 Plane view of sediment flow and its storage around cylindrical structure: $R_o/L=L/4$

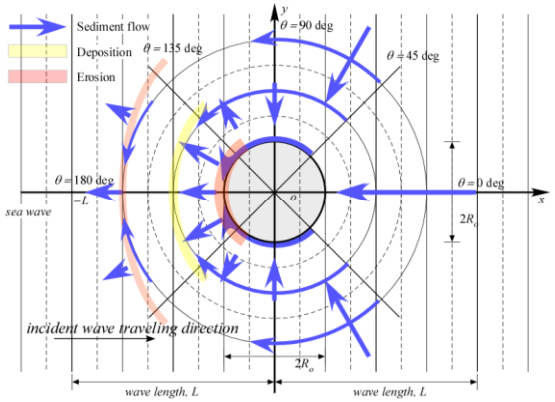

Fig. 9 Schematic explanation of sediment flow behavior around cylindrical structure: $R_o/L=L/4$

of the disturbances by the cylindrical structure, sediment storage occurs, and erosion and/or deposition are caused.

Figure 9 explains the sediment flow behavior schematically, where arrows are for accumulated sediment flow vector q_T; the thickness of the arrows roughly corresponds to the intensity of q_T. The curved lines indicate the storage of sediment Q_T; the thickness of the lines corresponds to the intensity of Q_T; and light red and light yellow are for erosion (Q_T<0) and deposition (Q_T>0), respectively. Overall behavior of the sediment flow can be explained as follows. Sediment flows toward the structure in the wide range including structure back (−90deg <θ <+90deg). The sediment flows from back to front along structure side surface: the flow is followed by the radial, flows away from the structure in the range including the structure front (120deg<θ<240deg). It should be noted that the erosion and deposition on the parabolic lines are repeated in the wide range of the structure front, which occurs under the influence of sea wave behavior similar to stationary wave with loops and nodes (see Figs. 5, 6). It would be important that the notable erosion on the structure front side surface possibly destabilizes the structure.

CONCLUSIONS

We explained the analysis method comprised with "the linear wave theory analysis", "effective stress analysis by poroelastic model" and "empirical evaluation method for traction sediment flow", and the sediment flow characteristics when the plane wave meets upright cylindrical structure was examined.

CARACTERIZATION OF CEMENTITIOUS BACKFILL WITH HIGH SULPHUR CONTENT

Daniela Ionescu[1], Joe Petrolito[2] and David Morton[3]
[1]School of Mathematical Sciences and Engineering, [2]School of Leadership, [3]School of Molecular Sciences, La Trobe University, Australia

ABSTRACT

The extraction and use of mineral resources are critical to modern societies. New technologies and practices have ensured the development of the mining industry. Currently, the industry is striving to become more efficient and more environmentally-friendly. This paper reports on the effect of chemical and mineralogical changes (weathering due to sulphate attack) with time on the mechanical properties of backfills. Fines, sulphide-rich gold tailings from the local Fosterville Mine, were mixed with varied cementing binders for the purpose of this study. Sulphate resistant binders (fly ash, ground granulated blast-furnace slag, silica fumes) were used in addition to general purpose cement to identify the effects of the binder and the age of the hardened cemented paste on the mechanical properties, as well as the effect of sulphate attack on these properties. The findings to date show that there is potential to replace current backfill materials with cemented paste backfill to increase mine productivity and ore profitability.

Keywords: Binder type, Cemented paste backfills, Mining stopes, Sulphite Resistant Binders, Sulphide tailings

INTRODUCTION

Mining gold is a multi-billion dollar activity in many countries around the world. In Australia, gold extraction has a long history in Bendigo and its surroundings. In this area, the rich gold-bearing quartz reefs are hosted by tightly forded Ordovician (480 Mya) marine sediments [1]. Recent drilling and bulk sampling by Kirkland Lake Gold Ltd at their operation at Fosterville Gold Mine (FGM) have shown that the gold resources exceed 1.03 million ounces in this region, and more than half of the estimated gold reserve has an average grade of 58.8g/t [2]. Furthermore, high-grade gold resources at relatively shallow depths were also reported [2].

FGM is located about 155 km north of Melbourne, in Central Victoria. It uses open stoping mining with delayed backfill in its operation as shown in Fig. 1. This method employs blasting to create a void called a stope. The ore from the stope is removed using drilling and blasting, then is transported to the extraction plant to separate the gold. Subsequently, the created void is backfilled with waste rock (rockfill, RF) and cemented rockfill (CRF), which is left to cure. The CRF backfill is used to increase the recovery of ore by minimising the requirement of leaving ore pillars, and provides ground support for the mine structures and a safe working environment. In addition, the CFR backfill minimises the risk of surface subsidence due to underground stopes, provides a disposal site for the waste rocks, and controls ore dilution from hanging wall and footwall. This extraction technique is considered one of the

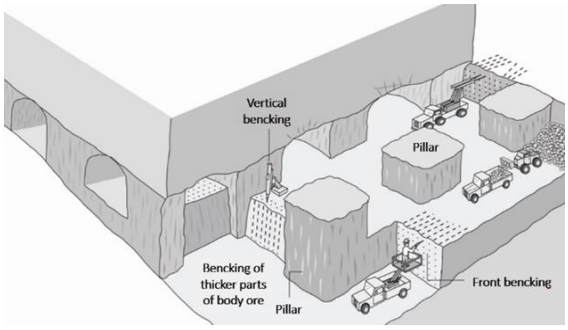

Fig. 1 Diagram of open stoping mining method.

better choices for mining steeply dipping tabular ore bodies [3]-[5], as is the case at FGM, and it also provides a good production and ore recovery rate. Annually, around 80,000 m^3 of voids are backfilled using a proportion of 75% CRF and 25% RF.

Whilst the current CRF backfilling method is considered to be working effectively, the operators at FGM have observed that when a new stope is created by blasting, hardened fill material from the adjacent stope can collapse [5]-[8]. This results in dilution of the ore, decreasing the productivity of the mine operation and increases the cost of ore processing. Furthermore, the ore extraction adjacent to newly CFR stopes is delayed by about a month, due to curing time required by the cemented rock fills to achieve the needed strength.

Farsangi [5], Belem and Benzaazoua [6], Kockler [7], Emad *et al.* [8], [9], Yumlu[10], and Miller *et al.* [11] have reported that vibrations from blasting are the main cause of collapse for CRF stopes.

However, the strength of cemented rockfill stope is affected by the type of binder, mix proportions, and the gradation and maximum particle size of the waste rock [12], [13]. In addition, factors such as cohesion and stiffness, and the size of the backfilled stope affect the strength of CRF [3], [6, [8].

More than three decades ago, new backfilling methods were introduced in underground open stoping mining with delayed backfill operations. One of these methods uses cemented paste backfill, which has gained worldwide acceptance in recent years as an integral part of underground mining processes. Cemented paste backfill (CPB) is a heterogeneous material made of tailing having about 70 % - 80 % solid content, water and a hydraulic binder [14]. This developing technology has both economic and environmental benefits [15]. Hence, FGM operators have commissioned this study to identify if cemented paste backfill provides higher strength for the exposed stopes, a faster curing time to enable a reduction in gold extractions costs and an increase in the operation productivity when compared with the current CRF backfill system.

This paper discusses the results of a continuing study at La Trobe University into the use of fine tailings supplied from FGM for cemented paste backfill. FGM has an annual production of about 606300 tones per year, which is expected to increase in the near future. The gold processing plant grinds the ore so about 80% of its mass is smaller than 75 μm. Flotation is then used to extract the gold locked within the pyrite/arsenopyrite minerals. The stream of tailings resulting from the gold production consists of 30% solids, and it is discarded in the tailings storage facility to desiccate. A significant volume of tailing results from the gold production, and hence FGM operators are interested in finding environmentally-friendly ways to use this waste material, while increasing their productivity and minimizing production costs.

MATERIAL REQUIREMENTS

Cemented paste backfill takes the form of a non-Newtonian fluid consisting of the full mine tailings that is mixed with a binding agent and water, and it has the consistency of a fine slurry [14], [15]. The pumping of the CPB is done over relatively long distances through the mine and then into the open stope [14]. Therefore, the mix should have a slump value of around 200 mm [16]. Typically, CPB contains about 75-85% by weight tailings, around 3-6% by weight cement and water to form the dense, pumpable mix [17], [18]. To increase the pumpability of the mix, researchers have suggested that tailings should have a minimum of 15% of the solid particles finer that 20μm, as this allows the surface tension of the water to form a lubricating film on the paste grains [18], [19].

In terms of the compressive strength of CPB, the water to cement ratio influences the unconfined compressive strength (UCS), as is the case for concrete. A higher ratio lowers the strength, due to the increase in porosity that typically is around 30% [17]. Furthermore, sulphate or sulphide minerals present in gold mine tailings reduce the strength of CPB and increase setting time of the mix [20].

EXPERIMENTAL PROGRAM

The physical characteristics of the materials used in the study were determined in accordance with relevant Australian Standards [21]. The governing factors were the compliance with current specifications and the feasibility of obtaining an acceptable and economic material.

Tailings

Considering the economic aspects, the supplied tailings used in this study were 'moist' tailings that were reclaimed from one of the two TSF currently used at FMG. The chemical composition of the tailings used in this study is presented in Table 1. Tailings were sampled from both the entrance and exit to/from the ponding area of Hunt's TSF to provide a better picture on the gradation of the supplied tailings. Figure 2 shows that the particle size distribution of the tailings fit between close boundaries. The coarser tailings were sampled from the entrance into the sedimentation pond and the finer tailings were collected from the exit. The content finer than 20 μm was about 35% - 41%. Hence, these tailings are ideal for the production of CPB. The moisture content of the desiccated tailings varied from 22.6% for the coarser tailings to 31.3 % for the finer tailings, while the specific gravity of the tailings varied from 1.39 to 1.46 for the finer and coarser tailings, respectively.

Table 1 Main chemical properties of the tailings supplied from Fosterville Gold Mine

Chemical component/compound	Content (wt.%)
$(K)(Al)xSiO_2$	35-45
$CaSO_4.2H_2O$	30
$FeOOH.0.4H_2O$	~1-5
FeS	0.5-1
$Fe(AsO_4).2H_2O$	0.1-0.5
H_2SO_4	0.5
As^{5-}	0.2-0.3
Fe^{3+}	0.1-0.2
FeAsS	0.1-0.2
Sb_2O_3	0.1-0.2

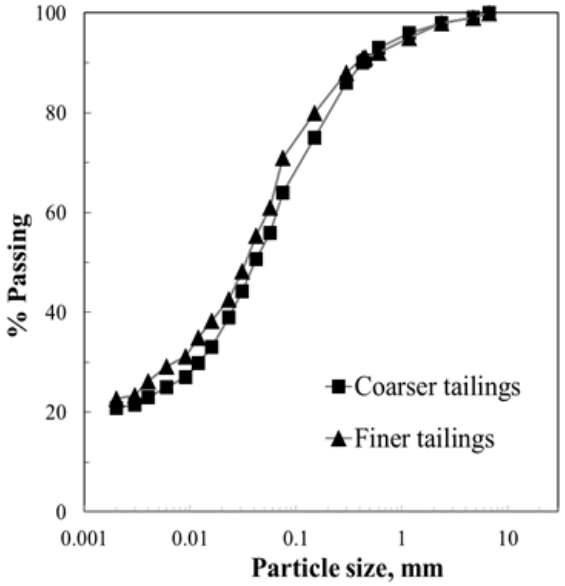

Fig. 2 Particle size distribution of tailings supplied from Hunt's tailing storage facility at FGM.

Binder

General-purpose Portland cement (type GP) was used for the control mix. To check the effect of binder type on the mechanical properties of CPB, three supplementary cementitious materials were also used in various proportions. These cementitious materials were class F fly ash (FA), ground granulated blast-furnace slag (GGBS) and silica fumes (SF). Past research [13], [22], [23] showed that CPB achieved acceptable strength even when the binder proportion was as low as 3% - 7% by weight. Hence, the binder content was limited to 5% in this study, and the following blends of cementitious materials were used:

- 5% General purpose Portland cement (5GP, the control mix)
- 3% Fly Ash + 2% GP Portland cement blend (3FA-2GP)
- 1% Silica Fume + 4% GP Portland cement blend (1SF-4GP)
- 4% Ground Granulated Blast-furnace Slag + 1% GP Portland cement blend (4GGBS-1GP).

Mix proportioning and specimen preparation

The required quantities of tailings, binder and water that were used for each batch type are summarized in Table 2. The moisture content of the supplied tailings was taken into account to achieve the required workability for a 200 mm slump [16]. The four batches were mixed in a flat pan mixer following the standard procedure for concrete preparation in the laboratory [24]. Compressive and indirect tensile strength specimens were prepared using the standard concrete molds corresponding to each test. Molds were removed after 24 hours, and specimens were placed in plastic containers and closed tightly. The specimens were dry-cured at room temperature until the test time (i.e., 7, 14 and 28 days), to simulate the underground environment where CPB would be placed. After the required curing times, the CPB specimens were subjected to various tests.

Table 2 Proportions of materials for the proposed mixes

Material	Mix type			
	5GP	3FA-2GP	1SF-4GP	4GGBS-1GP
Tailings (kg)	93.5	93.5	93.5	93.5
GP (kg)	10.8	4.1	8.0	2.2
FA (kg)	-	6.5	-	-
SF (kg)	-	-	2.2	-
GGBS (kg)	-	-	-	8.0
Water (L)	14	14	14	14

STRENGTH OF CEMENTED PASTE BACKFILL

One of the functions of CPB is to provide ground support to create a safe working environment, as well as to minimise surface subsidence. Hence, it is expected that the CPB would have reasonable strength for both short-term operations and the long-term management of backfilled stopes. The strength tests were performed following the standard procedure for laboratory measurement of concrete strength [25], [26].

Compressive strength of CPB

The variation of the compressive strength with the curing time is presented in Fig. 3. It should be observed that the partial replacement of general purpose cement with fly ash and silica fume caused a reduction in the compressive strength of about 36% - 45% and 12% - 35%, respectively when compared with the control batch prepared with GP cement. This reduction was independent of the age of the CPB. This shows that the hydration of the binder containing fly ash and silica fume was adversely affected by the sulphate content present in the supplied tailings. In contrast, partial replacement of GP cement with blast-furnace slag resulted a strength that is 2 to 3 times higher than the strength of the control batch (5GP). Typically, GGBS is used as a partial replacement for GP to produce sulphate-resistant concrete, and hence the test results were expected. It is interesting to note that the 4GGBS-1GP batch displayed a 16%

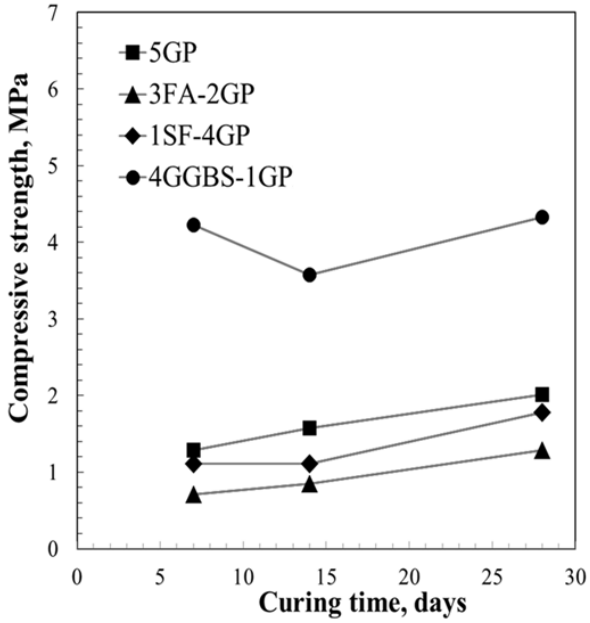

Fig. 3 Effect of binder type and proportion on the compressive strength of the proposed cemented paste backfills.

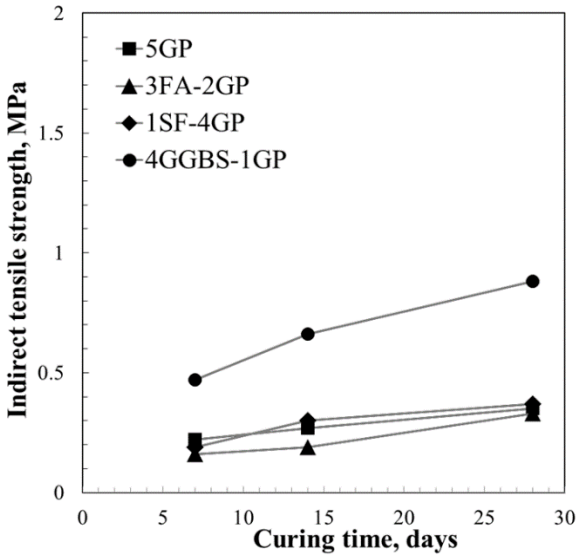

Fig. 4 Effect of binder type and proportion on the indirect tensile strength of the proposed cemented paste backfills.

reduction in compressive strength at 14 days. However, the loss in strength is recovered after longer curing times.

Indirect tensile strength of CPB

Another function of CPB is to provide stability for the freshly exposed stope during blasting processes, thereby avoiding dilution of the gold ore. Thus, it is expected that the CPB would have reasonable tensile strength, especially for short-term operations, to resist vibrations from blasting processes. The variation of indirect tensile strength with curing time is presented in Fig. 4. Similar trends were observed as for compressive strength, and the trends were independent of the age of the CPB. The partial replacement of general purpose cement with fly ash caused a strength reduction of about 15% - 28%. Interestingly, the effect of partial replacement of the general-purpose cement with silica fume caused an insignificant change in the strength when compared with the control batch (5GP). As expected, the highest indirect tensile strength was displayed by the batch containing GGSB, which had a strength of 2 to 2.5 times higher than the control batch (5GP). Furthermore, the rate of strength increase was highest for the 4GGBS-1GP batch.

CONCLUSIONS AND RECOMMENDATIONS

The effects of various binders on the strength of cemented paste backfill produced with tailings from a gold processing plant were discussed in this paper, and the following conclusions can be drawn.

Partial replacement of GP cement with FA resulted in lower compressive and indirect tensile strengths when compared with the CPB produced only with GP cement, and this result was independent of the curing time of the mix. Similar outcomes were obtained when GP cement was partially replaced with SF, although the change in the indirect tensile strength was minimal.

As expected, partial replacement of GP cement with GGBS resulted in a CPB with significantly higher compressive and indirect tensile strengths. In addition, the rate of increase of the indirect tensile strength was highest for this batch (4GGBS-1GP). Hence, the use of the GGBS binder as a partial replacement for GP cement proved to be the optimal cemented material for production of CPB using sulphide-rich gold tailings from FGM.

However, further research is needed on the elastic properties of the proposed mixes to enable numerical modelling of the performance of CPB in a practical mine to be undertaken. Furthermore, as the effect of sulphide has a detrimental long-term effect on the strength of CPB, this aspect needs to be further investigated.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the help provided by Fosterville Gold Mine with the supply of materials. The assistance with preparation and testing provided by Mr Adam Dare, Mr David Osborne, Mr Zac Pentreath and Ms Laura Sonnberger is also acknowledged.

ABSTRACT

Malaysia is a country which experiencing wet tropical weathering. Rock material in this country is affected by weathering action as they exposed to the weathering process throughout the year. In verifying the material properties of rock, laboratory tests are needed to ensure a safe design of structures and foundations.This paper presents the results of laboratory investigation of chemical properties, mineralogical content and mechanical properties of the rocks and the influence of the chemical and mineral contents to the rock strength. This experimental works is about to investigate the significant of chemical content to the rock strength particularly in sedimentary rock of sandstone type. For this purpose, Alkali Silica Reactivity (ASR), Petrographic Image Analysis, Unconfined Compression Strength (UCS), Shear strength and Tensile strength tests were carried out. The correlations between the chemical properties, petrographic characteristics (minerals) and engineering properties of sixteen sandstones samples by simple regression analysis and bar chart were presented. Abundance of quartz mineral, carbonate minerals and cement in the sandstone increase the rock strength, and reduction of easily dissolve mineral like carbonate minerals, reduced the strength of the rocks. This study also suggested that the ASR has less significant to the Shear strength and uniaxial compression strength as the quantity of these deleterious minerals such as opal, chalcedony, volcanic glass, cristobalite, tridymite and cryptocrystalline quartz are very low compared to main minerals.

Keywords: Mineral content; Strength properties; Weathering; Chemical properties; Sandstone

INTRODUCTION

In tropical country like Malaysia, weathering plays important role in determining the strength of rock. However, rock strength is also influenced by the rock type either it is in the group of igneous, sedimentary or metamorphic. Among these rocks, sedimentary rock with its physical characteristics of bedding, lamination and clastic grains provide an easy way that prone to weathering, thus weaken the rock mass and material. According to [1], [2] properties such as porosity, density, chemical content, mineralogy and degree of cementation are related to the rock strength. These rocks with their own chemical properties and mineral content could influence the rock strength as rock is composed of minerals. Mineral bond in rocks is known as cementation. Strength of rock increase proportionally with the degree of cementation [3], the minerals bond in rocks. According to [4], chemical composition of rocks influences its surface energy and its chemical reactivity. The chemical functionalities in rocks play a predominant role in rock strength. Aggregates containing certain constituents can react with alkali hydroxides in concrete [5]. The reactivity is potentially harmful only when it produces significant expansion. Alkali silica reaction (ASR) is chemical reactions which occur between certain reactive minerals in some aggregates and alkali in the pore solution of concrete. According to [6] the ASR results from the reaction of disordered forms of silica minerals in aggregates and the hydroxyl ions (OH–) in the pore fluid of concrete.

Even though many researches have been done to relate mineral contents and the mechanical properties of rocks [6],[7],[8], the relationship between the chemical properties and sedimentary rock strength is still not well identified. Most of the researches explained no conclusive finding on rock strength for the three types of rocks; igneous, sediment and metamorphic rock based on chemical and mineral contents of rocks. This paper is presented to identify the relationships between the chemical properties and mineral contents on the strength of weathered sandstone that widely distributed in tropical country like Malaysia. The results of this study could be used to estimate the strength of sandstone for future development in weathered environment like Malaysia

.

MATERIAL AND METHODS

A number of sixteen (16) sandstone rock cores were collected from the area of Jerantut in the state

of Pahang, Malaysia for this study. The strength tests that were carried out are uniaxial compressive strength, Triaxial Shear test, Direct Shear tests and indirect tensile strength (Brazilian) tests. The test for uniaxial compression strength was according to the ASTM D7012 specification. This test method covers the determination of the strength of intact rock core specimens in uniaxial compression load. Triaxial shear tests have been used to gain an understanding of rock behaviour under a three-dimensional state of stress and to verify, and even validate, mathematical expressions that have been derived to represent rock behaviour in analytical and numerical models. It is through the results of triaxial tests that yield strength criteria have been developed and material specific strength characteristics are determined. The parameters obtain from this test are the friction angle and cohesion in relation to the following equation:

$$\tau = \sigma \tan\theta + c \qquad (1)$$

where; τ is shear strength; σ is shear stress; ɵ is friction angle and *c*, is cohesion of rock material.

Direct shear strength test of rock core is purposely to establish the shear strength properties of discontinuities in rock. These core samples were to be tested for their shear strength along selected fracture plane (existing natural joint) and under a specified normal stress. Throughout the shearing process, the normal stress was maintained at constant level and as such this test is also termed as *single-stage direct shear* test in accordance to ASTM D5607-08. Data obtained from the test were shear behaviour (shear stress vs. shear displacement), peak shear strength, and the corresponding horizontal displacement where the peak strength occurs.

The tensile test method is also referred as Brazilian test where cylindrical intact rock specimens are loaded at diametrically –opposed surfaces by a uniformly distributed, radial stress (ASTM D3967-08). It is an indirect measurement of tensile strength of rocks by applying compressive on the rock samples. The parameters obtain from this test are the relation between splitting tensile and load applied, diameter and length of sample as following:

$$\sigma = \frac{2P}{\pi DL} \qquad (2)$$

where; σ is splitting tensile strength; *P* is maximum load; *H* is height and *D* is diameter of rock material. For chemical contents and mineralogical analysis, Alkali Silica Reactivity (ASR) test was measured the result of reaction of an aggregate with alkali where the procedure is recognized by as ASTM-C289-07. The potentially alkali reactive rocks are not used for the production of aggregates because deleterious aggregates will affect the soundness of concrete structures and adversely impact the construction industry. The objective of this test is to assess the potential alkali-aggregate reactivity of sandstone samples. Another test is petrographic analysis recognised by ASTM- C295-08 for mineral composition identification in sandstone.

RESULT AND DISCUSSIONS

Strength properties

Results from the laboratory experiments for strength properties are given in Table 1. The values in the tables shows the UCS was collected from uniaxial compressive strength test while the triaxial test provide parameters for cohesion (c) and friction angle (θ^o). The parameter collected from the direct shear test for discontinuities or joint on the rock core is named as friction angle at joint (θ^o).

Chemical properties and mineral content

Results for mineral contents were collected from petrographic analysis and alkali silica reactivity tests were tabulated as in Table 2. Distribution of minerals in sandstone that composes of quartz, carbonate matrix, calcite, rock fragments and accessory minerals is presented in Fig.1. Among these minerals quartz shows the highest content in sandstone with range from 18.5% to 92.4%, followed by carbonate matrix, 2.1% to 86.4% and rock fragments, 1% to 80.9%. Calcite and

accessories minerals presents lowest in sandstone ranges from 2% to 16% and 0.5% to 1.1% respectively. The mineral distribution of sandstone is similar as discussed in petrographic [4], confirmed that the samples are sandstone. In some cases, like in sample 1 to sample 6 the calcite mineral is absent. The high content of quartz in sandstone is due to the nature of sedimentation of weathered parent rock such as granite with high contain of quartz that broken to small particle called as sand. This quartz grains were transported by the weathering agent like water, glacier or wind to be deposited and cemented as sandstone.

Correlation between mineralogy and strength properties

Relationships between the percentages of the main minerals and uniaxial compressive strength (UCS)
The relation between the percentages of the main minerals and uniaxial compressive strength (UCS) is given in Fig. 2. As can be seen in this figure, quartz (Q) have a very important role in strength increment in Sandstone. In contrast the carbonate mineral (CM) have a very important role in strength reuction. The reason on why mineral can easily

react with and wash away thus weakened the material. The strong correlation between quartz content the increasing of quartz increased the strength and increasing of carbonate mineral decreased the strength of sandstone is that quartz is a high resistance mineral to weathering agent. Meanwhile, carbonate dissolve in water. So that quartz will stay longer in the rock as part of mineral composition and strengthen the rock material while carbonate will and compressive strength is validated by many researchers [10,11].

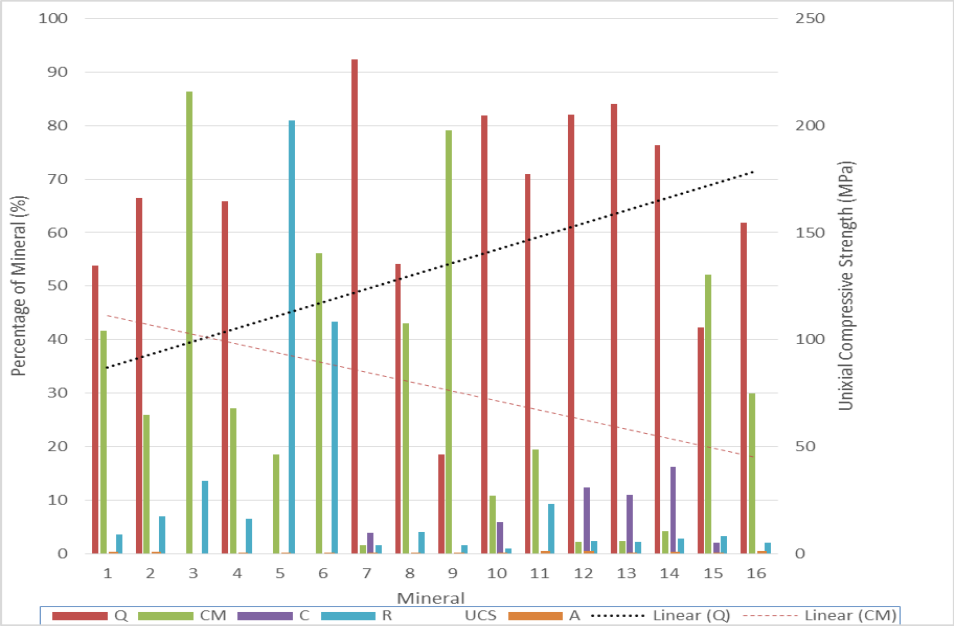

Figure 2: Relationship between the percentage of minerals and the uniaxial compressive strength

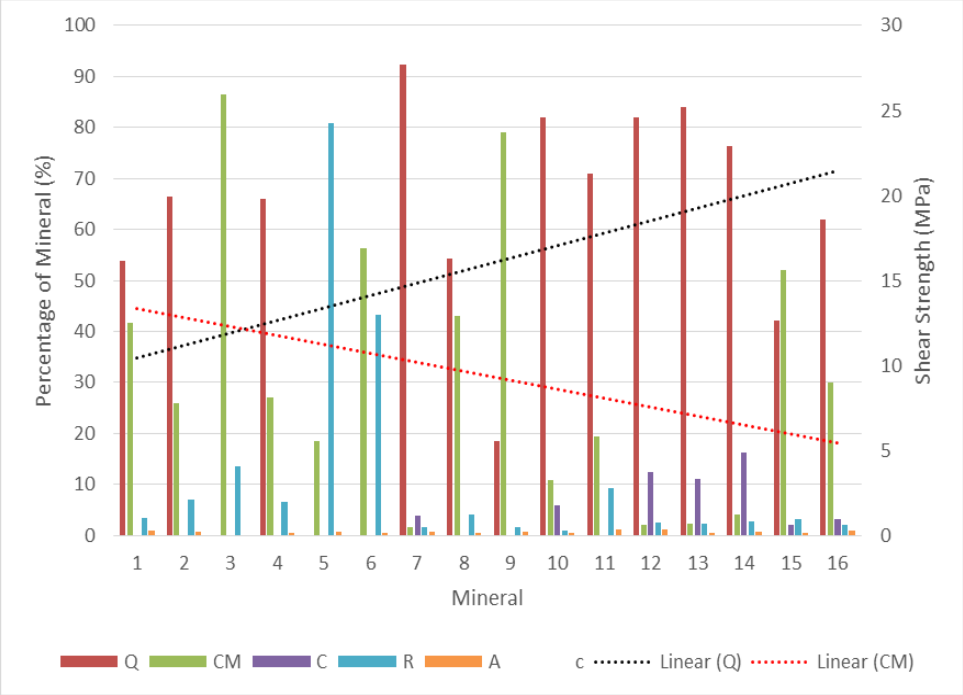

Figure 3: Relationship between the percentage of minerals and the shear strength

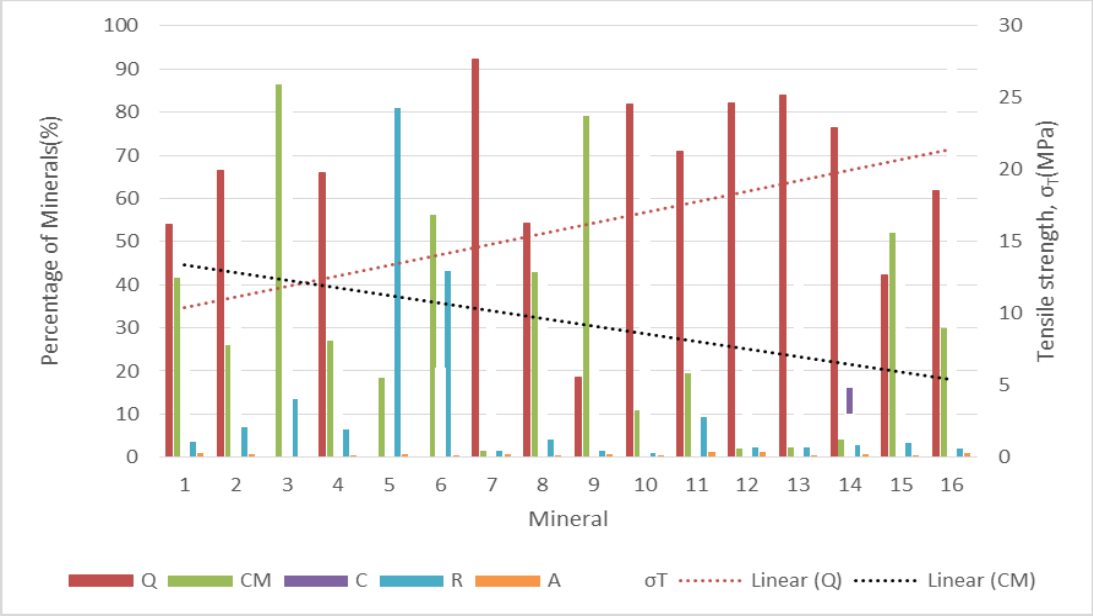
Relationships between the percentages of the main minerals and shear strength

The relation between the percentages of the main minerals and shear strength is given in Fig. 3. Similar to UCS quartz also have a very important role in shear strength increment in Sandstone. The carbonate mineral (CM) have a very important role in strength reduction. The reason on why the

increasing of quartz increased the strength and increasing of carbonate mineral decreased the strength of sandstone is that quartz is a high resistance mineral to weathering agent such as water, wind or heat. Meanwhile, carbonate mineral will wash away thus weakened the material. can easily react with and dissolve in water. So that quartz will stay longer in the rock as part of mineral composition and strengthen the rock material while carbonate will wash away thus weakened the material.

strength of rock material due to that the The hydroxyl ions usually originate from the sodium and potassium alkalis in the Portland cement during hydration. The reaction produces a gel-like material that can be expansive when exposed to water. Reactive silica materials that can cause deleterious expansion listed in decreasing order are: opal, chalcedony, volcanic glass, cristobalite, tridymite and cryptocrystalline quartz [7] These ASR minerals are not abundance in the sandstone and thus, will not influence the strength of the rock.



Relationships between the percentages of the main minerals and tensile strength

In the case of indirect tensile strength, the relationship follows the same trend, where the tensile strength increase with the increment of percentage of quartz mineral and the tensile strength reduce with the reduction of the percentage of carbonate mineral in the sandstone as shown in Fig.4. The composition of quartz mineral in sandstone strengthen the rock as quartz is a strong mineral with hardness of 7 however samples with low percentage of carbonate mineral weakened the sandstone with the same reason that the carbonate mineral can easily dissolve in water when react with water. Furthermore, the hardness of the carbonate mineral is less than 3.

Correlation between Alkali Silica Reactivity (ASR) and Strength Parameters

The relationships between ASR and UCS; ASR and shear strength; and ASR and tensile strength showed poor correlations as the R^2 is 0.13, 0.034 and 0.063 respectively as shown in Fig 5. This indicates that the ASR is less significant to the

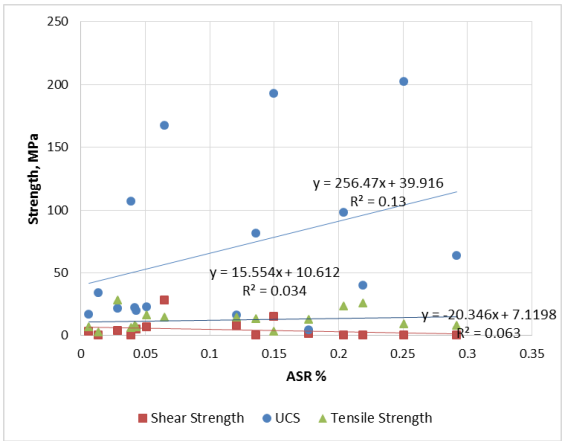


Figure 5: Relationships between the ASR and strengths of sandstone**.**

CONCLUSIONS

The correlations between the minerals and the strengths of sandstone rock samples were determined by simple regression analysis and bar charts. The first conclusion of the study is, quartz (Q) have a very important role in uniaxial

compressive strength increment in sandstone meanwhile the carbonate mineral (CM) have a very important role in strength reduction. The same trend also followed by the correlation with shear strength and tensile strength. Secondly, the percentage of strong minerals (i.e. quartz and cement) and weak minerals (i.e. carbonate minerals) can have opposite effects on the strength parameters of the rocks. The strength increases as the quartz and cement content increases. Thirdly, the relationships between ASR and UCS; ASR and shear strength; and ASR and tensile strength showed poor correlations between them as the ASR minerals is not abundance in sandstone and presents in very small amount .

NUMERICAL ANALYSIS ON MECHANISM OF DEWATERING AS A MITIGATION METHOD AGAINST LIQUEFACTION IN SOFT GROUND

Yukihiro Morikawa[1], Ho Cho[2]
[1,2] Department of Civil Engineering, Nagoya Institute of Technology, Japan

ABSTRACT

In recent years, liquefaction due to major earthquake caused serious damages to many infrastructures and houses around the world. In order to protect people's daily life and infrastructure from the disaster, development of effective and economical countermeasure against liquefaction that can be applied to existing houses is becoming increasingly important. Although many liquefaction countermeasures have been developed by many researchers, most of them require large construction machines and are costly, which limits their application to existing structures. For this reason, a liquefaction countermeasure, called as groundwater-level decreasing method, has been proposed in Japan. This method has already been put into practice and the construction of the countermeasure has finished several years ago. The purpose of this method is to change a liquefied layer to a non-liquefied layer by lowering the groundwater level. Yet the performance of this method has not been fully evaluated quantitatively. Therefore, in this paper, numerical analysis using FEM method was carried out to evaluate the liquefaction damage before and after the lowering of groundwater level. The calculation is conducted with 2D soil-water coupling finite element-finite difference (FE-FD) analysis based on a rotating-hardening elastoplastic constitutive model. From the analyses, it is found that the effective stress of the ground below under-groundwater level increases significantly because of the lowering of groundwater-level, resulting in an increase in resistance to liquefaction and mitigating the settlement damage of liquefiable ground.

Keywords: Liquefaction, FEM, Countermeasure, groundwater-level decreasing method

1. INTRODUCTION

In recent years, the liquefaction occurred seriously in the world, e.g., 1995 Southern Hyogo Prefecture Earthquake, 2004 Mid Niigata Prefecture Earthquake, 2011 off the Pacific coast of Tohoku Earthquake, 2011 Canterbury earthquake, 2016 Kumamoto Earthquake, and 2018 Hokkaido Eastern Iburi Earthquake. In particular, the liquefaction damages in Tohoku Earthquake (2011) [1]-[2] were the heaviest recoded ever in Japan history. As shown in Fig. 1, one of the damage site, the liquefaction area covered 600 km along the Northeast coast of Japan and about 27,000 houses experienced severe damaged.

Therefore, development of effective and economical countermeasure against liquefaction for existing houses is very important and urgently needed. In this study, particular attention is paid to the performance of the groundwater-level decreasing method that has been already put into practical use as a countermeasure against liquefaction with numerical tests. In this method, continue drainage of groundwater is necessary so that the effective stress of ground can be increased and the excess pore water pressure can be dissipated quickly in a wide area with relative low cost. It is thought that these effects are effective not only for the large main shock, but also for multiple aftershocks in a short period of time.

The purpose of the research is to evaluate quantitatively the performance of the method that is still not enough at current stage. In this study, numerical analysis is conducted on the liquefaction damages of the ground in Ibaraki prefecture, Japan, dynamic FEM method considering the main shock and aftershocks in a unified way. The earthquake waves in the calculation were recorded in the Tohoku Earthquake (2011). In the analysis, a series of repeated dynamic-static analyses, considering not only the earthquake loading but also the static consolidation after each earthquake shock, are conducted in a sequential way just the same as the scenario happened in the Earthquake.

Fig. 1 Liquefaction damage in the 2011 off the Pacific coast of Tohoku Earthquake

2. ANALYSIS METHOD

The numerical analyses to evaluate the effect of a liquefaction countermeasure were conducted by a 2D/3D soil-water coupled finite element method program named as DBLEAVES [3] using based on the Cyclic Mobility model [4]. The applicability and the accuracy of the DBLEAVES has been firmly verified by shaking table tests for piles [5]-[8] and various liquefaction case histories [9]-[11].

Cyclic Mobility model is a kind of rotating-hardening elastoplastic model based on Cam-clay model [12]. It can consider properly the effects of stress-induced anisotropy, density and structure of soils in a unified way by introducing concept of subloading yield surface [13] and superloading yield surface [14], as shown in Fig. 2.

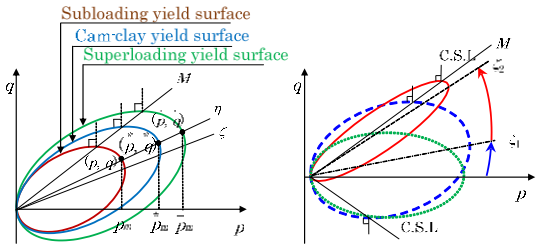

Fig. 2 Concept of Cyclic Mobility model [11]

The DBLEAVES can reproduce or predict accurately the overall mechanical behavior during and after the earthquakes, including the liquefaction and consolidation in repeated earthquake vibrations by describing properly the mechanical behaviors of soil subjected to monotonic/cyclic loading under drained/undrained conditions. In particular, the study of re-liquefaction using DAVLEAVES taking into account aftershocks [11], it was possible to reproduce the same phenomena as the observed phenomena, especially, a liquefaction happened easily by a small aftershock when the ground was not recovered from the damage by main shock and the range of liquefaction is expanded by aftershocks. For more detailed information about DBLEAVES and Cyclic Mobility model can be referred to references [3]-[4].

3. NUMERICAL ANALYSIS CONDITION

3.1 Investigated Site and Analyses Mesh for FEM

The investigated site, located at Ibaraki prefecture, experienced serious liquefaction damage during the 2011 off the Pacific coast of Tohoku Earthquake. Figure 3 shows the FEM mesh used in the calculation based on boring survey. The model ground consists of filling soil (Fs: 3.5 m), loose sand (As: 5.5 m) and dense sand (Ds: 11.0 m), and there is an embankment with a height of 1.0 m and a width of 60 m on the ground.

The ground area considered in the FEM analysis is 120 m in width and 20 m in depth, each mesh has width of 0.50 m and depth of 0.50 m. Here, the ground water level is set at -1.0 m of the ground level. In the case of dynamic analyses, an equal displacement boundary is adopted at side boundaries (x direction) to deal with the energy dissipation problem caused by artificial boundaries used in FEM. The bottom is assumed to be fixed in all directions.

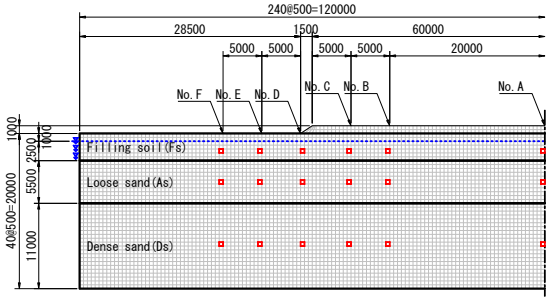

Fig. 3 FEM mesh for calculation

3.2 Earthquake Waves

The earthquake motion in N-S direction recorded at Hasaki-2 923m below the ground surface at Ibaraki Prefecture in the 2011 off the Pacific coast of Tohoku Earthquake (Tohoku wave) is selected to be the input earthquake motion in analyses, as shown in Fig. 4. A maximum acceleration of the main shock was 0.62 m/s^2 and that of aftershock was 0.94 m/s^2. The interval between the main shock and aftershock was approximate 24 minutes.

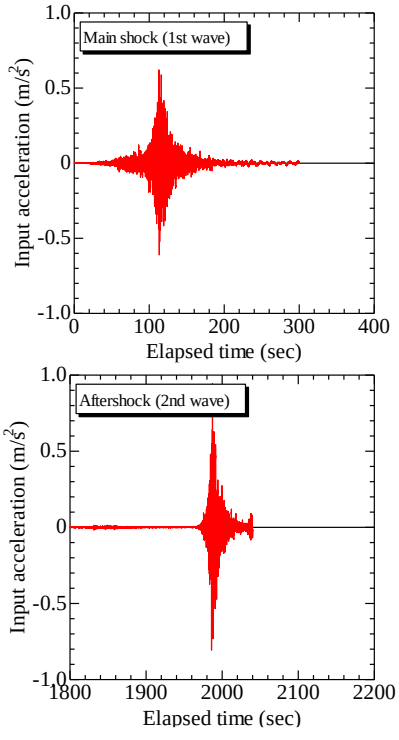

Fig. 4 Earthquake waves for calculation

3.3 Simulation Scenario

By lowering the groundwater level, it is expected that the effective stress of the ground can be increased in addition to the excess pore water pressure (EPWP) being dissipated quickly. Therefore the following four cases were carried out to evaluate the liquefaction damage before and after lowering the groundwater level:

Case A (Water Level: G. L. -1.0m): This is a basic case for unimproved ground.

Case B (Water Level: G. L. -2.0m): In this case, the groundwater level is lowered by 1.0m but initial effective stress is kept the same.

Case C1 (Water Level: G. L. -3.0m): In this case, the groundwater level is lowered by 2.0m but initial effective stress is kept the same.

Case C2 (Water Level: G. L. -3.0m): In this case, the groundwater level is lowered by 2.0m while the initial effective stress is increased accordingly.

In all cases, the calculation is conducted using the same Tohoku wave: (1) main shock, (2) 1440 seconds consolidation, (3) aftershock, (4) consolidation until the settlement of the ground ceased completely (50 years later).

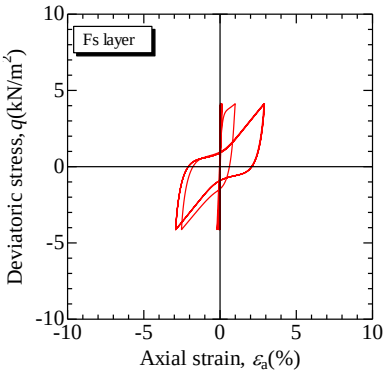
3.4 Material Parameters

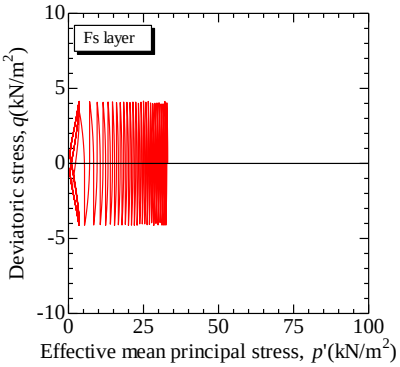
The material parameters used in calculation are shown in Table 1. The parameters of the embankment on the ground are the same values as the filling soil. Here, the initial effective stress in each ground is given as the vertical stress in the central part of each ground with the coefficient of earth pressure at rest K0 of 0.5. Near the investigated site, standard penetration test was conducted, and it was possible to obtain a columnar section, N value and unit weight. However, data other than N value and unit weight (such as result of tri-axial test with undrain cyclic loading of soils and permeability test) were not available, some of these parameters were determined with reference to the standard penetration tests and those of Toyoura sand. Therefore, studies in this paper is a numerical experiment on a virtual ground rather than a simulation for liquefaction damage that actually occurred in the 2011 off the Pacific coast of Tohoku Earthquake .

Figure 5-1 to 5-3 shows the simulation results of the element behavior in undrained cyclic loading test when the cyclic stress ratio is set to 0.10. From the results, it is known that the strain accumulates as the number of cyclic loading increases, and liquefaction accompanied by cyclic mobility occur in the filling soil and loose sand. However, liquefaction will not occur easily in the dense sand.

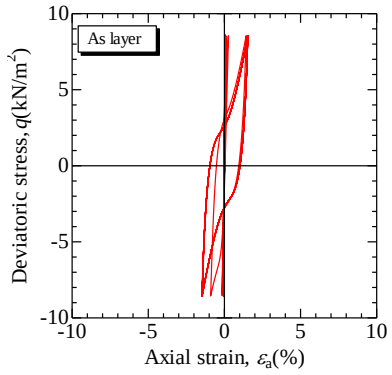
Table 1 Material parameters

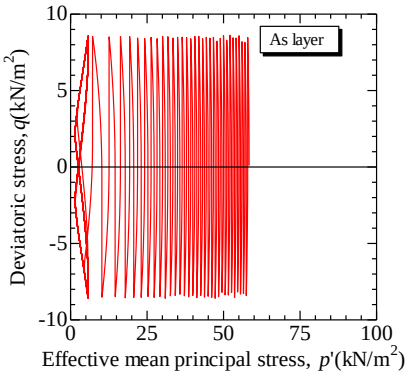
	Filling soil	Loose Sand	Dense sand
Compression index λ	0.026	0.022	0.017
Swelling index κ	0.005	0.004	0.003
Stress ratio at critical state R_f	3.000	3.840	4.600
Void ratio e_0 (p'=98kPa on N.C.L)	0.550	0.550	0.470
Passion's ratio ν	0.300	0.300	0.300
Degradation parameter of over-consolidation m	0.100	0.100	0.100
Degradation parameter of structure a	2.200	2.200	2.200
Evolution parameter of anisotropy b_r	1.500	1.500	1.500
Unit weight γ (kN/m^3)	18.62	19.31	17.84
Permeability k (m/sec)	5.0E-5	5.0E-5	5.0E-5
Initial structure R^*_0	0.800	0.800	0.800
Initial degree of over-consolidation $1/R_0$	6.000	8.000	10.000
Initial anisotropy ζ_0	0.000	0.000	0.000



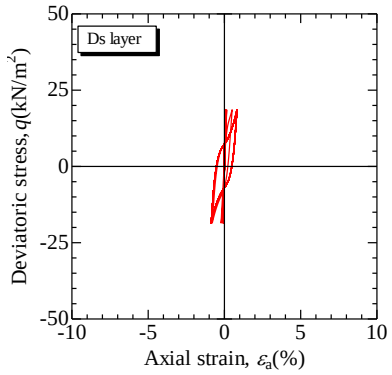


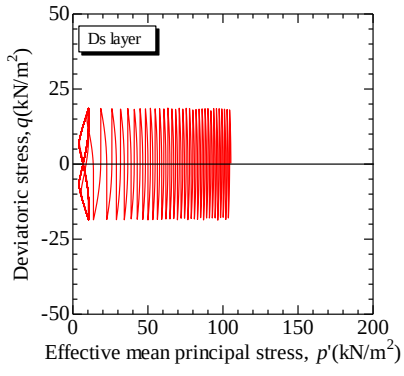
(a) Filling soil: Fs





(b) Loose sand: As





(c) Dense sand: Ds

Fig. 5 Simulated element behavior of soils

4. RESULT AND DISCUSSIONS

Figure 6 and 7 shows the calculated excess pore water pressure ratio (EPWPR) at the center of embankment (Point A) and the distribution of EPWPR in Case A. Here, Case A is the basic case, and the measurement points (Point A to F) are shown in Fig.3. EPWPR is defined as the ratio of excess pore water pressure to the initial vertical effective stress. Therefore, EPWPR reaching 1.0 means that the soil is liquefied completely.

From the results, it is known that the liquefaction damage in non-embankment area is greater than that in embankment area. This is the effect of the initial effective stress due to embankment loading. In addition, it is also known that the liquefaction damage is expanding due to the aftershock. This result is clear seen in Fig. 7, that is, EPWPR increased greatly due to the aftershock.

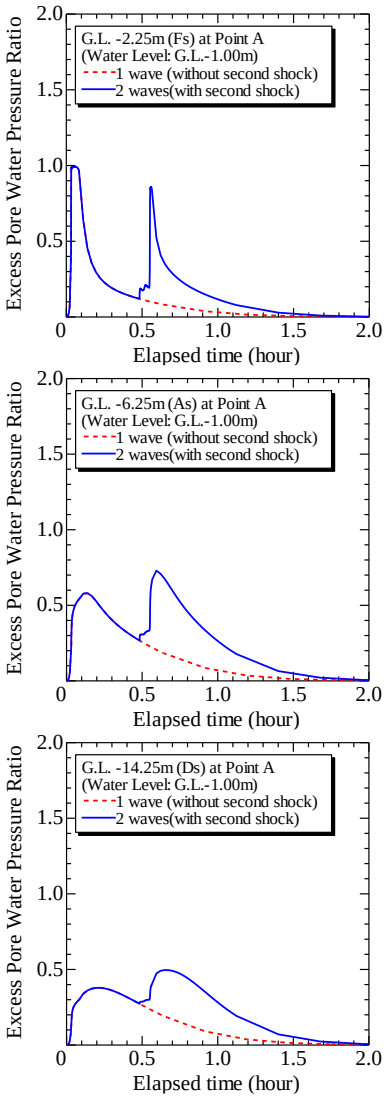


Fig. 6 Time history of EPWPR at Point A (center of embankment) in Case A

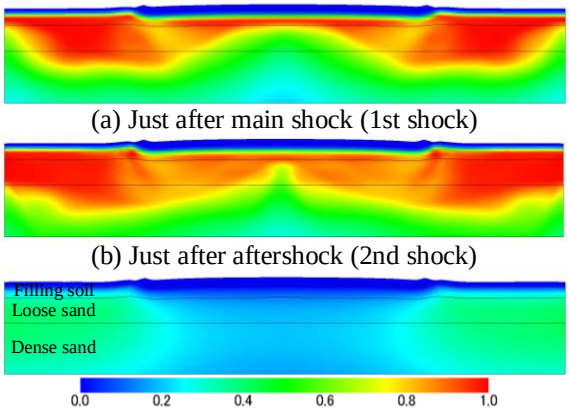

(a) Just after main shock (1st shock)

(b) Just after aftershock (2nd shock)

(c) 33 minutes after aftershock

Fig. 7 Distribution of EPWPR in Case A

Figure 8 shows EPWPR of loose sand at Point F (10 m from the toe of slope), where the liquefaction damage is large. As mentioned above, these cases have different groundwater depths, but have the same initial effective stress. From the results, it is known that EPWPR deceased due to the lowering of groundwater level, and that EPWP dissipated much faster.

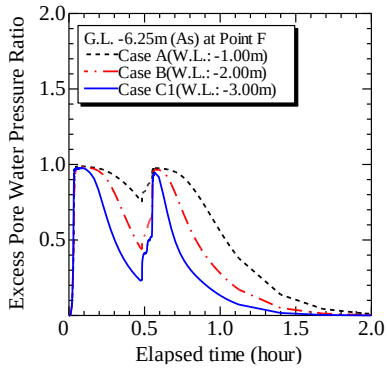

Fig. 8 Effect of groundwater level on EPWPR (Point F: 10 m from toe of the slope)

Figure 9 shows the comparison of EPWPR at Point F in Case C1 and C2. These cases have same groundwater depth in each case, but have the different initial effective stress. From the results, it is known that the countermeasure effect, such as suppression of excessive pore water pressure and early dissipation, is further enhanced by the increase of the initial effective stress compared to the case where only the groundwater level is lowered.

Figure 10 shows distributions of displacement vector in Case C1 and C2. In Case A, it is known that the outer side of the embankment is greatly uplifted right after liquefaction, and then settlement due to consolidation with dissipation of EPWP.

Therefore, it is clear that the ground deformation due to liquefaction is largely suppressed by the decrease of the groundwater level and the increase of the initial effective stress.

5. CONCLUSIONS

In this study, 2D soil-water coupled finite element-finite difference analyses based on Ciclic Mobility model were conducted to evaluate the liquefaction damage before and after lowering the groundwater level. The following conclusions can be obtained:

1. According to the calculated results, even if the initial effective stress does not increase, liquefaction damage can be greatly reduced only by lowering the groundwater level with 1 to 2 m.

2. If the effective stress of the ground also increases in addition to the lowering of groundwater level, the effect of the coutermeasure against liquefaction will be further enhanced.

ABSTRACT

Geosynthetics have been proved as a bona fide engineering material and a good alternative to the conventional design techniques in the field of geotechnical engineering. They are widely used for the construction of retaining walls, pavements, embankments and shallow foundations etc. The performance of geosynthetic reinforced soil structure greatly depends on the form (such as discrete, planar, vertical, cellular, 3D etc.) in which it is used. In this paper, the settlement behaviour of a model footing resting on sand bed reinforced with planar geogrid and three dimensional geogrid are numerically simulated using Plaxis 3D software. The behaviour of sand bed was modelled by Mohr Coulomb model. The planar geogrid and 3D geogrid were modelled in Auto CAD 3D and imported into Plaxis 3D and assigned the properties of geogrid structural element available in Plaxis. A uniformly distributed pressure was applied on the top of a plate element to simulate the load on model footing. The numerical analysis showed that the presence of geosynthetic reinforcement in sand bed improved the bearing capacity and reduced the settlement of model footing. However, geogrid in three dimensional form gave better results compared to planar geogrid. A single layer of 3D geogrid provided at an optimum embedment depth improved the load carrying capacity of soil by 66% and the settlement of footing was reduced by 30% compared to single layer planar geogrid reinforced sand bed.

Keywords: 3D geogrid, Load carrying capacity, Numerical modelling, Plaxis 3D, Settlement

INTRODUCTION

Reinforced soil foundation has been widely used in various geotechnical engineering applications, since it is a cost effective solution to increase the bearing capacity and reduce the settlement of shallow foundations. The concept was first demonstrated by Vidal [19] by incorporating galvanized steel strips in cohesionless soil to improve its mechanical properties. Later, the development of geosynthetics from strong and durable polymers changed the trend to planar geotextiles and geogrids. The performance of geosynthetic reinforced soil foundation has been investigated by several researchers [1], [3], [5] - [6], [11], [17] - [18], [20]. Several numerical studies are also performed by researchers to investigate the behaviour of reinforced soil foundation with planar geotextile or geogrid as reinforcement [3] – [4], [9] – [10], [15], [20].

Reinforcements in three dimensional forms are the recent trend in the construction of reinforced soil system. A few studies on the behaviour of soil reinforced with 3D inclusions are reported by [2], [12], [14], [21] – [22]. These reinforcements give the advantages of conventional planar reinforcements along with the passive resistance offered by the additional third dimension. The behaviour of three dimensional geocell reinforced soil has been numerically studied by [7] – [8], [16]. In the present investigation, the load-settlement behaviour of shallow footing resting on planar geogrid reinforced soil and 3D geogrid reinfored soil are numerically simulated and compared using plaxis 3D software.

NUMERICAL MODELLING

The laboratory plate load test conducted by Makkar et al., [13] in a steel tank of 750 mm x 750 mm x 750 mm was simulated in the numerical modelling. The model footing used was 150 mm square in size and 25 mm thick. To simplify the computational effort, only one quarter portion of the test model was modelled using Plaxis 3D software due to symmetry. In order to simulate the behaviour of soil, a suitable material model and appropriate material parameters has to be assigned to the geometry. The Mohr Coulomb model was used to simulate the behaviour of infill soil. The linear elastic- perfectly plastic Mohr Coulomb model requires a total of five parameters, namely, Young's modulus, E (kN/m^2); poisson's ratio, ν; cohesion, C (kN/m^2); friction angle. Φ (◦); and dilatancy angle, ψ(◦). The shear strength properties of the sand were determined from direct shear tests. The Young's modulus of sand bed modelled is directly taken from the pressure- settlement curve of plate

load test on unreinforced sand bed. The footing was modelled as a plate element. The behaviour of plate element is defined by the parameters Young's modulus and Poisson's ratio. The planar geogrid and 3D geogrid were used as the reinforcing material, and they are modelled in Auto CAD 3D and imported in to Plaxis 3D. Later, it was defined as the geogrid structural element by assigning the value of axial stiffness (EA).

After assigning the appropriate material properties for soil and structural elements, finite element meshes were generated. In the present study relatively coarser mesh was chosen for the analysis. In order to simulate the load on the model footing, a uniformly distributed pressure was applied on the top of the plate element and the corresponding settlements were found out. The displacement along bottom boundary was restrained both in horizontal as well as vertical direction. The displacement along side boundaries were restrained only in the horizontal direction, such that displacements were allowed to occur in vertical direction. Fig. 1 shows the plaxis 3D models of planar geogrid reinforced soil and 3D geogrid reinforced soil. The material properties assigned for the soil and structural elements are given in Table.1.

RESULTS AND DISCUSSIONS

The numerical models developed in the present investigation were validated with the experimental results reported by Makkar et al. [13]. Fig.2. shows the pressure-settlement curve for planar geogrid reinforced soil and 3D geogrid reinforced soil obtained from numerical study and reported by Makkar et al. [13]. From the graph, it is clear that the

(b)

results are in close agreement with each other. Table.2 gives the bearing capacity obtained from the numerical analysis and from the literature. Fig.3 shows the displacement contour for planar geogrid reinforced soil and 3D geogrid reinforced soil at an embedment depth of 0.25B.

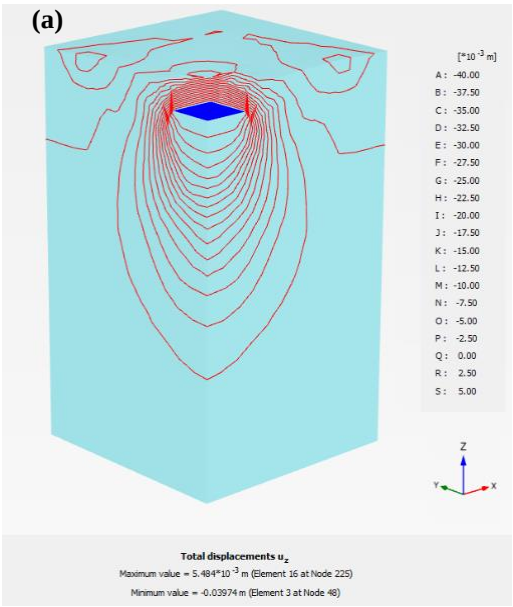
Type	Makkar at al. 2017	Numerical	% error
Geogrid reinforced	510	540	5.9
3DG reinforced	840	900	7.1



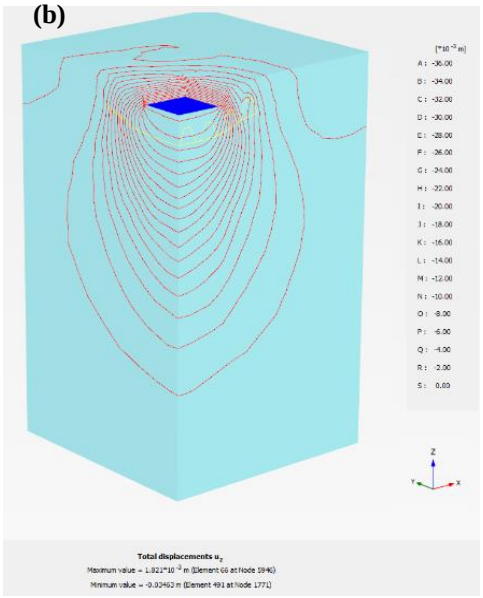


Fig.3 Displacement contour for (a) Planar geogrid reinforced soil; (b) 3D geogrid reinforced soil

The bearing capacity of reinforced soil has been taken as the bearing pressure corresponding to 25 mm footing settlement. To get the maximum benefit, the reinforcement should be placed at an optimum depth from the base of the footing. The effect of embedment depth of reinforcement on the bearing capacity and settlement was studied by placing the reinforcements at depths of 0.1B, 0.25B, 0.5B, and 0.75B, where, B is the width of model footing. Fig.4. shows the variation of Bearing capacity ratio (BCR) with reinforcement embedment depth (u/B). BCR is defined as the ratio of bearing capacity of reinforced sand bed at a given settlement to the bearing capacity of unreinforced sand bed at the same settlement. From Fig.3, it can be seen that the BCR is increased up to an embedment depth of 0.25B and thereafter, it decreases for both type of reinforcement. The reason is that, in order to develop the maximum interfacial frictional resistance, sufficient overburden pressure is required above the reinforcement which is attained at an embedment depth of 0.25B. Further increase in the depth of reinforcement reduces the bearing capacity improvement due the excessive settlement of thicker layer of soil above the reinforcement. It can also see that the bearing capacity improvement is higher for 3D geogrid reinforced soil compared to planar geogrid reinforced soil bed for all embedment depth. The beneficial advantage of conventional planar reinforcement along with the confinement effect of soil with in the cells of 3D geogrid imparts higher bearing capacity to the 3D geogrid reinforced soil. The bearing capacity improvement by 3D geogrid reinforced soil was 66% more than planar geogrid

reinforced soil, when both of them are placed at the optimum embedment depth of 0.25B.

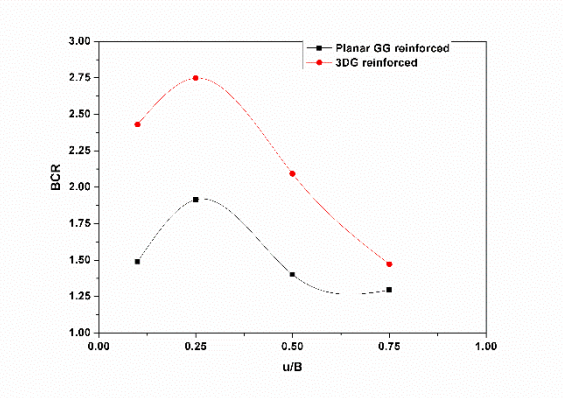

Fig.4 Variation of BCR with embedment depth

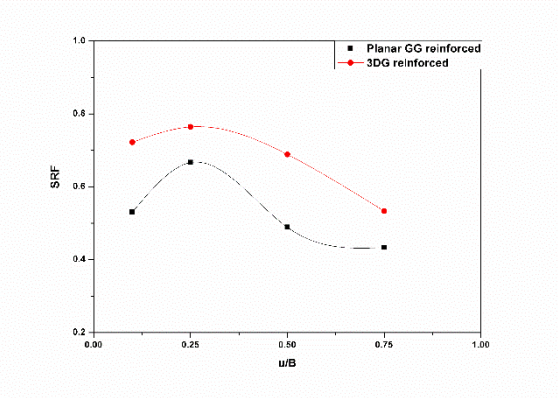

Fig.5 Variation of SRF with embedment depth

Considerable amount of reduction in the settlement of footing was observed with the provision of reinforcement. However, the footing resting on 3D geogrid reinforced soil shows more reduction in the settlement compared to planar geogrid. To quantify the reduction in settlement, a non dimensional parameter Settlement Reduction Factor (SRF) was introduced. SRF is defined as follows:

$$SRF = {(Su - Sr)}/{Su} \qquad (1)$$

Where, Su- settlement of unreinforced soil at a given pressure

Sr –Settlement of reinforced soil at the same pressure

The SRF was calculated for a normalized settlement of 30% of unreinforced sand bed. Fig.5 shows the variation of settlement reduction factor with embedment depth of reinforcement. The maximum reduction in the settlement was observed at an embedment depth of 0.25 times the width of footing for both type of reinforcement. At the optimum embedment depth, a single layer of planar geogrid reinforcement reduced the settlement of footing by 66%, while single 3D geogrid layer reduced the settlement by 77% compared to unreinforced soil. The model footing resting on 3D geogrid reinforced soil shows 30% more reduction in the settlement of footing compared to planar geogrid reinforced soil.

CONCLUSIONS

- 3D geogrid reinforced soil shows better performance compared to planar geogrid reinforced soil in improving the bearing capacity and settlement characteristics of model square footing.
- 66% improvement in bearing capacity was observed with single layer 3D geogrid reinforced soil compared to planar geogrid reinforced soil.
- The settlement of the model footing resting on 3D geogrid reinforced soil bed was reduced by 30% compared to planar geogrid reinforced soil.
- The optimum depth of embedment of single layer of reinforcement was obtained as 0.25 times the width of footing, in terms of bearing capacity and settlement improvement.

PARTICULATE MECHANICS PARAMETERS FOR GEOTECHNICAL AND AGRICULTURAL ENGINEERING APPLICATIONS

Joash Bryan Adajar[1], Irene Olivia Ubay[2], Zhiwei Zeng[2], Marolo Alfaro[2], and Ying Chen[2]
[1,2]Department of Civil Engineering, Faculty of Engineering, University of Manitoba, Manitoba, Canada

ABSTRACT

Discrete Element Method (DEM) is a numerical technique that uses particulate mechanics in simulating the discontinuous behavior of granular materials. DEM presents the advantage of modelling granular materials in a particulate level allowing specification of particle geometry including how their contacts interact. However, identifying microparameters to accurately simulate the behavior of particulate materials is challenging. This paper presents the determination of material microparameters for geotechnical and agricultural engineering applications using various calibration methodologies and laboratory tests. Sensitivity analyses were performed to develop a systematic calibration approach. For agricultural engineering application, crop residue microparameters that can be used for tillage simulations are identified. Linear contact model was used to describe the behavior of crop residue particles. Particle stiffness and friction were determined by simulating ring and direct shear tests. Tillage simulations can provide information on the dynamics of soil-tool-residue interactions. For geotechnical engineering application, microparameters of the constituents of a particular earth fill dam, such as rockfill and clay soil, were identified. Linear-based contact models such as rolling resistance and parallel-bond models were explored. Direct shear and triaxial tests were simulated to determine the microparameters of rockfill (particle stiffness, friction, and rolling resistance coefficient) and clay (particle stiffness, friction, bond strength, and bond stiffness). Microparameters were used to model the observed slope movements (landslide) of the earth fill dam. The model provided information on the velocity and runout distance of the landslide which are important for risk assessment. Calibration methodologies performed were successful in identifying appropriate microparameters which can be used to improve the reliability of large-scale models.

Keywords: Particulate, DEM, Landslide, Tillage, Calibration

INTRODUCTION

The discrete element method (DEM) is a numerical process that uses particulate mechanics to model the discontinuous response and behavior of granular materials when subjected to various conditions. It simulates the mechanical behavior of a particulate system by using a collection of distinct particles that interacts with each other [1]. DEM is a useful tool for simulating physical processes that involves separation of material constituent particles [2]. It has been used effectively in various fields like construction and building materials, agriculture, geotechnical, mining, mechanical, and industrial engineering.

The accuracy of DEM simulations are dependent on the input parameters. A challenge that researchers confront in using DEM is the identification of microparameters that define the behavior of particle interactions. There are not a lot of laboratory tests that can quantify material microparameters. These microparameters should also be able to compensate for the simplifications that were made on the particle geometry used in the model. Common approach to characterize material microparameters is through a back-calculation or calibration process wherein results of actual and simulated laboratory tests are matched. This paper focused on the identification of microparameters of materials necessary for a particular agricultural and geotechnical engineering application. For agricultural application, micro-parameters of crop residue and its interface with soil were identified. These microparameters are necessary to accurately simulate the tillage process and observe soil-toil-residue interactions. For geotechnical application, microparameters of the two components of a particular earth fill dam, clay and rockfill, were determined. Clay and rockfill microparameters were used in making a model that can simulate the observed excessive movement (landslide) of the dam slope. The model helped in understanding better the dynamics of the soil flow.

AGRICULTURAL APPLICATION

Tillage simulations are performed in order to observe and understand soil-tool-residue interactions during the tilling process. Comprehensive knowledge on soil-tool-residue interactions during tillage is significant in the design and optimization of high-efficiency soil-engaging tools [3]. For the development of an accurate DEM soil-tool-residue model, microparameters of agricultural soil, crop residue, and their interface are necessary. This paper only focused on the calibration of microparameters of crop residue and its interface with soil.

Ring Shear Test (RST)

Ring shear test was physically conducted and simulated with DEM to identify crop residue macro and microparameters. Measured shear strength macroparameter was the internal friction angle of the crop residues. Crop residues tested were canola, corn, flax, oats, and wheat.

For the RST model, the ring shear device was modelled using four walls having similar dimensions as the actual device. A total of 9,680 spheres of uniform particle size of 2 mm diameter was used to represent the crop residue. Figure 1 shows the DEM model of the RST. Same testing parameters as the actual test was assigned in the model to simulate the shearing process

Linear contact model was assigned to describe crop residue particle behavior. Microparameters calibrated for the linear contact model were particle stiffness (k) and friction coefficient (μ). Sensitivity analyses were performed to identify the influence of those parameters on the simulated material shear strength. Figure 2 displays the results of the sensitivity analyses and it shows that μ was a more influential microparameter. μ was chosen for calibration in order to match the actual and simulated RST results. The value of k for the crop residues is 7.5e3 N/m. Governing μ for flax and wheat are 0.425 and 0.025, respectively. For canola, corn, and oats, μ was 0.05. As an example, comparison of measured and simulated failure envelopes for flax are shown in Fig. 3. Similar behaviors having good agreements have been observed on the other crop residues. Computed values of the measured and simulated internal friction angles are listed in Table 1.

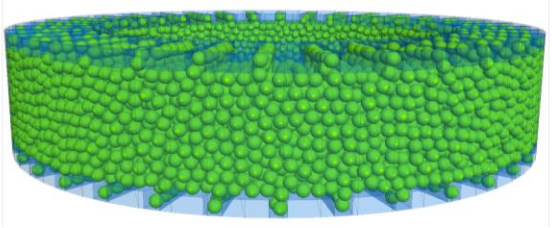

Fig. 1 Ring shear test DEM model.

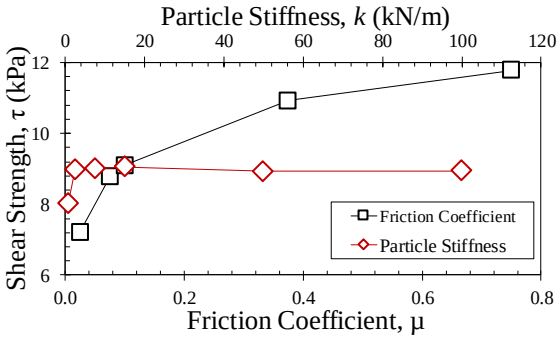

Fig. 2 Influence of μ and k on RST model results.

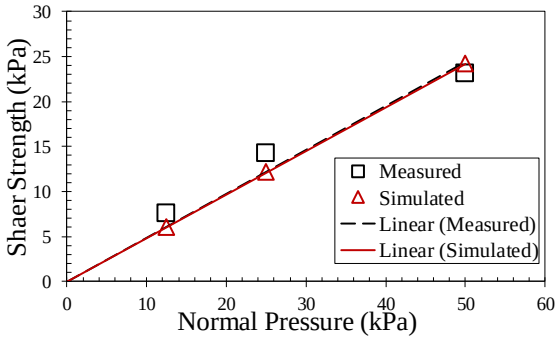

Fig. 3 Derived failure envelopes for RST of flax.

Table 1 Calculated internal friction angles.

Residue	Internal Friction Angle	
	Measured	Simulated
Flax	26°	25.8°
Canola	18.9°	19°
Corn	18.8°	19°
Oats	18.9°	19°
Wheat	16.4°	16.7°

Direct Shear Test (DST)

Direct shear test was carried out to characterize the shear strength macroparameter, interface friction angle, between the crop residues and agricultural soil. It was then simulated to back-calculate soil-residue interface microparameters. Agricultural soil used was classified as sandy loam having a composition of 70% sand, 14% clay, and 16% silt [4]. Crop residues tested were also canola, corn, flax, oats, and wheat. For the physical direct shear test, soil and crop residues were placed at the bottom and upper shear box, respectively. This was done to ensure that the shear plane will develop at the interface of the two materials.

To simulate DST, four walls were used to model the shear box. Two cylindrical walls of the same diameter and height to the actual equipment were generated to serve as horizontal enclosures. Two disks were generated to represent the top and bottom covers. Spherical balls having a uniform diameter of 2 mm were used to represent both the soil and crop residue particles. The compression and shearing of materials were simulated using the same testing parameters as the actual experiment. Figure 4 shows the sheared condition of the DST model.

Linear contact model was once again designated on the crop residue particles. Initial microparameter values set were the same values identified from the RST model. For the soil particles, linear parallel-bond model (LPBM) was assigned. Microparameter values used for the soil particles are listed in Table 2. Nandanwar et al. [4] calibrated the microparameters of the same soil used in this research with triaxial test simulations.

Sensitivity analyses on the direct shear test model were performed. It was observed that both μ and k was influential for DST simulations (Fig. 5). Calibration approach considered was to maintain the μ obtained from RST and perform bulk of the adjustments on k. This yielded results that are still valid for the RST model since it was only dependent on μ. Interface microparameters between crop residues and soil particles were computed with the surface inheritance approach defined in the DEM software used. In this approach, k of the two different particles are expected to behave in series while the smaller value between the μ governs upon contact.

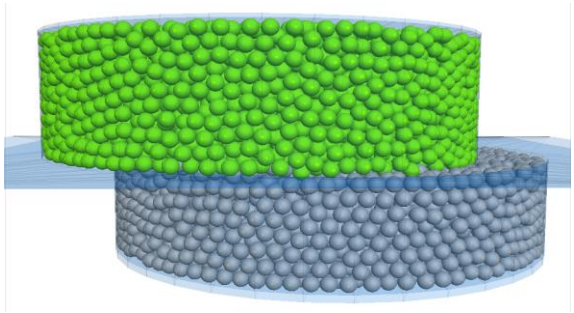

Fig. 4 Direct shear test DEM model.

Table 2 Soil microparameters [4].

Parameters	Units	Value
Particle Normal Stiffness (k_n)	N/m	5.4e3
Particle Shear Stiffness (k_s)	N/m	2.57e3
Friction (μ)	-	0.7
Bond Normal Stiffness ($\bar{k}_n$)	Pa/m	1.25e10
Bond Shear Stiffness ($\bar{k}_s$)	Pa/m	5.95e9
Bond Normal Strength ($\bar{\sigma}_c$)	Pa	2e4
Bond Shear Strength ($\bar{c}$)	Pa	2e4
Bond Radius Ratio	-	0.5

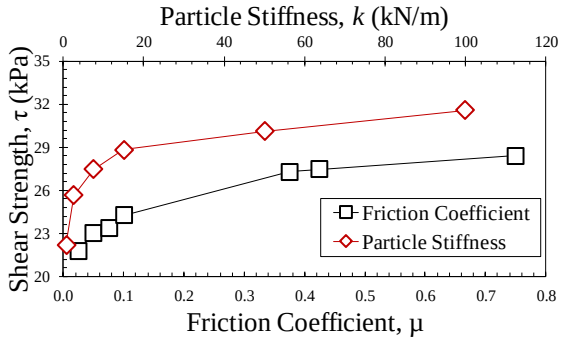

Fig. 5 Influence of μ and k on DST results.

The final microparameters of crop residue and its interface with soil are listed in Tables 3 and 4. An example comparison of the derived failure envelope for both the simulated and measured DST is shown in Fig. 6. Good agreement can be observed on the computed interface friction angles (Table 5).

Table 3 Crop residue microparameters.

Crop residue	$k_n = k_s$ (N/m)	μ
Flax	1e4	0.425
Corn	5e4	0.05
Canola	5e4	0.05
Oats	5e3	0.05
Wheat	2.125e4	0.025

Table 4 Soil-residue interface microparameters.

Material		k_n	k_s	μ
Crop	Soil	(N/m)	(N/m)	
Flax	Sandy Loam	7e3	4.1e3	0.425
Corn		9.7e3	4.9e3	0.05
Canola		9.7e3	4.9e3	0.05
Oats		5.2e3	3.4e3	0.05
Wheat		8.6e3	4.6e3	0.025

Table 5 Calculated interface friction angles.

Material		Interface Friction Angle	
Crop	Soil	Measured	Simulated
Flax	Sandy Loam	47.4°	47.7°
Canola		43.6°	43.9°
Corn		44.4°	43.9°
Oats		41.3°	41.5°
Wheat		41.6°	41.5°

Tillage Simulation

The microparameters identified in the previous section can be used to help improve the accuracy of soil-tool-residue interactions in simulations of tillage in agricultural fields (Fig. 7). One example of a soil-tool-residue model was the straw-sweep-soil model developed by Zeng et al. [3] (Fig. 8). The dynamics of soil and oats straw can be studied and predicted as it gets ploughed by a sweeping tool with the help of the model. It was able to quantify and observe information like residue cover, kinetic energy, and soil/straw moving area, velocity, acceleration, displacement, and movement trajectory. The model developed can also be used for other tilling equipment and can help in improving their design and performance when it comes to straw management.

Fig. 7 Tillage in agricultural fields [5].

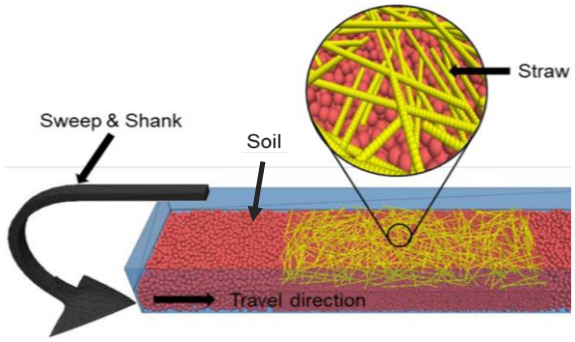

Fig. 8 Straw-sweep-soil DEM model [3].

GEOTECHNICAL APPLICATION

Excessive soil movements were observed in a particular earth fill dam in Canada. Developing a landslide DEM model is beneficial in order to observe the dynamics of the soil flow and predict the possible behavior of a future landslide. Information that can be derived from landslide models can be used for risk assessment and planning of mitigation measures. Major constituents of the earth fill dam were compacted clay, as its core, and rockfill, as its protective layer. Microparameters of these two materials were identified to aid in the development of a landslide model. Calibration methodology carried out in determining the microparameters are discussed in the succeeding sections.

Large-scale Direct Shear Test (LDST)

Alfaro et al. [6] carried out experimental testing using a large-scale direct shear box to measure the shear mobilization of rockfill materials. The shear box has a diameter of 600 mm. LDST results presented in the research were used as the basis for the calibration of rockfill microparameters.

Similar process as the DST model discussed previously was followed in creating the shear box. However, cylindrical walls having larger diameters and heights were generated for the LDST model. Spherical particles having 25 mm diameters were used to represent rockfill particles. Figure 9 shows the LDST DEM model developed. Similar testing parameters as the actual experiment were considered for the simulation of the shearing process.

Rolling resistance linear contact model was assigned for the rockfill particles. A rolling resistance coefficient (μ_r) was introduced to represent the angular nature of rockfill particles. μ_r is significant in modelling materials of high shearing resistance due to particle shape angularity.

Similar to the observed influence of k and μ from the previous DST model, both parameters are also influential on the simulation results of LDST. μ_r and μ were adjusted to match the shear strength at the end of the test, while calibration of k focused on matching the rate of increase or development of shear strength as the material was being sheared. After calibration, good correlation can be observed on the measured and simulated stress-strain relationships (Fig. 10). Characterized rockfill microparameters are listed in Table 6.

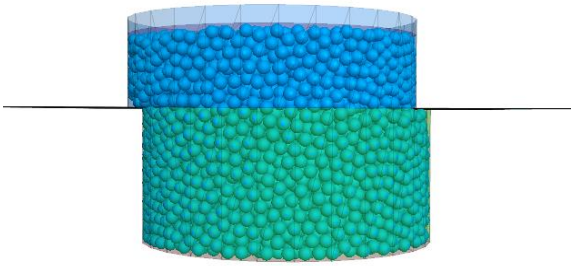

Fig. 9 Large-scale direct shear test DEM model.

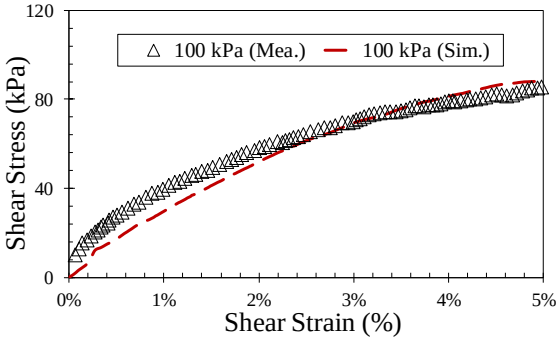

Fig. 10 Rockfill stress-strain relationship.

Table 6 Rockfill microparameters.

Parameters	Value	Units
Particle Stiffness (k)	3e5	N/m
Friction (μ)	1	—
Rolling Resistance (μ_r)	0.2	—

Triaxial Test (TT)

The clay material used for dam construction was classified as lacustrine clays of high plasticity [7]. Clay stress-strain behavior and shear strength macroparameters were obtained by carrying out undrained consolidated triaxial test. For the TT model, three walls were generated; one cylindrical wall to radially confine the material, and two disks to confine and strain the material vertically. 5,155 spherical particles having 5 mm diameters were generated to represent clay. Figure 11 shows the developed TT DEM model. For simplification and to mimic the zero volumetric strain throughout the shearing process, a strain-controlled boundary condition was assigned on the three walls [8].

Linear parallel-bond was the chosen contact model for the particles. Upon the execution of preliminary simulations, it was observed that parallel-bond microparameters ($\bar{k}$ and $\bar{c}$) dictate the peak shear strength. On the other hand, linear contact microparameters (k and μ) control the critical-state shear strength. With the said findings, calibration methodology considered was to match the measured peak shear strength by adjusting $\bar{k}$ and $\bar{c}$, while the measured critical-state shear strength was matched by adjusting k and μ. The model was able to match the identified peak and critical-state points in the deviator stress (q) vs mean effective stress (p') graph (Fig. 12). Good agreement can be observed on the comparison of the measured and simulated stress-strain relationships (Fig. 13). Identified clay microparameters are listed in Table 7.

Fig. 11 Triaxial test DEM model.

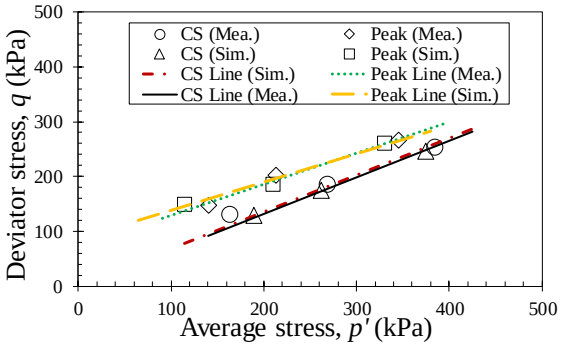

Fig. 12 Critical-state and peak stress points.

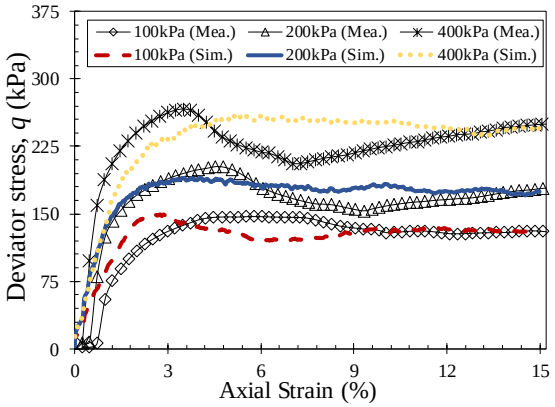

Fig. 13 Clay stress-strain relationships.

Table 7 Clay microparameters.

Parameters	Value	Units
Particle Stiffness (k, $k_n = k_s$)	3.5e4	N/m
Friction (μ)	0.15	—
Radius Multiplier	1	—
Bond Stiffness ($\bar{k}, \bar{k}_n = \bar{k}_s$)	1e9	Pa/m
Bond Strength ($\bar{c}$)	1.1e5	Pa

Landslide Simulations

The 3D digital terrain model that shows the landslide that occurred in the dam slope can be viewed in Fig. 14, wherein the observed dam crest depression is encircled.

Fig. 14 Dam post-landslide digital terrain model.

The clay and rockfill microparameters can be used to aid in the development of the landslide DEM model. The landslide model was able to recreate the post-failure soil flow of the earth fill dam slope. Figure 15 shows the model condition after the landslide runout or when soil flow movement has stopped. It displays the z-displacement (m) contour where depression and bulging on the dam crest and toe, respectively, can be observed. Simulated movement or changes in the model topography have good agreement on the post-landslide topography observed from the 3D digital terrain model. This validates the improved reliability of a landslide DEM

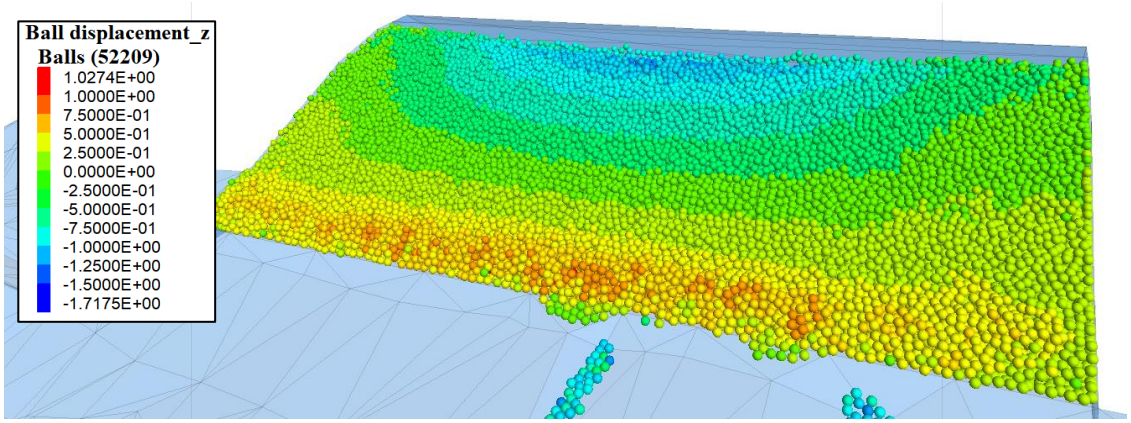

Fig. 15 Landslide DEM model.

model with input microparameters calibrated from the laboratory tests considered in this paper. The model can be used to simulate potential future landslides at the vicinity, which can give researchers insights on the behavior of the soil flow. Information on the velocity of different portions and overall kinetic energy of the moving soil mass can also be extracted from the model. These information are helpful in the design of possible mitigation structures or in identifying the extent of the area that can possibly be affected.

CONCLUSIONS

There are different methods that can be explored to calibrate and back-calculate material microparameters. The use of direct shear, ring shear, and triaxial test for microparameter calibration purposes has been found to be effective in this research. The laboratory test DEM models were able to simulate the macroscopic behavior of the materials which were obtained from carrying out actual laboratory tests. From the different calibration methodologies performed, it can be concluded that the sensitivity and behavior of microparameters are complicated making it impossible to define a robust or general approach for the calibration and identification of its values. The influence of the contact model microparameters varies for different laboratory test simulated. It is recommended to perform sensitivity analysis and design an effective calibration approach based from the results.

Presented tillage and landslide simulations highlighted the applicability of identified microparameters on a broader research that involves large-scale physical processes. Results of the landslide simulation reaffirmed that the calibration approach followed in this research can successfully characterize microparameters which can improve the reliability of the model.

Identified microparameters in this research should be used with caution. It is important to take note that characterized microparameters are considered as apparent microparameters that are only applicable for material models having identical cases and conditions as what is presented in this research. Differences in model behavior may be observed upon the use of different particle geometry and distributions.

ABSTRACT

The use of marginal materials stabilized by cement for base course applications has grown rapidly. Marginal materials consist of marginal crushed rock (MCR), marginal lateritic soil (MLS), and reclaimed asphalt pavement (RAP). However, the use of cement will release high CO_2 causing greenhouse effect. This research investigates stabilization of marginal crushed rock using cement (C) and fly ash (FA) as a green base course material. FA used as pozzolanic binders was obtained from Mae Moh power plant in Thailand. The physical and engineering properties of MCR stabilized by OPC-FA were evaluated according to the specification of Department of Highways in Thailand. The influencing factors studied included binder content of 1%, 3% and 5% by weight of the crushed rock material, C/FA ratios of 100/0, 90/10, 80/20, 70/30, 60/40, and 50/50, and curing time of 7. The optimum ingredient of MCR stabilized by B was found at binder content of 3%, and C/FA ratios of 70/30. This research enables FA, which is a residue material, to be used as a green base course material.

Keywords: marginal crushed rock, binder, cement, fly ash

INTRODUCTION

Transportation is significant for development of country. Roadways and Highways are one major mode of transportation. According to the Ministry of Transportation (2013), it was found that total of roads in Thailand were 115,707 km, divided into Department of Highways, 68,253 km and 47,454 km of the Department of Rural Roads. Figure 1 shows characteristic of road structure. Generally, roadways are constructed in four layers which composed of subgrade, subbase, base and surface layer. An available material at the road construction site is used for road construction. However, some of available material does not typically meet the standard requirement as base materials. Marginal available materials can be effectively improved by chemical stabilizing agents with an additive, such as Portland Cement (PC) [1-4], lime and bitumen. However, the production of 1 ton of OPC releases about 1 ton of carbon dioxide, resulting in a significant amount of greenhouse gas into the atmosphere [5-15].

Fly ash (FA) is a aluminosilicate-rich materials which is a by-product from electrical manufacturing factory, Mae Moh, Thailand. The objective of this research is to investigate the possibility of using fly ash (FA) to improve compressive strength of marginal crushed rock (MCR) as a green pavement materials. The influential factors studied include MCR:binder ratios and cement:FA ratio. Unconfined compressive strength (UCS) of MCR mixed with cement and fly ash was investigated and compared the results with the standard of the Department of Highways, Thailand. The microstructural analyses of BA geopolymer stabilized MLS via scanning electron microscopy (SEM) were carried out to enlighten the role of influence factors. This research enables FA, which is a residue material, to be used as a green base course material.

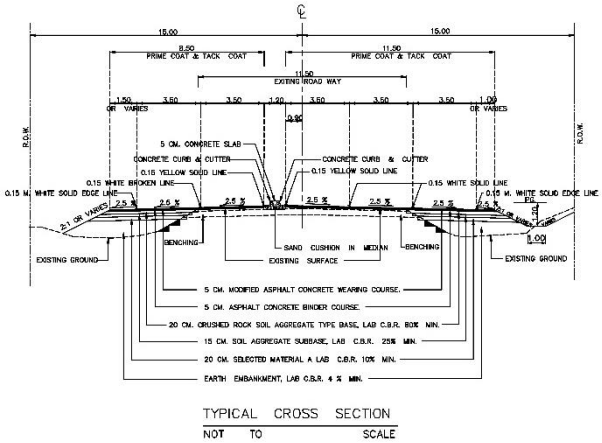

Figure 1 Characteristic of road structure

MATERIALS AND METHODS OF TESTING

Material

The marginal crushed rock (MCR) was collected from Nakhon Ratchasima province, Thailand. Figure 2 shows the grain size distribution of the MCR. The MCR is classified as GC in accordance with the Unified Soil Classification System. The maximum dry unit weight and optimum water content under modified Proctor energies of MCR were 2.308 gm/m^3 and 5.2%, respectively (Figure 3).

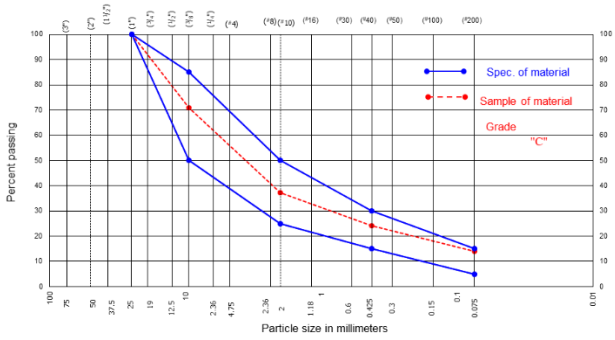

Figure 2 grain size distribution of the MCR

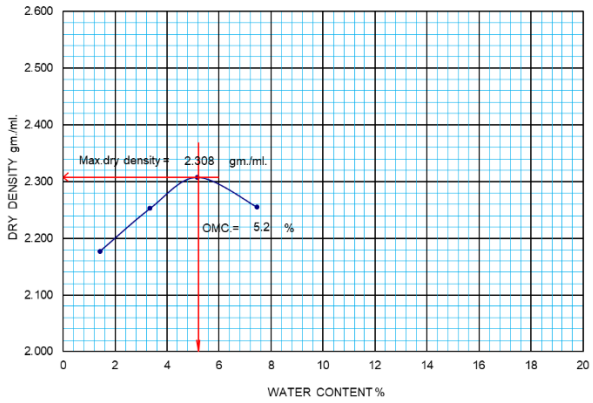

Figure 3 Compaction curves of MCR

Portland Cement Type 1 (OPC) has a specific gravity (Gs) = 3.10. The chemical composition of OPC are shown in Table 1. It is found that the main chemical composition of OPC was calcium oxide (CaO) content which was 75.96%

Fly ash (FA) was culledted from Mae Moh Power Plant, Lampang, Thailand. It is found that FA has brown color FA has a specific gravity (Gs) = 2.31. The chemical composition of FA by using X-Ray Fluorescence Spectrometer (XRF) technique. According to ASTM C618 is shown in Table 1. It can be soon that the amount of SiO_2 + Al_2O_3 + Fe_2O_3 is 67.31% by weight. The calcium oxide (CaO) content was 30.24% and Loss of Ignition (LOI) was 0.42 by weight. This fly ash is classified as a Class C fly ash.

Table 1 Chemical Properties of OPC and FA

Chemical composition	OPC (%)	FA (%)
SiO_2	9.81	47.51
Al_2O_3	4.64	13.14
Fe_2O_3	2.03	6.66
CaO	75.96	30.24
SO_3	2.58	ND
K_2O	1.62	1.63
NO_2	0.24	0.40
LOI	3.12	0.42

Sample preparation

The composition of marginal crushed rock (MCR) stabilized with cement (C) and fly ash (FA) sample was MCR, C, FA and water. Binder (B) is a mix of C and FA. The B content was added by 0, 1, 3, and 5% by weight of MCR. The C/FA ratios were 100/0, 90/10, 70/30, 60/40, and 50/50. Mixing ratio used in the study are shown in Table 2. The MCR and B were mixed until an observable consistency was observed for 2 minutes. The optimum water content was added and 5 minutes mixed. Under modified Proctor energies in preventing liquid evaporation, compaction was continued immediately thereafter. The mixture was then compacted in a standard mould of 101.6 mm in diameter and 116.4 mm in height. The Unconfined Compressive strength (UCS) specimens were wrapped in clear vinyl, after that cured at room temperature for 7 days.

Table 2 Mixing ratio used in the study

Mixed proportion	OPC (%)	FA (%)
M1	100	0
M2	90	10
M3	80	20
M4	70	30
M5	60	40
M6	50	50

TEST RESULT

Compaction of MCR mixed with C and FA

Fig. 4 shows the compaction results of MCR mixed with C and FA at the B content of 1%, 3%, and 5% and C/FA ratios of 100/0, 90/10, 70/30, 60/40, and 50/50. It can be seen that the maximum dry unit weight of MCR mixed with C and FA increases as B content increases because of the higher specific gravity of C. The optimum water content of MCR

mixed with C and FA was about 4.1-4.85%. The maximum dry unit weight of MCR mixed with C and FA was 2.288 gm/m^3.

Table 3 The compaction results of MCR with C and FA

	MDD (gm/m^3)			Optimum water content (%)		
	1 (%)	3 (%)	5 (%)	1 (%)	3 (%)	5 (%)
M1	2.236	2.261	2.257	4.85	4.40	4.33
M2	2.245	2.260	2.288	4.80	4.30	4.29
M3	2.28	2.254	2.268	4.60	4.28	4.20
M4	2.268	2.255	2.260	4.55	4.20	4.20
M5	2.273	2.263	2.257	4.50	4.15	4.18
M6	2.259	2.246	2.256	4.40	4.10	4.10

Compressive strength of MCR mixed with C and FA

Figures 4 indicate the 7-day Compressive strength of MCR mixed with C samples at various at the B content of 1%, 3%, and 5% and C/FA ratios of 100/0, 90/10, 70/30, 60/40, and 50/50. The 7-day compressive strength of MCR mixed with C and FA increases with the increase in binder (C and FA). The 7-day UCS of MCR mixed with C and FA samples at B content of 5% and C/FA ratios of 100/0 give the highest UCS values, Which is about 40 ksc. The 7-day UCS values of MCR mixed with C and FA at B content greater than 3% are also met the minimum strength requirement for UCS of 17 ksc specified by the Department of Highways, Thailand. The optimum ingredient of MCR stabilized by B was found at binder content of 3%, and C/FA ratios of 70/30.

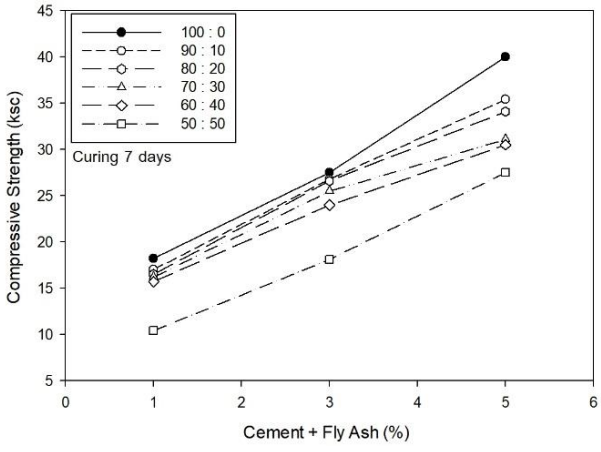

Figure 4 Compressive strength of MCR mixed with C and FA

CONCLUSIONS

The marginal crushed rock mixed with cement (OPC) and fly ash (FA) as a green base course material is presented in this study.

1. The maximum dry unit weight of MCR mixed with C and FA increases as B content increases because of the higher specific gravity of C.

2. The optimum water content of MCR mixed with C and FA was about 4.1-4.85%. The maximum dry unit weight of MCR mixed with C and FA was 2.288 gm/m^3.

3. The 7-day UCS of MCR mixed with C and FA samples at B content of 5% and C/FA ratios of 100/0 give the highest UCS values, Which is about 40 ksc.

STATIC PILE LOAD TEST: INTERNATIONAL PRACTICE REVIEW AND DISCUSSION ABOUT THE EUROPEAN AND JAPANESE STANDARDS

Fabien Szymkiewicz [1], Taisuke Sanagawa[2] and Hidetoshi Nishioka[3]
[1]IFSTTAR, Université Paris-Est, France; [2]Railway Technical Research Institute, Japan, [3]Chuo University, Japan

ABSTRACT

This publication aims to describe the European and Japanese standards in order to discuss about the ongoing project of revision of the Japanese standard for static pile load tests, keeping in mind that the future version of this standard will have to take into accounts Japanese past experience, as well as the future needs to adapt to overseas practices, if necessary, for economical purposes. To do so, the different derived parameters that can be obtained by carrying out a static pile load test on a vertically loaded pile (instrumented or not) are described. Then, the current practice for static pile load tests in Japan is described, and the main current overseas practices (with an extra focus on the European practices) are inventoried, and their differences (if any) with the Japanese practice are highlighted. Finally, these differences are discussed, and their importance assessed for a possible integration in the future Japanese standard, that could this way be seen for an oversea point of view as viable and legitimate alternative to the other and until now more common practices.
Keywords: Piles, Load Test, State of the Art, Standardisation

INTRODUCTION

Static pile load tests are usually time consuming, difficult, and expensive. It necessitates thorough soil investigations and detailed planning, as well as involving skilled and dedicated staff.

However, such tests are the most reliable way to assess correctly the ultimate bearing capacity of piles and their behavior. Depending on the level of monitoring put into action, shaft resistance and base resistance can be differentiated, and even unit shaft friction can be measured. Also, depending on the testing protocol chosen, different behaviors can be studied in detail, such as creep, cyclic behavior, or tensile strength.

Moreover, while these kinds of tests are often performed to verify a design hypothesis for a particular project, they can and should always be used to create and continuously improve databases used to build the design rules for deep foundations, increasing the accumulated experience and hence the robustness and reliability of these design rules. This should in time translate into improved design standards, saving natural resources, and making the solutions proposed overseas more attractive and competitive.

Therefore, having a complete and well detailed test standard that is thoroughly linked to the design standard is a necessity.

This publication aims to first inventory the current practices for static pile load tests in Japan as well as overseas (mainly in the USA and in Europe), then to describe the ongoing project of revision of the Japanese standard for static pile load tests, keeping in mind that the future version of this standard will have to take into accounts Japanese past experience, as well as the future needs to adapt to overseas practices, if necessary, for economical purposes.

In this paper, only the compression load test is described with a focus mainly centered on:
(1) The distance between test pile and reaction piles,
(2) Loading protocols
(3) Failure criteria of pile loading tests.

MAIN MEASURED AND DERIVED PARAMETERS

Two main categories of tests can be carried out: non instrumented or instrumented tests. The purposes of these two kinds of tests are different, with the instrumented test evidently giving more information on the behavior of the pile.

Non Instrumented Test

This is the simplest test carried out on piles, giving also least information on the behavior the pile.

The first information available when performing a static load test is the load-displacement curve. This curve gives rough information about the behavior of the pile.

However, as this curve depend on the nature and state of the soil, as well as on the piling method and the pile geometry (Fig. 1), and furthermore on the loading procedure, its use is clearly limited to the determination of the bearing capacity or the validation of the design behavior of the pile for

control tests.

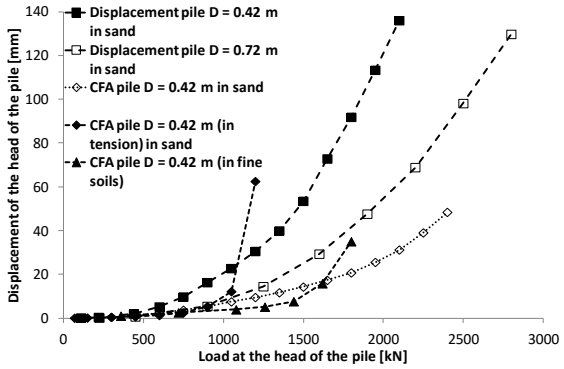

Fig. 1 Examples of load-displacement curve for different piles and sites.

The only other information given by a non instrumented test is the time-displacement curve and the load-creep rate curve, which can be used to determine the creep load of the pile (Fig. 2).

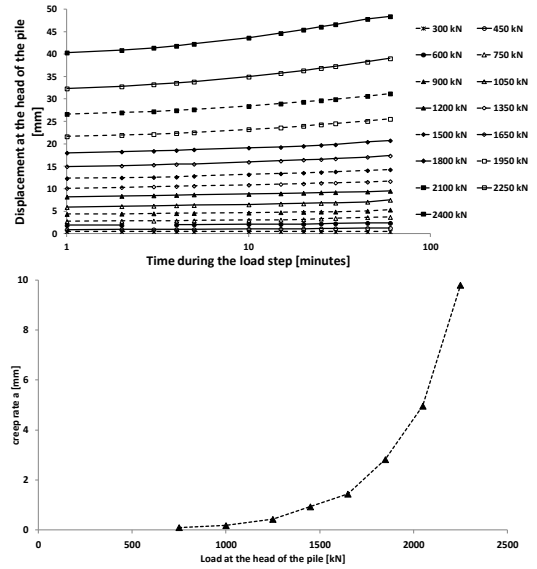

Fig. 2 Evolution of the displacement rate and creep rate during a load test.

Instrumented Test

Instrumented tests give away much more detailed information on the behavior of the pile.

Piles can be instrumented with strain gauges, vibrating wires or any other mean of achieving strain measurements, and also with embedded load cells (these are however much rarer).

Embedded load cells, when used, are often placed at the base of the pile, to measure directly the effort at this level, and therefore to distinguish the base resistance of the pile from its shaft resistance. However, this is relatively costly, and the quality of the concrete around this cell is often not as good as expected due to the presence of the cell, and therefore giving lower than expected results.

The distribution of the shaft resistance as well as the base resistance can also be determined by measurement of the strain at different depths. By knowing the strains at different depths, one can evaluate distribution of the efforts along the pile (Fig. 3), and from there determine the t-z curves (Fig. 4).

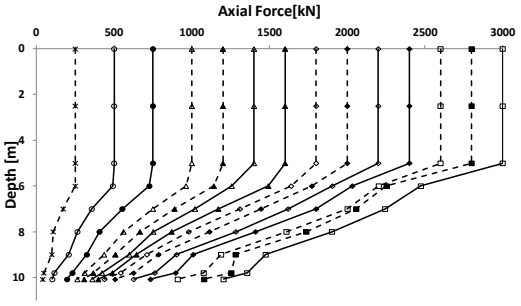

Fig. 3 Evolution of the distribution of the efforts along the shaft during a load test.

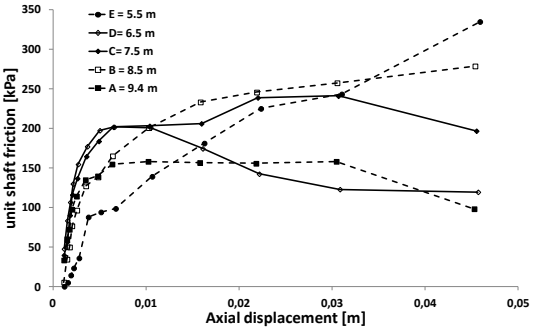

Fig. 4 *t-z* curves achieved from an instrumented load test.

To determine load from strain, the cross section and the pile material modulus of elasticity have to be assessed and all the materials present in the pile shall be considered. Strain sensors close to the pile head can be used to do this, if the geometry of the cross section and its composition is constant along the depth. Compression test on cored samples can also be considered. It is important to keep in mind that the type of strain sensor used has an impact on the modulus to take into account.

TESTING PROCEDURES OF JAPANESE STANDARD

History of Standard Revision

In Japan, the first standard "Method for Static Axial Compressive Load Test of Single Piles" was published in 1972 by the Japanese Geological Society (JGS). This standard has been revised twice in 1993 and 2002. And the third revision committee was established in 2018, and the discussion is still continuing now. In this chapter, the testing

procedures of the current standard revised in 2002 is mainly mentioned.

Distance Between Test Pile and Reaction Piles

Usually, the reaction device can be tension piles or anchors. In the JGS standard (2002), the following rules are defined as such: "As a general rule, the distances between the centers of the test pile and the tension piles (or anchors) shall be more than 3 times the maximum diameter of the test pile, and also more than 2.5 meters." (Fig. 5).

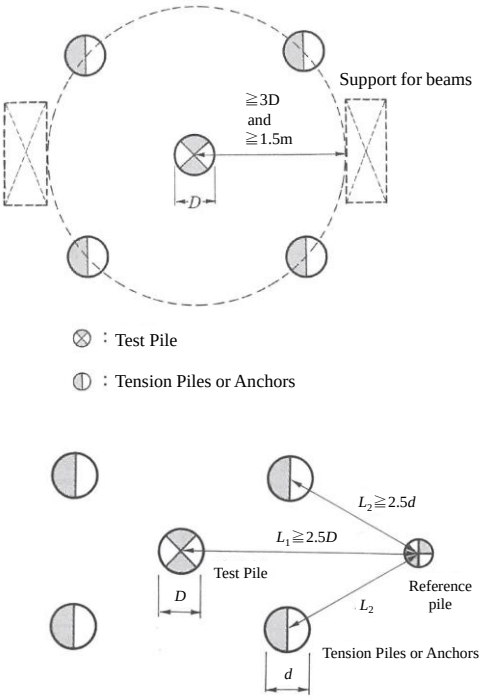

Fig. 5. Distance between the support point or tension piles (or anchors) and the test pile.

The rule of "more than 3 times the maximum diameter of the test pile" has been traditionally used since the first edition of the standard in 1972. In the revision of 2002, the experiment using model piles and the re-analysis of the data of the bi-directional load tests using the actual piles were conducted. As a result, it became clear that when this rule was satisfied, it did not have a big influence on the value of the second limiting resistance force which will be described later, and therefore this rule was judged to be appropriate for the purpose of assessing the resistance of the pile.

Time of testing

It seems reasonable to think that a waiting period of more than 5 days for the piles in sandy soil is needed, and a period of more than 14 days is necessary for the piles in cohesive soil.

Loading method

In the JGS standard, four loading methods are defined as shown in Fig. 6. These are classified into "step loading method" in which load holding is performed step by step and "continuous loading method" without load holding. In addition, two methods of "single cycle" and "multi cycle (not less than 4 cycles)" are defined respectively. The continuous loading method is a new loading method added as a revision in 2002 seen as a method suitable for reproducing the load condition acting in the short term such as seismic action.

Also, if the step loading method is applied, the load holding time for new loading steps is defined as "a constant period not less than 30 minutes". Regarding the validity of this load holding time, it was carefully examined at the time of revision in 1993. Thirty-four test cases with a load holding time of 120 minutes were collected and "the limit-resistance" and "the second-limit-resistance", which will be described below, were calculated. Then, when the load holding time is virtually shortened, it is calculated how much these errors occur. The result shows that the error is large when the load holding time is about 10 minutes, but the error has converged to several percent in about 30 minutes. As a result, it was judged that a rule of "not less than 30 minutes" is enough for the duration of a load step for engineering applications.

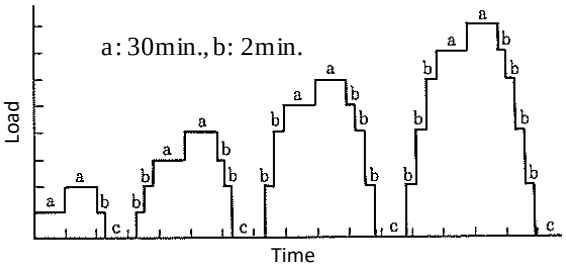

Fig. 6. Procedure of multi cycles loading method.

Failure Criteria of Pile Loading Tests

In JGS standard, two failure criteria are defined, and called "the first-limit-resistance" and "the second-limit-resistance", which is defined by the 1993 revision.

"The first-limit-resistance shall be defined as the load at the point of maximum curvature which appears clearly in the log *t* - log *z* curve.

"The second-limit-resistance shall be defined as the largest load measured within the displacement of the pile toe less than 10 % of the pile toe diameter." In the design standards for each field (railway, road, port etc.), the second-limit-resistance is considered

as the bearing capacity, and used for deriving the estimation formula of bearing capacity from the database of the loading tests.

D is the diameter of the test pile

OVERSEA LOADING PROCEDURES AND REACTION DEVICES SETUPS

In this section, the main differences between several loading procedures are presented, mainly from Europe (French standard NF P 94-150-1 [2], German recommendations on piling [3], Swiss standard SIA 267/1 [4], ICE Specifications for piling and embedded retaining walls [5], European standard on Overhead lines – testing of foundations for structures [6], the European standard (also ISO) on static compression load testing NF EN ISO 22477-1 [7]) and USA (the Standard Test Methods for Deep Foundations Under Static Axial Compressive Load D 1143-07 [8] and the Geotechnical Control Procedure GCP-18 [9]) as well as the expected impact on the result.

Reaction Devices

Usually, the reaction device can be dead load or tension piles or anchors. Alternatively, in some cases, an existing structure situated over the test pile can be used. Moreover, for piles with a very high loading capacity, embedded jacks can be used.

When using dead load, tension piles or anchors, special attention should be paid to the distance between the test pile and the reaction piles (or anchors), so as to minimize the influence of the reaction system on the test pile, during the setup and the loading sequences.

Table 1 summarizes some of the practices in Western countries.

It can be seen that there are some notable differences between the different procedures, especially when a dead load is used. However, for more common reaction devices using vertical tension piles, characteristic values tend to stand out

Table 2 Recommended waiting time between the realization of the pile and the load test

Type of piles	NFP 94-150-1 [2]	NF EN 61773 [6]	ICE Specifications [5]	SIA 267/1 [4]	EA Piling [3]	GC P-18 [9]	ASTM D1143_07 [8]	NF EN ISO 22477-1 [7]
Displacement piles	7 to 28 days without any other precisions	7 (non cohesive soils) to 21 (cohesive soils) days	12 hours	At least 10 days in saturated clayey soils	3 (non cohesive soils) to 21 (cohesive soils) days	7 days	3 to 30 days without any other precisions	7 (sandy soils) to 28 (cohesive) days
Cast in place piles (bored)		14 days	4 days		N/A			7 (sandy soils) to 21 (cohesive) days

Time of Testing

The period of time between the day of the completion of installation of the test pile and testing is an important factor, for two reasons:

(1) In the case of displacement piles, this period allows for the dissipation of any excess pore pressures due to the installation of the pile;

(2) In the case of a cast in place pile, this period allows for the strength of concrete to build up so as to ensure that the pile shall not be damaged during the test.

No clear pattern can be extracted from the analysis of the different standards and recommendations: nevertheless, it seems reasonable to think that a waiting period of 14 days for bored piles is enough to reach a sufficient concrete strength, and a period of 21 days is sufficient for displacement piles. Table 2 summarizes the recommended intervals in Western countries.

Size of Pile Related to Piles Project

This question is of great importance, when the objective of the test is to verify a design hypothesis: indeed, the ratio diameter to length has a direct impact on the performance of the pile, as the rigidity of the pile change with it. Moreover, quality of concreting at the base can also be impacted by the diameter: for some execution methods, base resistances for large diameter are smaller than for smaller diameter.

Therefore, it seems logical to keep the test piles founded at the same level and in the same soils as the project piles, with a diameter as close as possible to the diameter of the project piles.

Loading Sequence and Load Steps Durations

The international (meaning not Japanese) standards and recommendations cited in this paper offer two different approaches for performing a maintained load compression test: with or without cycles.

Some standards are offering the possibility to perform a one cycle procedure, whereas the others offer a multi-cyclic procedure only, or both. Most of the procedures use the displacement rate as a criterion to increase the duration of the load step, so as not to allow a change of load step without stabilization of the pile. The magnitude of the load steps is mostly adjustable.

It is important to note that these differences in the procedures may be explained by the necessity to adapt to the local design method, as well as to the purpose of the test. When a sudden increase appears in the duration of a load steps, it is usually because the pile has to be tested at the working load. Then the magnitude and duration of the steps vary again to assess the overall bearing capacity. However, these changes in the loading pattern are detrimental to other aspects, like the determination of the critical load, which can be used in some countries for serviceability limit state. This is the case in France, for example, where the national standard reflects this particular need, by fixing the length and duration of all the load steps.

Moreover, some standards allows, like the Japanese one, the possibility to carry out test at a constant rate of penetration. However, it is very uncommon and will not be described here.

Failure Criterion

The most widely accepted failure criterion is the load at 10 % displacement of the diameter. However, some other standards recommend a higher displacement (to 15 %) or a combination of the

displacement rate and a percentage of the diameter in terms of displacement.

Table 3 Key points of the loading procedures

	NFP 94-150-1 [2]	NF EN 61773 [6]	ICE Specifications [5]	SIA 267/1 [4]	EA Piling [3]	GCP-18 [9]	ASTM D1143_07 [8]	NF EN ISO 22477-1 [7]
Cycles (number)	Multi-cyclic (2)	1 or more	1 or more	Multi-cyclic (3)	Multi-cyclic (2)	Multi-cyclic (3)	1 or more	1 or 2
Typical length of a load step	60 min	3 to 10 min	10 to 360 min	90 min	N/A	30 min	20 to 60 min	60
Shortening of a load step	no							Yes
Criterion for the shortening	/							Disp. rate
Prolonging a load step	no			Yes				
Criterion for lengthening	/		Overall head displacement	D, load applied			Overall duration	
				+ displacement rate				
step of equal magnitude	yes	no	no	no	no	no	no	not if multi-cyclic

CONCLUSION

In this paper, we described the Japanese standard (JGS standard) of the compression pile loading test, and compared with international standards.

The revision work of JGS standards is currently ongoing, and harmonizing with overseas standards, including ISO, is one of the important viewpoints, for economical reasons for instance. In addition, it is necessary to consider the situations unique to Japan. One is the very large earthquake action in the Japanese standards for seismic design, and the other is the interaction between the installed pile and the neighboring structures in very narrow places such as renewal projects.

Comparisons of the different procedure tend to show clear similarities between the different practices, from which we can conclude that the Japanese method and its interpretation of the results is already transposable overseas.

It is still expected that this paper will be useful for the revision of the JGS standards and further improvement of pile foundation design standards.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the work of the members of the JGS Pile Loading Standards Revision Committee and especially its Chairman, Professor Kikuchi.

COMPARISON OF DIFFERENT METHODS FOR ANALYSIS OF COMBINED PILED RAFT FOUNDATION

Irfan Jamil[1], Irshad Ahmad[2], Muhammad Shoaib Khan[3]
[1,2]Department of Civil Engineering, UET Peshawar, Pakistan;

ABSTRACT

In a combined piled raft foundation (CPRF) both raft and piles take their share of total load applied. However, in practice, the contribution of raft in taking load is usually ignored and the load is assumed to be totally supported on piles. This way of CPRF becomes excessively conservative and uneconomical. To economize the design, relative load sharing of raft and piles in CPRF has to be found. In this connection, different simplified methods have been developed- each one with some limitations. In this study, three simplified methods have been applied to two cases of pile raft system. These methods are Randolph, Poulos-Davis-Randolph and Modified Poulos-Davis-Randolph. The first case is a hypothetical case consisting of a 12 m. x 12 m. raft supported on a square group of nine piles. The second case study is an actual eight story building to be constructed in Peshawar, Pakistan. The building is supported on pile raft system, with raft resting on very soft clay underlain by dense sand. The two case studies are also modelled in finite element program PLAXIS-3D. The results of all the simplified methods are comparable with PLAXIS-3D. However, results of the Randolph method are much close to PLAXIS-3D for the two cases studied. Furthermore, it is also shown that piles in a piled raft system can be used as a "stress reducers" as well as a "settlement reducers".

Keywords: Analytical methods, Raft, PLAXIS-3D, Stress reducers, Settlement reducers.

INTRODUCTION

CPRF system consists of three foundation bearing elements Piles, Raft and Supporting Soil. The thickness of Raft, Length and dimension of Pile, location of Piles in Raft, the soil Properties and Stiffness of pile and raft play a crucial role in the analysis and design of CPRF foundation [11]. Applied load from the superstructure are transferred to soil through these foundations bearing elements Raft and Pile by taking into account interaction between these foundations bearing elements. There are mainly two types of interaction which are Pile-to-Pile interaction and Pile-to-Raft Interaction. These interaction factors are highly dependent upon elastic modulus of soil, S/d ratio of piles and length of piles. Ignoring these interactions will lead to unsafe design and will underestimate settlement and bending moments in raft [1].

Every element in a piled raft system have their advantages. Raft can contribute in taking some percentage of load and can reduce substantially differential settlement depending upon raft thickness. Piles can be used as a "stress reducers" as well as a "settlement reducers" [5], [2] in addition to increase in bearing capacity of soil. Taking into account these contribution of both elements, piled raft foundation can be made very economical in terms of no of piles, length of piles and reinforcement in raft.

Researchers have put their efforts to solve problem of load sharing and analysis of CPRF like (Poulos and Davis, 1980 [3]; Randolph, 1994 [4] and Burland, 1995 [5]) have proposed some simplified methods involving a number of simplifications. Other approximate methods like "strip on springs" proposed by Poulos [6] in which raft is represented by Strip and Piles as Springs and "plate on springs" method proposed by Clancy and Randolph [7] in which raft is represented by Plate and Piles as Springs. Finite Elements software's like SAP2000 (Method proposed by Nguyen) [8], and PLAXIS-3D foundation (Brinkgreve and Broere, 2004) [9] can provide a good option for numerical analysis.

For structure design of raft in a piled raft system, there are several simplified approaches, which includes Burland [5] method and Winkler model for piled raft foundation system (WMPR) method [12]. These methods can provide reasonable results for preliminary analysis of raft in a piled raft system.

Randolph Method (1994)

In this method response of equivalent raft with single pile is used to predict response of whole CPRF system. Using stiffness of raft in isolation and pile group stiffness, combined piled raft stiffness can be calculated. Using this method, we can estimate percentage load taken by piles and raft and average settlement of whole CPRF system. To incorporate variation of stiffness along depth of soil, Randolph include stiffness of soil along the pile shaft, at pile head and pile tip. Randolph do not consider flexibility of raft and strength properties of soil (Cohesion, friction angle).

Poulos-Davis-Randolph Method (2001)

Tri-linear settlement curve is used to establish this method. Using this method, we can find a point (load "P1") at which pile capacity is fully mobilized and ultimate capacity "Pu" of CPRF. Using stiffness of Pile group "K_p" and stiffness of raft "K_r" combined piled raft stiffness can be calculated "K_{pr}". Using this method, load sharing percent between piles and raft can be estimated. Pile raft interaction factor and stiffness of raft can be calculated from Randolph method and elastic theory respectively (Mayne and Poulos, 1999) [12]. The Combined piled raft stiffness can be calculated as follow:

$$K_{pr}=\frac{(K_p+K_r(1-2\alpha_{rp}))}{(1-\alpha_{rp}^2*\frac{K_r}{K_p})} \quad (1)$$

In this equation, Kp is the pile group stiffness, kr is only raft stiffness and αrp is pile-raft interaction factor.

Modified Poulos-Davis-Randolph Method

For this method, a hyperbolic settlement curve for piled raft system is used instead of tri-linear settlement curve. Also, in this method, Stiffness of raft and piles will change according to the applied load. Using this method, we can find allowable settlement for CPRF and load level at which piled raft system gets non-linear and subsequently non-linear behavior of piled raft system can be capture. In order to avoid plastic behavior of CPRF system, it is focused not to exceed the non-linear load level.

Burland Method

One of the simplified approach for geotechnical and structure design of piled raft system. This approach is applicable only, when piles are developing their full geotechnical capacity. In this method, load is calculated corresponding to allowable settlement of raft out of total load. The remaining excess load is assumed to be carried by piles. Bending moments in raft of piled raft system can be calculated using a reduced column load "Qr" which is given by equation. 2.

$$Qr=Q-0.9Psu$$

where "Q" is total column load and "Psu" is the pile geotechnical capacity without factor of safety.

Winkler Model For Piled Raft System (WMPR)

WMPR method is based on Randolph method. Adjusted Stiffness's for piles and raft can be calculated based on settlement results of Randolph method and assign as Winkler Springs in any FEM software. Pile-pile and pile-raft interaction factors were incorporated while finding these stiffness's. Bending moments in raft of a piled raft system can be calculated using this simplified approach.

METHODOLOGY

For this research, the above-mentioned methods were applied on two case studies. The first case study is a typical piled raft of 12mx12m supported on a square group of nine piles while second case study is an actual piled raft of eight story building to be constructed in Peshawar, Pakistan. Both case studies were also analyzed using FEM software PLAXIS-3D. In second case study analysis of unpiled raft were also performed to show usage of piles as a "Stress Reducers" and "Settlement Reducers".

Case Study (1)

First case study consists of 12mx12m raft with nine piles as shown in Figure 1 and 2.

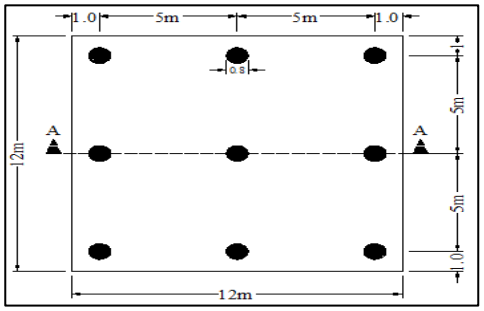

Fig. 1 Piled raft Layout

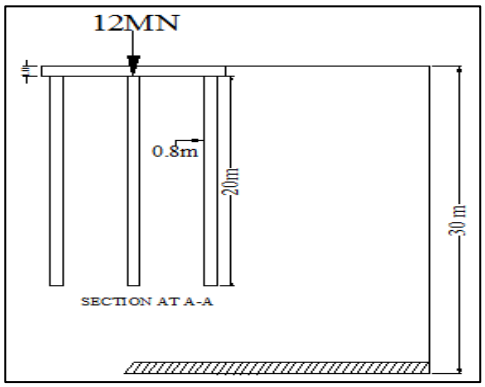

Fig. 2 Piled raft Layout cross-section

The Soil, pile and raft properties selected are shown in Table 1, 2 and 3 respectively. Similarly, PLAXIS 3D meshed and general model is shown in Figure 3 and 4.

Table 1 Soil Properties

Properties	Value
Soil modulus, E_s	50 [MPa]
Cohesion of soil, c_u	50 [KPa]
Poison's ratio of soil, υ_s	0.45
Angle of internal friction, ϕ	0 [degrees]
Unit weight	γ_{sat} = 20 [KN/m^3] γ_{unsat}=19 [KN/m^3]
FE model	Elasto-plastic [Mohr-coulomb]

Table 2 Pile Properties

Properties	Valve

Modified Poulos-Davis-Randolph Method	**75**	**8.6**
PLAXIS-3D Approach	**76**	**8.7**

Case Study (2)

For second case study, piled raft of eight story building which was to be constructed in Peshawar is selected. Raft dimension was 32mx83m with 132 piles underneath. Diameter of piles is 0.6 m with embedded length is 25 m. Architectural 3D view of the proposed constructed building is shown in Figure 5. Raft layout and position of piles are shown in Figure 6. Geotechnical Profile of the proposed site is also shown in figure.7. A 15m soft clayey soil layer is present at the top, which makes the foundation design challenging. PLAXIS 3D models are shown in Figure 8 and 9.

CONCLUSIONS

The analysis conducted shows Randolph method gives results which are much closed to numerical model result as compared to other methods. For preliminary analysis of piled raft design, Randolph method is recommended. Piles in addition to geotechnical advantage, can also be used to reduce state of stress in raft and settlement of piled raft foundation. Piled raft foundation can be make very economical by incorporating these aspects in piled raft design.

ABSTRACT

In urban areas, underground space is growing up and deep excavations are often used to solve this problem. In Ho Chi Minh City, deep excavation is often constructed in areas close to existing buildings, infrastructure or public services, so limiting the displacement of the retaining wall and surface subsidence is very important to ensure that the surrounding works are not affected or affected by the level of permission. In order to analyze the displacement and deformation of the excavation pit, it is necessary to determine the soil characteristics of the excavation pit foundation for inclusion in the soil models. However, the construction design of the project is mainly taken from normal geological experiments, yet it does not describe the behavior of the surrounding soil. Therefore, the problem is to use an experimental model with a reasonable stress path to determine input parameters that are appropriate to the behavior of the ground around the pit, expressed by the change the stiffness of the soil during the excavation work, which the current experimental process is considered unchanged. This paper uses triaxial tests to evaluate the shear strength behavior of soft soil in Ho Chi Minh City with stress paths for calculation deep excavations. The experiments were carried out on an undraining fixture scheme of 50, 100, 200kPa pressure ratings to determine the shear strength and deformation modulus parameters of the E_{50} during the unloading process.

Keywords: strain, stress paths, nonlinearity, deep excavation, soil model, unloading

INTRODUCTION

In recent years, the demand for underground space has been increasing in urban areas. Deep excavations are often used to solve this problem. In Ho Chi Minh City, deep excavations have usually constructed in areas close to existing buildings, infrastructure or public services, so it is important to limit the displacement of retaining walls and surface settlement. to ensure the surrounding buildings are not affected or affected by the permitted level.

Due to the lack of laboratory data in the room, engineers often use conventional geological test data or correlate design parameters from available parameters and are often limited to simple model land in design of deep excavations. In fact, the construction of excavation can be considered a loading and unloading problem for the ground, this unloading changes the deformation stress state in the ground. If the correlation is irrelevant or determine parameters from test with improper stress paths, the engineer often faces the problem of deformation the actual deep excavations will be different from the predicted value.

Deep excavations is influenced by geotechnical conditions, the most important calculation is the control of horizontal displacement of the retaining wall at the lowest level, so it is necessary to determine the actual stress state of the soil around the deep excavations.

Many studies [11] have divided the area affected by the excavation process into four parts, as shown in Figure 1.

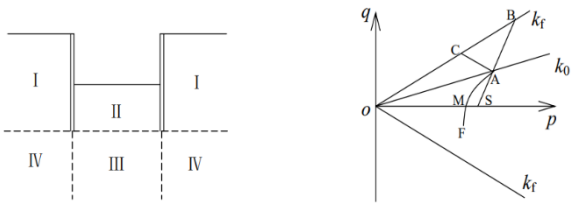

Fig. 1 Area of influence of deep excavation and stress paths

Zone I: when removing soil out of the excavation, horizontal displacement of the retaining wall will occur and horizontal stress decreases while vertical stress remains unchanged. Stress paths as the AC segment in Figure 1.

Zone II: during excavation, vertical stress decreases and lateral stress increases due to wall displacement, reduced soil strength, and ductile region may appear at the bottom of the pit. The stress path for this region is represented by the AMF segment in Figure 1.

Zone III: During the excavation process, vertical stress decreases continuously; horizontal stress

changes a little; and stress path is shown in the AS segment in Figure 1.

Region IV: Vertical stress is basically constant; there is a slight change in horizontal stress; the main shaft of the stress is deflected by shear; and the stress path is still near the AC segment in Figure 1.

The most significant effect on the deformation of the deep excavation is Zone I and Zone II, in which Zone I is the main factor causing horizontal displacement and Zone II causing bottom heave, which has important effects on deformation of deep excavation. Zone I and Zone II correspond to stress paths AC and AMF. In the AMF, the AM part is the unloading part and the MF part is loaded, which can be analyzed by a general geotechnical model. The AC line is the horizontal unloading stress line. Unlike AB stress lines in conventional experiments, there are different behaviors and stress paths.

In practice, the soil productivity change is very complicated. It can be seen that in order to analyze the behavior of Zone I (behind the retaining wall) and Zone II (at the bottom of the excavation pit), the analysis of soil strength and stiffness parameters of these two areas is a major issue focus on solving.

In order to have accurate data on the deformation of the excavation, it is necessary to have the soil characteristics of the area around the excavation to provide input data to be included in the calculation models. However, the current design of construction activities is mainly taken from normal geological tests, not describing the behavior of the land around the excavation pit. Therefore, the question is to use an experimental model with a reasonable stress path to determine the input parameters in accordance with the behavior of the ground around the excavation, expressed through change soil stiffness during excavation, which the current experimental procedure is considered to be constant.

In this study, the author performed a series of three undrained triaxial tests (CU) on 27 soft soil samples with a depth of 4 to 24m with load levels of 50, 100, 200 kPa, respectively, with the stress paths. Different stresses for evaluating shear and stiffness behavior of soft soil in Ho Chi Minh City.

APPARATUS

The test was carried out with the load frame system of Humboldt (USA) according to ASTM D4767. This system includes pressure, deformation, pressure and volume sensors connected to ADAM View 32-channel datalogger system. Advantech Adam view software allows collecting data from sensors over time. The system is connected to the computer via a network card to allow chamber pressure control and testing to be performed automatically from the beginning to the end.

Fig. 2 Humboldt tri-axial equipment system

Principles for design of the compression cell of the experiment with loading models based on Bishop and Wesleys's hydraulics (1975) [7] to control the different stresses during the unloading experiment.

Testing samples and testing parameters according to different stress paths shows in Table 2. A total of 27 soft soil samples were tested, of which 18 samples of very soft clays and 9 samples of soft clays, experimented according to the stress paths. The stress program is as follows:

- Conventional triaxial compression model (CTC - increase σ_1 and fixed σ_3): Saturated soil samples are isotropic consolidation and undrained samples according to the usual compression schedule: 9 samples;
- Triaxial drag model (RTE - reduced σ_1 and fixed σ_3): Saturated soil samples are isotropic consolidation and non-draining samples according to vertical stress reduction schedule: 9 samples;
- Model of cell pressure reduction (RTC - reduction σ_3 and fixed σ_1): Saturated soil samples are isotropic consolidation and non-draining samples according to horizontal stress reduction schedule: 9 samples;

ANALYSIS AND EVALUATION OF TESTING RESULTS

Stress and strain relationship (q-ε_1)

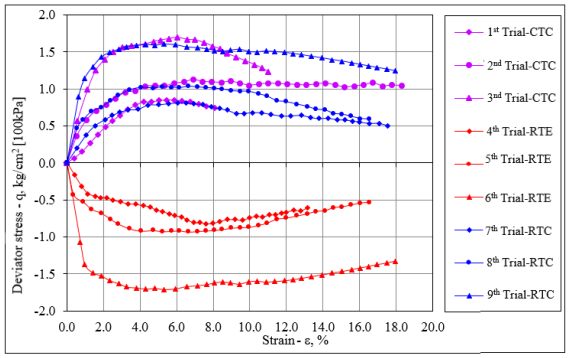

Fig. 3 Relationship (q - ε) of stress paths at depths 4-6m

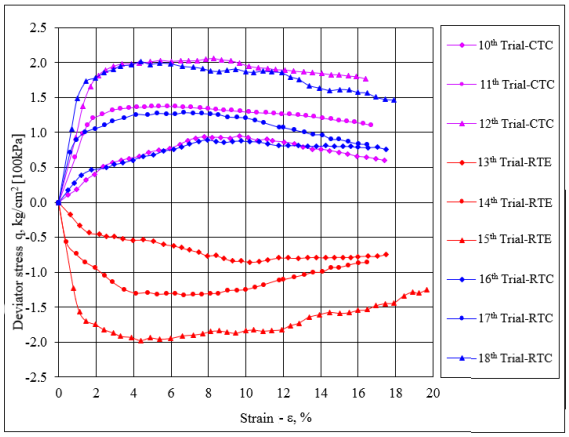

Fig. 4 Relationship (q - ε) of stress paths at depths 12-14m

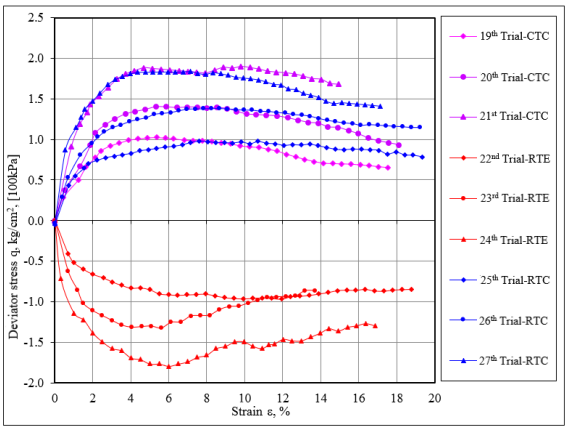

Fig. 5 Relationship (q - ε) of stress paths at depths 18-20m

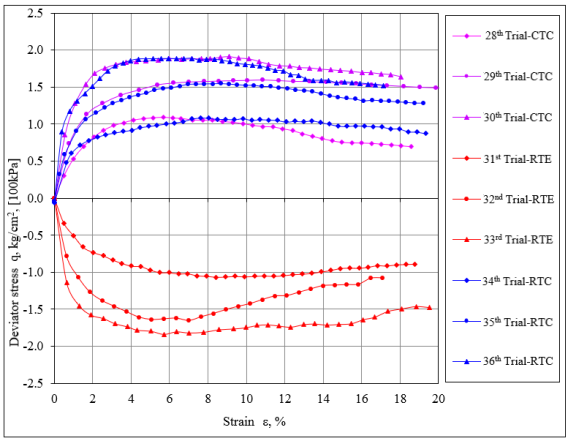

Fig. 6 Relationship (q - ε) of stress paths at depths 24-26m

In the above section, the triaxial test according to the three stresses CTC, RTE and RTC is performed with the CU diagram. The relationship of stress - deformation and change of pore water pressure with deformation with the above 3 stress paths at the cell pressure levels (σ_3) are respectively 50kPa, 100kPa and 200kPa are shown from Figure 3 to Figure 6.

In conventional triaxial compression test with CTC stress curve, stress relationship - deformation is progressively nonlinear and deformed with increasing deviation stress until the sample is destroyed, value maximum deviation stress increases with cell pressure level. The pore water pressure is always positive and also increases immediately along with the deformation in the axial stress increase process.

In contrast, for the RTE stress paths in a triaxial tensile test, the pore water pressure decreases at low stress levels and gradually increases at higher stress levels. The initial pressure of the pore water is negative and the positive sign is changed according to the increase of the deviation stress due to the reduction of σ_1. Therefore, the destructive stress and the change of pore water pressure for triaxial tensile tests also depend on the stress paths. Experimental results with RTE stress paths show that axial strain corresponding to maximum stress increases with cell

pressure and pore water pressure represents elasticity, which corresponds to the corresponding. The expansion of volume of ground soil outside reality when unloading during construction of excavation pits. This expansion behavior may be partly explained by the change in the pore water pressure of the soil sample at the end of the saturation and consolidation period during shear stress. In most cases, these soil samples were damaged by declining deformation. The destruction of the sample is seen in the middle of the sample like the bottleneck shape as shown in Fig. 7. It can be seen that, during the increase in stress, the pore water pressure also increases similarly corresponding to each stress paths. The destructive pattern when deforming is about 6 ÷ 8%.

Testing results show that in the axial stress strain RTE paths, it increases more slowly than CTC stress paths, especially shown at the maximum cell pressure level, which means that the initial tangent modulus is higher in the RTE stress paths and has a lower value for the CTC stress paths. From this, it can be concluded that the elastic parameters depend on the initial stress and strain modulus paths in the process of unloading.

Fig. 7 Sample destruction by RTE (left picture) and RTC stress path (right picture)

With the triaxial compression stress paths reducing horizontal stress RTC, when the horizontal stress is reduced during the sample cutting process, the deformation also increases but is slower than the deformation compared to CTC stress paths, so the strain deformation modulus The intention to calculate deep excavation by HS model has much greater results than CTC stress paths due to the curvature of stress strain relationship with greater slope. The pore water pressure in the RTC route is opposite to the CTC stress path but has a significantly smaller magnitude and has a different nonlinearity, this pressure gradually increases to the destructive threshold of the sample and decreases when the sample starts destructive. Testing results indicate that the parameter values determined from the strain stress relationship of the ground soil depend on the stress path of the triaxial test. Different stress paths will give different shear strength values and the deformation characteristics of soil samples will change as cell pressure increases. The initial deformation module E_i in experiments with unloading path is also of different value than when determining from the usual tri-axial compressive stress paths. Therefore, with the problem of designing deep excavations, the determination of input parameters with appropriate stress paths will give economical and safety results.

Analysis of deformation modules of stress paths

The relation (q, ε_1) Figure 3 to Figure 6 calculate the deformation module E_{50} of soft clays samples at different depths and different cell pressures as determined stiffness parameters of HS model. The results are shown in Table 2.

The magnitude of the E_{50} strain module increases gradually with depth. At the same depth, the distortion module will also have a greater value if tested with a larger cell pressure level.

Testing results show that the stiffness of soil depends on the stress paths. With HDS, the selection of stiffness parameters in the displacement calculation should be taken from the test with the unloading stress paths.

Table 2 E_{50} deformation modules from CTC, RTE and RTC stress paths

		RTE	RTC	CTC		
Depth [m]	σ_c [kPa]	E_{50} [kPa]	E_{50} [kPa]	E_{50} [kPa]	$\frac{E_{50,RTE}}{E_{50,CTC}}$	$\frac{E_{50,RTC}}{E_{50,CTC}}$
Very soft clays						
4÷6	50	3611	3494	2085	1.73	1.68
	100	8202	7495	4774	1.72	1.57
	200	14528	13997	8553	1.70	1.64
12÷14	50	2750	2968	1853	1.48	1.60
	100	11575	9427	5981	1.94	1.58
	200	15194	17774	9389	1.62	1.89
Soft clays						
18÷20	50	5811	5391	3673	1.58	1.47
	100	8640	6442	4510	1.95	1.48
	200	14652	14121	9273	1.58	1.52
24÷26	50	4579	4201	2861	1.60	1.47
	100	7765	7026	4922	1.58	1.43
	200	16688	15107	9161	1.82	1.65

The difference in the value of the elastic modulus according to the stress paths can be explained by the dependence of the elastic modulus according to each stress paths on the plastic strain level. The magnitude of plastic deformation depends on the flexible potential function and flexible flow function. Thus, the elastic modulus of the ground at some point has only one value in the state without deformation. When the ground is deformed, the value of the elastic modulus decreases with a degree of dependence on the stress path. The value of the elastic modulus of the

ground soil is determined by the initial slope of the strain-strain relationship curve in such a conventional tri-axial compression test that results in a large error in the calculation. Therefore, it is recommended to use the value of the elastic module from the unloading tri-axis compression test.

With triaxial test according to RTE and RTC stresses, the results of the deformation modulus are much larger than those calculated from the test results according to the normal tri-axial compressive stress path:

$$\frac{E_{50,RTE}}{E_{50,CTC}} \approx \frac{E_{50,RTC}}{E_{50,\mathrm{RTC}}} = [1.48 \div 1.57] \quad (1)$$

Shear strength of soil with different stress paths

From the above diagrams of stress-strain relationship (Figure 3 to Figure 6), destructive contour lines can be drawn to determine the effective shear resistance parameters for soil layers as follows:

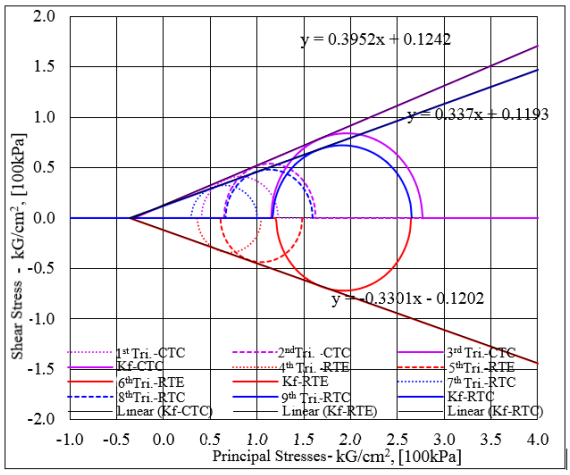

Fig. 8 Mohr circle according to stress paths at depth of 4-6m

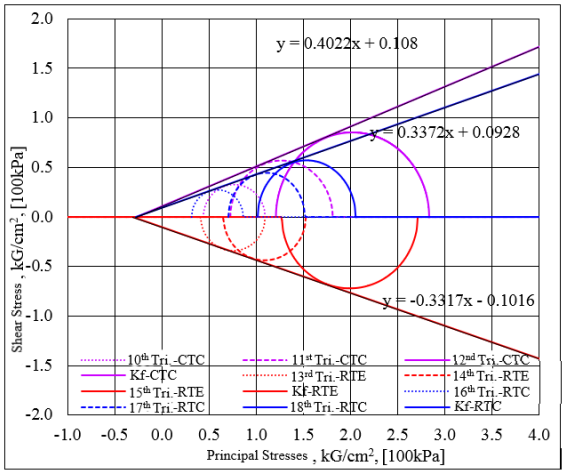

Fig. 9 Mohr circle according to stress paths at depth of 12-14m

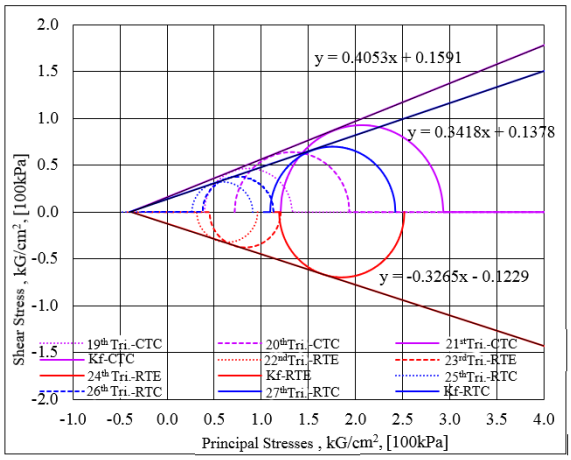

Fig. 10 Mohr circle according to stress paths at depth of 18-20m

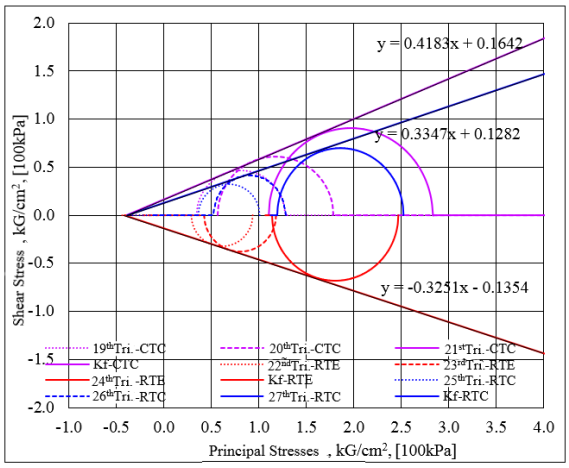

Fig. 11 Mohr circle according to stress paths at depth of 24-26m

The slope of the K_f destructive lines according to the stress paths is clearly different.

The effective friction angle of the RTE and RTC unloading route is similar and smaller than the CTC schedule. For each load level, the stress circle of RTE and RTC routes is back to the origin of the coordinates compared to the normal tri-axial compression stress paths CTC.

From the diagrams of Figure 8 to Figure 11, determine the effective shear strength parameters of the soil as shown in Table 3.

Table 3 Value of c' and φ' of soft soil in HCMC. according to stress paths

Depth [m]	Stress paths	*c'* [kPa]	*Δc'* [%]	*φ'* [^{0}]	*Δφ'* [%]
Very soft clays					
4÷6	CTC	13.58		21.56	
	RTC	11.21	0.83	18.62	0.86
	RTE	11.17	0.82	18.26	0.85
12÷14	CTC	13.87		21.90	
	RTC	11.12	0.80	18.63	0.85

	RTE	11.39	0.82	18.35	0.84
Soft clays					
18÷20	CTC	15.32		22.00	
	RTC	12.45	0.81	18.87	0.86
	RTE	12.17	0.79	18.08	0.82
24÷26	CTC	14.94		22.70	
	RTC	11.72	0.78	18.51	0.82
	RTE	11.64	0.78	18.01	0.79

From the results of the analysis, it can be seen that the effective friction angle of the ground (φ') in the three-axis test calculated by RTE and RTC is similar and smaller than that determined by the usual triaxial compression stress paths (CTC), this value is about 15% to 23% smaller:

$$\frac{\varphi'_{RTE}}{\varphi'_{CTC}} \approx \frac{\varphi'_{RTC}}{\varphi'_{CTC}} = 0.77 \div 0.85 \quad (2)$$

Experimental results show that the effective shear strength (φ') of soft soil in HCMC declined from 15% to 23% under the unloading stress schedule in case of deep excavations.

CONCLUSIONS

- Behavior of soil depends greatly on stress paths. Determining the shear strength parameters as well as the stiffness parameters for the deep excavation problem should be determined from the tri-axial experiment with the unloading stress paths because these experiments describe the actual working state of the ground during the construction process
- The results show that experiments with different stress paths will give different shear resistance values and strain characteristics will change with cell pressures. In the experiment with the unloading schedule, the shear resistance of the soil is significantly reduced compared to the conventional tri-axial compression test, because the excavation process is the process of unloading so the horizontal displacement of the soil will cause the soil to deteriorate (soft soil when digging).
- The effective friction angle of the ground (φ') in the tri-axial test calculated by RTE and RTC is similar and smaller, determined by the usual tri-axial compression stress path (CTC), which is smaller between 15% and 23%:

$$\frac{\varphi'_{RTE}}{\varphi'_{CTC}} \approx \frac{\varphi'_{RTC}}{\varphi'_{CTC}} = 0.77 \div 0.85$$

- Deformation modulus of soil also depends on stress paths. The linear sand deformation module of the triaxial test reduces the stress greater than the conventional triaxial test. Triaxial test according to RTE and RTC stresses results in equivalent modulus of modulus but larger than conventional tri-axial CTC stress path. With soft soil, scale ranges from [1.48 ÷ 1.57] times:

$$\frac{E_{50,RTE}}{E_{50,CTC}} \approx \frac{E_{50,RTC}}{E_{50,CTC}} = 1.48 \div 1.57$$

ABSTRACT

Deep cement mixing (DCM) is widely used to improve the strength and stiffness of soil by mixing it with cement. When DCM is used as a low permeability barrier for water cut off, permeability must be tested in addition to the usual strength values. One concern in DCM construction is the quality assurance and quality control (QA/QC) of this technique to ensure uniformity along the DCM column. It is even more crucial when low permeability is required for the DCM column to be used as a seepage cutoff in an earth bund, in addition to its strength requirement. In this application, the DCM columns require low permeability and adequate strength. In this paper, two QA/QC aspects will be evaluated: the operational control and the evaluation of the treated DCM column. The operational control in terms of mixing time, cement content, rotation speed and mixing energy will be studied to gain understanding on how strength and permeability changes with the variability of the soil with depth. A rational QA/QC plan will be briefly proposed to ensure a consistent and rational method is developed for the evaluation of the strength and permeability variation of the treated soils over the area and over the depth. These will help in the development of acceptable characteristic value for the geotechnical parameters of soils treated with DCM (in line with Eurocode 7).

Keywords: Deep Cement Mixing, Soil Improvement, Permeability, Quality, Eurocode 7

INTRODUCTION

Deep cement mixing (DCM) is widely used to improve the strength and stiffness of soil by mixing it with cement and its application has gained popularity over the years in Singapore [1]. When installed in an earth bund, the DCM not only improves the stability of the slope but also act as a low permeability barrier for water cutoff if the earth bund is used to retain water, for example in a reservoir. When DCM is used as a low permeability barrier for water cut off, permeability must be tested in addition to the usual strength values.

When used to increase stability, there is usually no limit in strength requirements for the DCM column. However, a higher strength implies a more brittle behavior and the likelihood of crack formation when the DCM column is subjected to higher loads. This is not acceptable if the DCM columns are used as a seepage cutoff. Hence, the strength of the DCM columns needs to be capped.

One concern in DCM construction is the quality assurance and quality control (QA/QC) of this technique to ensure uniformity along the DCM column. It is even more crucial when low permeability is required for the DCM column to be used as a seepage cutoff in an earth bund, in addition to its strength requirement. In this application, the DCM columns require low permeability and adequate strength.

In this paper, two QA/QC aspects will be evaluated: the operational control and the evaluation of the treated DCM column. The operational control in terms of mixing time, cement content, rotation speed and mixing energy will be studied to gain understanding on how strength and permeability changes with the variability of the soil with depth. A rational QA/QC plan will be briefly proposed to ensure a consistent and rational method is developed for the evaluation of the strength and permeability variation of the treated soils over the area and over the depth. These will help in the development of acceptable characteristic value for the geotechnical parameters of soils treated with DCM (in line with Eurocode 7).

The results, values, and parameters presented and suggested in this paper are only indicative and are intended to illustrate principles. They do not refer to any specific project and should not be used contractually.

PROPOSED QA/QC CONTROL FOR ACTUAL WORKS

Two QA/QC aspects will be evaluated: the operational control and the evaluation of the treated DCM column strength and permeability.

(a) Operational QA/QC Control

The operational control in terms of mixing time, cement content, rotation speed and mixing energy are to be studied to gain understanding on how strength and permeability changes with the variability of the soil with depth.

To ensure the installation of good quality DCM columns, stringent operational controls are to be set up. For every column installation, a digitized record of the mixing efficiency, in terms of mixing time, cement content and mixing energy, etc. are to be recorded. Contractors will be required to submit records of the DCM column installation and compare that with the designed operation curves. These operation curves must be established with a site trial. An example of a design operation curve is shown in Fig. 1(a), (b) and (c). The values in this figure are only indicative.

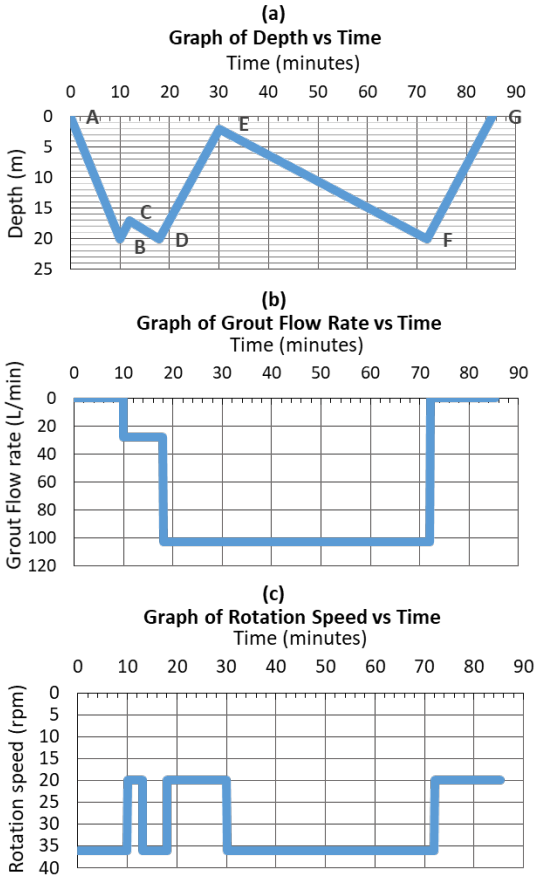

Fig. 1 Example of a design operation curve.

In Fig. 1(a), the vertical axis is the depth of penetration, while the horizontal axis is the time. Fig. 1(b) and (c) are the grout flow rate with time and the mixing blade rotation speed with time respectively.

Based on this information, the amount of cement mixed with the soil at a depth of interest can be evaluated based on the grout flow rate at that depth. The calculated rate of mixing and cement used must be consistent with the design value. Any variation will suggest that the column was not properly installed, and remedial action could be necessary.

(b) End Result Evaluation

The properties of Singapore Marine Clay treated with cement mixing has been well studied [2], [3]. However, due to the changes in soil profile with depth in the ground and differences in operation parameters, the quality, and properties of the DCM columns can vary greatly from laboratory studies.

To understand the long-term characteristics of the DCM columns, the qualities of the DCM columns were inspected by coring the completed columns after 91 days. The conventional method of using only absolute average strength values often indicate highly varied and inconsistent results and will result in difficulty to access the overall performance of the DSM columns. In addition, permeability is usually not tested or specified. Hence, an improvement to the QA/QC criteria is needed.

To provide consistent and representative quality sampling, the DCM treated area will be divided into sections of 100m along the cutoff wall.

Coring tests

The quality of DCM columns is to be inspected by coring the completed columns throughout the depth. The coring shall consist of at least two cored locations per section of 100m along the cutoff wall.

Representative zones along DCM columns

Sampling at 1.5m intervals will be conducted along each cored location of the selected DCM column. Unconfined compressive strength tests will then be carried out for all cored samples, while permeability tests will be carried out on five selected samples per cored location.

Acceptance criteria for DCM column

The acceptance criteria for the cored sampled obtained from the selected DCM column are as follows:

(1) The minimum unconfined compressive strength (UCS) for all the samples must be greater than 200 kPa, while the maximum UCS for all the samples must be less than 450 kPa;
(2) At least 70% of the total number of cored samples have to attain a UCS between 250 kPa and 350 kPa;
(3) Lower bound limit: not more than 15% of the total number of cored samples are to attain a UCS between 200 kPa and 250 kPa;
(4) Upper bound limit: not more than 15% of the total number of cored samples are to attain a UCS between 350 and 450 kPa;
(5) For the five samples per cored location tested for

permeability, the average permeability for all five samples must be less than 10^{-9} m/s. No single permeability value should be more than 10^{-7} m/s.

PRELIMINARY DCM SITE TRIAL DESIGN

Before implementation of the actual works, a site trial was conducted to determine the optimal cement dosage and operation parameters in order to achieve the stringent strength and permeability requirements. Too high a cement dosage will likely lead to a higher strength but more brittle behavior of the DCM; which is not acceptable in this case. The site trial, as compared to laboratory tests mix results, is also more representative of the actual DCM construction as it considers variability in the actual DCM behavior due to installation methods.

The DCM columns for the site trial were installed beneath the site's existing seabed, with the top level of the columns at -7.5 mCD and the toe level at -23.5 mCD, resulting in a design column length of 16m. The ground consists soft marine CLAY (M) overlaying fluvial CLAY/SILT (F2) and fluvial SAND (F1) and underlined by the original formation of sandy SILT residual soils (RS). Figure 2 shows two reference borelogs with respect to the DCM columns installed in the site trial.

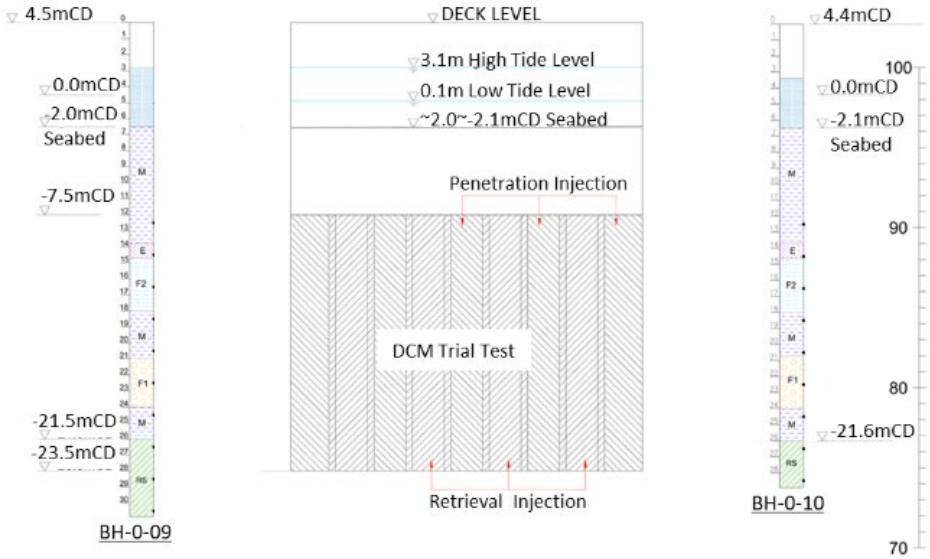

Fig. 2 Reference borelogs for site trial.

The DCM columns were constructed using four mixing blades, resulting in four overlapping columns that form a 2.8m by 2.8m block. A total of 18 DCM blocks with varying cement dosage and installation method (penetration/retrieval injection of cement) were installed for the site trial as shown in Fig. 3. All blocks were installed within a week. As shown in Fig. 3, the DCM blocks labelled with circles represent the DCM columns constructed with a cement dosage of 120 kg/m^3 of treated soil volume. Similarly, the DCM blocks labelled with stars and triangles represent cement dosages of 140 kg/m^3 and 160 kg/m^3 respectively. All mentioned above are for the retrieval injection installation method. The other DCM blocks that were not labelled were constructed using the penetration injection method, and will not be discussed in this paper.

The operational QA/QC control will be closely monitored during the construction of these blocks, and the cored samples obtained from the completed DCM columns after 28 and 91 days will be tested for strength and permeability.

SITE TRIAL RESULTS

Two QA/QC aspects will be evaluated: the operational and end result. However, this paper will only summarize the 28 and 91-day results.

(a) Operational QA/QC Control

The operation parameters of every DCM block constructed were recorded and monitored. One of the actual operational curves is shown in Fig. 4.

For the site trial, the preliminary set of key operational parameters adopted were as follows:

(1) The maximum main penetration and withdrawal rate should not be more than 0.5 m/min.

(2) The grout flow rate should not be less than 100 *l*/min for the main penetration and withdrawal steps.

(3) The blade rotation speed should not be faster than 40 rpm for the penetration step and 30 rpm for the withdrawal step.

(4) The current supplied to the four blades must be more than 300A and less than 1200A for all effective penetration and withdrawal steps.

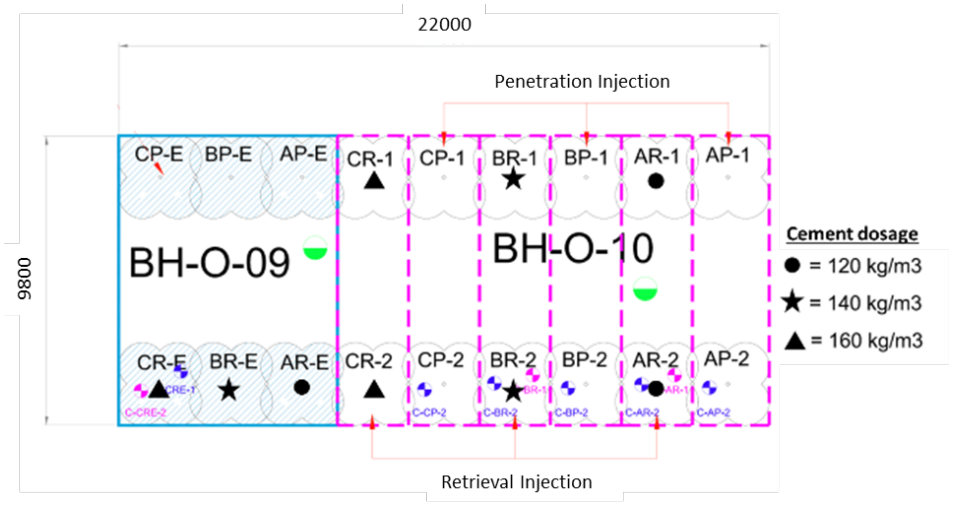

Fig. 3 DCM site trial plan

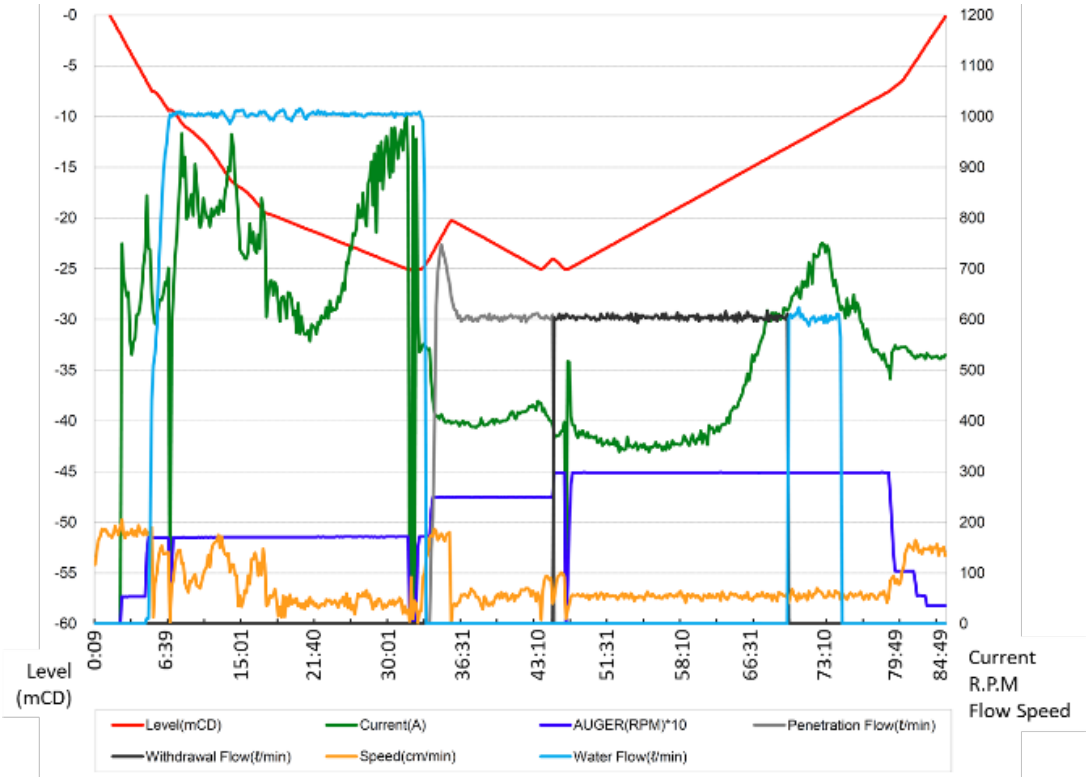

Fig. 4 Actual DCM site trial operation curve.

Every DCM block was found to satisfy and/or are close to the limiting operational parameter values stated above. Hence, if the core strength and permeability results satisfy the minimal specification requirement, the above operational parameter values will indicate the minimum requirement needed to achieve a good quality DCM block. Otherwise, if the core strength and permeability results do not satisfy the requirements, the above operational parameters have to be adjusted accordingly.

(b) End Result Evaluation

The recovered cored samples comprised of cement mixed with the different types of in-situ soils occurred through the depth of the DCM columns. This ranged from M (clay) to F1 (sand) and RS (residual soils). Different strengths and permeability values were obtained for the different soil mixes even when the cement dosage is kept constant throughout the depth.

Unconfined Compressive Strength (UCS)

For ease of comparison, the 28 day and 91 day UCS results have been plotted with depth for the cement dosages of 120, 140 and 160 kg/m^3 and are shown in Fig. 5, 6 and 7 respectively. In general, the 91-day results show an increase in UCS as compared to the 28-day result. However, the increase in strength resulted in a more brittle behavior in DCM column as observed from the increase in stiffness and reduction in elastic strain limit and failure strain. In addition, all the samples had exhibited a UCS higher than the allowable maximum limit of 450 kPa. This implies that cracks may develop in the DCM columns due to shrinkage. This could affect the overall permeability of the DCM columns, leading to its inability to function as a seepage cutoff wall.

By comparing the UCS result with depth for a constant cement dosage, it can be observed that the UCS varies greatly in the different soil types, and the DCM column does not have a uniform strength throughout its depth. In addition, for the same soil type treated with a constant cement dosage, the UCS results obtained also varied greatly as shown in the clay (M) layers treated with a cement dosage of 140 kg/m^3 shown in Fig. 6. This indicates that the operational QA/QC control is not adequate and further refinement is necessary.

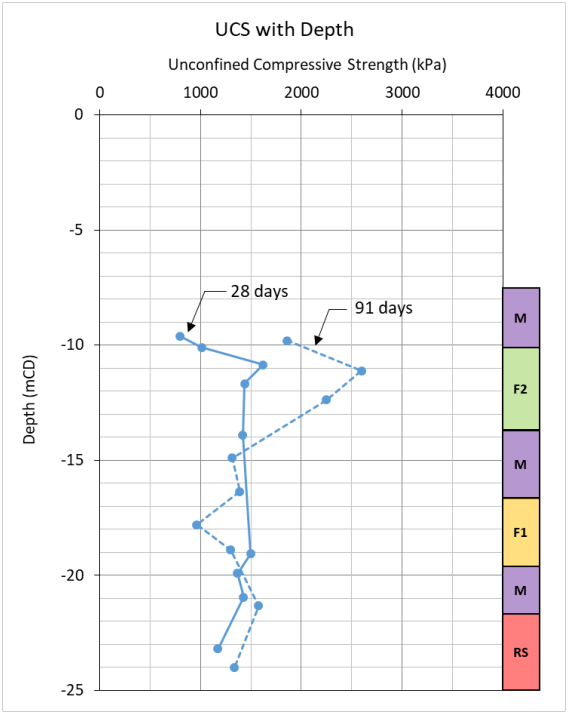

Fig. 5 UCS with depth for the cement dosage of 120 kg/m^3 of treated soil.

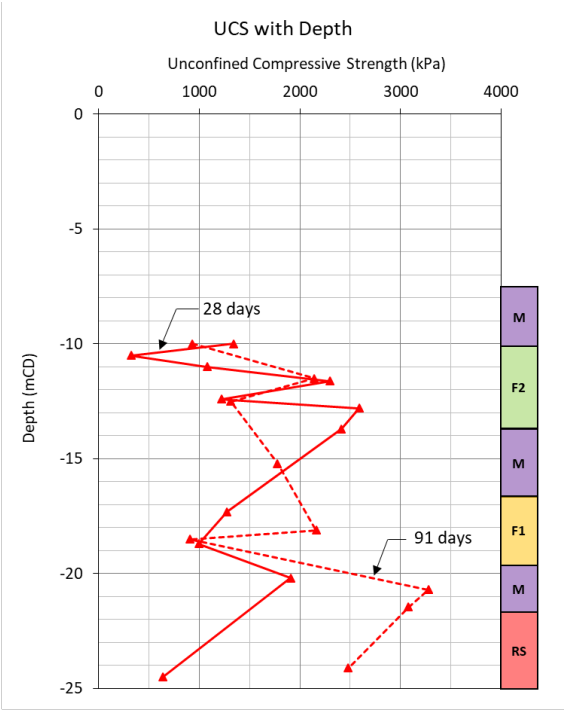

Fig. 6 UCS with depth for the cement dosage of 140 kg/m^3 of treated soil.

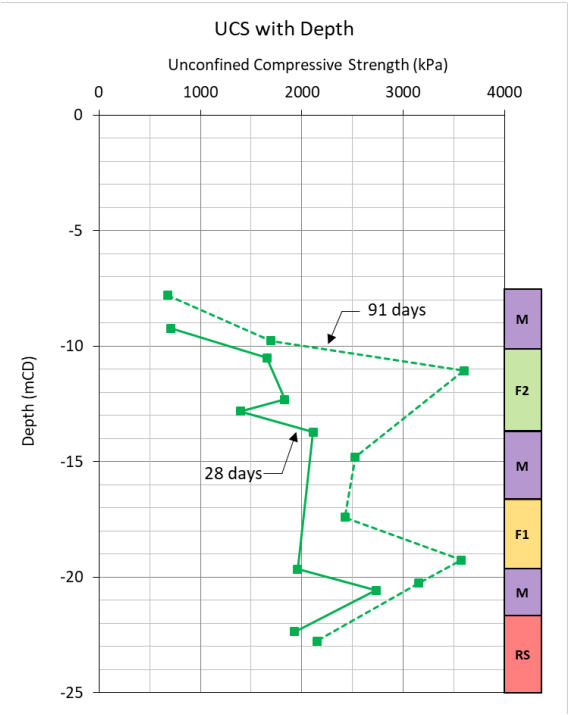

Fig. 7 UCS with depth for the cement dosage of 160 kg/m^3 of treated soil.

Permeability

Triaxial permeability tests were carried out for some of the cored samples. The permeability results at the various depths of the DCM columns have been plotted in Fig. 8.

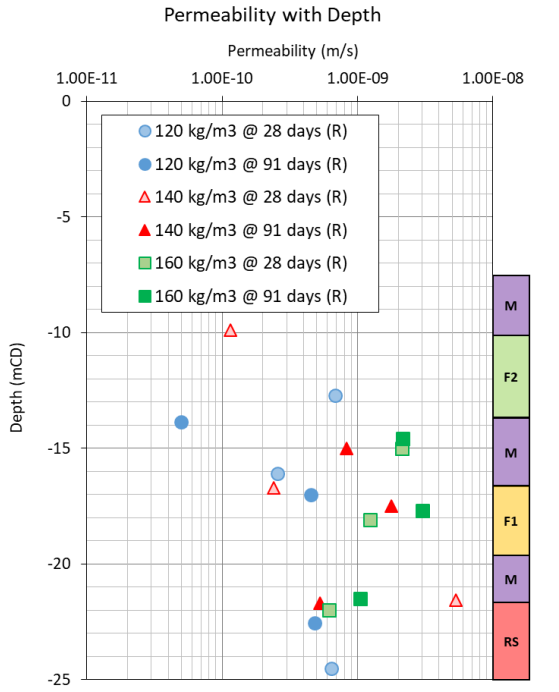

Fig. 8 Triaxial permeability tests result for some of the cored samples.

The permeability test results show that the core samples obtained from the DCM columns constructed with a cement dosage of 120 kg/m^3 were able to meet the permeability requirements of less than 10^{-9} m/s after 28 days and 91 days of curing. The permeability test results obtained from the DCM columns constructed with a cement dosage of 160 kg/m^3 was not satisfactory as it had obtained higher permeability values than the required. In addition, it was also observed that the sand (F1) layer tended to have higher permeability results. This is due to a lot more granular particles present in this layer.

A summary table of the UCS and permeability tests result obtained from the three different cement dosage of DCM core samples is shown in Table 1.

CONCLUSION

A quality assurance and quality control (QA/QC) plan for the construction of a DCM cutoff wall was proposed and consisted of two components: the operational mixing control the end result check.

To ensure the adequacy of the QA/QC plan, a site trial was conducted before the actual site works. Another objective of the site trial is to determine the optimal cement dosage and operation parameters in order to achieve the stringent strength and permeability requirements.

It was found that the DCM design implemented for the site trial did not fulfilled the DCM strength and permeability requirements. As observed from the non-uniform UCS results obtained through the DCM depth, different cement dosage may be required for the different soil types.

As such, the proposed QA/QC plan is not suitable. Additional site trials should be carried out to further refine the operation process such that good quality DCM columns with adequate strengths and low permeabilities can be constructed. This will enable the satisfactory performance of the DCM columns to improve slope stability and function as a seepage cutoff wall.

Table 1 Summary of UCS and permeability tests result.

Cement Dosage	Remarks	
	Unconfined Compressive Strength	Permeability
120 kg/m³	Almost all samples obtained higher than the upper limit of 450 kPa	All samples lower than $10\times^{-9}$ m/s
140 kg/m³		Average at 2.5×10^{-9}
160 kg/m³		Average at 1.7×10^{-9}

GEOTHERMAL ENERGY PILE-SOIL INTERACTION UNDER MECHANICAL LOADING AND THERMAL CYCLES

Alitking Anongphouth[1], Pooneh Maghoul[2] and Marolo Alfaro[3]
[1,2,3]Faculty of Engineering, University of Manitoba, Canada

ABSTRACT

Harvesting shallow geothermal energy for heating and cooling building spaces in winter and summer is considered environmentally friendly and renewable. Recently, geothermal energy piles have been used as heat exchanger elements in ground source heat pump systems to exchange heat with the ground underneath buildings for heating and cooling purposes. However, imposing thermal cycles on such piles may result in possible adverse effects on their structural and geotechnical performance. Comprehensive understanding of the behavior of these geothermal energy piles; therefore, is vital for their successful applications. This paper aims to investigate the geothermal energy pile-soil interaction subjected to a combination of mechanical loading and thermal cycles. Coupled thermo-hydro-mechanical (THM) finite element analyses were carried out on a generic geothermal energy pile using local climatic and geological conditions in Winnipeg. Numerical results are presented in this paper in terms of pile head displacements, strains, and stresses developed in the pile, as well as shaft friction and effective radial stresses along the pile-soil interface. The effects of heating and cooling on the ultimate geotechnical pile capacity are also presented. Based on the numerical results, it was found that the thermo-mechanical loads have considerable effects on the geothermal energy pile responses.

Keywords: Geothermal energy pile, Pile-soil interaction, Thermal cycles, Coupled THM modeling

INTRODUCTION

In recent years, geothermal energy piles or simply energy piles have been increasingly used as ground heat exchangers in ground source heat pump (GHSP) systems to harness shallow geothermal energy for building heating and cooling purposes. The systems are considered renewable and environmentally friendly. The energy piles are structural piles with heat exchange pipes (loops) attached inside the rebar cages before casting concrete. They serve as structural elements to support the buildings and also as ground heat exchangers to exchange heat between the buildings and the underlying ground. Using working structural piles as ground heat exchangers; however, has raised concerns about possible adverse effects of thermal loads on the structural and geotechnical performance of the piles. This means that thermally loading the piles may lead to over-stressing, loss of load-carrying capacities of the piles, and excessive settlements. Energy piles were first used in the construction industry in Austria more than three decades ago [1]. Their use then has spread throughout Europe and to North America in recent years. Nonetheless, there is still limited understanding of their behavior under the combined effects of thermal and mechanical loads. This paper aims to numerically investigate the behavior of the energy pile subjected to thermo-mechanical loads and under local climatic and geological conditions in Winnipeg, Manitoba, Canada.

NUMERICAL MODEL DESCRIPTION

Axisymmetric thermo-hydro-mechanical (THM) finite element analyses using PLAXIS 2D-2018 were carried out. Note that in this paper the negative sign (-) is used for compression and positive sign (+) is used for tension. A generic energy pile was hypothesized based on local ground conditions and pile foundation engineering practice in Winnipeg. The pile was assumed to have a diameter of 0.8 m and a length of 20 m. It was installed through Winnipeg lacustrine clay with a pile toe embedded 5 m into very dense silt till.

Material Characteristics

For numerical modeling, the soil profile was simplified based on [2] and consists of three main layers. The first layer is Winnipeg lacustrine clay, from 0 to 15 m below ground level (bgl). This layer is underlain by silt till, from 15 to 21 m bgl. Below this silt till is dolomitic limestone bedrock, extending to a great depth. The groundwater table is at 3 m bgl. For constitutive material models, the concrete energy pile was modeled as non-porous (solid) elastic material using the linear elastic model (LEM). Hardening soil with small strain stiffness model (HSSM) was used for the clay and till. The LEM was also used for the dolomitic limestone. Table 1 gives a summary of some material parameters used for numerical modeling.

Table 1 Some material parameters used for numerical modeling of the Winnipeg energy pile

Parameter	Winnipeg clay	Silt tilt	Dolomitic limestone	Concrete pile
Hydraulic conductivity, k_x, k_y (m/day)	$6.70x10^{-5}$	0.028	8.64	-
Specific heat capacity, c_s (kJ/t/°C)	830	720	1300	800
Thermal conductivity, λ_s (kW/m/°C)	$1.2x10^{-3}$	$1.5x10^{-3}$	$2.3x10^{-3}$	$1.8x10^{-3}$
Soil density, ρ_s (t/m^3)	1.83	2.34	2.45	2.55
Linear thermal expansion coefficient, α_{sL} (1/°C)	$5x10^{-6}$	$5x10^{-6}$	$5x10^{-6}$	$10x10^{-6}$

Model Setup and Boundary Conditions

The pile was assumed to be located right underneath the center of the building with a width of 30 m and without any basements. With these assumptions, the axisymmetric finite element model was used. The model domain was set at a distance of 50 m (> 2L) and 75 m (> 3L) for the side and bottom boundaries; respectively, as illustrated in Fig. 1. These distances were considered to minimize the potential effects of the assumed boundary conditions. The model domain was divided into zones for discretization in which very fine mesh sizes were used for the pile body, along the pile-soil interface, and around the pile toe in order to ensure that there were enough elements to capture the correct pile behavior. Coarser mesh sizes were used for the zones further away from the pile.

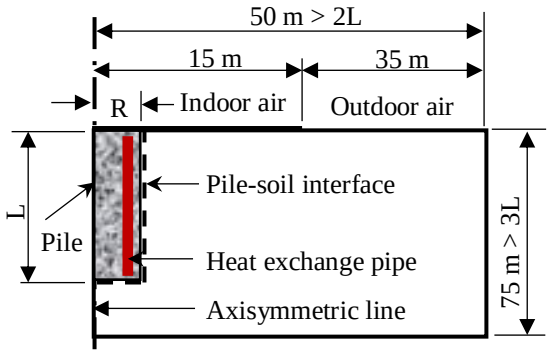

Fig. 1 Axisymmetric geometry setup (not to scale).

Free displacements were allowed at the top boundary. Both vertical and horizontal displacements were restrained at the bottom. Only vertical displacements were allowed at the left- and right-hand side boundaries. Drainage was allowed at the top and right-hand side boundaries. A closed flow boundary was assigned along the axisymmetric line and the bottom boundary. The heat flow was closed at the left- and right-hand sides. At the top boundary, the indoor air temperature was used as a boundary condition inside the building with a constant temperature of 20°C. The outdoor air temperature corresponding to climate variation was used as a boundary outside the building. A constant ground temperature of 7°C was assigned at the bottom boundary. The initial ground temperature for the entire model domain was also set at 7°C which was approximately the undisturbed average ground temperature in the Winnipeg area [3], [4].

A mechanical load of -1300 kN (compression), corresponding to the stress on the pile head of -2586 kPa, was applied in a drained manner and maintained on the pile head. In addition to this mechanical load, the energy pile was also subjected to thermal cycles due to heating and cooling by the circulating heat-carrying fluid in the heat exchange pipe installed inside the pile. In this study, a change of temperature of the fluid in the pipe inside the pile as a function of time from 0 to 40°C was used, as shown in Fig. 2. The convective boundary condition (line-based internal thermal boundary which implies a circular shell in the axisymmetric models) at 70 mm from the pile shaft was used to represent the heat exchange pipe. It was assumed that the changing pattern of the temperature in the pile with time followed the rising and falling pattern of the seasonal air temperature. The assumption was made based on the field observation by [1] on the operational energy geostructures. In the simulations, the energy pile was subjected to six heating-cooling cycles, corresponding to six years of heating and cooling of the building. Here, the term at the end of heating (EOH) means the pile was heated to the maximum temperature (the peak). Likewise, the term at the end of cooling (EOC) means the pile was cooled to the minimum temperature (the trough) in the particular year.

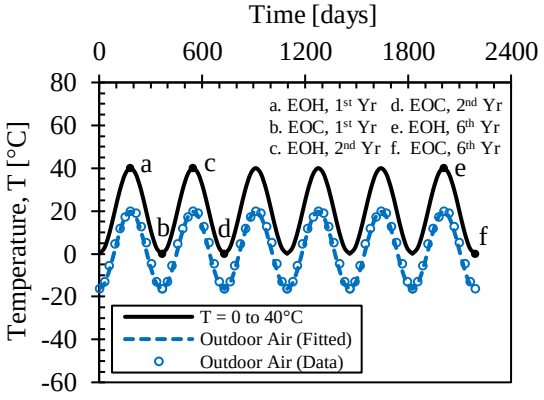

Fig. 2 Outdoor air temperature variation and thermal cycles applied to the pile starting from the first of January.

NUMERICAL RESULTS AND DISCUSSIONS

Temperature Distributions

Temperature profiles along the pile-soil interface were relatively constant, except reductions or roll-offs near the pile ends due to mechanisms of heat transfer at these locations. There were little changes (increased from 38.5 to 38.7ºC and from 7.9 to 8.9ºC) in the maximum temperature values at the EOH and EOC from the first to sixth year, respectively. Nonetheless, the ground temperatures seemed to increase marginally with time (overall ground warming over time). This was due to the influence of heat loss through the ground floor slab that accumulated in the ground underneath the building with time and also due to the imbalance in thermal loads during heating and cooling periods in relation to the initial ground temperature. Fig. 3 shows the horizontal temperature profiles at the mid-depth of the pile from the pile center to 15 m away at the EOH and EOC. As seen in the figure, large changes in the ground temperatures only occurred within a distance of about 2 m (≈ 2.5D) from the pile center.

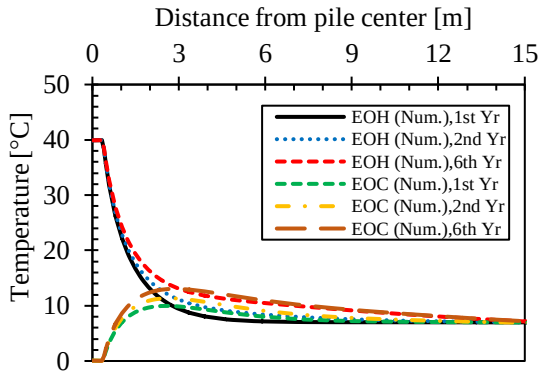

Fig. 3 Temperature profiles at the mid-depth of the pile from the pile center to 15 m away at the EOH and EOC in the 1st, 2nd, and 6th year.

Excess Porewater Distributions

Thermally induced excess porewater pressures (EPWPs) were induced in the clay layer with low permeability. There were no EPWPs induced in the till layer located below -15 m because of its high hydraulic conductivity. Heating induced negative EPWPs and cooling produced positive EPWPs. As shown in Fig. 4, the maximum negative values of EPWPs at the EOH were -9.1, -8.8, and -7.5 kPa in the first, second, and sixth year, accordingly. The reduction in EPWPs may be partially due to the consolidation. Another reason may result from the lesser temperature difference between the pile and surrounding ground at the EOH due to overall ground warming. The opposite occurred during cooling in which the negative EPWPs were generated with the maximum values of 5.2, 5.7, and 6.6 kPa at the EOC in the first, second, and sixth year, respectively. The negative EPWPs somewhat increased with time from the first to the sixth year, resulting from the larger temperature difference between the pile and surrounding ground at the EOC due to overall ground warming.

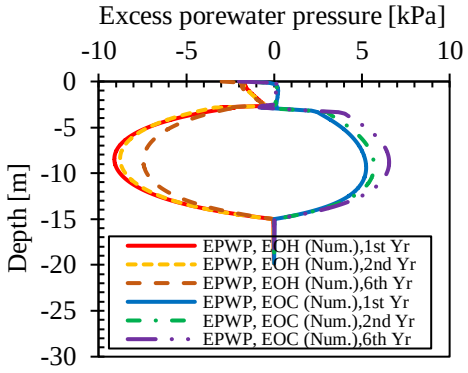

Fig. 4 Thermally induced excess porewater pressures (EPWPs) along the pile-soil interface at the EOH and EOC in the 1st, 2nd, and 6th year.

Pile Head Vertical Displacements

Figure 5 shows the simulated vertical pile head displacements (settlements and uplifts) for six-year heating and cooling cycles. The mechanical load (M) caused a pile head settlement of -1.89 mm (-0.24% D). The thermal cycles caused to pile head displacements to move downwards gradually (a phenomenon of ratcheting settlements). This was because of the cyclic accumulated plastic strains in the surrounding soils. The dissipations of excess porewater pressures in the clay may also contribute to the continuing settlements. At the EOH in the first to sixth year, the uplifts of the pile head of 2.78 mm and 0.52 mm were obtained, a drop of 81.3%. On the other hand, the settlements at the EOC in the first to the sixth year were -4.18 mm and -5.91 mm (-0.74% D), increasing by 41.4%.

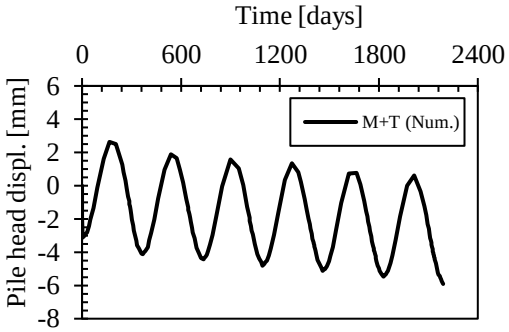

Fig. 5 Pile head vertical displacements (uplifts and settlements) during six thermal cycles.

Pile Axial Strains

The mechanical load (M) produced contractive strains (negative) in the entire pile as shown in Fig. 6. In contrast, heating induced expansive strains (positive) in the pile as shown in Fig. 7(a). The strains at the EOH in the sixth year were generally higher than in the 1st year. Similar to the M load, cooling induced contractive strains in the pile as shown in Fig. 7(b). As seen in the graph, lower contractive strains were observed at the EOC for the higher simulated times.

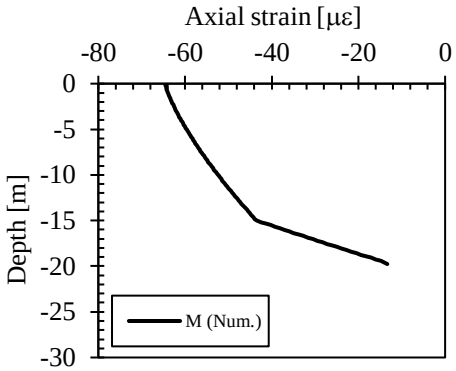

Fig. 6 Axial strain profiles due to the mechanical load (M) only.

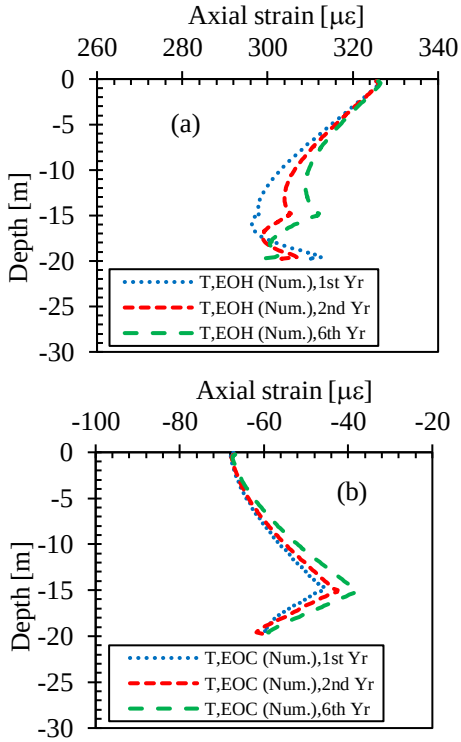

Fig. 7 Axial strain profiles (a) thermal load (T) at the EOH and (b) at the EOC in the 1st, 2nd, and 6th year.

Pile Axial Stresses

The M load of -1300 kN on the pile head induced compressive stresses in the pile, which were plotted in all figures for reference as shown in Fig. 8 and Fig. 9. In these figures, the mechanically induced stresses transferred mostly into the till layer, located below -15 m, beneath the Winnipeg lacustrine clay. Heating induced axial compressive stresses in the pile, which is similar to the effect of the mechanical load. The maximum thermally induced compressive stresses, as shown in Fig. 8(a), were -1391 kPa at the EOH in the first year. This value reduced to -1302 kPa in the sixth year. As shown in Fig. 8(b), at the EOH, the axial compressive stresses increased in the pile as a result of thermo-mechanical loads. This was because heating induced additional compressive stresses in the pile.

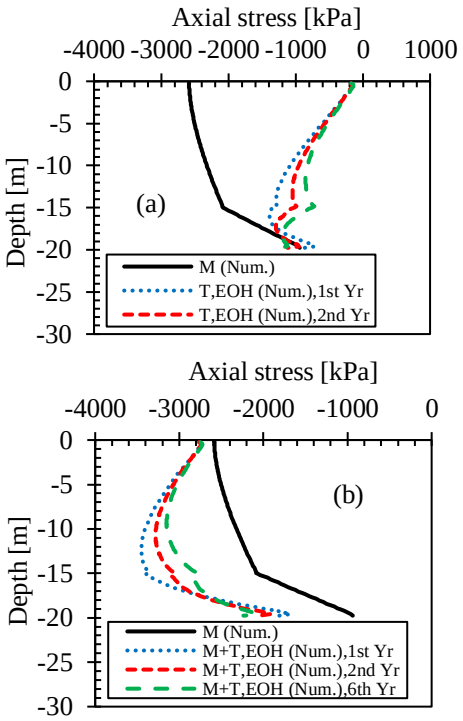

Fig. 8 Axial stress profiles (a) thermal (T) and (b) thermo-mechanical (M+T) at the EOH in the 1st, 2nd, and 6th year.

On the other hand, cooling generated axial tensile stresses in the pile in contradiction to the effect of the mechanical load as shown in Fig. 9(a). The maximum thermally induced tensile stresses located at about -15 m were 982 kPa and 1290 kPa at the EOC in the first and sixth year, accordingly. This shows an increase in the maximum thermally induced tensile stress of 31.4% from the first to sixth year. As shown in Fig. 9(b), there were large reductions of the axial compressive stresses in the pile for the combined effects of mechanical load and thermal cooling.

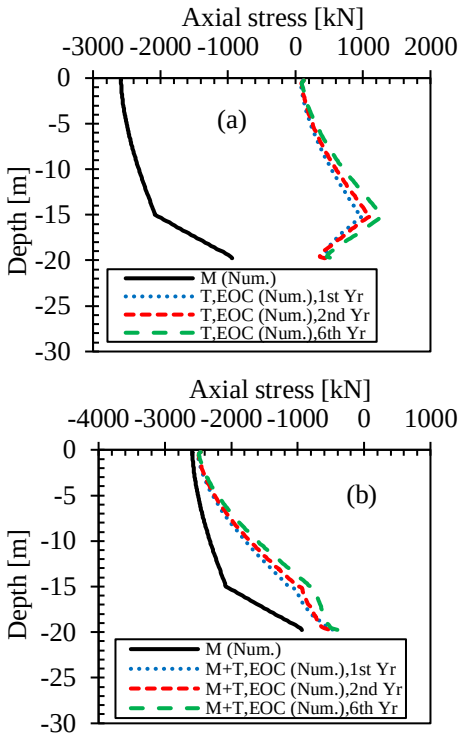

Fig. 9 Axial stress profiles (a) thermal (T) and (b) thermo-mechanical (M+T) at the EOC in the 1st, 2nd, and 6th year.

Mobilized Shaft Friction

Figure 10 shows the mobilized shaft friction along the pile-soil interface at the EOH and EOC in the first, second, and sixth year. It was observed that the M load induced positive skin friction along the whole pile length. Larger values were mobilized in the till layer below -15 m depth than in the overlying clay layer. This is because the till has much higher stiffness and strength. At the EOH, as shown in Fig. 10(a), the shaft friction in the upper two-thirds of the pile reduced and resulted in small negative values. In the lower one-third; the shaft friction increased considerably. Conversely, at the EOC, the shaft friction increased in the upper two-thirds portion, but it reduced in the lower one-third part where the pile was installed through the till layer as shown in Fig. 10(b). Some irregularities in shaft friction in the till were observed as shown in the graphs. This may be due to a sudden change in the soil stiffness from a very low value in the clay to a very high value in the till and also high permeability of the till which somehow caused oscillations in the THM computations.

Mobilized Effective Radial Stresses

Mobilized effective radial stress profiles along the pile-soil interface at the EOH and EOC are shown in Fig. 11. In Fig. 11(a), heating generally caused the effective radial stresses to increase along the entire pile length. There were marked rises in the till layer, and again, some irregularities in the radial stresses were noticed which may be due the same reasons explained earlier in the mobilized shaft friction section. Cooling did the opposite to the heating in which the radial effective stresses reduced in the lower two-thirds of the pile in the till layer but slightly increased in the upper two-thirds as shown in Fig. 11(b). This later stress increase was due to the stress redistributions to somewhat compensate the reduction in stresses at the lower part of the pile and at the pile toe at the EOC. The change in effective radial stresses could be caused by a change in a lateral soil pressure coefficient (K) due to relative thermal expansions or contractions of the pile and the surrounding soils.

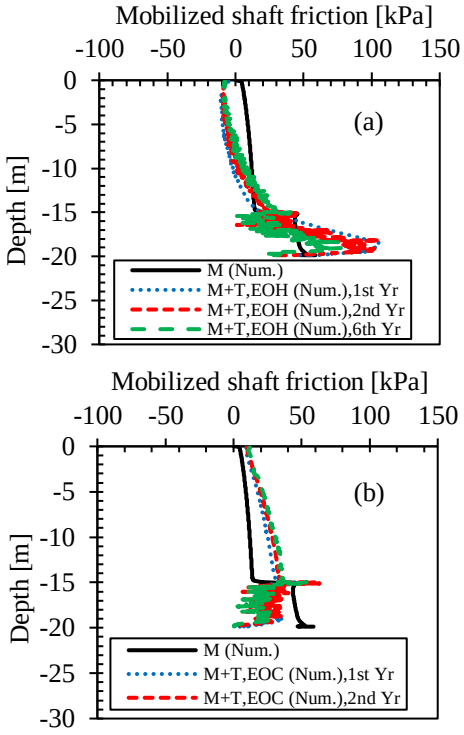

Fig. 10 Mobilized shaft friction profiles along the pile-soil interface (a) at the EOH and (b) at the EOC in the 1st, 2nd, and 6th year.

Thermal Effects on Geotechnical Pile Capacities

As shown in Fig. 12, a geotechnical pile capacity was generally increased upon heating. At the EOH, the ultimate pile capacity, determined using the 10% D failure criterion [5], increased by 12%. On the other hand, cooling caused the ultimate pile capacity to reduce. The reduction of 9% was observed at the EOC. The reason for the increase in ultimate geotechnical capacities of the piles during heating was mainly due to the increase in effective radial stresses along the pile. When the pile was heated, it would try to expand

vertically and radially. The radial expansion, in this case, could not fully mobilize because of the restriction of the surrounding soils. Consequently, higher radial stresses were developed along the pile-soil interface, leading to an increase of the ultimate geotechnical capacity of the pile. The opposite reason seemed to be valid when the pile was cooled. In addition, because of the contraction (moving upwards) of the pile toe during cooling, there was a reduction of the end-bearing stress which could also contribute to the decrease in the ultimate geotechnical capacity of the pile at the end of cooling.

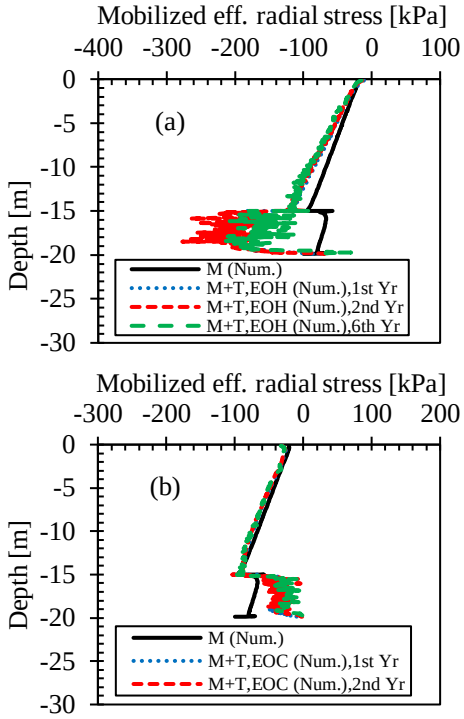

Fig. 11 Mobilized effective radial stress profiles along the pile-soil interface (a) at the EOH and (b) at the EOC in the 1st, 2nd, and 6th year.

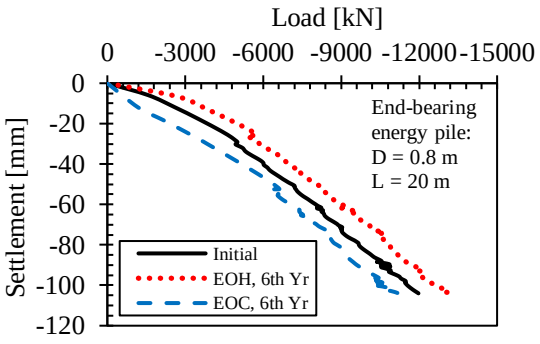

Fig. 12 Load-settlement curves simulated at the initial stage, at the EOH and EOC in the 6th year.

CONCLUSIONS

Temperature changes in the pile had significant effects on its displacements, strains, and stresses. In general, heating caused the pile to expand. These expansions resulted in expansive strains in the pile. If the pile cannot expand freely due to the shaft friction and end restraints, thermal compressive stresses would be generated in addition to the mechanically induced stresses. Therefore, for the thermal and mechanical combined effects, the compressive loads in the pile would be higher during heating. Cooling caused reverse effects in which the pile contracted. In consequence, compressive strains were generated and led to the tensile stresses build up in the pile. Therefore, the compressive stresses in the pile were less for the combined thermo-mechanical effects. In terms of pile head displacements, heating produced uplifts of the pile head while cooling caused settlements. The settlements kept on increasing with increasing thermal cycles (ratcheting settlements).

The heating-cooling cycles of the pile also affected the surrounding ground temperatures to some distances which were dependent on the simulation times. Excess porewater pressures were generated in the clay with low hydraulic conductivity. The mobilized shaft friction and the effective radial stresses along the pile-soil interface were also affected by the temperature changes to some extent.

Geotechnical pile capacities generally increased during heating but reduced during cooing. For the Winnipeg energy pile, the ultimate pile capacity increased at the end of the heating by about 12% but decreased at the end of cooling by about 9%.

ABSTRACT

Interaction between the soil and the structure is complex problematic. For the better understanding of the behaviour of the flat concrete slab in contact with the subsoil series of tests were performed in the Faculty of Civil Engineering in Ostrava in the Czech Republic. This article focuses on the fibre reinforced concrete flat slab with dimensions 2000 x 2000 x 150 mm loaded by vertical and horizontal force. This loading is typical for building in undermined areas. The article describes the course, results and the evaluation of the experimental test, which was performed on special test equipment Stand over a four day period. Slab was exposed to constant load of 100 kN in vertical direction and about 50 kN in horizontal direction. The deformations of the top surface of the slab were monitored by many sensors in both directions. Concrete deformation and cracks was also observed during the experiment. Deformation curves in the selected cross-section of the slab were evaluated from the measured data. Together with experiment the laboratory tests were performed from the same dough of concrete like the slab itself. The laboratory results are also present. The slab is compared to the vertically loaded slab with same characteristics.

Keywords: Fibre-reinforced concrete composite, soil-structure interaction, vertical and horizontal loading, sliding joint, punching

INTRODUCTION

This article deals with slab-soil [1-3] using fiber reinforcement concrete (FRC) [4-7]. A specific research task is focusing to horizontal loading with sliding joint [8]. This problematic is typical for undermined areas and mining activities, which affect the landscape on the surface [9]. As a result of deep mining, terrain deformations gradually occur on the surface. Terrain deformation can be described by the following parameters: slope, curvature, displacement, and horizontal displacement. This is mainly the region Ostrava-Karviná region in the Czech Republic. Friction and significant normal forces occur between the foundation structure and the subsoil as a result of deep mining and the terrain deformations.

Possible solutions to this problem include a sliding joint design - sliding joints from an asphalt belt [8], which was used in the present experimental program. The idea of using an asphalt belt as a sliding joint comes from the 70's of the 20th century. The first experiments have already been implemented by Balcarek and Bradac [8]. However, the number of experiments and horizontal / vertical load configurations was limited. With regard to the development of materials engineering and properties of asphalt belt, the performed experiments give insufficient results for further research.

The selected board composite is FRC. FRC has improved mechanical properties compared to plain concrete. FRC belongs to the group of fiber concrete. The fiber concrete group is divided according to the material used, the shape and length of the wire in the concrete mixture [11-13]. An important factor is the dosage amount of wires in the concrete mixture. The FRC has typically a better tensile strength and toughness. The actual determination of the responsibility and mechanical testing of FRC are dedicated experts in researches and recommendations [14-17]. In particular, there are a number of approaches that differ in the test configuration to determine the tensile strength. The scope of the tests and the description of the mechanical properties are also influenced by the used design procedure. Research in the field of concrete structures and punching of concrete slabs are also related [18-24].

Fig. 1 Special testing device Stand.

FRC typical applications include the construction of industrial floors and foundations. This also falls within the research area. The slab-subsoil interaction needs to be taken into account while designing industrial floors [25-26]. Analytical and numerical methods are used to solve this problem [27-29]. Numerical methods based mainly on finite element method (FEM) finds wider application with the development of computer technologies. It is important to use a suitable interaction system between the upper structure, foundation and subsoil in the computational model of construction when solving a task. Interaction occurs in the interconnection system, where physical, geometric and design nonlinearities are also included in the calculation.

EXPERIMENTAL PROGRAM

The experimental program involves testing two fiber-concrete slabs interacting with the subsoil. The tests variants of the experiments differ in the load character. The experimental tests are performed on a specialized test facility, the so-called Stand [30] shown in Fig. 1.

The plate tests are also supplemented by laboratory testing to determine mechanical properties. Special testing equipment Stand allows to test the interaction of concrete slab with subsoil. The test device can develop a vertical load up to 1000 kN using a hydraulic press [30]. The device was specially modified by adding horizontal hydraulic cylinders to develop a horizontal loading in addition to vertical loading. Improved device can develop a horizontal load up to 295 kN. The test equipment includes a data logger for evaluating deformations using up to 24 track sensors. Tested slab has dimensions 2000 x 2000 mm with height 150 mm. Used concrete mixture is described in Tab. 1.

Table 1 Material composition of concrete.

Description	Type/Amount
Consistency	S3
Maximum grain	CEM I 42.5
Minimal cement content	300 kg
Water Factor: *v / c*	0,6
Aggregates 0/4	870 kg
Aggregates 4/8	150
Aggregates 8/16	820 kg
Water	189 l
Plasticizer	2.9 l

The Dramix® 3D 65/60 BG fiber type was used in dosage 25 kg/m^3. The basic material characteristics of the wires are given in Tab. 2. These wires ends with double bending, their shape is shown in Fig. 2.

The first experiment was focused on tracking the vertical deformation of the plate using the deformation sensors and the load capacity of the plate. The loading of the FRC was in steps of 75 kN / 30 min to its maximum bearing capacity. The second part of the experiment attempted to approximate the conditions corresponding to the undermined area. Sliding joint was created between the FRC slab and subsoil using asphalt strips and underlay concrete width 50 mm. A horizontal load was caused by a gradual increase of horizontal load of about 50 kN with two hydraulic cylinders from one side of the plate. One hydraulic cylinder exerted a load of about 25 kN. This load was kept constant throughout the experiment. Uniform transmission of this load was ensured by a specially designed construction created for this type of experiment. Construction consists of mounting frame, hydraulic cylinder brackets and support frame.

Table 2 Fiber properties Dramix® 3D 65/60 BG.

Description	
Length [mm]	60
Diameter [mm]	0.9
Aspect Ratio	67
Tensile strength [N/mm^2]	1160
Effect on consistency [s]	8
Impact on concrete strength [kg/m^3]	15
Modulus of elasticity [GPa]	200

LABORATORY TEST OF FRC

The experimental tests of the plates are supplemented by laboratory tests. Samples for laboratory tests were performed at the same time as casting slabs from the same batch of mixture. The following characteristics were tested in laboratory: compressive strength on cube ($f_{c,cube}$), compressive

strength on cylinder ($f_{c,cyl}$), Modulus of elasticity ($E_{c,cyl}$), transverse tensile strength perpendicular to filling direction ($f_{ct,split,A}$), transverse tensile strength parallel ($f_{ct,plit,B}$), three point bend test with no cut for a span 500 mm ($f_{c,fl,3B600BZ}$) and four point bend test for span 500 mm ($f_{c,fl,3B600BZ}$).

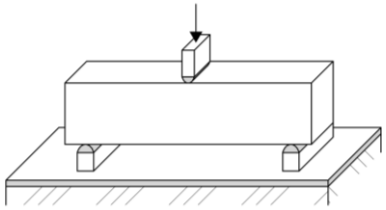

Fig. 3 Three-point test scheme.

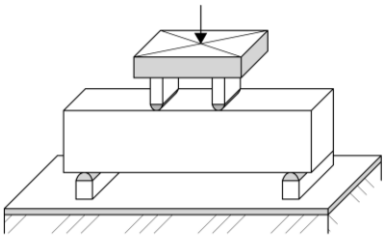

Fig. 4 Four-point test scheme.

The test scheme is shown on Fig. 3 and Fig. 4. Laboratory test results are given in Table 3 in summary.

Table 3 Laboratory test results.

Notation.	Number samples	Min. value	Max. value	Medium value
$f_{c,cube}$	12	24.5	37.4	30.4
$f_{c,cyl}$	12	20.3	27.9	23.5
$f_{ct,split,A}$	12	2.1	3.2	2.6
$f_{ct,split,B}$	12	1.4	3.3	2.1
$E_{c,cyl}$	6	15.6	24.5	19.3
$f_{c,fl,3B600BZ}$	5	4.0	4.4	4.2
$f_{c,fl,4B600BZ}$	4	2.6	4.0	3.6

The influence of wire orientation results has showed during the testing. The tensile strength perpendicular to the filling direction was bigger than in parallel direction. The modulus of elasticity is only 19.3 GPa. With comparison of bending tests, it is seen that the strength of the four-stroke test is smaller. Typical course of load-displacement diagrams from performed bending tests is on Fig. 5.

FRC SLAB OF EXPERIMENTS

The first performed experiment is a variant with a vertical load. Vertical deformation was observed during the experimental testing using 24 tensometers (Fig. 6). The vertical loading was performed in steps 75 kN / 30 min until the maximum bearing capacity reached. The loading process is in Fig. 7.

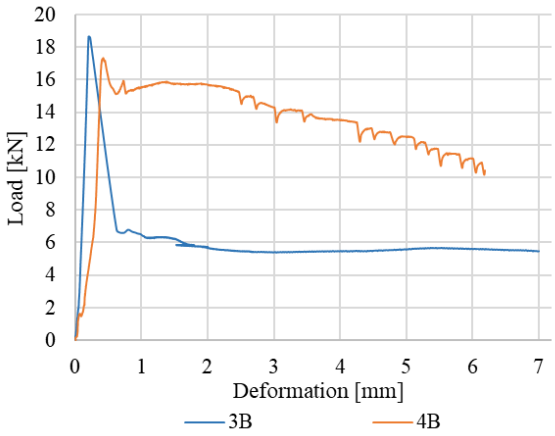

Fig. 5 Typical load-displacement diagram for three and fourth-point bending test.

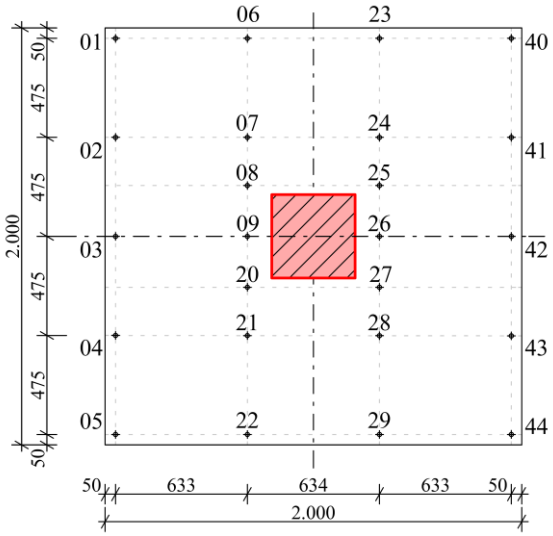

Fig. 6 Placement of vertical deformation sensors for vertical loading.

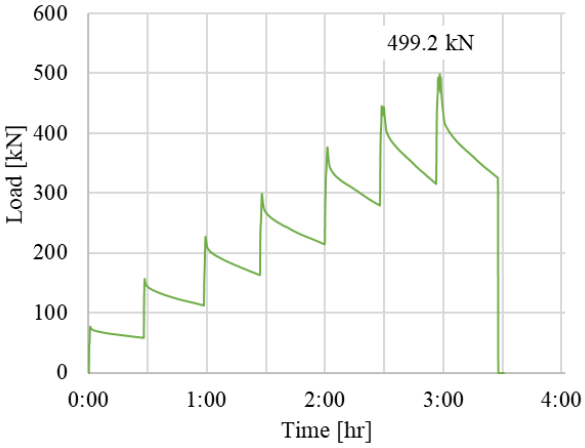

Fig. 7 Loading process.

The vertical deformation in cross-sections and maximum bearing capacity were evaluated based on

measured data. The deformation of vertical sensors for selected cross-section are displayed at Fig. 8. Maximal measured vertical deformation was 26.72 mm in sensor 09. The lifting of edges occurs at higher load intensities. Maximum lifting was observed in sensor 42 at amount of 13.06 mm. Maximum bearing capacity of the slab was reached in 7th loading step under load of 499.2 kN.

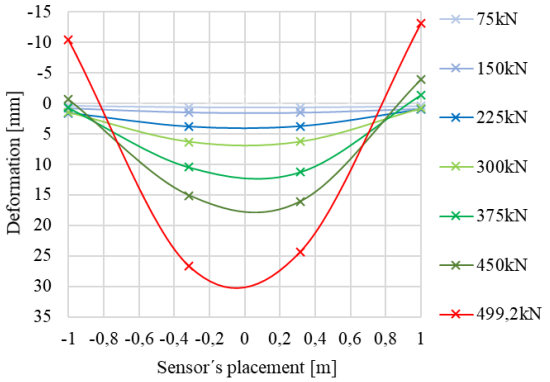

Fig. 8 Deformation in cross-section for potentiometers 03-42.

Gradual decrease in bending stiffness is well visible from Fig. 8. The decrease was caused due to the gradual development of cracks in concrete. The cracks in concrete can be seen in Fig. 9.

Fig. 9 Deformation of the slab for constant increase of vertical force.

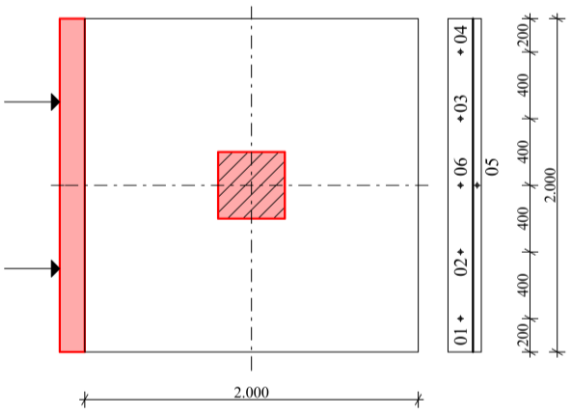

Fig. 10 Location of horizontal measuring potentiometers for horizontal loading experiment.

The second experiment contained the combination of the vertical and horizontal loading. The experiment also included the sliding joint created by the asphalt belt and the concrete bed width 50 mm. The experimental testing scheme is in Fig. 10.

Constant load of size 100 kN was maintained in vertical direction using hydraulic piston. This force represents the load from the upper structure. Furthermore, a horizontal load of about 50 kN was applied from one side of the plate using two hydraulic cylinders. The horizontal load represents the effects caused by undermining. This load was kept constant throughout the experiment. Uniform transmission of this load was ensured by a specially designed construction created for this type of experiment. The horizontal displacement between the concrete bed layer and the FRC was monitored from the other side of the board. The vertical and horizontal deformation was recorded by data logger every 5 minutes. The experiment scheme is drawn in Fig. 11. The ambient temperature, temperature in the middle of slab and temperature at the edge of the slab to verify slab temperature stability were measured every 15 minutes. The ambient temperature was reaching 5-22°C during experiment. The temperature in the middle of slab was around 10°C and the temperature at the edge of the slab was slightly higher about 13°C. The experiment took 4 days.

Fig. 11 Positioning of the sensores for experment with horizontal load.

The final horizontal displacements are at Fig. 12. Course of the ambient temperature and the temperature in the middle of slab are at Fig. 13.

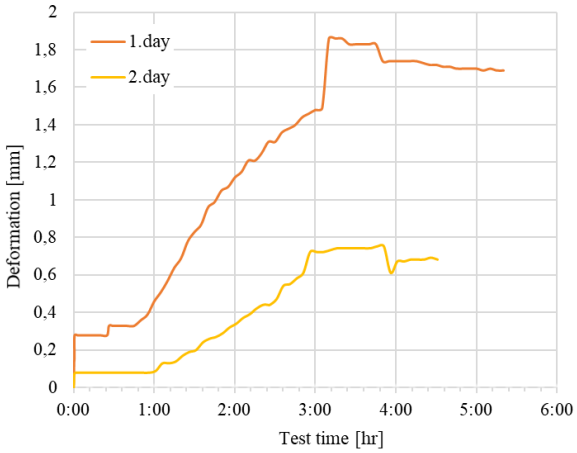

Fig. 12 Horizontal deformation corresponding to 06 sensor.

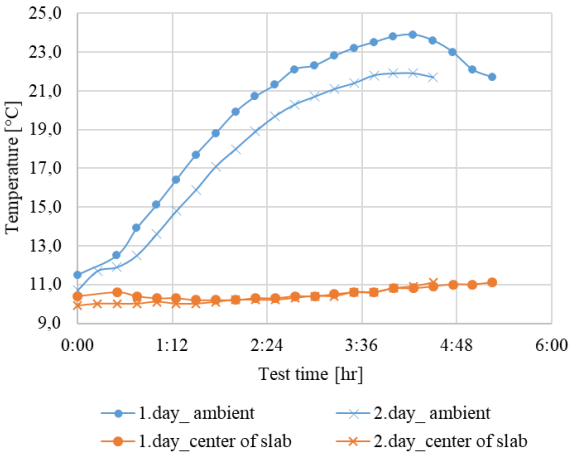

Fig. 13 Temperatures course.

CONCLUSIONS

The article is focused on interaction of slab and subsoil. The performed experiment focused on application of FRC for horizontal loading. Experiment was performed on slab with dimension 2000 x 2000 mm and height 150 mm. The special testing equipment Stand was used for testing. The sliding joints was used among the specifics of the experiment. Experimental testing proved increase of total bearing capacity and ductility of tested slabs already at dosage of 25 kg/m^3 fibres in previously tested slab [10]. The cracking and destruction of FRC occurred gradually. The use of sliding joint was confirmed in case of horizontal loading. The laboratory program can be also described as very usefull since it allows to describe in detail the mechanical properties of FRC, which are necessary for follow-up tasks for research like numerical modeling of the task which will be performed in the future by the authors of article.

STABILITY ASSESSMENT OF AN AGING EARTH FILL DAM CONSIDERING ANISOTROPIC BEHAVIOUR OF CLAY

Irene Olivia Ubay[1], Moises Alfaro III[2], Marolo Alfaro[3] and James Blatz[4]
[134]Faculty of Engineering, University of Manitoba, Canada; [2]KGS Group, Canada

ABSTRACT

Anisotropic behaviour of the clay core, blanket, and foundation of an aging water retaining earth fill dam may be a result of environmental loading. The repeated wetting-drying and freezing-thawing cycles produce fissures that can cause degradation of strength with time. The compaction of clay core and clay blanket during the construction of the dam may also play a significant role in its anisotropic behaviour. Undisturbed clay samples taken from field investigations of an existing aging water retaining earth fill dam were tested in the laboratory to obtain the parameters used in the numerical modeling. A testing program was implemented in order to determine the soil classification along with mineralogy, strength, and deformation characteristics of the collected clay samples. Laboratory tests include index property tests, Scanning Electron Microscopy (SEM) tests, X-Ray Diffraction (XRD) tests, one-dimensional consolidation oedometer tests, consolidated drained direct shear tests, and isotropically consolidated undrained triaxial compression tests. Results from slope stability analyses to assess the aging earth dam, using parameters from laboratory investigation results, are presented in this paper.

Keywords: Anisotropy, Earth fill dam, Stability, Clay core, Clay blanket

INTRODUCTION

Anisotropic soils have directionally dependent properties. Anisotropy is sometimes referred to as the difference of a physical soil property along different directions. Most natural clay has a particle arrangement or fabric that is initially anisotropic due to its platy particle shape and deposition process. Repeated expansion and contraction of clays due to wetting-drying and freezing-thawing can also cause fissures leading to mechanical anisotropy. Fissures tend to create planes of weaker strength and higher permeability in clays [1]. Anisotropy in structural composition, mechanical behavior, and shear strength of Lake Agassiz clays had been studied extensively by different researchers and was thought to influence embankment performance [2]–[6].

Despite the increasing awareness of anisotropy in geotechnical engineering, most geotechnical design approach would typically describe soil as isotropic due to convenience or lack of information. Research is currently ongoing to evaluate the stability of earth dams in hydroelectric generating stations considering anisotropic behaviour as part of its periodic dam safety review. It will also aid in evaluating long-term performance of earth dams and in carrying out proactive rehabilitation, if the performance does not meet current dam safety standards. This paper presents the stability assessment of an aging earth dam considering clay anisotropic behaviour using parameters determined from laboratory test results performed on undisturbed samples taken from field investigations.

SITE INVESTIGATION AND SOIL SAMPLING

An aging water-retaining earth fill dam that was constructed in the 1950s with an upstream inclined clay core. The local clay material used in the construction of the dam was classified as high plasticity lacustrine clay, often described as highly fissured in nature with nuggetty or crumbly appearance.

Undisturbed soil sampling of the clay core and foundation were completed during the fall season when the ground was still unfrozen. Continuous soil sampling by means of a Hollow Stem Auger (HSA) using Shelby tubes with a diameter of 102 mm (4 in) was used to collect samples from predetermined borehole locations.

Shelby tube samples of the clay foundation were obtained from test pits. These samples have two orientations: vertical and inclined. Vertical Shelby tube samples were simply pushed perpendicular into the test pit floor. Inclined Shelby tube samples were pushed into the wall of a test pit with an angle of inclination of 53° from the horizontal, as shown in Fig. 1.

Soil sampling of the clay blanket was done during the winter season as the frozen reservoir allowed the drilling equipment to be appropriately positioned over borehole locations. Typical 76 mm (3 in) diameter Shelby tubes on a track-mounted piston sampler was used to collect clay blanket samples. Multi-directional sampling of the clay core and blanket were not performed to reduce further disturbance in these locations.

Fig.1 Shelby tube clay foundation sample with inclined orientation

EXPERIMENTAL INVESTIGATION

Several laboratory tests were conducted to determine the index properties, deformation characteristics, mineralogy, and strength characteristics of the collected clay core, blanket, and foundation samples. Tests were in accordance with ASTM standards.

Index Properties and Deformation Characteristics

The index properties of the tested samples are shown in Table 1. Extruded clay core samples were a mottled mix of brown and grey with random silt lenses and silt pockets. It had a matted texture with medium to stiff consistency. Clay blanket samples were brown in color, with soft to medium consistency in the upper layer; and mottled mix of brown and grey with stiff to very stiff consistency from 0.6 m and below. The clay foundation samples were mottled mix of brown and grey in color with random silt pockets and was intensely fissured. All tested samples were classified as "fat clay" of high plasticity (CH) according to the Unified Soil Classification System (USCS). Deformation characteristics were based on one-dimensional consolidation (oedometer) test results.

Particle Orientation and Mineralogy

Scanning Electron Microscope (SEM) with back-scattered electron and Energy Dispersive X-ray (EDX) system was used to examine the particle orientation of the prepared carbon coated specimens. SEM images of the clay core (Fig. 2) displayed an edge-to-edge contact and slight particle orientation whereas clay blanket samples (Fig. 3) showed that most particles formed broad overlapping sheets. Images of clay foundation samples (Fig. 4) show predominantly edge-to-edge contacts with random non-clay particles without a preferred alignment or orientation.

X-ray diffraction (XRD) testing was performed to determine the mineralogical composition of the clay and non-clay constituents of the samples. Figure 5 shows XRD results from clay core, foundation, and blanket. All samples show the same mineralogical composition. Clay minerals present are mostly interlayered smectite and illite, with some kaolinite, mica and traces of attapulgite. Non-clay minerals are composed of quartz, feldspar, and dolomite. The clay was thought to be an expansive type as the dominant clay mineral was smectite. Observed non-clay minerals such as quartz and feldspar are typical composition of silt, consistent with the observed of silt pockets. Similar findings were also reported by Baracos [2] found in his study on Lake Agassiz clay and by Loh and Holt [6].

SHEAR STRENGTH PARAMETERS

Multi-directional shearing tests were conducted to determine strength anisotropy. Vertical clay foundation Shelby tube samples determined cross shear strengths from isotropically consolidated undrained triaxial compression (CIU) tests. Inclined Shelby tube samples of clay foundation that underwent CIU testing provided horizontal shear strength values. For clay core and clay blanket test specimens, cross-shear strengths were determined from CIU tests. As it was not possible to obtain inclined samples from the clay core and blanket, horizontal shear strengths were determined by means of consolidated drained (CD) direct shear testing from vertical Shelby tube samples. Residual strengths were determined from direct shear tests. Multiple reversal method was used wherein clay samples were repeatedly sheared until 100 % strain was reached, which corresponded to about 63 mm of displacement.

Undrained shear testing results are shown in Fig. 6, Fig. 7, and Fig. 8 for clay core, blanket, and foundation samples, respectively. Figure 6 shows that clay core samples sheared at a mean effective stress between 100 kPa to 300 kPa exhibit an isotropic elastic behaviour ($m\Delta p \approx \Delta u$), with a slight anisotropy observed when the clay core was sheared under a lower confining stress less than 100 kPa. This could be due to the tendency of fissured materials to dilate. Clay blanket samples also show slight elastic anisotropy as seen in Fig. 7. Both vertical and inclined clay foundation samples show elastic anisotropy as shown in Fig. 8. Inclination of stress paths to the left ($m>1$) indicated that the sample had higher horizontal stiffness than its vertical counterpart [4]. Specimens sheared higher than 300 kPa behaved typically for a normally consolidated specimen.

The clay core and blanket CIU results exhibited a more uniform failure envelope compared to the clay foundation, which exhibited a bilinear failure envelope. Higher frictional resistance was observed for confining stresses less than 100kPa, and decreased as the confining stress increased. The bilinear failure envelope was thought to be attributed to the intense fissuring of the clay foundation leading to an increase in dilatancy under lower stress levels [7]

The stress-strain behavior from drained shear strength test results conducted on all samples is seen in Fig.9. The foundation clay and clay blanket behaved similarly as both underwent strain softening as compared to the clay core. This behaviour could be attributed to the fissured nature of the clay blanket and foundation.

Cross-shear and horizontal shear strength parameters were interpreted using Critical State Soil Mechanics (CSSM) approach and summarized in Table 2. Strength anisotropy is evident having cross shear strength values different that horizontal shear strength in all tested clays. Clay core and blanket

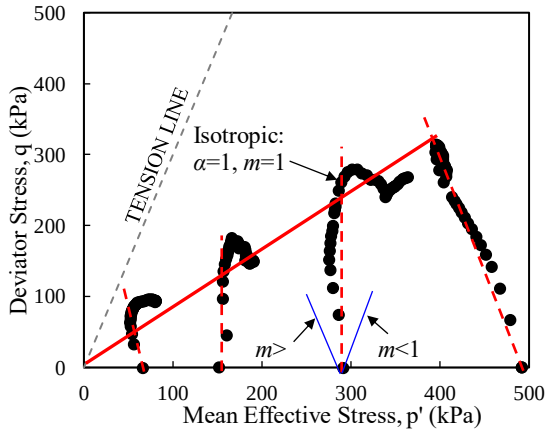

Fig.6 Clay core CIU triaxial test results.

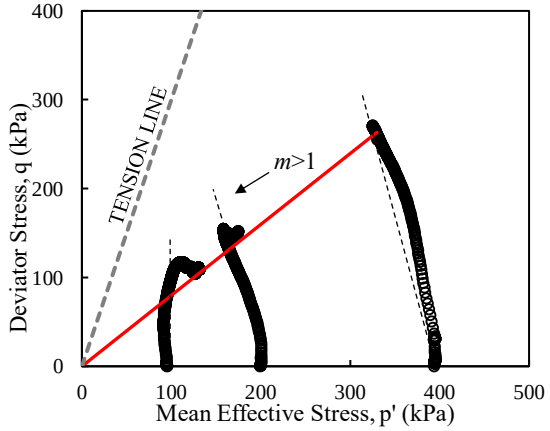

Fig.7 Clay blanket CIU triaxial test results.

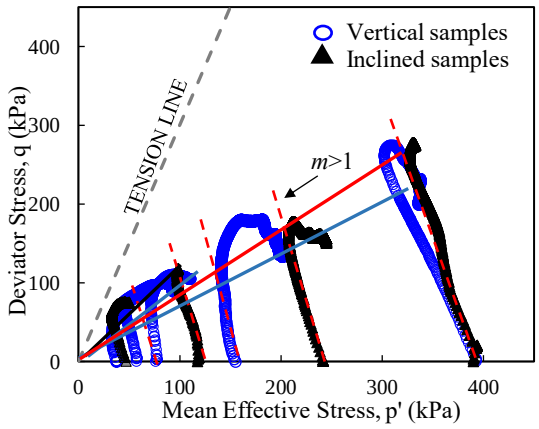

Fig.8 Clay foundation CIU triaxial test results.

samples have higher cross shear strength than that along the horizontal shear plane and the values are independent of the stress range. Clay foundation results show that in addition to anisotropic strength, shear strength values were dependent on the stress range, which indicated a bilinear failure envelope. For both cross shear and horizontal shear, the strengths were higher at a lower confining stress and decreased as the confining stress was increased. Strength anisotropy seem to decrease as the confining stress increased as expressed in the decreased difference in shear strength values. The bilinear failure envelope could be once again due to the dilatancy behaviour of the intensely fissured clay foundation.

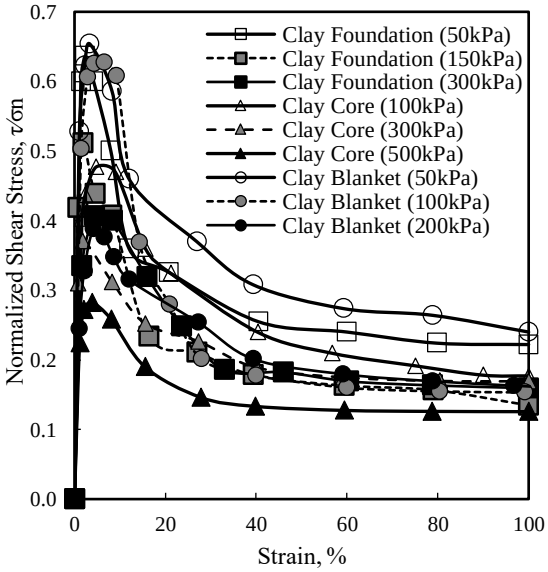

Fig.9 Stress-strain behavior from CD direct shear tests.

Table 2 Summary of estimated effective shear strength parameters

Stress Range (kPa)	Clay Core		Clay Blanket		Clay Foundation	
	CS	HS	CS	HS	CS	HS
<100	19	13	21	17	24	29
>100	19	13	21	17	18	16
Residual		8		9		7

Note: CS = cross shear, φ' (deg), HS = horizontal shear, φ' (deg)

NUMERICAL MODELING

Numerical modeling was implemented using the GeoSlope 2018 program suite in order to evaluate the stability of the earth fill dam using a 2-dimensional plane strain model. The location of the phreatic surface was determined using the steady-state seepage analysis in SEEP/W and was confirmed by readings from vibrating wire piezometers installed on site. Finite element method (FEM) of stress distribution method was performed using SIGMA/W to establish in-situ stresses conditions. Results from the stress distribution and seepage analysis were imported in the SLOPE/W slope stability analysis.

The dam of interest has two sections, depending on the foundation conditions. Section A has a clay

foundation that stretches from the upstream to the downstream side of the dam, overlying dense silty sand. Section B has an absence of an impermeable natural clay layer with only a layer of dense silty sand and gravely sand underneath the dam. In order to control seepage in this section, a compacted clay blanket was placed in the upstream side and was tied into the inclined clay core. Irregular movement was observed in the upstream section of Section B despite its good performance for over fifty years.

Post peak or critical state shear strength parameters were used in the numerical modeling as the clay materials in the dam were thought to have reached its fully-softened condition over the years. Cohesion was assumed to be zero for fully softened shear strengths of fissured clays [8]. Two cases of slope stability analyses were conducted. Case 1 considered the anisotropic strength model for clay materials to simulate the difference in strength along the cross-shear and horizontal direction. Case 2 used Mohr-Coulomb strength model with parameters based on the shape of the postulated slip surface. Cross-shear strength was assigned for the clay core whereas the clay blanket used horizontal shear strength values. Clay foundation horizontal shear strengths were inputted using a bilinear soil model for Case 2. Input parameters used in the numerical modeling can be seen in Table 3.

Table 3 Input parameters for numerical modeling

Parameters	Clay Core	Clay Blanket	Clay Foundation
γ (kN/m^3)	17	17	17
υ	0.35	0.45	0.35
λ	0.125	0.145	0.124
κ	0.024	0.042	0.028
c' (kPa)	0	0	0
$\Phi'_{cross\text{-}shear}$ (°)	19	21	18
$\Phi'_{horizontal}$ (°)	13	17	16
$\Phi'_{bilinear}$ (°)	n/a	n/a	29,16

The results of the SLOPE/W slope stability analyses are presented in Table 4. The calculated factors of safety (FS) indicate that the use of anisotropic soil analysis (Case 1) tend to generate lower values for both dam sections compared to Case 2. Results also show that the upstream slope was more critical than the downstream side for both sections of the dam using either Case 1 or 2, primarily due to the geometry of the inclined core. Moreover, the upstream side of Section B had a factor of safety value less than unity (FS = 0.99) when anisotropy was considered. This corresponds to the observed irregular movement in this section, which could be a precursor to instability. The results were compared to the following safety criteria: a factor of safety of 1.5 against normal water level load cases, and a value of 1.0 considering normal water levels and seismic loading. It is evident that the upstream slope does not pass the safety criteria, with Section B as the most critical. Proactive rehabilitation measures in this dam is on-going in order to address this. The results of the analyses performed also indicated that considering anisotropic behaviour in clay was a better representation of the dam as the numerical model was able to capture the observed behaviour on site. The critical slope stability results for both Sections A and B can be seen in Fig. 9 and Fig. 10, respectively.

Table 4 Factor of safety values from slope stability analyses

	Section A		Section B	
Case	U/S	D/S	U/S	D/S
Case 1	1.31	2.37	0.99	2.88
Case 2	1.48	2.37	1.15	2.88

Note: U/S = upstream, D/S = downstream

CONCLUSION

Observations from site investigation and soil sampling indicated that the clay core, blanket and foundation of an aging water-retaining dam had fissured structures. The clay foundation fissuring was more intense than the clay in other locations and had more silt pockets. Despite the difference in the degree of fissuring, all tested samples were similar in terms of structural and mineralogical composition. The micro fabric of the clay was considered anisotropic from interlayered smectite and illite. The presence of silt could also influence the anisotropic behaviour of the clay foundation in general such as in terms of strength and permeability.

Experimental investigation indicated that other than anisotropy in its mineralogical composition, the undrained and drained strength of the materials used in construction of old earth fill dams were anisotropic. Strength anisotropy was evident in all tested clay as samples had different cross shear and horizontal shear strength values. Clay core and clay blanket samples have higher cross shear strength than that along the horizontal shear plane. Intense fissuring of the clay foundation resulted to a bilinear failure envelope, while the clay core and clay blanket had a more uniform failure envelope.

The slope stability analysis considering strength anisotropy was a better representation of what was observed on site concerning the aging earth dam in this study. Based on site exploration, laboratory investigation, and numerical modeling analysis, the dam operator and owner have carrying out proactive measures in order to meet current dam safety standards.

RAINFALL-INDUCED DEFORMATION BEHAVIOR OF CRACKS ON BROWN COAL OPEN PIT BATTER IN AUSTRALIA

Lei Zhao [1], Greg You [1]
[1] School of Science, Engineering and Information Technology, Federation University Australia, Australia;

ABSTRACT

After a 26mm rainfall in 24 hours, noticeable ground movements were observed on the north batter at Maddingley Brown Coal Open Pit Mine, Victoria, Australia in February 2014. The batter is brown coal sandwiched by confining beds. Cracks manifested on the north batter months before the rainfall event, and then an emergency buttress was immediately constructed to maintain the batter stability. A three-dimensional geologic model is developed to study the rainfall-induced ground movement in this paper. The finite element program encoded in Plaxis 3D is employed to conduct the complex two-phase (fluid-solid) coupled numerical simulation. It is found that the simulated deformation is well agreed with the observed data from field survey markers. There are ground movements along the length of cracks on both sides with larger movement towards the pit bottom. These movements are the results of the combined reactions of surface run-off and sudden increased underground water level. The 26mm rainfall event did not cause instability of the batter.

Keywords: Crack, Rainfall, Deformation, Brown Coal, Open-Pit Mining

INTRODUCTION

Brown coal is won by open pit mining in Victoria, Australia, benefiting from its shallow depth and thick seam. A number of open pit walls and permanent batters have been formed due to the open pit mining activity lasting for a century in this area. Depth and size of mining excavations are still increasing, it was reported [1] that Loy Yang Brown Coal Open Cut in Latrobe Valley, Victoria, had reached a depth of 200 meters. As a result, the slope instability has become a major risk of geo-hazard in Victoria Brown Coal Open Pits. Although, different from the hazards kinds [2] caused by underground coal mining, the batter instability issues of open pits often result in serious casualties, property loss, and environmental damage [3]-[4]. Also, coal batter failures have been reported from time to time in Victoria brown coal open pits. A block failure occurred in the northeast batter at the Yallourn East Field Mine on 14th November 2007 as shown in Fig.1. It was a very large failure, approximately 80m high and 500m long, and about six million cubic meters of materials were encompassed [6]. This failure caused Yallourn river diverted into the mine site that resulted in over $200 million costs to the mine and an immediate loss of one-fifth of Victorian power generation capacity [7]. A clear understanding of coal batter failure mechanism is crucial in slope instability control and prediction. Though groundwater pressure, coal joints, the shear strength of batter composition, batter slope and height are generally known as the factors involved in the batter instability problem, it is a challenge to adequately interpret batter failures due to the complex interaction of those factors. Owing to the quick-growth computer technique, numerical simulation has become a promising way to solve such kind of problem. The numerical simulation method can analyze batter stability under the conditions as close to reality as possible by employing full-scale three-dimensional model and high-performance computers. Over past years, number of scholars [8]-[12] studied slope instability using numerical simulation method, and the outcomes were positive. The numerical simulation method has become a reliable way to solve the complicated geotechnical problems.

Fig. 1 Yallourn batter sliding on 14th November 2017 [5]

In Victorian brown coal mines, batter movements and failures observed are roughly attributed to circular type sliding of overburden faces and block type sliding of brown coal faces [13]-[14]. Brown coal batter with overburden tends to lead a circular

sliding while the coal batter after overburden removal has a blocking slide trend at Maddingley brown coal mine [15]. Brown coal block sliding is a unique and common failure type in this region after overburden removal. Block failure occurred not long after cracks (opened joints) emerging on coal batter surface or heavy rainfall event in Victorian brown coal open pits, as reported in Yallourn mine in 1950 [14] and 2007 [6].

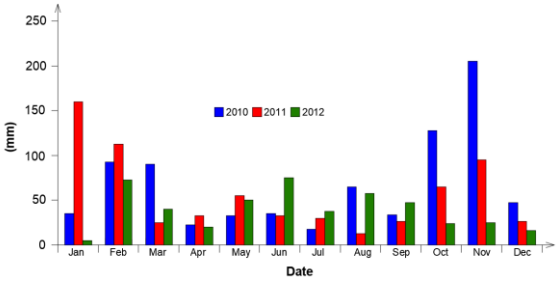

Fig. 2 Monthly rainfall values (mm) for 2010, 2011 and 2012- Bacchus Marsh, Victoria

In Maddingley brown coal (MBC) mine, where this study is based on, a block failure occurred in the southern wall of the open pit in October 1994 which caused a water leakage along cracks from the adjacent Parwan Creek; cracks were observed in the northern batter in November 2013, and then an emergency buttress was immediately constructed to maintain batter stability. The further development of the cracks had been well controlled in the northern batter with the buttress, but horizontal movements along cracks were monitored immediately after a 26mm rainfall in February 2014. In previous studies, high tensile strain behind the batter and high shear strain underneath the coal seam could be developed after the overburden is stripped in the north batter, and cracking propagation was a result of stress relief due to the overburden removal [15]; rainfall event can accelerate the cracking propagation process [16]. The observed cracks on north batter of MBC did not penetrate the coal batter as high tensile strains are generally developed at the surface of the coal seam due to its low-modulus, ductile nature [6]. On the other hand, the high tensile strain could lead to the open of pre-existing joints in the coal seam. It is also interesting to note that batter failures are prone to occur in summer or close to summertime in Victoria. There is high precipitation in summer in Victoria, Australia. Figure 2 shows the distribution of precipitation in Bacchus Marsh from 2010 to 2012, where MBC mine site is located. This study interprets how opened cracks deform under a 26mm rainfall condition by developing and simulating a three-dimensional geologic model of the north batter of Maddingley brown coal mine. The batter is sandwiched by confining beds, and there are opened joints in the coal seam.

MADDINGLEY BROWN COAL OPEN PIT OVERVIEW

Geology and Hydrogeology of MBC Mine Site

MBC is a typical Victorian Brown Coal Open Pit, located on the southern outskirts of the township of Bacchus Marsh, Victoria, Australia. Open pit mining was commenced in the 1940s, and simultaneous coal excavation (on the north batter) and waste landfill operation (in the south of pit bottom) are in progress in MBC at present. Three main formations (Fig.3) constitute the typical sandwiched MBC brown coal batter. The top formation consisting of sands, silts and clays is Fyansford Formation (overburden), with a thickness of 5m to 20m; the middle Maddingley Brown Coal Seam Formation consists predominantly of brown coal, which is in a thickness of between 35m and 60m; underlying coal seam is Werribee Formation consists predominantly of silty clays and silty sands, fine to medium grained sands and minor sandy gravels. Description of the main hydro-stratigraphic units underlying the site is summarized in Table 1.

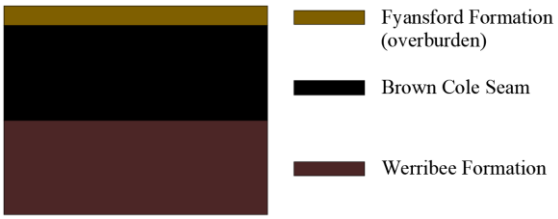

Fig. 3 Geologic formations of MBC

Table 1 Main Hydro-stratigraphic Units in MBC

Hydro-stratigraphic Unit	Function Within the Regional Groundwater System

Brwon Coal Seam;	Aquitard and confining Aquifer
Werribee Formation.	Confined Aquifer

MBC Brown Coal Characterizations

Victorian brown coal is a material with high organic content and low permeability [17]-[18], whose strength is between normal engineering soil and rock, and its stiffness is similar to very stiff clay. It is also a highly deformable and low-density material. The unit weight of saturated MBC brown coal is about 11.5kN/m^3 while the dry unit weight is about 5kN/m^3. The low density means the batter

stability is very susceptible to the water pressure from groundwater or rainfall runoff, and the deformable character tends to cause the formation of cracks and open of existing joints in Victorian brown coal [6].

Fig. 4 Major cracks on North Batter in November 2013

Northern Batter of MBC

Stripping and mining operations were commenced on the north batter in MBC in early 2013, and before that the north batter was stable for many decades. It was a single bench, about 25m high and extended over approximately 150m in length orientated from west to east, at a slope angle >80 degree. Cracks (Fig. 4) were observed on the surface of north batter in November 2013, which was located about 20m from the batter crest, when there was a large scale of overburden stripping commenced in early 2013 and minimal mining of coal. The length of these cracks was almost throughout the overall length of the batter, and the width was from a trace to approximately 150mm. The cracks opened wider in the east than in the west as there was an old 5m high buttress left at the toe of the western end of the batter. An emergency buttress was constructed immediately after the observation of these cracks. From the monitored data, movements were well controlled benefitting from the construction of the emergency buttress, except some new minor cracks appeared in the south of the cracks (Fig. 5).

Ground Deformation Monitoring System

Eight survey markers were installed along the major cracks in November 2013 to monitor the ground movement. The locations of these survey markers (from Marker 1 to Marker 8) were demonstrated in Fig.6.

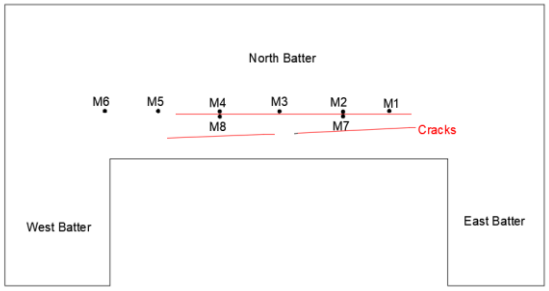

Fig. 5 Survey markers (M1 – M8) on MBC north batter

Monitored Ground Movement Induced by Rainfall Event

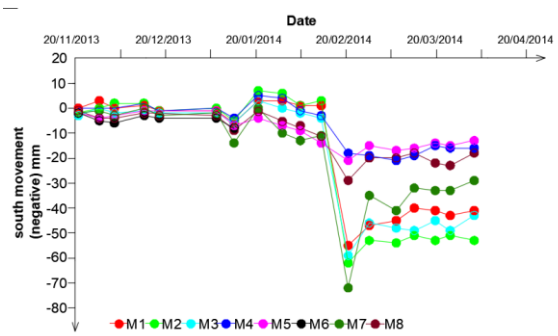

Fig.6 Monitored ground deformation on North Batter (no data for M6)

From the monitored data (Fig.6), the ground deformation on the north batter was well controlled within 10mm in both north and south directions in the following three months after the installation of survey markers. However, a 26mm rainfall occurred on 14 February 2014 (one day after the buttress was fully completed), and noticeable movements (Fig.6, south movement is negative and north positive) were observed. The movements were 56mm, 65mm, 55mm, 15mm, 7mm, 61mm and 18mm towards pit bottom (south), seen from survey marker 1 to 8 respectively (survey marker 6 was destroyed prior to the rainfall event due to mining).

NUMERICAL SIMULATIONS

In this paper, a three-dimensional geological model of MBC north batter with cracks was developed to study the ground movement under

rainfall event. This model was developed based on the MBC north batter on 13 February 2014 at that moment the emergency buttress was in position. One day later, a 26mm rainfall event occurred. Figure 7 shows the geometry of the model that is 400m in length from west to east and 250m in width from north to south. The model covers the north batter, east batter and west batter of MBC open pit.

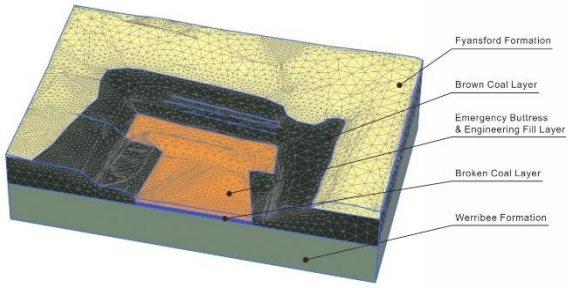

Fig.7 Three-dimensional model of north batter (meshed)

The model consists of 5 layers, which are, from top to bottom, Fyansford Formation (overburden, RL 87m to RL 100m), brown coal layer (RL 50m to RL 87m), emergency buttress (RL 60m to RL 72m) and engineering fill layer (RL 55m to RL 60m), broken brown coal layer (RL 50m to RL 55m), and Werribee Formation (RL 0m to RL 50m). Groundwater flows towards pit bottom. Based on the measured borehole logs in the field, the top groundwater level is set at RL 92m in the Fyansford Formation at the initial state, which flows down to the pit bottom (RL 60m). The cracks constructed in the model include the major crack and the subsequent minor cracks, which are shown in Fig.8. The major crack is approximately 20m back from the coal face, and the two minor cracks are located on the south of the major one. The cross-section view of cracks is shown in Fig.9.

Fig.8 Aerial view of cracks on the north batter surface

The numerical simulation is a two-phase procedure. The first phase is defined as initial gravity calculation phase which simulates the initial state of the model; the second phase is a fully coupled flow-deformation calculation phase that is to simulate the deformation of the model under the defined condition of a 26mm rainfall evenly distributed in 24 hours. The mechanics of soils and brown coals adopted in this numerical simulation are listed in Table 2.

Table 2 Mechanical prosperities adopted in the three-dimensional simulation

Parameters	Unit	Fyansford Formation	Brown Coal	Buttress and Fill	Broken Brown Coal	Werribee Formation

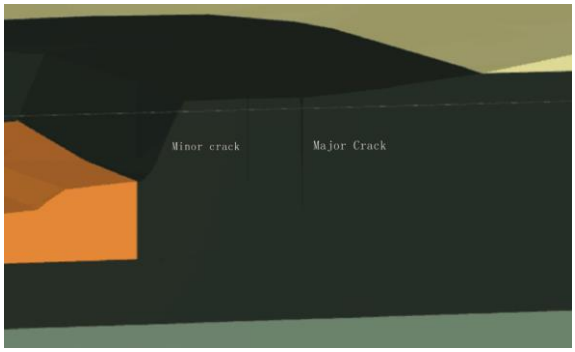

Fig.9 Cross-section view of cracks

RESULTS AND DISCUSSION

From the results of simulation, noticeable movements are generated along the length of both sides of cracks in the direction perpendicular to the cracks after the 26mm rainfall event, while no apparent lateral movements in the direction parallel to the cracks (Fig.10). The monitored data of deformation after the rainfall event was recorded by survey markers installed along the major crack (four on north side, two on south, two on lateral). The magnitude of monitored deformations are 56mm, 65mm, 55mm, 15mm, 7mm, 61mm and 18mm from marker 1 to 8, respectively, excluding Marker 6 that was damaged and no data available. The simulated movements of the seven markers are 48mm, 52mm, 44mm, 32mm, 4mm, 28mm, and 8mm correspondingly, which are shown in Fig.11. The simulated result is in good agreement with the monitored, with comparatively less southern movements than the observed data except for Marker 4.

The largest movement towards open pit (south) appears close to the north of the major crack, reaching up to 52mm. Deformations around 28mm towards open pit are seen in the north of the two minor cracks, whereas in the opposite side (south) of the minor cracks, smaller movements of less than 8mm towards north are simulated. These movements between the

major and minor cracks are the overlapping effects of both south and north movements resulted from the major and minor cracks after rainfall. There is up to 24mm positive (towards north) movement in the central south of the major crack, where exists a gap between the two minor cracks. Thus, there is less effect from the minor cracks.

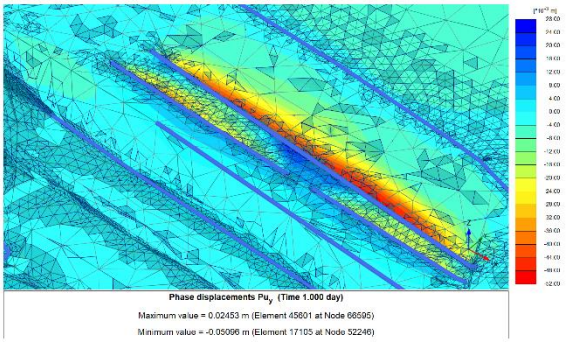

Fig.10 Movement of cracks after a 26mm rainfall in 24hours

The ground appears to move towards the centerline of the crack and the deformation in the north of crack is larger than that in the south. The ground movements mainly concentrate in the vicinity of cracks, and there is no noticeable movement in other parts of the batter. It is inferred that the surface run-off entering cracks exerts a hydrodynamic force on the initially unsaturated surface brown coal that could be pushed move along the direction of rainfall run-off; as a result, the deformation tends to move towards the centerline of the crack. The overall water flow is towards pit bottom (or towards south); thus the suddenly increased groundwater level in the cracks and brown coal increase the south-direction hydrodynamic force and horizontal hydrostatic water pressure to the brown coal, which could result in that the south-direction movement is larger than north-direction. From the simulated results, the groundwater level increased in the coal layer north of the minor cracks, but not of the south part. Therefore, the movements in the north of the minor cracks are larger than that of the south. The deformation generated around the major crack is larger than the deformation around the minor cracks. It is inferred that the deformation could be larger with the increase of the crack's depth. In summary, the movements are the results of the combined reactions of surface run-off and suddenly increased groundwater level. Although noticeable deformation is generated after the rainfall, the batter is still in a safe state after the rainfall event. It would benefit from the support of the emergency buttress, the moderate rainfall intensity and the short duration of the rainfall.

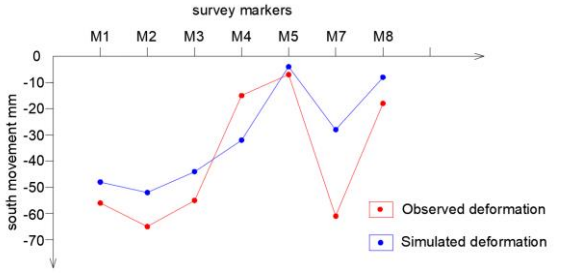

Fig.11 Comparison of observed and simulated movements along the crack

CONCLUSIONS

A three- dimensional model was developed using Plaxis 3D to study the effects of rainfall on batter movement in a Victorian brown coal open pit. The following conclusions can be made.

1. The simulated deformation is well agreed with the observed data from the seven field survey markers, which in turn verifies the three-dimensional numerical model developed.

2. From the simulation, the 26mm precipitation in 24hours results in noticeable movements on both sides along the cracks, while no apparent movements are seen in either lateral side of cracks or other parts in the batter. The overall movement is towards the pit bottom. The ground tends to move towards the centerline of the crack, and the deformation is larger in the north of the crack than in the south. The deformation generated around the major crack is larger than the deformation around the minor cracks.

3.These movements are the results of the combined reactions of surface run-off and suddenly increased groundwater level. This 26mm rainfall event did not cause the batter instable. A further study is to address what is the relationship between rainfall and potential block failure of brown coal batter.

ACKNOWLEDGMENTS

The authors sincerely express their appreciation to the support of this research project from Maddingley Brown Coal Pty Ltd., in particular, to Mr. Tim Tillig, the Environmental, Quality & Safety Officer.

STABILIZATION OF CLAYEY SOILS USING POWDERED MARINE SHELLS

Giancarlo P. Ventura[1], Ma. Michaela B. Biscocho[1] and Jose Maria Ferdinand V. Calaunan[1]
[1]Institute of Civil Engineering, University of the Philippines Diliman, Philippines

ABSTRACT

The Philippines, as an archipelago, is surrounded by different bodies of water. Along with these are the abundant marine resources the country has such as mussels, oysters, and scallops. These marine organisms are widely used especially in the food industry. Upon consumption, the shells of these species are being put into waste, which in turn, causes issues regarding disposal of these organic wastes. With this, the study aims to analyze the effectiveness of powdered marine shells as soil stabilizers by identifying the changes in the unconfined compressive strength, plasticity index, and activity number, brought about by increasing marine shell concentration specifically 0%, 4%, 6%, and 8%. Application of increasing shell concentration yielded the following effects: increasing trend of unconfined compressive strength, decreasing values of plasticity index, and lower activity number. The significant increase in unconfined compressive strength of the soil changes the stiffness of the soil from a medium state to a very stiff state. The reduction of plasticity index changes the soil property from very high plasticity to high plasticity. Consequently, the decreasing activity number alters the soil from normal to inactive, lowering the swelling potential of the soil. Both stabilized and unstabilized soil samples underwent scanning electron microscopy (SEM) analysis to see the effect of the marine shells on the soil particle structure. The application of calcined marine shells and consequent increase in shell concentration lead to the clustering of the soil particles with the aid of connectors, reducing the intergranular voids, and further strengthening the soil.

Keywords: Marine shell, Stabilization, Compressive strength, Plasticity index, Activity number

INTRODUCTION

The history of aquaculture is known to be very rich in the Asia and the Pacific with Southeast Asia producing 10.2% of this resource (Silpachai, 2001). The Philippines is the largest contributor in Southeast Asia with 33.6% in production (Silpachai, 2001). In the 1930s, the production of these resources was originally confined in the Manila Bay area but with the help of technological advancements, oyster and mussel farming eventually became widespread in the country. At present, the Philippines specializes in the production of oysters and green mussels, producing approximately 12,000 MT in 1987 (Aypa, 1990) and still growing rapidly until today with farms ranging from 300 to 1,000 m^2 (Yap, 1999).

Along with the flourishing economy of oyster and mussel farming comes the issue of the disposal of these organic wastes. After these have been consumed, shells go straight to landfills and cause problems with increased microbiological activity, the introduction of diseases and parasites and the production of anoxia in the sediments and bottom water in turn leading to the production of toxic substances such as hydrogen sulfide (OSPAR, 1998). Because of these, the marine shell waste's potential for use must be explored, specifically to clayey soils [5].

Shells have been used as heterogeneous catalysts for biodiesel production [2], an alternative liming material for increasing crop productivity [4], and substitute aggregates in mortar (Yoon, et al., 2004). These studies have shown that the main material in shells that increases its potential for use is calcium carbonate ($CaCO_3$), a material also found in lime which is commonly used in soil stabilization. Lime is one of the most commonly used soil stabilizers [1]. However, its helpfulness in the engineering industry causes environmental problems such as the demolition of natural ecosystem and the consumption of huge amounts of energy (Lee, et al., 2008). This serves as another motivation for researchers to explore the use of marine shells as soil stabilizer so as to limit the use of lime in the field.

The researchers aim to analyze the effectiveness of powdered marine shells as soil stabilizer. This is done by identifying the changes in unconfined compressive strength, plasticity index, and activity number of the soil when stabilized with marine shells. This objective is achieved by varying the amount of concentration of powdered marine shells, and analyzing their effects on the clayey soil. The effect of powdered marine shells to soil particle structure shall also be taken into consideration. All of the experiments will be done to both stabilized

and unstabilized soils for comparison to validate the study's effectiveness.

METHODOLOGY

Sample Acquisition

Clayey soil sample was provided by Geotechnics Philippines, Inc. from an area in Sikatuna Village, Quezon City, Philippines. The marine shells were obtained from Dampa sa Libis Restaurant in Libis, Quezon City, Philippines. A mixture of oyster, mussel, and scallop shells weighing 5.5 kg were acquired.

Soil Sample Preparation

The soil sample was cleaned by removing plastic, glass, and other materials that mixed up with the soil. The sample was then passed through Sieve No. ⅜ and oven-dried for 24 hours to remove excess moisture and to declump the particles for sieving. A mortar and pestle was then used to declump the soil further in preparation for preliminary soil investigation.

Preliminary Soil Investigation

The grain size analysis involves the use of a set of sieves to separate soil particles into different size ranges. The mass of particles in each range was then determined using a mass balance. The experiment was done as guided by ASTM D6913-04.

The Atterberg Limits such as liquid limit and plastic limit were obtained, following the standard method indicated in ASTM D4318-10. Consequently, the plasticity index and activity number were calculated to correlate these with different engineering behaviors.

Two classification systems were used to classify the soil. These are the USCS and AASHTO Soil Classification System. Both systems are used to classify mineral and organo-mineral soils for engineering purposes based on laboratory determination of particle-size characteristics, liquid limit, and plasticity index.

The laboratory test for the generation of compaction curve is based from the Standard Test Methods for Laboratory Compaction Characteristics of Soil using Standard Effort provided in ASTM D698-07. This test method covers laboratory compaction methods used to determine the relationship between molding water content and dry unit weight of soils compacted in a 4-in. (101.6-mm) diameter mold with a 5.50-lbf (24.5-N) rammer dropped from a height of 12.0 in. (305 mm) producing a compactive effort of 12,400 ft-lbf/ft^3 (600 kN-m/m^3).

Shell Cleaning

The shells were washed using water and brushes to free the shells from dirt and dust. The clean shells were sun-dried for 2 days then oven-dried at 110^{0}C for 2 hours [6]. This method for cleaning was taken from a study by Rashidi, et al. (2011).

Fig. 1 Marine shell samples after oven-drying

Shell Crushing

The shells were then crushed and grounded using a ball mill located in the Pilot Plant of the UP Department of Mining, Metallurgical, and Materials Engineering. It was crushed in the ball mill in two batches, revolving for 30 minutes per batch. The product of this process is the shell in powder-like form.

Calcination

After the powdered shells have been obtained, they were placed in the furnace at UP Department of Mining, Metallurgical, and Materials Engineering and in the Environmental Engineering Laboratory for calcination. To avoid contamination, the shells were placed in 30 milliliter porcelain crucibles. The furnace was set at 850^{0}C for 4 hours, as done in the study by Buasri, et al. (2013). The shells were passed through Sieve No. 100 for particle size uniformity. The shells were then stored in airtight plastic bags to prevent carbonation.

X-ray Fluorescence

X-ray Fluorescence (XRF) analysis is an analytical technique used to determine the chemical composition of the shells. This process was done to verify the presence of CaO after calcination. The XRF analysis was done in the National Institute of Geological Sciences in UP Diliman.

Soil Stabilization

The weight of the oven-dried soil and powdered shells was predetermined depending on the required concentration needed in the mixture. The mixture was then dry-mixed for 1 minute using the mortar mixer. The mortar mixer used is located in the Construction Laboratory in UP Institute of Civil Engineering. The obtained optimum moisture content by weight of the mixture was added to the soil in a thin stream and mixed for 5 minutes. The mixture was then transferred to a bowl and immediately covered with a plastic bag to prevent the loss of moisture and carbonation.

Unconfined Compression Test

The unconfined compression test is used to determine the stress-strain behavior of a given sample. ASTM D2166 and D5102-09 are used for cohesive soils and soil-lime mixtures respectively. Samples were compressed using an Instron 3366 UTM located in the Construction Laboratory in UP Institute of Civil Engineering, at a rate of 2% per min. The compression stops at an axial strain of 15% and 5% for unstabilized and stabilized soil respectively, or until the load values decrease, whichever happens first. The cylindrical mold used had a diameter of 2 inches and a height of 4 inches. An improvised rammer was also made using a PVC pipe and a tamping rod. To be able to maintain a standard effort of 12,400 ft-lbf/ft^3 given the dimensions of the instruments, the number of blows is recomputed, resulting to 12 blows per layer for 3 layers. After extrusion of the soil specimens from the mold, they were immediately stored in airtight plastic bags to prevent the loss of moisture and carbonation. The plastic bags were then stored in an airtight, and moisture-proof container at room temperature for a curing period of 7 days.

Atterberg Limits

With the addition of calcined marine shells to the clayey soils, stabilization at 4%, 6%, and 8% shell concentrations produce different effects on the soil. These alterations on the properties per concentration are expressed in terms of the changes in their respective liquid limits, plastic limits, plasticity indices, and activity numbers.

Scanning Electron Microscopy

The Scanning Electron Microscopy (SEM) was used to obtain the micrographs of both stabilized and unstabilized soil samples. These were determined to compare the differences on the textural characteristics and the particle structure of the soil specimens. The magnification used for all samples are 2000x and 5000x. This laboratory test is done at the Department of Chemical Engineering in UP Diliman using Hitachi S-3400N.

RESULTS AND DISCUSSION

Preliminary Investigation

Sieve analysis determines the particle-size distribution for coarse-grained particles of the soil. The results of the sieve analysis of unstabilized soil are noted to have a 53.68% finer than Sieve No. 200. The coefficient of uniformity (Cu) is 8.732 while the coefficient of curvature (Cc) is 1.031. Since the uniformity coefficient of the unstabilized soil is greater than 6 and the coefficient of gradation is within the range of 1 to 3, the soil is well graded. The liquid limit test is done and using the multipoint method. With the equation of the best-fit line from the liquid limit graph, the water content corresponding to 25 blows is considered to be the liquid limit of the unstabilized soil, obtaining a value of 81. The plastic limit is considered to be the average of the two values, 33.33 and 34.88, which is 34. The plasticity index is 47, considering it with a very high plasticity. The activity number is calculated to be 0.8756 and is known to be a normal clay soil with minerals of illite in it. Given these values, the classification of the soil is CH or High-Plasticity Clay according to USCS, and A-7-5 consisting of clayey soils according to AASHTO Soil Classification System. The standard proctor test was performed to obtain the optimum moisture content of the unstabilized soil, which is 32%.

X-ray Fluorescence

Table 1 shows the results of the X-ray Fluorescence as performed in the National Institute of Geological Sciences. It was verified that the $CaCO_3$ in the shell was transformed to CaO by the calcination process. The calcined shells contain 95.22% CaO.

Table 1 X-ray Fluoresence Results

Component	T1 (%)	T2 (%)	T3 (%)	Ave
CaO	93.25	98.06	94.33	95.22
MgO	5.02	0.00	3.91	2.98
SiO_2	0.67	0.81	0.86	0.78
Sr	0.23	0.25	0.25	0.24
Fe_2O_3	0.49	0.43	0.36	0.43
S	0.16	0.19	0.13	0.16
P	0.09	0.12	0.04	0.08
Ti	0.08	0.11	0.10	0.10
Mn	0.01	0.02	0.02	0.02

Unconfined Compression Test

The unconfined compression test was done using 2-inch molds and the improvised rammer. Table 2 shows the summary of the maximum compressive stress reached by the soil specimens and their corresponding consistencies.

Table 2 Summary of Compressive Strength

% Shell	Compressive Strength (MPa)			
	T1	T2	T3	Ave.
0%	0.095	0.096	0.079	0.090
4%	0.132	0.135	0.158	0.142
6%	0.189	0.143	0.158	0.163
8%	0.203	0.208	0.224	0.212

As seen in Table 2, the relationship of the compressive stress and the concentration has an increasing trend and to be able to identify if the increase in compressive strength is statistically significant, the data is analyzed using one-way analysis of variance (ANOVA) using Minitab 18.

The Tukey Pairwise post hoc test will be done to analyze where the differences occur in the data. Running one-way ANOVA, results show that there is a significant difference in the values as shown in Figure 2.

One-way ANOVA: 0%, 4%, 6%, 8%

Method

Null hypothesis	All means are equal
Alternative hypothesis	Not all means are equal
Significance level	α = 0.05

Equal variances were assumed for the analysis.

Factor Information

Factor	Levels	Values
Factor	4	0%, 4%, 6%, 8%

Analysis of Variance

Source	DF	Adj SS	Adj MS	F-Value	P-Value
Factor	3	0.022979	0.007660	31.91	0.000
Error	8	0.001920	0.000240		
Total	11	0.024899			

Fig. 2 One-way ANOVA results

The one-way ANOVA results show that the P-value is less than 0.05 therefore rejecting the null hypothesis that all means are equal. The Tukey post hoc test then determines where the differences occur. The results are shown in Figure 3.

Tukey Pairwise Comparisons

Grouping Information Using the Tukey Method and 95% Confidence

Factor	N	Mean	Grouping
8%	3	0.21191	A
6%	3	0.1632	B
4%	3	0.14186	B
0%	3	0.09001	C

Means that do not share a letter are significantly different.

Fig. 3 Results of Tukey Post Hoc Test

Minitab groups the data in letters to show whether or not the means are significantly different. Comparing the data relative to the unstabilized soil represented by 0%, all 3 concentrations have a significant difference with 0%.

Figures 4, 5, 6, and 7 show the stress-strain curves of the soil specimens. All of the stress-strain curves exhibit strain softening with the sudden decrease in compressive stress with increase in compressive strain after reaching a peak in stress. Strain softening often occurs for specimens that do not fail homogeneously. This is the case for all soil specimens since all failed due to a barreling failure.

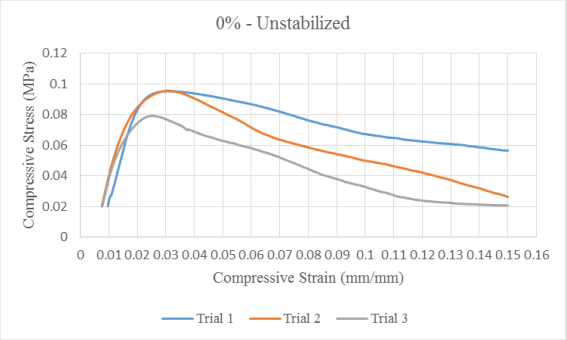

Fig. 4 Stress-Strain curve of unstabilized soil

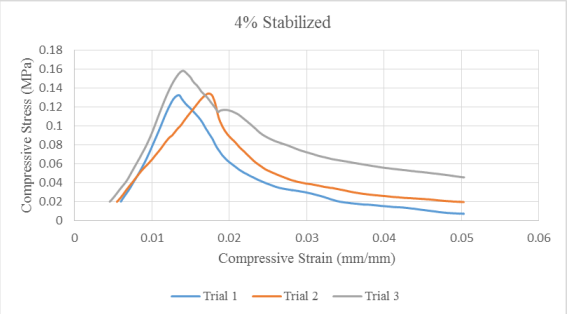

Fig. 5 Stress-Strain curve of 4% stabilized soil

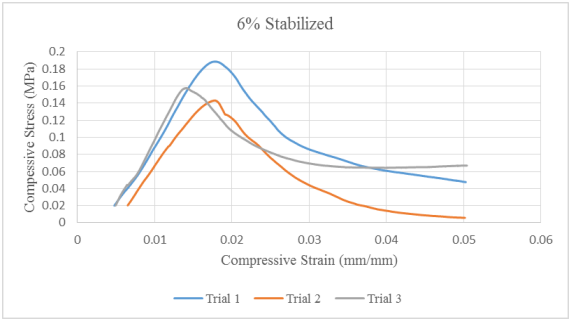

Fig. 6 Stress-Strain curve of 6% stabilized soil

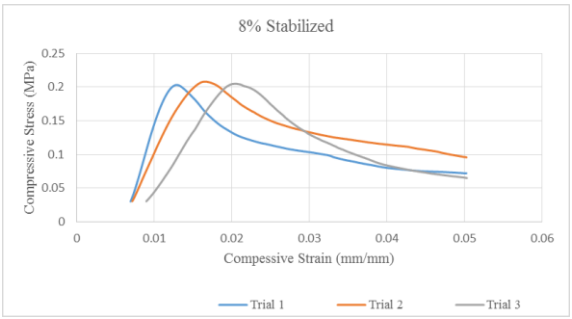

Fig. 7 Stress-Strain curve of 8% stabilized soil

The elastic moduli of the stress strain curves were computed to further verify the increase in stiffness of the soil sample with the addition of marine shells. For all points in all the stress-strain curves, the elastic modulus was approximated by solving for the ratio of the stress and strain. Table 3 contains the summary of elastic moduli values.

Table 3 Summary of Young's moduli

%	Young's Modulus (MPa)			
Shell	T1	T2	T3	Ave.
0%	2.669	3.425	3.329	3.141
4%	4.397	4.601	5.355	4.784
6%	5.372	4.123	5.532	5.009
8%	5.915	5.723	4.406	5.348

An increasing trend in Young's modulus values can be observed based from the average of the moduli of the three trials. The more closely packed the soil particles are, the higher the value of the modulus of elasticity, therefore the increase in soil stiffness is verified.

Atterberg Limits

As expected from previously discussed references, there was a decrease in the plasticity index of the soil, implying the reduction of the soil's expansivity. Table 4 shows the summary of results for Atterberg limits.

Table 4 Results of Atterberg Limits

%	Atterberg Limit			
Shell	LL	PL	PI	A
0%	81	34	47	0.8756
4%	75	36	39	0.7266
6%	72	35	37	0.6893
8%	74	38	36	0.6707

The plasticity index of unstabilized soil fell under clays of very high plasticity. The stabilized soils were classified under soils of high plasticity with their plasticity indices falling in the range of 20 to 40. The reduction of plasticity index also decreases the activity number of composite materials. The activity number indicates the swelling potential of the soil. As the marine shell concentration increases, the activity number decreases. From an activity number of 0.8756, the unstabilized soil is a normal type of soil in terms of its activity. However, the rest of the concentrations for the stabilized soils yield activity numbers less than 0.75. Because of this, the soils have turned to inactive clayey soils, and therefore lowering its swelling potential. The application of marine shells as soil stabilizer causes this alteration and gives us an idea of how susceptible to swelling the soil is.

Scanning Electron Microscopy

The unstabilized and stabilized soils were subjected to the scanning electron microscope to clearly visualize the microstructures, its arrangement and assemblage. These micrographs were generated with both magnifications of 2000x and 5000x. Figure 8 shows the micrographs for 5000x.

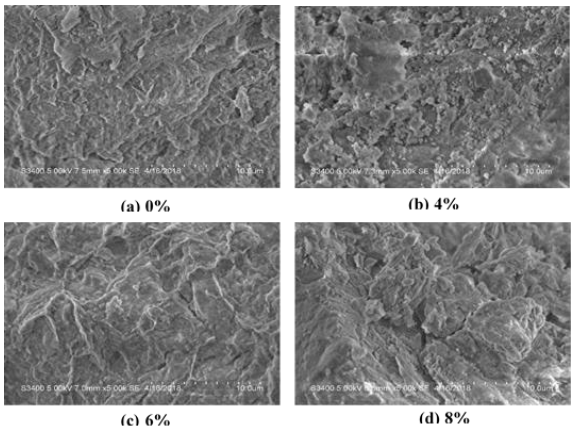

Fig. 8 Scanning Electron Micrographs: 5000x

For the unstabilized soil, sharp edges are seen, as well as crystal-like structures, indicating its initial arrangement as clayey soil. The 4% stabilized soil showed the dispersal of rounded and subangular

particles, reduced the presence of sharp-edged particles but exposes the intergranular voids. The rounded particles were combined with the irregularly-shaped particles, forming various lines and making the 6% stabilized soil more homogeneous. Clustering of these molecules into bigger particles evidently showed the clumping and binding of particles in 8% stabilized soil. For the overall arrangement, the application of marine shells and consequent increase in shell concentration to the soil exhibited the binding of the soil particles with the aid of connectors, reducing the intergranular voids, and therefore strengthening the soil.

Soil Application Assessment

For subbase and base materials, the National Lime Association recommends unconfined compressive stress values ranging from 0.345 MPa to 0.9 MPa, for soil-lime mixtures cured for 8 days. Based from the unconfined compressive strengths obtained from curing the samples for 7 days, the requirements were not met. With this, it is recommended to have longer curing periods for soil-shell mixtures since this may be a factor in the increase of strength.

The Department of Public Works and Highways Blue Book also set the requirements for suitable embankment materials. The soil used for homogenous embankment must not have more than 15% of its mass passing Sieve No. 200. Also, the material should have a plasticity index and liquid limit not more than 6 and 30, respectively. Using obtained data, it was found that the soil was not a suitable material for homogenous embankment.

Finally, using requirements for zoned embankments as specified in the Earthworks Materials Specification of the Australian Rail Track Corporation, it was found that only part of the requirements for zone D were met by the values obtained in the study.

CONCLUSIONS

The potential for the use of marine shell is explored as it is made up of a useful product, specifically the calcium carbonate ($CaCO_3$), a chemical compound also found in lime. This study was conducted to identify the changes in some mechanical properties of clayey soils upon stabilization with various shell concentrations.

With the aid of X-ray fluorescence, it was verified that the calcined marine shells from a mixture of waste mussels, oysters, and scallops are composed of 95.22% CaO by weight.

The unconfined compressive strength of the unstabilized soil significantly increased with that of all the stabilized soils. From the medium consistency given by the unstabilized soil, the soil improved to a very stiff consistency due to 8% marine shell concentration. In addition to that, the plasticity index decreases as the marine shell content increases, changing the soil from a classification of very high plasticity to high plasticity. Consequently, the reduction of plasticity index also decreases the activity number of the soil. The unstabilized soil is a normal type of soil, in terms of its activity. All stabilized soils yielded activity numbers less than 0.75, reclassifying the soils to an inactive type, and therefore lowering its swelling potential.

The stress-strain curves displayed a strain softening behavior due to the barreling failure of the soil specimens. The elastic moduli of the soils were also obtained and it was found that there was an increase in its value, supporting the unconfined compressive strength results showing the increase in stiffness of the clay.

The application of calcined marine shells leads to the clustering of the soil particles with the aid of connectors, reducing the intergranular voids, and further strengthening the soil.

UNDRAINED TRIAXIAL COMPRESSION BEHAVIOR OF CARBON-DIOXIDE-HYDRATE-BEARING SAND AND ITS CONSTITUTIVE MODELING

Hiromasa Iwai[1] and Takaya Kawasaki[2]
[1] Nagoya Institute of Technology, Japan; [2] Nagoya Railway Company, Japan

ABSTRACT

Recently, carbon-dioxide-hydrate (CDH) has attracted attention from the viewpoint of the energy and environmental related issues in geotechnical engineering, since a larger amount of CO_2 gas can be captured in form of the CDH and it can be stored beneath submarine sediments. In order to achieve the reduction of the CO_2 gas emission, it is important to understand the mechanical response of CDH-bearing soils such as stress-strain relations and deformation behavior. Further, a constitutive model for CDH-bearing soils will be also required for numerical simulations to evaluate the safety and the geotechnical risk of CDH-bearing sediments. In the present study, we have proposed a new constitutive equation considering the hydrate morphology, and then the proposed model is applied to the past experimental results of CDH-bearing sand specimens; a series of undrained triaxial compression tests were conducted by the author myself. The result shows that the proposed constitutive equation well fit both the stress-strain curves and the effective stress path of CDH-bearing specimens.

Keywords: Carbon dioxide hydrate, Triaxial compression test, Elasto-plastic constitutive model, CCS

INTRODUCTION

Gas hydrates (GHs) are compounds which the cage-like structure of water molecules traps guest gas molecules inside and solidifies under low temperature and high-pressure conditions. In the past decades, the mechanical properties of soil materials containing GHs have been investigated by many researchers. Methane hydrates(MHs)-bearing marine sediments, for example, have been recognized as an important geomaterial in terms of energy geotechnics, since a large amount of methane gas is trapped inside MHs. Recently, not only MHs but also carbon dioxide hydrates (CDHs) have attracted attention from the viewpoint of carbon dioxide (CO_2) gas emission, because the CDHs can store an enormous volume of CO_2 gas inside its cage-like solid structure. In addition, the formation of CDHs in marine sediments can also be used as one of the methods for enhanced MHs recovery. At present, the method considered to be the mainstream of MHs production is "depressurization method" in which the pore pressure of MH reservoir is reduced to a pressure where MHs cannot exist as a solid phase; MHs dissociates into water and methane gas. In this depressurization method, however, the recovery rate of the MHs may decrease due to the endothermic reaction of MH dissociation. Fig. 1 shows a schematic drawing of MHs production with simultaneous formation of CDHs in marine sediments. The simultaneous formation of CDHs with MHs dissociation will prevent temperature decrease and it will lead to continuous methane gas production.

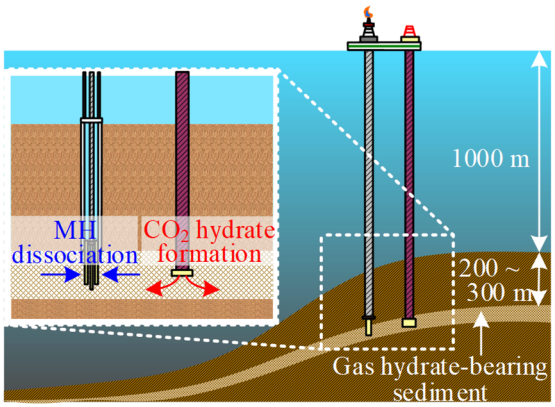

Fig. 1 Schematic drawing of MHs production and simultaneous formation of CDHs in marine sediments

This method not only contributes to the enhanced recovery of MHs, but also it is expected as one of the technologies for carbon capture and storage (CCS). For example, Inui and Satoh (2006)[1], Inui (2011)[2] and Nakashima et al. (2013)[3] focus on sequestering CO_2 in form of CDH state beneath the seafloor. In this method, CO_2 is injected into the unconsolidated sand layer under low temperature and high-pressure conditions where the CDH can be generated, and it reacts with pore water in the sediment. The CDH storage is expected to be able to stably store a large amount of CO_2 gas in a long period with a smaller volume. It is, therefore, important for MHs production and carbon dioxide storage to clarify the fundamental mechanical characteristics of the submarine sediments containing CDHs.

In the present study, undrained triaxial compression behavior of CDH-bearing sand are investigated by means of a comparative study of the experimental results and the results of the constitutive model. For the experimental results, the result presented by Iwai et al. (2018)[4] is referred; they carried out a series of undrained triaxial compression tests on the CDH-bearing sand specimens. As for the constitutive modeling, we propose an elasto-plastic constitutive equation for GH-bearing sediments considering the different type of morphology of GHs, and the proposed model is then applied to the experimental results of Iwai et al. (2018)[4].

SUMMARY OF THE UNDRAINED TRIAXIAL COMPRESSION TESTS ON CDH-BEARING SAND

In order to have further knowledge of CDH-bearing sediments, Iwai et al. (2018)[4] carried out a series of undrained triaxial compression tests on synthetic CDH-bearing sand specimens. They used a high-pressure and low-temperature triaxial testing apparatus which can reproduce an environment where GHs can exist stably [5]. Fig. 2 shows the view of the experimental apparatus. The details of the equipment can be found in the paper by Iwai et al. (2016)[5] or Iwai et al. (2018)[4].

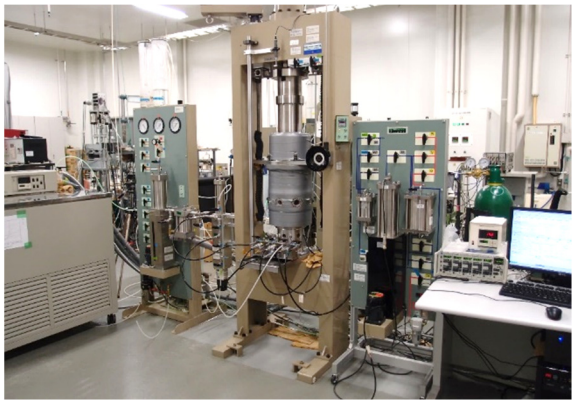

Fig. 2 View of the experimental apparatus

They conducted the tests for a total of six cases with different hydrate saturations; one of these cases is the sample without CDHs, that is, just water-saturated sand. The initial mean effective stress is 2.0MPa and the back pressure is set to be 10MPa in all the cases. The strain rate is constant at 0.1%/min. From the undrained compression test, it is found that both stiffness and strength increase with an increase in total hydrate saturation. The stress ratio at the critical state becomes M=1.20 in all cases and it seems to be independent on the hydrate saturation when it is less than about 50%; when the hydrate saturation is larger than about 50%, on the other hand, the critical stress ratio becomes larger than that of the host geomaterial. As to the dilatancy behavior, the positive excess pore water pressure was observed at the early stage of the shearing. The maximum value of the excess pore water pressure seems not depending on the hydrate saturation, while the negative value of the excess pore water pressure at the end of the shearing clearly depends on the hydrate saturation.

CONSTITUTIVE MODELING CONSIDERING GAS HYDRATE MORPHOLOGY

In general, the mechanical behavior of GH-containing soil changes depending on the content of GH in pore spaces; the strength and the stiffness increase with the increase in hydrate content. On the other hand, the past researches have also found that there are obvious differences in the peak strength, the stiffness and the dilatancy behavior among GH-bearing samples even though they have the same degree of hydrate saturation (e.g., Hyodo et al., 2014[6]; Miyazaki et al., 2016[7]). Some researchers have pointed that those differences may come from the difference in hydrate morphology, that is, pore-filling (PF) type, load-bearing (LB) type, and cementing (CM) type as shown in Fig. 3 (i.e., Waite et al., 2009[8]). Various constitutive equations have been proposed by many researchers (e.g., Kimoto et al., 2007[9]; Klar et al., 2010[10]), however, nothing considers differences of the hydrate morphology into the constitutive model. In order to make the constitutive model which can express the stress-strain relations and deformation behavior of GH-bearing sediments more precisely, we propose the new model for GH-bearing sediments considering the variation of the hydrate morphology.

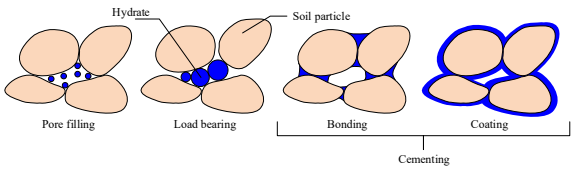

Fig. 3 Three types of GHs morphology

Basic settings of each GHs morphology

At first, the total hydrate saturation is defined as follows:

$$S_r^H = V^H / V^v \tag{1}$$

in which V^H is the volume of the hydrate phase in the pore space and V^v is the volume of the void,

respectively. In the present study, we newly propose the hydrate saturation for each hydrate morphology assuming that there three different types of the hydrate morphology. The total hydrate saturation S_r^H is divided into three parts, that is, CM-type, LB-type, and PF-type.

$$S_r^H = S_{CM}^H + S_{LB}^H + S_{PF}^H \tag{2}$$

$$S_{CM}^H = \alpha S_r^H, \quad S_{LB}^H = \beta S_r^H, \quad S_{PF}^H = \gamma S_r^H \tag{3}$$

$$0 < \alpha, \beta, \gamma < 1, \quad \alpha + \beta + \gamma = 1 \tag{4}$$

in which α, β, γ are the ratio of each hydrate morphology with respect to the total hydrate saturation, and the total should be equal to 1.

Yield function and plastic potential function

Uchida et al. (2012)[11] have developed the methane hydrate critical state (MHCS) model based on the concept of the critical state of soil mechanics. In a similar manner to Uchida et al. (2012)[11], the following yield function is used in the present study.

$$f = g = q^2 + M^2 p' \left[p' - R\left(p_c' + p_{CM}' + p_{LB}' \right) \right] \tag{5}$$

where q is the deviator stress, M is the stress ratio at the critical state of the host material, p' is the mean effective stress, p_c', p_{CM}', and p_{LB}' are the hardening parameters that expand the original yield function: modified Cam-clay model. In the present study, the associated flow rule is adopted to evaluate the plastic strain vector. The plastic potential function g, therefore, is the same function as the yield function f. The parameter R is the sub-loading surface ratio proposed by Hashiguchi (1989)[12] and its evolution law is given by:

$$dR = -m_R \left[\left(p_c' + p_{CM}' + p_{LB}' \right) / p_c' \right] \ln R \left| d\boldsymbol{\varepsilon}^p \right| \tag{6}$$

where m_R is a fitting parameter and $d\boldsymbol{\varepsilon}^p$ is the increment of the plastic strain vector. The schematic drawing of the yield surface is shown in Fig. 44.

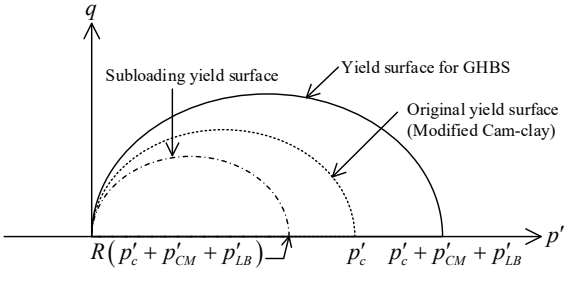

Fig. 4 Yield function [11]

By using the associated flow rule in the presenting model, the plastic strain increment vector can be expressed as follows.

$$\left\{ d\varepsilon_v^p \;\; d\varepsilon_v^p \right\}^T = \left\{ \partial f / \partial p' \;\; \partial f / \partial q \right\}^T \tag{7}$$

Hardening parameters

Consolidation yield stress

The hardening parameter p_c' is the effective consolidation yielding stress which represents an isotropic strain hardening behavior of the soil. As for the hardening rule, the conventional relationship between the p_c' and the plastic volumetric strain is adopted as follows:

$$dp_c' / p_c' = (1+e) d\varepsilon_v^p / (\lambda - \kappa) \tag{8}$$

where e is the void ratio, λ is the compression index, κ is the swelling index, and $d\varepsilon_v^p$ is the increment of the plastic volumetric strain.

Hardening parameters of gas hydrates

In order to express the greater strength and the dilatancy of GH-bearing sediments comparing with that of sand without hydrates, the additional hardening parameters p_{CM}' and p_{LB}' are newly introduced to the yield function, which expands the original yield function to the right-hand side. The p_{CM}' and p_{LB}' are the function of each of the hydrate morphology; the different type of morphology will involve the different hardening behavior.

$$p_{CM}' = a_{CM} \left(S_{CM}^H \right)^{b_{CM}} \tag{9}$$

$$p_{LB}' = a_{LB} \left(S_{LB}^H \right)^{b_{LB}} \tag{10}$$

In which a_{CM}, b_{CM}, a_{LB}, and b_{LB} are the fitting parameters controlling the expansion of the yield function. These parameters are determined so that the degree of material hardening becomes much larger in the CM-type than that in the LB-type.

Hydrate morphology transition by shearing

The hardening parameters p_{CM}' and p_{LB}' increase or decrease with the changes in the total hydrate saturation and the hydrate morphology ratio. Each hydrate morphology ratio will vary due to shearing and deformation of void spaces even if the total hydrate saturation is constant. The following assumptions in regard to the morphology transition are adopted.

- First, the CM-type changes into the LB-type due to crush and breakage of the hydrates bonding with soils particles as shown in Fig. 5. Thus, the increment of the CM-type ratio α is given by the following equation as depending on the shear strain.

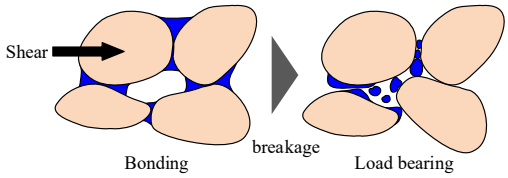

Fig. 5 Morphology transition from CM-type to LB-type

$$d\alpha = -m_\alpha \alpha \left| d\varepsilon_d^p \right| \tag{11}$$

where m_α is a material parameter which determines the transition rate from the CM-type to the LB-type.

- The second assumption is that the LB-type and the PF-type of the hydrate morphology mutually changes with increase and decrease in the volume of void. The LB-type changes into the PF-type in the case of the volume expansion: positive dilatancy. In contrast, the PF-type changes into the LB-type when it is compression: negative dilatancy. This transition between the LB-type and the PF-type is schematically illustrated in Fig. 6.

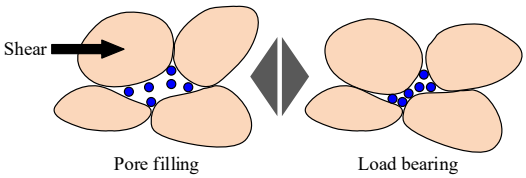

Fig. 6 Morphology transition between LB-type and PF-type

As shown in Fig. 6, the ratio of the PF-type γ depends on the volume of the pore space, and the increment of the ratio $d\gamma$ is defined as the function of the plastic volumetric strain increment (positive in compression)

$$d\gamma = -m_\gamma \gamma d\varepsilon_v^p \tag{12}$$

in which m_γ is a material parameter which determines the transition rate between the LB-type and the PF-type of the morphology.

Since the summation of the morphology ratio is equal to one as shown in Eq. (1), the increment of the morphology ratio of the LB-type $d\beta$ is expressed by the following equation.

$$d\beta = -d\alpha - d\gamma \tag{13}$$

Considering Eq. (8)~Eq. (12) gives the evolution laws for the hardening parameters p'_{CM} and p'_{LB} as

$$dp'_{CM} = a_{CM} b_{CM} \left(\alpha S_r^H\right)^{b_{CM}-1} \left(\alpha dS_r^H - m_\alpha \alpha \left| d\varepsilon_d^p \right| S_r^H\right) \tag{14}$$

$$dp'_{LB} = a_{LB} b_{LB} \left(\beta S_r^H\right)^{b_{LB}-1} \left\{\beta dS_r^H - \left(d\alpha + d\gamma\right) S_r^H\right\} \tag{15}$$

MODEL APPLICATION

In this chapter, the performance of the proposed model evaluated by comparing with the past experimental data by Iwai et al. (2018)[4]. The model is applied to the results of undrained triaxial compression tests for CDH-bearing sand samples, and mechanical behavior such as the undrained shear strength and the effective stress path is investigated.

Material parameters

The material parameters for the constitutive model are listed in Table 1. The parameters from the initial mean effective stress p'_0 to the initial void ratio e_0 are determined based on the experimental results; the initial void ratio varies depending on the experiment condition. The parameters for the hardening rules are determined so that the model results fit that of the experiment.

Table 1 Material parameters

Parameters		value
Initial mean effective stress [MPa]	p'_0	2.0
Poisson's ratio	ν	0.2
Stress ratio at the critical state	M	1.20
Compression index	λ	0.16
Swelling index	κ	0.004
Initial void ratio	e_0	variable
Initial yield stress	p'_{c0}	11.0
Material constant for sub-loading surface	m_R	15.0
Transition parameter (CM → LB)	m_α	1.0
Transition parameter (PF ↔ LB)	m_γ	7.0
Hardening parameter for p'_{CM}	a_{CM}	21.0
Hardening parameter for p'_{CM}	b_{CM}	1.0
Hardening parameter for p'_{LB}	a_{LB}	6.0
Hardening parameter for p'_{LB}	b_{LB}	1.0

Initial hydrate morphology ratio

In addition to the material parameters, the initial ratio of each hydrate morphology α_0, β_0, and γ_0 should be determined. It is preferable that the initial morphology ratio is directly determined by visualizing the microscopic structure of soil particles and hydrates. In the present study, however, the initial ratio is treated as the fitting parameter and it is

determined so that the results by the constitutive model fits the experimental data because of the lack of research data on the microstructure of the hydrate morphology. Table 2 shows the initial void ratio of each case, the total hydrate saturation, and the initial morphology ratio. In determining the initial ratio, we use the following findings obtained from the past researches.

[1] All the type of the hydrate morphology, that is, the CM-type, the LB-type and the PF-type, exist at the initial state.

[2] The increase in the strength and the positive dilatancy becomes greater in the order of CM > LB > PF-type of the hydrate morphology.

[3] The proportion of the LB-type and the CM-type increases as the total hydrate saturation increases. Furthermore, the CM-type becomes dominant when the total hydrate saturation increases much more.

Table 2 Total hydrate saturation and the initital morphology ratio

e_0	p'_0 [MPa]	S^H_r [-]	α_0	β_0	γ_0
0.74	2.0	0.0	-	-	-
0.74	2.0	25.8	0.1	0.3	0.6
0.73	2.0	27.8	0.1	0.3	0.6
0.74	2.0	36.3	0.1	0.4	0.5
0.74	2.0	42.2	0.1	0.4	0.5
0.74	2.0	56.9	0.1	0.4	0.5

RESULT AND DISCUSSION

The comparison result of the stress-strain relation and the effective stress path between the experiment and the constitutive equation is shown in Fig. 7~Fig. 9. As mentioned in the previous section, the undrained shear characteristics of the CDH-bearing specimens are that the maximum deviator stress increase with an increase in the total hydrate saturation. From the effective stress path, it can also be found that the increase in the mean effective stress after reaching the point of the phase change becomes larger with the increase in the total hydrate saturation; the degree of the positive dilatancy depends on the total hydrate saturation. It should be noted that the negative dilatancy in the early stage of the shearing is almost the same regardless of the hydrate saturation.

First, the stress-strain curves of the proposed model fit the shape of the experimental curves very well. The maximum deviator stress, that is, the undrained shear strength obtained from the constitutive model increases with the increase in the total hydrate saturation. For the case where the hydrate saturation is 56.9%, the maximum deviator stress at closely matches the experimental and analytical results, but the initial stiffness is greater in the model than that of the experiment. Secondly, in the stress path, it is found that the mean effective stress initially because of the negative dilatancy and the minimum value of the mean effective stress is almost the same in each case. The model result supports the fact that the degree of the negative dilatancy at the early stage of the shearing independent on the hydrate saturation. In contrast to that, the positive dilatancy increases after the phase change in all cases, and the increase to reach the critical state is also well consistent with the behavior of the experiment. The reason for this is that the PF-type is the predominant morphology at the initial stage and the plastic strain is easy to progress because of the less bonding effect of hydrates. The PF-type morphology gradually shifts to the LB-type as the increase in the plastic volumetric strain by the shearing, and it comes to exhibit the positive dilatancy more clearly.

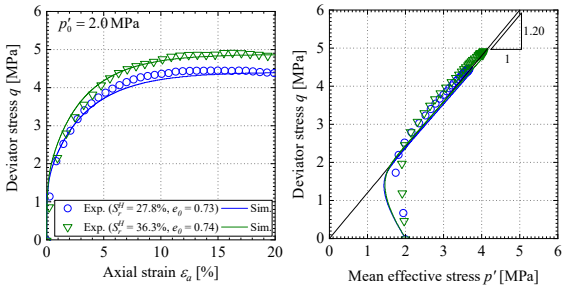

Fig. 8 Comparison of the constitutive model with undrained triaxial compression test (2)

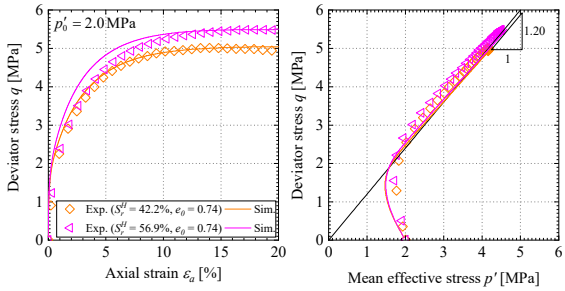

Fig. 9 Comparison of the constitutive model with undrained triaxial compression test (3)

CONCLUSIONS

In order to clarify the mechanical behavior of synthetic CDH-bearing sand under undrained conditions, we performed a comparative study of the experimental result and the element simulation by the proposed constitutive model. As for the constitutive model, the difference of the hydrate morphology was taken into account for the hardening parameters. The main findings of this study are summarized below:

- The maximum shear strength increases with the increase in the total hydrate saturation. The result is the same as the past experiment results of methane hydrate-bearing specimens.
- The positive excess pore water pressure, that is, the negative dilatancy, can be found in the early stage of the loading, and the maximum value of the pore water pressure seems to be independent on the total hydrate saturation. It implies that the PF-type, which has little hardening effect on the CDH-bearing sand, is the dominant hydrate morphology at the beginning of the shearing.
- The positive dilatancy, on the other hand, clearly depends on the total hydrate saturation. The hydrate morphology of the PF-type changed into the LB-type as the increase in the plastic volumetric strain by the shearing.
- The proposed constitutive model well fits both the stress-strain relation and the effective stress path by considering the difference of the initial hydrate morphology and its transition.

ABSTRACT

Enzyme-mediated calcite precipitation (EMCP) method has been established for soil improvement technique. This study discussed the possibility of plant-derived urease enzyme as bio-catalyst. The urease enzyme was utilized for hydrolysis of urea, which causes the supply of calcium ions to precipitate calcium carbonate. Extract of cabbage and soy pulp without purification were utilized as a substitute for commercial urease enzyme product. The solution was composed of 15 g/L crude extract, 1 mol/L urea, and calcium chloride. Test tube experiment and mineralogy analysis of precipitated materials were conducted. The mineralogy and morphology of precipitated calcite were confirmed by using X-Ray Diffraction (XRD) and Scanning Electromagnetic (SEM) tests. The precipitation ratio of crude extract as the replacement of the urease enzyme was more than 60% of the maximum theoretical mass. The calcite mineral was formed as the precipitated materials revealed from the mineralogical and morphological analyses, which concludes that crude extract from cabbage and soy pulp should be a potential material for sources of urease enzyme.

Keywords: Plant-derived urease, Crude extract, Calcite precipitation, Soil improvement

1. INTRODUCTION

Calcite precipitation method was establish for improving the mechanical properties of soil [1, 2, 3], for reducing the permeability of porous materials [4-8] for increasing shear strength and stiffness of soil [1-8], for decreasing the swelling potential of clay soil, and for mitigating the liquefaction potential [2, 3]. Specifically, microbial-induced carbonate precipitation (MICP) may be used to improve the engineering properties of soil, such as shear strength, stiffness, and permeability of the soil [4, 10]. In this method, bacterial cells, e.g., Sporosarcina pasteurii, has been utilized to hydrolyze urea into ammonium and carbonate ions [7,10,11]. The produced carbonate ions may be precipitated as calcite crystal in the existence of calcium ion. However, the complexity of mechanical and hydraulic properties of soil may not be easy to control because it may be impossible to constrain the extinction and/or the generation of living bacteria in natural environments [8]. Examination of other alternative methodology for calcite precipitation technique is necessary.

Recently, enzyme-mediated calcite precipitation (EMCP) technique have been investigated [3, 8, 9, 12] to enhance the mechanical properties of soil. Urease enzyme from jack beans may be used to dissociate urea into ammonium and carbonate ions instead of bacteria. Using enzyme may be more straightforward than using bacterial because the biological treatment does not need to be considered [13]. The calcite precipitation should occur after the chemical reaction between the powdered urease enzyme mixed with urea and calcium chloride. The method using urease enzyme with purification is expensive when purchased from a commercial supplier. However, the utilization of the enzyme is very effective for laboratory-scale models [13]. The reaction of calcite formation are shown in the following equations:

$$CO(NH_2)_2 + 2H_2O \xrightarrow{\text{Urease}} 2NH_4^+ + CO_3^{2-} \quad (1)$$

$$CaCl_2 \longrightarrow Ca_2^+ + 2Cl^- \quad (2)$$

$$Ca_2^+ + CO_3^{2-} \longrightarrow CaCO_3 \text{ (precipitated)} \quad (3)$$

Urease enzyme has been found in various bacteria, fungi, and higher plants. Some of the studies have used plant-derived urease enzyme to increase the shear strength of the soil. Watermelon seed crude extract and urea may be effective to induce the precipitation of calcium phosphate compound. The maximum UCS using the method is 125.6 kPa after 28 days of curing [16]. Meanwhile, plant-derived urease enzyme has a limited lifespan; its activity, and function decrease with time. This limited lifespan is beneficial in soil improvement as the enzyme can naturally degrade and eliminate the long-term effect on the environment [14, 15].

The current study aims to obtain new sources of urease enzyme as a replacement of the purified

enzyme. The crude extract of cabbage and soy pulp, which are both waste materials, was selected in this work and was examined to produce calcite precipitation. Test-tube experiments were performed to determine the effect of the crude extract and to evaluate the material precipitation. The XRD and SEM tests were conducted to observe the effects of crude extract on the mineralogy and morphology of the precipitated materials. This study mainly focuses on replacing commercial urease enzyme with crude extract of cabbage. The use of waste materials may result in lowering the cost and the negative impacts on environments. The current method may be used to increase the soil strength as soil improvement. The schematic of soil improvement with plant-derived urease is shown in Fig. 1.

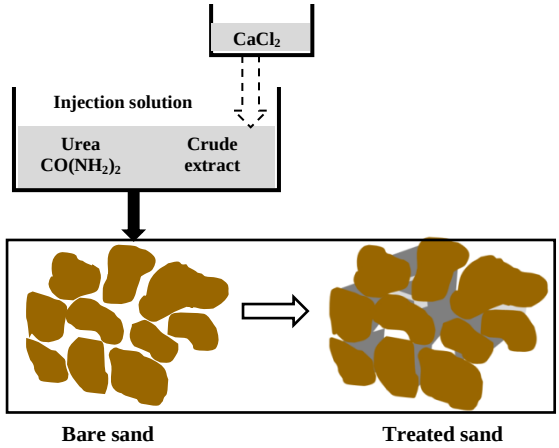

Fig. 1 Schematic of soil improvement using calcite precipitation with plant-derived urease enzyme

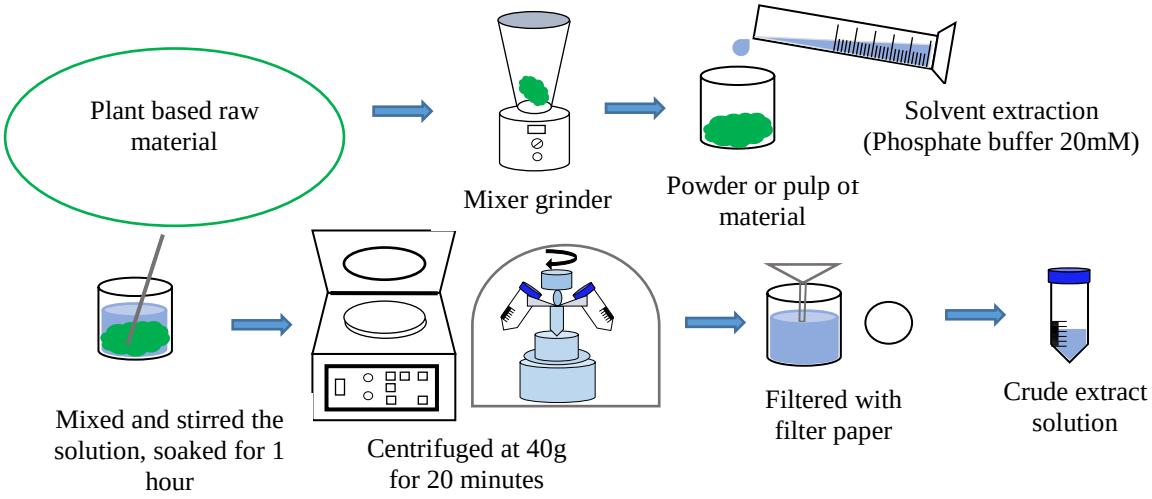

Fig. 2 Procedures of the make the crude extract

2. METHODOLOGY

2.1 Extraction of Urease Enzyme

The crude extract from plant-derived urease was performed as follows: the plant-based raw material was finely ground using a mixer grinder, and 1.5 g of the pulp or powder was soaked in 0,1L of solution with 20mM buffer phosphate as a solvent extraction for 1 hour with occasional agitation. The suspension was then centrifuged, stirred at 40 g for 20 minutes and the clear or slightly turbid solution without dregs was produced, and then filtered using filter paper (pore size 11μm) to remove the undissolved particles of crude extract. The procedures to make a crude extract from the plant-based raw material are illustrated in Fig. 2.

2.2 Test-Tube Experiment

In this experiment, the precipitation of calcium carbonate was evaluated directly in transparent test tubes. The solution consisted of 15 g/L of crude extract and 1mol/L urea and calcium chloride. Urea-$CaCl_2$ was mixed with distilled water. The combination of Urea-$CaCl_2$ and the crude extract source of urease solution were mixed thoroughly to make a total solution volume of 30 mL and allowed to react until the system reached the steady state. During the entire curing time, the test tubes were kept in a box without shaking, and the samples were always cured at a room temperature of 20°C. The precipitation of $CaCO_3$ was produced after curing time (2 weeks), and the solution was filtered with filter paper. The procedures of a test-tube experiment with crude extract are illustrated in Fig. 3. The particles deposited on the filter paper and the particles remained in the tubes were dried at 60°C

for 24 hours. The precipitation ratio, which is the ratio of actual mass of the precipitated materials to the theoretical mass of the maximum precipitation of calcium carbonate, is determined as the equation below:

$$\textbf{precipitation ratio}\ (\%) = \frac{\textbf{actual mass}\ (a_m)}{\textbf{theoretical mass of}\ CaCO_3 (t_m)} \quad (4)$$

$$t_m = C \times V \times M \quad (5)$$

Where a_m is mass of the precipitated materials obtained from the test (g); t_m theoretical mass of $CaCO_3$ (g); C is concentration of the solution (mol/L); V is the volume of the solution (L); and M is molar mass of $CaCO_3$ (100.087 g/mol).

The comparison of the precipitation ratio between commercial urease enzyme and plant-derived urease enzyme was conducted to determine the effect of the crude extract used in this work.

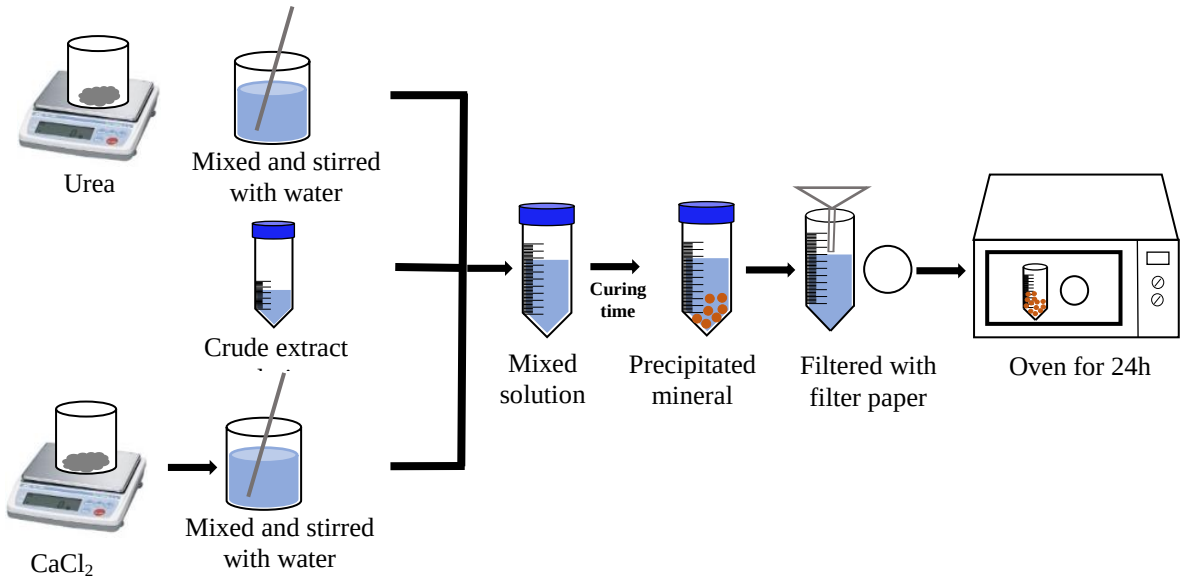

Fig. 3 Procedures of test tube experiments

3. RESULTS AND DISCUSSION

The addition of the crude extract of cabbage and soy pulp as a replacement of urease enzyme for the test-tube experiment may be effective to produce precipitation. The precipitation ratios of various sources of urease enzyme with concentration 1 mol/L of urea-$CaCl_2$ and 15 g/L of urease for several curing time were evaluated. A summary of the precipitation ratio obtained from the experiments are shown in Fig. 4.

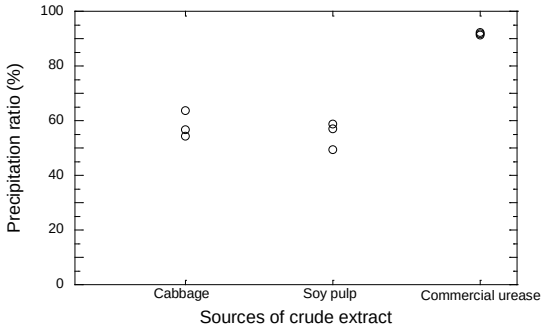

Fig. 4 The comparison test-tube experiment result between plant-derived urease and commercially of urease enzyme.

According to Fig. 4, the average of the precipitation ratio from the crude extract of cabbage and soy pulp is more than half of the precipitation ratio of the purified commercial product.

The addition of crude extract from cabbage and soy pulp should be effective to produce mineral precipitation.

The precipitation was assessed by X-Ray Diffraction (XRD) to confirm the occurrence of mineral. The obtained results are shown in Figure 5. The x-axis of XRD graph analysis indicates the 2θ of minerals while the y-axis represents the intensity. The main peak intensity of the materials was plotted on the curve and was compared with the intensity of the main peak of calcium carbonate. The growth of the crystal phase was observed by SEM, which is shown in Fig. 6. In Fig. 6(a), the crystal structure image of the precipitated materials obtained using the crude extract of cabbage is obvious, and in Fig. 6(b) rhombohedral precipitation is obtained when using the crude extract of soy pulp. The rhombohedral shape of precipitated material was also apparent when the extract of cabbage without purification is used to replace the commercial urease enzyme. Furthermore, the agglomeration form is also promoted in addition to rhombohedral shape. The using of extract soy pulp without purification

also has the significant effect on the precipitated material. The polymorph and agglomeration carbonate precipitated are obtained. The different shape of precipitated material resulting from the use of cabbage and soy pulp may be affected by the urease activity in the cabbage higher than soy pulp. Hence, the crystallization process on the soy pulp hasn't completed yet in the curing time of 2 weeks. The previous research reported that the delaying of precipitated process may promote the agglomeration form in the precipitated material [20].

4. CONCLUSIONS

The possibility of plant-derived urease enzyme as bio-catalyst in enzyme-mediated calcite precipitation (EMCP) method has been evaluated. Development of alternative sources for urease enzyme, which are cost-effectiveness and easy to be controled in the natural environment, is the crucial issue in the sustainability of calcite precipitation technique. In this study, the applicability of extract of cabbage and soy pulp as the bio-catalyst instead of the commercial urease enzyme was examined. The results of the test-tube experiment show that the precipitated materials of 40-60% are achieved using the cabbage and soy pulp without purification as the bio-catalyst. The mineralogical analysis of precipitated material using XRD confirms that the polymorph of calcite, aragonite, and vaterite are promoted. The SEM analysis has shown that the utilization of cabbage and soy pulp results in the different shape of precipitated material. The cabbage promotes the rhombohedral crystal, and the polymorph precipitated material is promoted by the utilization of soy pulp. The results of this study indicate that the plant-derived urease enzyme using the crude extract of cabbage and soy pulp is the potential source for urease enzyme in the EMCP method.

AN EXPERIMENTAL STUDY ON THE EVOLUTION OF UNSATURATED SOIL PARAMETERS DUE TO VARIOUS DEGREE OF SATURATION

Galih Bhekti Sula Pratama[1], Roh Santoso Budi Waspodo[1], and Heriansyah Putra[1]
[1]Department of Civil and Environmental Engineering, Faculty of Agricultural Technology and Engineering, IPB University (Bogor Agricultural University), Bogor, Indonesia

ABSTRACT

Landslide is a natural disaster that often occurs in Indonesia, which is associated with the rainy season. Infiltration of water from rainfall increases the degree of saturation; thus, the reducing of the shear strength parameters of soil and promote the imbalanced of the slope. Understanding of slope failure of the mechanism is the main challenge in the slope stability analysis due to rainfall. The evolution of the engineering properties of soil as the effect of water infiltration during the rainfall should be fixed. Undisturbed samples of well-graded silty sand (SW-SM) and silty sand (SM) from the site are used as the soil sample in this study. In this study, the experimental works are conducted to evaluate the evolution of unsaturated soil parameters, i.e., suction, cohesion, and internal friction angle in various degree of saturation. The filter paper tests are conducted to evaluate the matric suction of soil and develop the soil water characteristic curve (SWCC). Shear strength parameters of soil sample are examined using direct shear test method with the normal stress of 0.5, 1.0, 1.5 kgf. The results of this study show that the correlation of various degree of saturation and evolution of matric suction and shear strength parameters. The increase in the degree of saturation brings about the reduction in suction and shear strength parameters.

Keywords: Unsaturated soil, Shear strength, Suction, Slope stability

INTRODUCTION

Landslide is a geological phenomenon and one of the most scattered disasters on various surfaces of the earth. This phenomenon is indicated by the presence of large-scale soil movements, both in the form of rock falls, slope failures or shallow discharge flows, which can occur inland, coast and sea environments [1]. Landslide is a natural disaster that often occurs in Indonesia, which is associated with the rainy season [2]. Infiltration of water from rainfall increases the weight and degree of saturation of the soil [3], [4]. This condition is corresponding to reduce the suction of the soil . Decreasing suction of the soil, can make the normal stress of the soil decrease and result in the decrease of soil shear strength. Finally, it will promote the imbalanced of the slope [5]

Research about the landslide induced by rainfall has been studied extensively [2]-[17]. Understanding of slope failure mechanism is the main challenge in the slope stability analysis due to rainfall. The evolution of the engineering properties of soil as the effect of water infiltration during the rainfall should be fixed. In this study, Undisturbed samples such as well-graded silty sand (SW-SM) and silty sand (SM) from the site are used as the soil sample. The experimental works are conducted to evaluate the evolution of unsaturated soil parameters, i.e., suction, cohesion, and internal friction angle in various degree of saturation. The filter paper tests are conducted to evaluate the matric suction of soil and develop the soil water characteristic curve (SWCC). Shear strength parameters of soil sample are examined using direct shear test method with the normal stress of 0.5, 1.0, 1.5 kgf. Finally, all data were analyzed, and the mechanism of slope failure has known. Hence, the slope failure can be predicted, and the effect of the landslide can be minimized.

METHODOLOGY

Material

Undisturbed samples from Raya Puncak street were collected in March 2019 as the specimen of this experimental work. The undisturbed samples are well-graded silty clay (SW-SM) and silty clay (SM) that classified by USCS method.

Soil Water Characteristic Curve (SWCC)

The soil-water characteristic curve (SWCC) expresses the relationship between matric suction and gravimetric water content, volumetric water content or saturation [18]. The SWCC is a fundamental soil characteristic, which is necessary to determine parameters of many processes in the soil such as infiltration, drainage, solute movement, and water

availability for plants. It is also an essential tool in the study of the strength and deformation of unsaturated soil [19], [20].

In this study, Whatman 42 filter paper based on ASTM D5298-2003 was used to measure the evolution of the matric suction in various degree of saturation of the soil. The scheme of the filter paper method is depicted in Figure 1. Two blocks of the soil samples were prepared inside the core cutter cylinder as the container. Three layers of filter paper were put between the soil samples. The sample was kept in the vacuum condition for 7 days to approach the equilibrium condition. The initial and final mass of the soil samples and filter paper were measured to know the water content of each case and develop the degree of saturation.

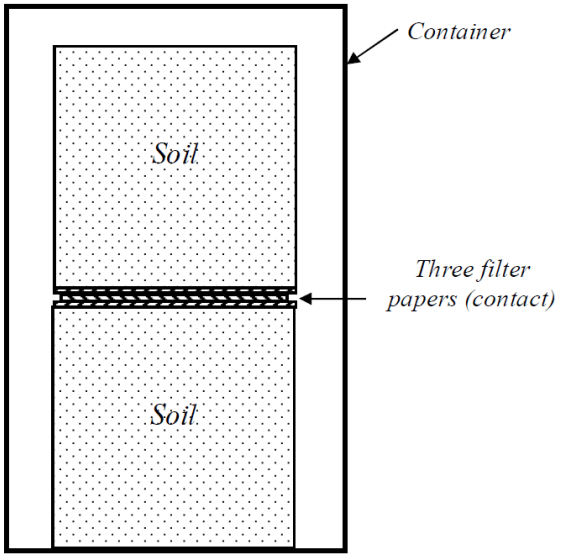

Fig. 1 Scheme of the filter paper method [21]

A calibration curve based on ASTM D5298-03 in Figure 2 is used to obtain the matric suction from the water content of the filter paper.

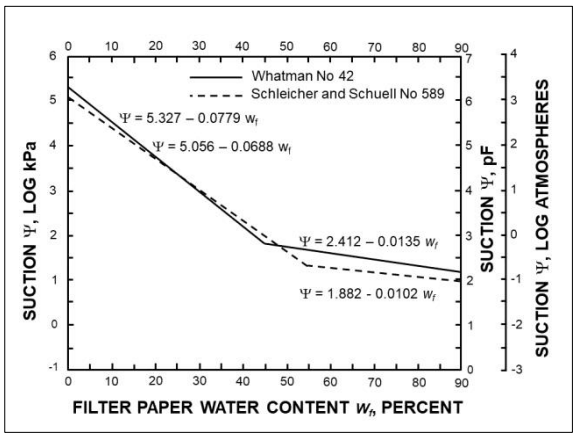

Fig. 2 Calibration curve for the matric suction [21]

Direct Shear Test

The direct shear test is a laboratory test that used to measure the shear strength parameters of soil such as cohesion and internal friction angle [22]. In this study, the direct shear test was performed on silty sands in several degrees of saturation condition. It conducted according to the ASTM standard for the direct shear test (ASTM D3080-11).

The test is performed on three specimens for each sand from a remolded soil sample. The specimen is placed in a shear box which has two stacked rings to hold the sample. The contact between the two rings is at approximately the mid-height of the sample. The normal stress of 0.5, 1.0, 1.5 kgf is applied vertically to the specimen, and the upper ring is pulled laterally until the sample fails, or through a specified strain.

The load applied and the strain induced is recorded at frequent intervals to determine a stress-strain curve for each confining stress. Several specimens are tested at varying confining stresses to determine the shear strength parameters, the soil cohesion (c) and the angle of internal friction, commonly known as friction angle (ϕ). The results of the tests on each specimen are plotted on a graph with the peak (or residual) stress on the y-axis and the confining stress on the x-axis. The y-intercept of the curve which fits the test results is the cohesion, and the slope of the line or curve is the friction angle.

Fig. 3 Direct shear test tool

Experimental Condition

Experimental conditions for matric suction test and shear strength test experiments to evaluate the effect of degree of saturation on soil parameters changes are beginning from wet condition to dry condition (drying process) — each experiment conducted in five various degrees of saturation. Undistributed samples are used for matric suction test, and remolded samples are used for the shear strength test. Each soil samples are modified on wetting weight using oven to obtained various condition. The degree of saturation can be measured by knowing the specific gravity and initial condition

of the soil. A formula to measure the degree of saturation refers to Eq. (1).

$$Sr = \left(\frac{Wb - Ww}{V - \left(\frac{Wd}{Gs}\right)}\right) \quad (1)$$

where ;
Sr : the degree of saturation
Ww : wet weight
Wd : dry weight
Gs : specific gravity
V : volume of specimen

RESULT AND DISCUSSION

Laboratory Test

The laboratory test results for physic and mechanical properties of soil are present in Table 1. Two types of soil were examined in this work. The saturation condition was obtained in the initial state.

Table 1 Physic and mechanical properties of two type soil samples

Parameters	SW-SM	SM
Spesific gravity, Gs [-]	2,593	2,508
Initial water content, *w* [%]	62,5	52
Initial saturation, Sr [%]	86,2	92,7
Porosity, n [-]	0,70	0,63
Dry density, γ_d [g/cm^3]	0,83	1,02
Permeability, k [cm/s]	0,35	0,0036
Liquid limit, LL [%]	56,7	66,6
Plastic limit, PL [%]	32,3	34,2
Plasticity index, PI [%]	24,4	32,4

Two types of soil were classified based on the USCS (United States Classification Soil) method by using grain size distribution data and atteberg limit test data. Soil 1 was classified as well-graded silty sand with SW-SM symbols. Soil 2 was classified as silty sand with SM symbol. Grain size distribution curve for soil 1 and soil 2 are depicted in Fig. 4 and Fig. 5. All of the curves was fitted with the unimodal method by using Soil Vision program. Vision for two types of soil are depicted in Fig. 6

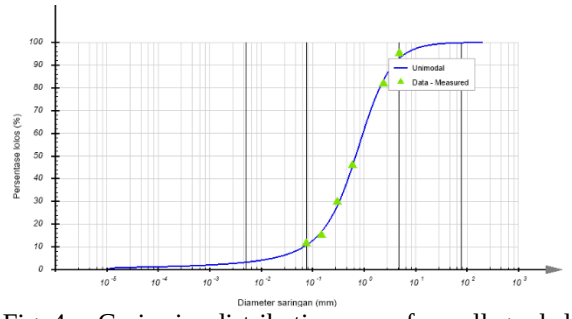

Fig. 4 Grain size distribution curve for well-graded silty sand (SW-SM)

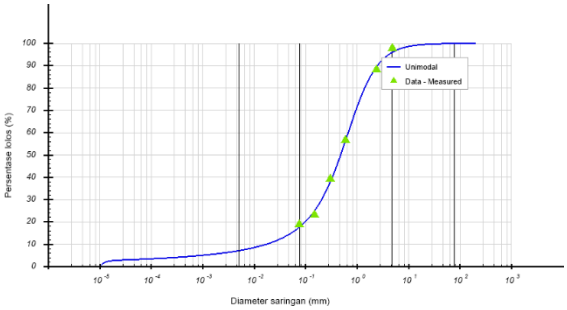

Fig. 5 Grain size distribution curve for silty sand (SM)

(a) (b)

Fig. 6 (a) Well-graded silty sand, (b) Silty sand

Evolution of Matric Suction

Filter paper method was conducted in various degree of saturation. Five conditions were obtained in this test for each type of soil. The drying method was used to reduce the water content for each condition. Each condition after drying was used in the filter paper test. Table 2 presents the matric suction for each type of soil sample in several conditions of the degree of saturation. Calibration curve in Figure 2 is used to obtain the matric suction.

Table 2 Summary result for matric suction test of two type of soil

Cases	Well-graded silty sand		Silty Sand	
	Sr [%]	Matric Suction [kPa]	Sr [%]	Matric Suction [kPa]
1	75,2	4,8	86,1	17,3
2	62,8	14,1	66,2	796,4
3	51,0	1786,8	59,2	2814,6
4	38,7	5181,4	26,3	96764,5
5	25,0	38297,5	24,7	106361,6

Soil Vision program was performed to fit the soil-water characteristic curve (SWCC) from the matric suction experimental data. The fitting curves are depicted in Fig. 7 for well-graded silty sand (SW-SM) and Fig. 8 for silty sand (SM). In these cases, 3 formulas are used to fit the SWCC curve. They are Freedlund and Xing,Van Genucthen, Brooks and Corey. The highest coefficient of the determinant (R^2) for each equation is picked for the fitting of SWCC. The highest R^2 for each SWCC curves is Freedlund and Xing formulas. The value is 0,9032 for well-

graded silty sand and 0,9708 for silty sand.

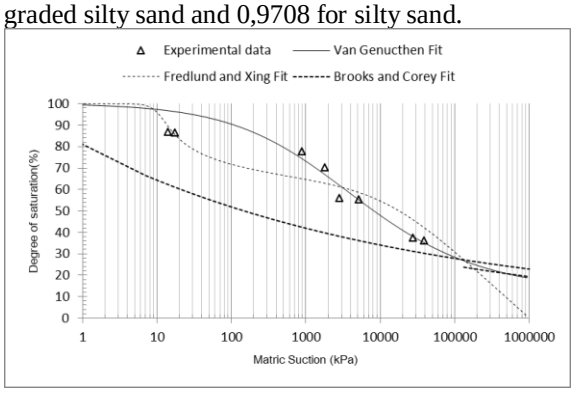

Fig. 7 SWCC for well-graded silty sand (SW-SM)

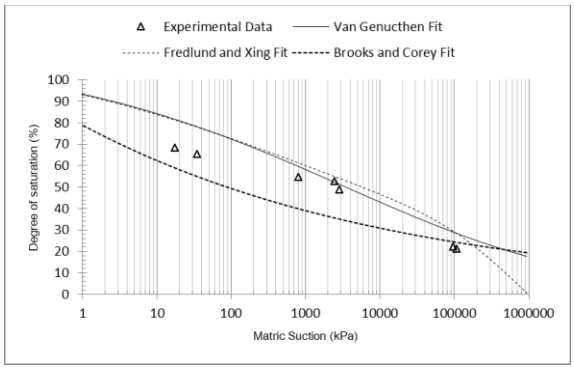

Fig. 8 SWCC for silty sand (SM)

Evolution of Shear Strength Parameters

The direct shear test was conducted in various degree of saturation. Five conditions of the degree of saturation were obtained in this test for each type of soil. Three remolded samples for each condition are used as a specimen of the test. The dry density of initial condition for each soil type is used as a control when the samples are remolded. Table 3 and 4 present the result of shear strength test for well-graded silty sand (SW-SM) and silty sand (SM). There is a change of soil shear strength parameter for each condition of the degree of saturation. The value of cohesion achieved in less than 1 kN/m^2 for each soil. This result confirmed that soil with sand type has a little cohesion value . It can be caused by the surface roughness of the soil [23].

Table 3 Summary result for the shear strength test of well-graded silty sand (SW-SM)

Cases	Dry density (γ_d) [gr/cm^3]	Saturation (Sr) [%]	Cohesion (c) [kN/m^2]	Internal friction angle (φ) [°]
1	0,83	9,4	0,29	11,3
2	0,83	32,7	0,26	9,7
3	0,83	45,9	0,24	10,2
4	0,82	88,8	0,19	10,2
5	0,81	90,2	0,09	6,3

Table 3 Summary result for the shear strength test of silty sand (SM)

Cases	Dry density (γ_d) [gr/cm^3]	Saturation (Sr) [%]	Cohesion (c) [kN/m^2]	Internal friction angle (φ) [°]
1	1,05	22,7	0,71	11,3
2	1,09	49,3	0,58	16,7
3	1,07	58,2	0,53	16,5
4	1,06	71,9	0,46	12,1
5	1,00	92,7	0,42	9,94

Both table 2 and 3 show that the internal friction angle has constant values, relatively.Value of internal friction angle for well-graded silty sand is about 6,7˚ until 11.3˚, and internal friction angle for silty sand is about 9.94˚ until 16.7˚. The change of internal friction angle value caused by dissimilarity of dry density of the soil.

Fig. 9 presents the evolution of cohesion for each soil type in various degree of saturation. Saturation of the soil effect on the change of cohesion. The increasing degree of saturation of the soil corresponding to reducing the value of cohesion. Well-graded silty sand has a value of cohesion lower than silty sand. It caused by the grain size of the soil. Silty sand has more fine materials than well-graded silty sand so it will affect the cohesion of the soil. It appropriate for the research conducted by Nugroho 2011. If a soil has more fine materials, it will increase the cohesion of the soil [24]

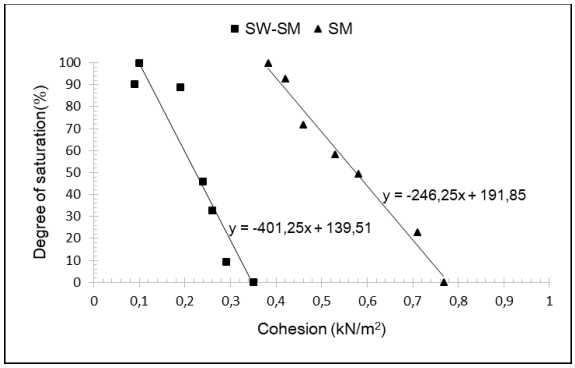

Fig. 9 Evolution of cohesion for each soil type

Correlation of Saturation, Matric Suction, and Cohesion

Shear stress is essential parameter in geotechnical engineering. SWCC that expresses the relationship between matric suction and gravimetric water content, volumetric water content or saturation is the primary tool to predict shear strength parameter in

unsaturated soil. Beside cohesion and internal friction angle, the value of matric suction also affects on shear stress of unsaturated soil.

Fig. 10, and Fig. 11 present the change of cohesion and matric suction effected by soil saturation changes. Fig. 10 curves for well-graded silty sand and Fig. 11 curves for silty sand. There is a correlation between the various degree of saturation and the evolution of matric suction and shear strength parameters. The increase in the degree of saturation brings the reduction in suction and shear strength parameters. The shear strength of the soil increases as matric suction increases. It has similarity with research conducted on sandy clay soil [24]

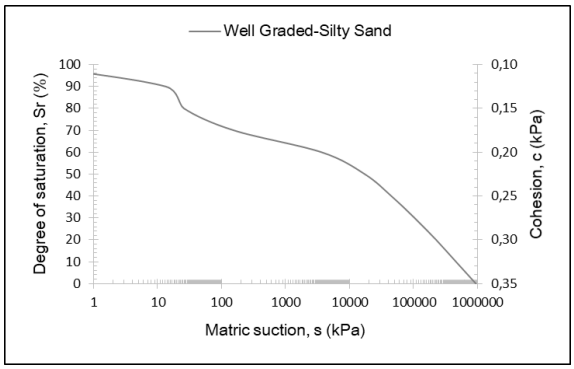

Fig. 10 Correlation between saturation, matric suction and cohesion on well-graded silty sand (SW-SM)

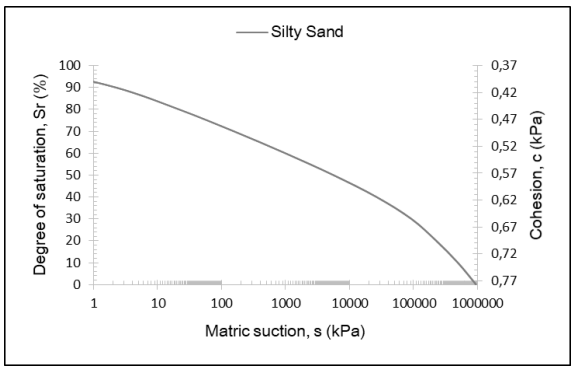

Fig. 10 Correlation between saturation, matric suction and cohesion on silty sand (SM)

CONCLUSIONS

The effect of infiltration induced by rainfall on the unsaturated soil parameters was evaluated. Laboratory experiments are conducted to obtain the significant effect of soil parameters changes influenced by soil saturation. Soil Vision knowledge-based system was used to give an approximation of the entire soil water characteristic curve (SWCC) using a proper curve fitting equation which represents measurable data points. In this study, Freedlund and Xing equation was utilized. Based on the results of fitting of SWCC, the value of correlation coefficient (R^2) is 0,9032 for well-graded silty sand and 0,9708 for silty sand.

The results of this study show that there is a correlation between the various degree of saturation and evolution of matric suction and shear strength parameters. The increase in the degree of saturation brings about the reduction in suction and shear strength parameters.

EFFECT OF CROSS-SECTIONAL SHAPE ON PILLAR STRENGTH

Greg You[1], Dake Zhao[1], Shuo Liu[1] and Zhou Gao[1]
[1]Federation University Australia, Ballarat, Victoria, Australia

ABSTRACT

Pillars of different cross-sectional shapes are widely used in civil and mining engineering. Are different shapes affecting the strength of pillars? Three cross-sectional shapes were designed in this study, which are circular, rectangular and square, and of the same height (150 mm) and the same cross-section area (1963.5mm^2). They were mortar pillars. The diameter of circular specimens is 50 mm, the width and depth of rectangular specimens are 62.67 mm×31.33 mm and the widths of square specimens are 44.31 mm. Uniaxial compressive strength (UCS) and point load strength tests were conducted for 36 specimens to comparatively analyse the effect of different shapes. From this study, it is found that the rectangular pillar has the highest average strength in both UCS and point load strength, while the square pillar has the lowest in both. Both the UCS and point load strength increase with the increase of density of pillars for the three shapes.

Key words: Cross-sectional shape, Pillar strength, Uniaxial compressive strength, Point load strength index

INTRODUCTION

Pillar is a common load-bearing structure in civil and mining engineering. Pillar can be made of steel, masonry, concrete and reinforced concrete in civil engineering, but rock pillars are universally used in underground mines to take the advantage of the self-supporting capacity of rock. Pillars can have different cross-sectional shapes, including circular, square and rectangular. Strength of pillar is an important parameter in pillar design and its application. Does different cross-sectional shape affect the strength of pillar?

Shape effect, which is referred to the pillar width (w) to height (h) ratio, is reported in literature [1]. The strength of pillar (s_p) in coal and hard rock can be calculated using empirical formulas. Coal pillar strength is related to the compressive strength (σ_c) of coal and the shape (w/h) of pillar as shown in Eq. (1) [2].

$$s_p/\sigma_c = 0.778 + 0.222w/h \quad (1)$$

Esterhuizen, Dolinar and Ellenberger [3] reported that pillar strength is influenced by its volume and its shape. The shape effect on the stability of hard rock pillar can be empirically assessed using the ratio of width to height (w/h). When the $w/h > 2$, the likelihood of pillar failure is seldom [4]. Hence, pillar strength, s_p, can be calculated using Eq. (2).

$$s_p = k\, w^{\alpha}/h^{\beta} \quad (2)$$

Where k is a parameter related to the strength of rock, α and β are parameters related to the geomechanical conditions of rock mass [3].

Shown in Table 1 are the average, minimum and maximum w, h and w/h of 91 pillar layouts in 34 mines in the USA [3]. All of the pillar layouts are successful in providing global stability by supporting overburden load up to the ground surface. Pillar failure will occur when a pillar has reached its peak load bearing capacity. As indicated by Eq. (1)-(2), a declining w/h may cause the strength of pillar to rapidly decrease and the potential of pillar failure to increase.

Table 1 Width to height ratio of stone pillar [3]

Dimension	Average	Minimum	Maximum
Pillar width (ft)	43.0	15.0	70.5
Pillar height (ft)	36.5	15.8	124.6
w/h ratio	1.41	0.29	3.52

Del Viso, Carmona and Ruiz [5] studied cube and cylinder specimens, and found that (1) the compressive strength of cubes is higher than that of cylinders, (2) there are different crack patterns between the cubes and cylinders, and (3) the micro cracking is denser in the cubes than in the cylinders specimen. The diameter and height of cylinders were 75mm×150mm and 100mm×200mm, and the dimension of cubes were 33mm×33mm, 50mm×50mm, 67mm×67mm and 100mm×100mm, where the cross-sectional area (CSA) of each specimen is different.

While the shape effect of pillars has attracted many studies, they appear mainly focusing on the w/h ratio. In addition, the w/h ratio of rock pillars ranges from 0.29 to 3.52 with an average of 1.41 in 34 underground mine applications [3]. Its inverse (e.g. h/w) is required greater 2.0 by test standards governing uniaxial compressive strength test [6]. To

better understand the shape effect, this study aims to investigate the effect of different cross-sectional shapes on the strength of pillars of the same height and the same CSA.

RESEARCH METHODOLOGY

Laboratory experiments employed in this study are uniaxial compressive strength (UCS) tests [7] and point load strength index tests [8] according to Australian Standards (AS) [6], [9], [10].

Experimental design

Design of pillar shapes

To investigate the effect of shapes on pillar strength, three different cross-sectional shapes, namely circular, rectangular and square, are selected. All specimens have the same length of 150 mm and the same cross-sectional area of 1963.5 mm^2. The diameter of the circular cross-section is 50 mm, the width of the square one is 44.31mm, and the rectangular cross-section is designed at a width/depth ratio of 2:1, or 62.67mm×31.33mm (Fig. 1).

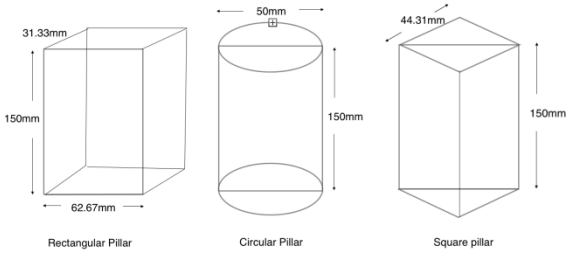

Fig. 1 Shapes and dimensions of the test specimens designed for the study.

Design of the mortar formula

Cement, fine sand and coarse sand are employed to mix the mortar specimens. Water to cement ratio commonly ranges from 0.4 to 0.7 to mix mortar. A water to cement ratio of 0.6 is used for this study. In accordance with mortar mix proportions guidance, cement to sand ratio is 1 cement: 3 sand (60% fine sand and 40% coarse sand) [11]. Thus, the mortar mix formulation is defined as 0.6 water: 1.0 cement: 1.8 fine sand: 1.2 coarse sand. Shown in Fig. 2 are the 18 mixed specimens prepared for the UCS tests. The mixed specimens were cured for 28 days in a curing tank at constant temperature of 21.5℃. The same procedure was followed for the specimens used in the point load strength index tests.

Fig. 2 Model mortar pillars prepared for the UCS tests.

Laboratory test

The procedures of sample preparation and UCS test of specimens were conducted in compliance with the Method 9: Compressive strength tests-Concrete, mortar and grout specimens [9]. In the meantime, the specimens also meet the dimensional requirements specified in the Methods of testing rocks for engineering purposes (Method 4.2: Determination of uniaxial compressive strength) [6]. Liu [7] conducted the UCS tests in this study.

Gao [8] conducted the point load strength tests in this study according to the Methods of testing rocks for engineering purposes (Method 4.1: Determination of point load strength index) [10]. The diametric test method is used as the length to diameter ratio of the circular specimens is three.

TEST RESULTS

Uniaxial compressive strength (UCS) test

18 specimens were tested for UCS, which are six each for square, rectangular, and circular cross-sectional pillars. The test results are tabulated in Tables 2-4, respectively.

Table 2 UCS experimental results of square cross-sectional pillars

No.	Weight, g	Density, kg/m^3	Maximum load, kN	UCS, MPa
1	640	2097.97	44.1	21.70
2	640	2085.17	47.5	23.26

Point load strength test

18 specimens were conducted using the diametric point load tests. The point load test results are recorded in Tables 5-7 for square, rectangular, and circular cross-sectional pillars, respectively. The point load strength index was calculated as follows [10]. Firstly, the uncorrected point load strength (I_s, MPa) is calculated by Eq. (3).

$$I_s = \frac{P \times 1000}{D_e^2} \quad (3)$$

Where, P is the load at failure, kN; D_e is the "equivalent core diameter" derived from the Eq. (4), mm.

$$D_e{}^2 = \frac{4 \times A}{\pi} \quad (4)$$

Where, A = CRA, mm^2.

Secondly, the point load strength index, $I_{s(50)}$, is calculated by Eq. (5).

$$I_{s(50)} = I_s \times \left(\frac{D_e}{50}\right)^{0.45} \quad (5)$$

Table 5 Point load test results of square cross-sectional pillars.

ANALYSIS

The average UCS and the average point load strength index, $I_{s(50)}$, are tabulated in Table 6 for the square, rectangular and circular pillars, respectively. It is interesting to know that the rectangular pillar has the highest strength in both the UCS and point load strength index, while the square pillar has the lowest. However, the difference is not big: the average UCS of rectangular pillars is 0.63% higher than the UCS of square pillars, and the $I_{s(50)}$ is 4.05% higher.

Table 8 Average UCS and $I_{s(50)}$ of square, rectangular and circular pillars

Shape	UCS, MPa	$I_{s(50)}$	Remark
Square	22.52	1.952	Lowest in average UCS and $I_{s(50)}$
Rectangular	22.67	2.031	Highest in average UCS and $I_{s(50)}$
Circular	22.56	1.964	

Shown in Figs. 2-3 are the UCS-density and $I_{s(50)}$-density curve, respectively. The data appear scattered in a narrow band and trend linearly,

indicating that both UCS and $I_{s(50)}$ increase with the increase of density.

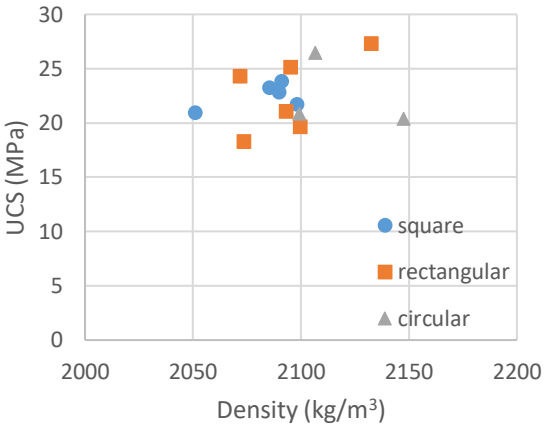

Fig. 3 UCS – density curve of square, rectangular and circular pillars.

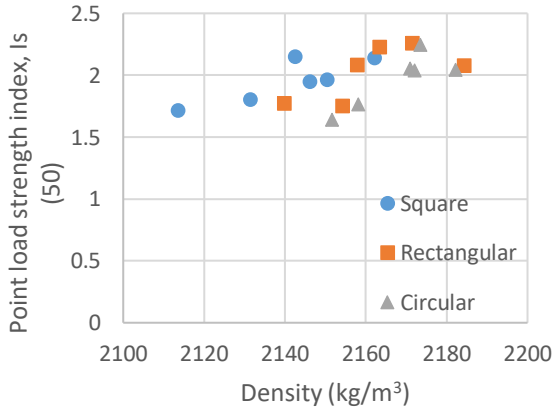

Fig. 4 Point load strength index – density curve of square, rectangular and circular pillars.

CONCLUSION

36 laboratory tests have been conducted to investigate the effect of cross-sectional shapes on the UCS and point load test strength of pillars. The model pillars were made of mortar and the three different cross-sectional shapes are square, rectangular and circular. From the study, it might be concluded that the cross-sectional shapes have some effect on the strength of mortar pillars.

Through the comparative analyses of the average uniaxial compressive strength and point load strength of the three different shapes of pillars, the rectangular specimens have both the highest uniaxial compressive strength and the highest point load strength. On the other hand, the square specimens have the lowest in both strength. However, the difference may not be significant in the uniaxial compressive strength.

Both the uniaxial compressive strength and the point load strength increase with the increase of the density of pillar for all the three different cross sectional shapes.

EVALUATING MSE WALL DEFORMATION USING TERRESTRIAL LASER SCANNING AND FINITE ELEMENT MODELLING

Devon Adamson[1], Marolo Alfaro[1], James Blatz[1], and Kent Bannister[2]
[1]Civil Engineering Department, University of Manitoba, Canada; [2]TREK Geotechnical Inc., Canada

ABSTRACT

Mechanically Stabilized Earth (MSE) walls are now commonly used as retaining structures in bridge-approached embankments. They have an ability to accommodate more deformations without structural distress and are cost-effective compared to conventional concrete gravity retaining structures. Engineers prefer to monitor the deformations of the wall during and after construction to verify their design. Instrumentation and/or surveying techniques are commonly used to monitor deformations of structures. Current measuring methods are in discrete locations of the walls and do not provide movement profile of the entire wall. In this study, Terrestrial Laser Scanning (TLS) technique was used to monitor the deformations of newly-constructed MSE walls. TLS uses lasers to create a 3D point cloud in a 360° range of its surroundings with their relative X,Y,Z coordinates. Post-processing of the data in its subsequent computer software register all scans of the wall and develop them into a larger project point cloud. The point clouds are used to determine the deformations from periodic scans. The use of Finite Element Modelling (FEM) will be develop and calibrate the measured deformations into a model of the site. Once calibrated, the numerical model will be used to investigate important factors affecting the performance of the MSE walls. The vertical settlements observed from the TLS compared to the modelling analysis were in agreement with the behavior as well as the magnitudes, 50mm and 106mm in centre and critical sections for TLS and 57mm and 111mm for the modelling respectively.

Keywords: Terrestrial Laser Scanning, Finite Element Modelling, MSE Walls, Deformation

INTRODUCTION

A bridge interchange project began construction in April 2018 to extend across an existing high-speed roadway. The interchange was first proposed as commuter traffic in the area has increased to a point where safety and environmental concerns required action. The bridge interchange has 2 lanes of traffic for the 80km/h speed limit roadway travelling East-West and 2 lanes for the neighbourhood street Northbound and one lane for Southbound at 60km/h. The new bridge has three lanes over the existing roadway. The bridge structure is supported by a total of 21 Cast-In-Place (CIP) belled piles. Approach fills for the bridge are approximately 8 to 9 m high and have an MSE wall face running parallel to the high-speed roadway.

The approach fills are supported by a total of 240 vibration-compacted stone columns (120 each at the North and South Abutments). A study has been undertaken to determine if Terrestrial Laser Scanning (TLS) can provide a reliable and applicable surveying technique to measure movements in the MSE wall and whether Finite Element Modelling (FEM) can predict the actual movements of the wall during and after construction.

Soil stratigraphy observed at site from previous test holes found silty clay overlying clay till. The properties of the silty clay is generally highly plastic and stiff, with a soft transition layer above the till. The clay till is silty with trace to some sand and gravel, has low plasticity, and ranges from firm to very stiff depending on depth **[1]**.

Fig. 1 South Abutment MSE Wall

TLS DETAILS

TLS is a surveying tool that with lasers can measure coordinates of its surroundings in a 3D space by shooting out a web or mesh of data points. The collection of these data points is called a “point cloud” and with the addition of pictures taken by the scanner, objects and surfaces in the point cloud are colourized, replicating the site conditions. Scanning larger objects and areas is done by performing multiple scans along the desired object/surface (in this case it is the MSE wall of a bridge interchange) and then register each scan together using identical targets in each point cloud. These targets can either be cooperative targets like spheres and placards, or

identifiable targets like edges and planes on the bridge structure **[2]**. Registering together the multiple scans create a "project point cloud" which can be used for design, such as settlements and displacements, preliminary site conditions, and inspections for structure integrity **[3]**

The scanner used for the project is the *FARO Focus X330* and uses the software *FARO Scene* for processing the data. The specifications of the scanner includes a ranging error of 0.3mm at 10m with 90%, and a max scan distance of 330m. FARO Scene allows the user to combine scans into the project point cloud by using Target and Cloud-to-Cloud registration. Target registration best fits the scan clouds together using the identical targets for alignment in an X,Y,Z coordinate space. Cloud-to-Cloud registration is a finer registering tool that using the computer software's algorithm, will input parameters such as number of iterations, search distance between data points, and subsampling distance to align point clouds together based on the criteria. After registration is completed, a registration report is produced to show the mean point error, maximum point error, and minimum overlap percentage of data points. This report will allow the user to determine if the registration satisfies the error tolerance required for the application. If the error is out of tolerance, re-registering different targets than aligned previously or using a different registration tool will be required. If the amount of error is accepted, measurements are reported with the registration errors to detail the accuracy of the results. An example of a finished project point cloud is provided in Fig. 2.

Fig. 2 Project Point Cloud of MSE Wall

FINITE ELEMENT MODELLING

FEM is implemented into preliminary design work for its capabilities to simulate foundation soil behavior. FEM is a great tool when there is sufficient testing for soil properties and site conditions are well known. The model will only produce results based on the user parameters. Therefore, the parameters should be carefully selected to best represent site conditions and should not use conservative values without justification as model results will lose validity.

A numerical model was developed using the computer software program Geostudio 2019. The model was built using Geostudio's SIGMA/W model component, running different analysis types to determine the short-term and long-term deformation behaviour of the walls. By using this software, a limitation on the deformation analysis is that Geostudio does not have 3D capabilities and therefore, conversion into 2D parameters is required. Stone columns in the foundation design are spaced in triangular and rectangular grids, expressed in axisymmetric parameters. Using the equivalent area method, the columns are treated as a solid wall with plane strain conditions. This conversion equation is designated as Eq. (1) **[4]**

$$\mathbf{D'} = \frac{\pi \mathbf{D^2}}{4d} \quad (1)$$

Where D = diameter of column, d = spacing of columns, and D' = equivalent diameter of column

Since the orientation of the wall is planar and surcharge loading from the backfill is applied normal to the wall, the assumption for foundation design characteristics to be represented in plane strain may be acceptable.

METHODOLOGY

The laser scanning occurs during construction and post-construction of the wall to determine the displacements of the wall as backfill material is built up in lifts for each row of wall panels is placed (clay material for the embankment and granular material for behind the wall). The scanning schedule began while the first row of panels was erected to establish a baseline for following scans. During construction, it is recommended to scan each row of panels being placed with monthly scans after it has been completed **[5]**. With that in mind, scanning was performed for the completion of the first row, last row, and one intermediate row (May 9, May 25, and June 2, 2018). Post construction was limited to two scans in the summer (July 05 and August 28) with two more scheduled in the summer of 2019 (May 07 and August 06) following the spring thaw to observe and longer term settlement.

The scans were registered using multiple spheres and placards set up around the wall. The wall required multiple scans to gather data points for each panel surface. To reduce bounce back error, each successive scan shall maintain an incident angle of 45° between one another; therefore more scans were required in the range from 4-6. For the scanner to orient itself with the other scans, each scan will need to reference at least 3 targets for X,Y,Z coordinate alignment **[6]**. However, aligning targets in a single line should be avoided as there will be more uncertainty in the control target locations.

FEM of analysis begins with an in-situ phase, establishing initial stress conditions and Pore-Water Pressure (PWP) conditions of the site. This dictates the rate and volume of consolidation the foundation material encounters during construction. Initial stress conditions were formulated from the soil layers, material properties and initial PWP conditions were from an assumed initial phreatic surface. This was set at 505.4m, taken from previous water elevations observed in borehole logs. Following the in-situ phase, subsequent analyses model the effects of the reinforced backfill material during erection of the MSE wall and the clay fill used for the approach embankment; analyses classified in 4 stages: Lift 1, Lift 2, Lift 3, and Lift 4. The analysis type for the staged backfill loading is Load/Deformation as the scope of this paper is to determine the magnitudes of vertical movement and compare how accurate the model is to the TLS results. Boundary conditions include Fixed X/Y movement along the bottom of the clay till and a Fixed X movement along the sides of the model layers. The model boundaries were stretched out far enough that they had no effect on the settlement foundation due to the backfill layers.

The output reports from the model include settlement along the MSE wall plane and cross-sections at the centre of the wall and at the edge of the wall slope section. The particular sloped section is where stormwater and sewer pipes run underneath the stone columns, preventing the columns from reaching till, resulting in the critical section of the wall. Models for each analysis are provided in Fig. 3, 4, and 5.

The model was analyzed using effective-drained conditions with the parameters outlined in Table 1. The parameters were determined reviewing previously completed soils lab testing and recommended modelling values, made available by the foundation design report **[1]**. Effective-drained conditions were considered since preliminary design modelling is used to predict the magnitude of settlement the structure will encounter during its service life. The use of stone columns in the design also act as vertical drains, allowing the PWP to dissipate quickly for immediate consolidation. The subsoil and backfill material were modelled with Linear-Elastic criteria as the stress conditions the materials are loaded with are estimated to be below the yield strength of the soil. Modified Cam Clay (MCC) parameters were used for the soft silty clay layer as MCC can better predict soil behaviour for slightly over-consolidated clay than the linear-elastic model.

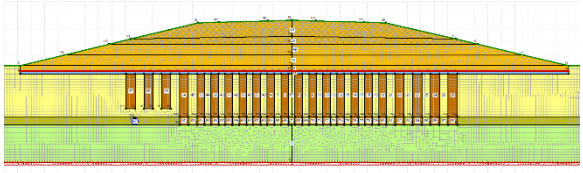

Fig. 3 Model of MSE Wall Cross-Section

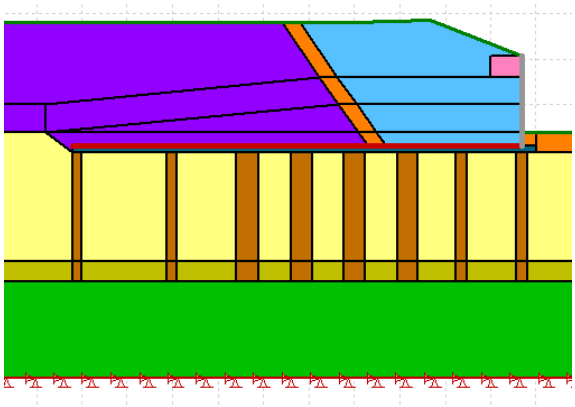

Fig. 4 Model Profile at the Centre of the MSE Wall

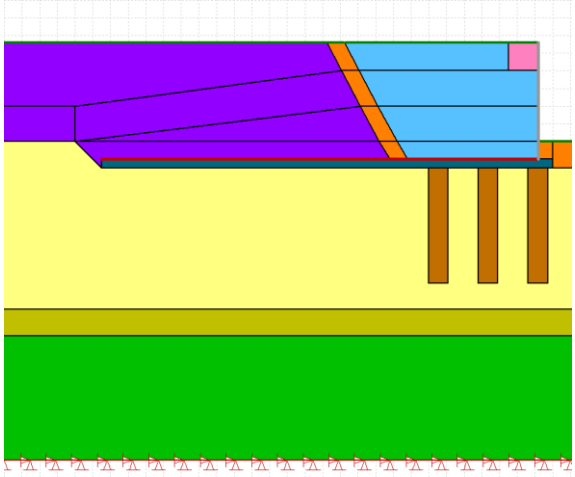

Fig. 5 Model Profile at the Critical Section of the MSE Wall

The south abutment has a larger embankment, allowing it to be more susceptible to settlement, resulting in a more critical case than the north abutment. Therefore, modelling was focused on just the south abutment.

Geosynthetic (Tensar BX1500)	492	0.004	0

DEFORMATION ANALYSIS RESULTS

TLS Results

The settlement analysis from TLS in this paper will include the three construction scans and the two post-construction scans from the summer of 2018. The parameters for each of the scans was set to a resolution of 44MPts and a quality of 4x to minimize noise and error for each scan **[7]**. Since the bridge deck is expected to exhibit minimal movements and it has been constructed prior to wall erection, it was used as a reference target for deformation analysis. The bridge deck is expected to have a final settlement magnitude of 20mm **[1]**. Control targets were surveyed using Real-Time Kinematics (RTK) which causes the satellites to communicate to the rover station, providing the UTM coordinates of its position. Communication error between the satellites and rover and duration of the rover stationed over a reference location, 2D errors can range from 3-10mm, 1D errors range from 6-14mm, and 3D errors range from 9-20mm. Therefore, the movement from the bridge deck is within the error tolerance of the RTK measurement and is accepted for reference.

The results generated from the TLS will be represented in seven different locations: three spaced out between the bridge deck and wall descent on the East and West side (total of six) and one in the centre of the wall, as shown in Fig. 6.

1D Settlement Analysis

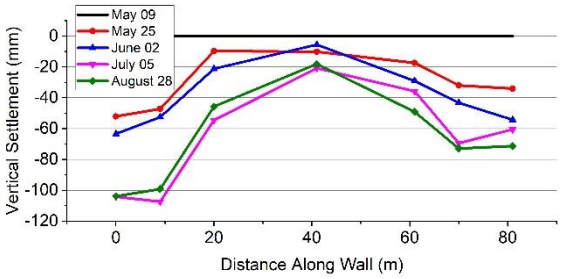

Fig. 6 Terrestrial Laser Scanning Results for Settlement along Wall

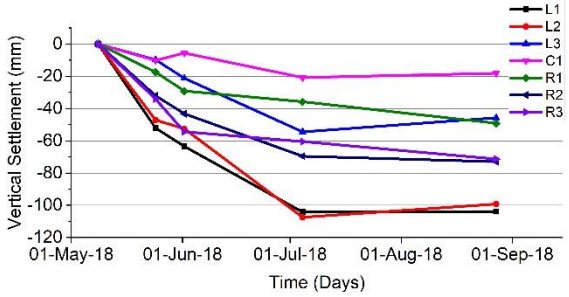

Fig. 7 Terrestrial Laser Scanning Results for Rate of Settlement Plot

The settlement profile of the south abutment resembles a 'W' pattern, greater magnitudes of settlement outside of the bridge deck section, and lower amounts of settlement in the centre of the wall. Stone columns were placed primarily in the area where higher embankments were planned (near the centre of the wall) with embankment height reducing near the edges. The 'W' pattern observed indicates the influence of the stone columns in the centre of the embankment.

As shown in the settlement profile, the largest movement exhibited by the wall was 107mm on July

5th, 2018 between the slope of the wall and the bridge deck. August 28 at the same location was measured at 99mm of settlement, causing some concern over the amount of error induced in the measurements. Since both measurements are within 10mm to each other, it is reasonable to assume settlements are low in that area and are largely complete. Measurement error is also evident in other locations that appear to have upheave between successive scan dates which would also be assumed to have minimal movement between measurements. This is consistent with design estimates relative to the MSE wall settlement (settlement was projected to be completed shortly after wall construction due to the PWP dissipation effects of the stone columns).

Finite Element Modelling Results

Settlement results were measured underneath the load transfer pad (granular base on top of the stone columns) and are presented below

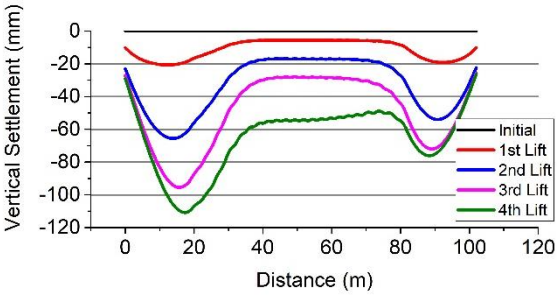

Fig. 8 Finite Element Results for Settlement Cross-Section along Length of Wall

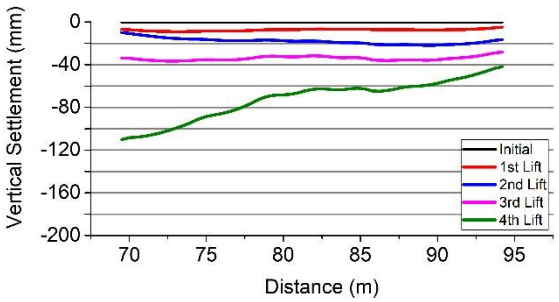

Fig. 9 Finite Element Modelling Results for Settlement Profile along Centre of Wall

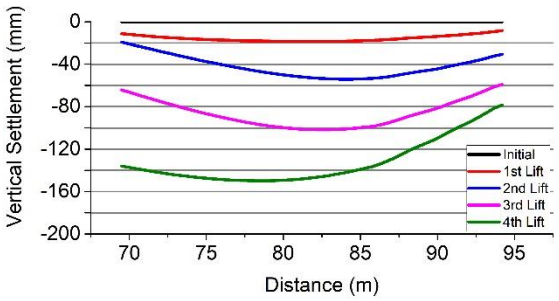

Fig. 10 Finite Element Modelling Results for Settlement Profile Overlying Pipe Section

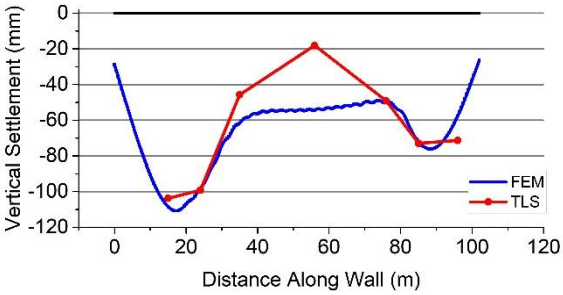

Fig. 11 Vertical Settlement Cross-Section August 28 Scan (TLS) vs 4th Lift (FEM)

From the cross-sectional settlement figure, the behaviour or trend of the wall is very similar to the TLS as it settles in a 'W' shape with most of the settlement occurring just outside of the stone columns. As well, the most settlement occurs on the left side of the wall, located above the pipes. The short columns not drilled to till are the big influence for the additional 30mm of settlement of difference between the two sides. Additionally, the amount of settlement in the centre of the wall slopes down towards the left side because of less reinforcement in the subsoil. Fortunately, it is a small difference of 10mm over 40m of wall so the implications of differential settlement underneath the bridge deck will be negligible (consistent with design intent).

When comparing the magnitudes of settlement to the TLS results, the prediction from the model is within a reasonable estimate of what was observed. The May 25 scan in Fig. 8 is taken when the second lift was installed, June 2 when the third lift was installed, and July 5 and August 28 for the final lift. The model estimates a larger amount of settlement than the TLS for the first three lifts being erected which should be expected as the model is assuming completely drained conditions for soil consolidation. When comparing the final lift with the TLS as seen in Fig. 11, the model settlements are more comparable to the observed survey measurements on the extents of the wall, however the centre of the wall is predicted to settle another 30mm. This is interesting as the stone columns underneath the wall in that section will allow for immediate settlement. The soil settling more than double what it has already moved is unreasonable and therefore, error in the measurements, the presence of the belled piles behind the wall, and/or the transformation from 3D to 2D conditions has influenced the results of the settlement behaviour.

Figures 9 and 10 represent the settlement underneath the approach embankment settlement with the last point on the right of the graph is the wall settlement. First looking at movement underneath the centre of the wall, the settlement is consistent

throughout the length of the granular pad up until the final lift is installed. The most settlement occurs where it is reinforced with two spaced out columns where it reaches a maximum of 126mm. For the critical section, ground settled in a more 'U' shape, with the most settlement occurring past the columns in the centre of the pad with 160mm. The reduced number of columns greatly impacts the amount of settlement occurring as the entire section settles at least 10cm, compared to the centre of the wall where approximately 80% of the soil underneath the granular pad won't settle more than 10cm.

For confirmation of representing the wall settlements in a cross-section and profile, comparing the last point in the profile graphs with settlement at the same location on the cross-section plot will be observed. The profile models calculated wall settlements to be 50mm and 106mm for sections at the centre and critical sections of the wall respectively. Comparing that to the cross-section model, values of 57mm and 111mm are within 7mm of each other which is very reasonable to assume that the plane strain transformations into each 2D model was consistent with depicting the site conditions.

RECOMMENDATIONS

From comparing the observed TLS results with the calculated FEM results, the behaviour and magnitude of the settlements were similar as both methods displayed a 'W' pattern of movement. The maximum settlements in both TLS and FEM were 103mm and 111mm, respectively. There was great disparity between the results for the centre of the wall with results of 21mm and 57mm for TLS and FEM, respectively. More information on the collection of measurements should be examined. With the limitations of FEM and the errors incurred by the TLS, the results both methods produced are satisfactory for evaluating the performance of bridge interchange projects.

The use of plane strain parameters for 2D modelling seems reasonable in predicting the settlement behaviour of the wall but for research interests, a 3D model would be interesting to observe the movement without assuming plane strain conditions. Another interest would be how the PWP would affect the rate of settlement during construction. The stone columns accelerates the dissipation of PWP but the soil around the short columns would not drain out as quickly and therefore may not reach the settlements as depicted by effective drained conditions.

MODELLING OF GRANULAR PILE COLLAPSE BY USING MATERIAL POINT METHOD AND DISCRETE ELEMENT METHOD

Yi Yang[1]

[1]Department of Civil Engineering, Chu Hai College of Higher Education, Hong Kong, China

ABSTRACT

Granular debris flows can be observed in many regions of the world. The process is accompanied with large deformation and phase transitions from solid to fluid states. In this paper, material point method (MPM) and discrete element method(DEM) are used to identify the flow mechanism and energy dissipation from continuum to discrete perspectives. These two methods are also compared from many aspects. In addition, this study will be helpful for the future combined MPM and DEM study.

Keywords: material point method; discrete element method; granular pile collapse

1. INTRODUCTION:

Granular materials are important constituents in many fields. Understanding the evolution of internal structures of granular flows will certainly help the description and prediction of nature geophysical hazards in mountainous areas. Although extensive researches have been carried out worldwide to study different aspects of granular-type debris flows, the fundamental initiation and propagation mechanisms are not yet fully understood. Existing theoretical models and numerical approaches are not captured all the key features of debris flows, especially for the large deformation and phase transition analysis [1]. In current paper, we focus on the numerical part to describe and predict the flow mechanism and patterns.

Numerical models have been adopted and developed to fully describe the mechanism of debris flows over decades [2-11]. Due to the inherent multiscale feature of debris flows, these numerical methods can be mainly divided as continuum, discontinuum and multiscale methods [11].

Continuum approaches are only used when the scale separation between grain-scale and macro-scale is very large [8]. The most commonly adopted continuum methods for simulating debris flows include the finite element method (FEM) [3], smooth particle hydrodynamics (SPH) [2,12], material point method (MPM) [8,9,13] , etc. Soga and his colleagues (2015) have reviewed the numerical techniques for modeling large deformation landslide problems and summarized their advantages and limitations. The MPM is a particle-based method that represents the material as a collection of material points, and Newton's laws of motion determine their deformations. It combines the advantages of Eulerian and Lagrangian approaches to elimate the mesh distortion. Meanwhile, the application of boundary conditions is more straightforward than SPH method. During the last decade, MPM has been applied to solve large deformation geotechnical problems, which include granular flows, retaining walls, slopes, anchors and others [8,14,15]. Most of previous publications consider the soil as a single-phase material.

The discrete element method (DEM) proposed by Cundall and Strack [16] are capable of simulating the granular material as a discontinuous system. DEM is a robust research tool to explore the behavior of dry granular materials at the grain scale. Within the last two decades, DEM has been used to study the fundamental mechanisms of landslides from 2D to 3D [17-19]. The modeling of granular flow using DEM is a possible way to study the complicated behavior of landslides. Its drawback is that it is difficult to consider the presence of water in granular flows, which cannot explain the high mobility of debris flows [20].

In the current paper, we study the pile collapse problems by using MPM and DEM respectively to capture the similarities and differences. We compare in detail the evolution of the profile of the granular pile to observe the energy dissipation and other physical indexes for different approaches.

2. NUMERICAL SET UP:

Initially, a granular packing with 5200 particles is randomly generated by YADE with a mean particle radius 2.2275×10^{-3}m. Then, all particles will be allowed to fall by gravity force to generate a mimicking sample with the dimensions 0.2×0.4m. The density and friction coefficient are 2600 kg/m^3 and 0.4 respectively. Additionally, a MPM packing with the same geometry is set up. The initial numerical sample for DEM and MPM can be seen in Fig. 1.

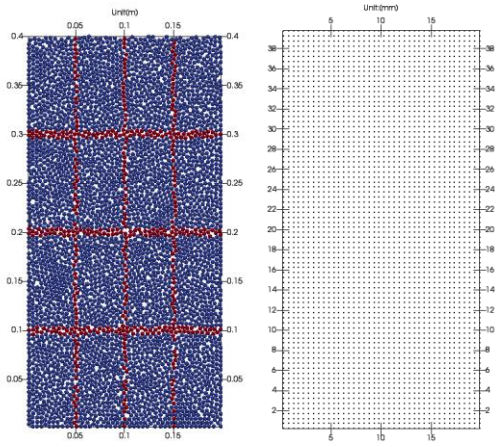

Fig. 1: Initial geometry and dimensions of the granular pile collapse

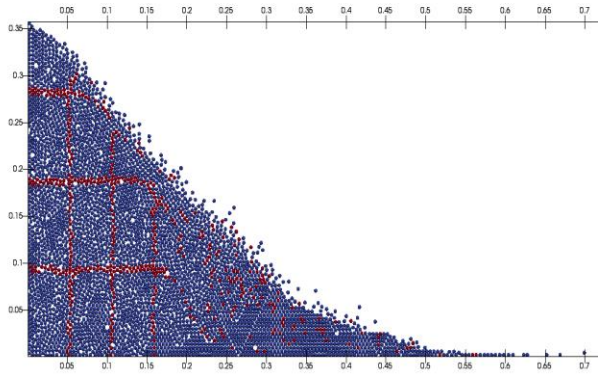
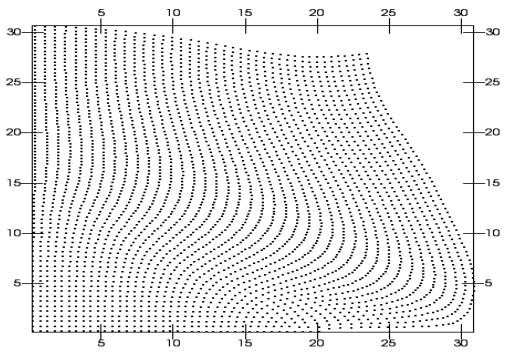
It can be found that the difference between the DEM and MPM is clear at the initial collapse part in Fig. 2. DEM will show a much more reliable simulation where the particles will abruptly flow down. In MPM all the simulations show a continuous feature.



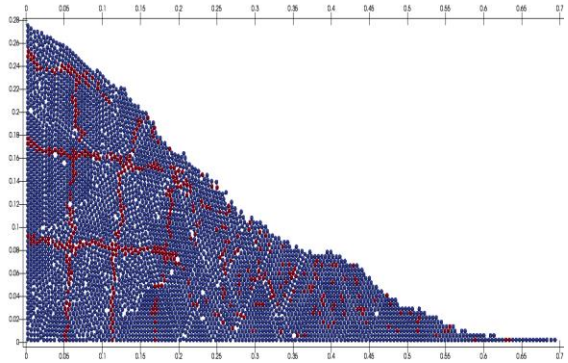
(a) DEM



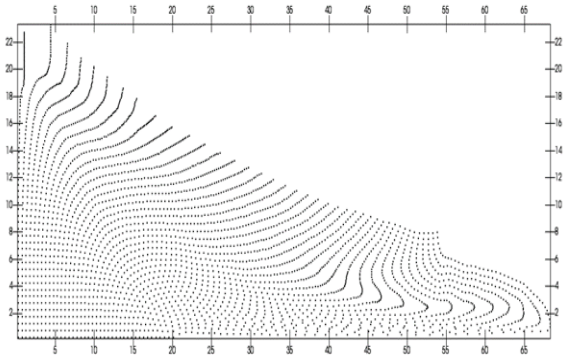
(b) MPM

Fig.2: Initial collapse between DEM and MPM

In Fig.3, it can be found that the final deposition of both numerical approaches is similar. This part proves MPM is useful for simulating large deformation problems in geotechnical engineering. And the computing efficiency of MPM is better than DEM. By using DEM, we can obtain a lot of physical quantities at a mesoscale. For example, in Fig. 4 it can be easily predict the displacement vectors by DEM.



(a) DEM



(b) MPM

Fig. 3: Final Profile of the granular collapse.

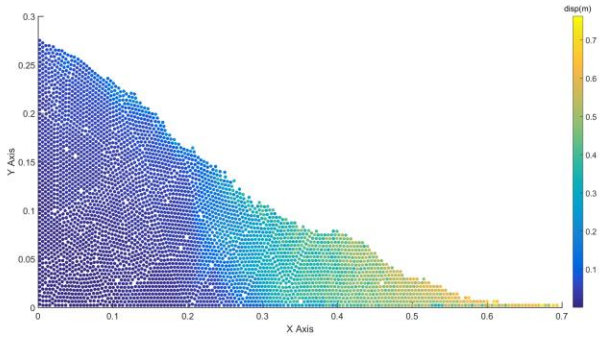


Fig. 4: Evolution of displacement by DEM

3. CONCLUSIONS:

This work shows a comparison study between MPM and DEM. DEM is better for simulating the granular pile collapse problems at the initial stage. Moreover, DEM can also provide a lot mesoscale information. A similar result at the final stage can be found by MPM and DEM. The efficiency of MPM is better than DEM. Additionally, this study will be benefited for the later couple approach between MPM and DEM.

THREE-DIMENSIONAL STABILITY OF CIRCULAR OPENING

Ji-Sung Lee[1], Mohammad Hassan[1] and Jim Shiau[1]
[1]School of Civil Engineering, University of Southern Queensland, Australia

ABSTRACT

The stability of a circular opening trapdoor in undrained cohesive soils was numerically investigated. Three-dimensional (3D) numerical simulations were performed to analyze the stability of a circular trapdoor with a series of opening diameter-to-depth ratios and soil properties. The shear strength reduction method (*SSRM*) built in finite difference method (*FDM*) is employed to determine the *FoS* solutions, which are functions of the depth ratio and stability number. The results are compared to numerical solutions from previous related studies and other published literatures. The numerical results were presented in the form of factor of safety that is a function of the depth ratio and the shear strength ratio. Practical examples were used to demonstrate how to use the design charts and equations in practice. The investigation of *FoS* suggested that the 3D circular opening results are almost twice larger than those in 2D plain strain. The strong arching effects has been noted for deeper cases, and the corresponding failure mechanism has not been observed.

Keywords: Sinkhole, Circular opening, FLAC 3D, Finite Difference Method, Surface failure extent

INTRODUCTION

The stability of the trapdoor was initiated by Terzaghi [1], which experimentally investigated the effect of the distributed stress in sand and defined the active and passive trapdoor failure. He described the active mode as surcharge or overburden pressure, and passive mode as an uplifting force, such as an anchor. In principle, there are two key elements that stimulate an underground cavity's failure, one being the overburden pressure (γH) and the other the surcharge load (σ_s). It is not unusual in geotechnical engineering analysis and design, to consider a greenfield condition (σ_s=0), with some examples being in Taylor's original slope stability charts [2]. Without considering weathering effects, a failure may occur due to overburden pressure (γH) above a cavity in the ground, which is a typical condition in the analysis of natural sinkholes and longwall mining.

Taylor's stability charts are one of the principal tools used in analysing slope stability problems, and they are still popular with engineers in the field. Using the limit equilibrium method, the stability of slopes is a function of the slope height (H), slope angle (β), and soil properties, such as the unit weight (γ) and undrained soil shear strength (S_u) [3], [4]. The undrained stability number introduced by Taylor is presented in Eq. (1), which can be used to investigate the stability of soil overlying a cavity.

$$N_s = \frac{S_u}{\gamma H \times FoS} \tag{1}$$

Craig [5] employed a large centrifuge model to investigate the critical stability of a circular cavity. In this investigation, Craig [5] used the lower and upper bond technique to estimate the stability of a shallow trapdoor (between 0.5-1.5) and concluded that, for a depth ratio greater than 1, the theoretical results are not valid. This approach to the problem has been continued and expanded in the finite element limit analysis (*FELA*) research by Yang et al. [6], Auguard et al. [7], Drumm et al. [8], Martin [9] and most recently by Keawsawvong et al. [10].

Recent studies have been conducted using a shear strength reduction method by Shiau et al. [11], to investigate tunnel heading stability in homogeneous cohesive soil. What was notable about this study is that the strength ratio defined following Taylor's [1] stability approach, was where the factor of safety became the function of the depth ratio (H/W) and the soil strength ratio ($S_u/\gamma W$).

This paper investigates the study of cavity's stability underlying homogeneous clay in an unsupported greenfield condition in a realistic three-dimensional circular opening condition. In this paper, shear strength reduction techniques are used to study the three-dimensional failure mechanisms of a circular trapdoor by using *FLAC*, a finite difference program. The stability results are presented in the form of a factor of safety and a failure extent ratio for various dimensionless ratios and verified by using the finite element limit analysis technique with upper and lower bound theorems.

The numerical results of three-dimensional circular trapdoor are compared with 3D square and rectangular results and 2D results which were obtained earlier in other available solutions. In addition, the practical examples are provided to illustrate the use of the charts and tables.

PROBLEM DEFINITION

The sinkhole propagation process is a complex for estimating by the numerical analysis. It is impossible to predict the actual propagation of the sinkhole occurrence. Hence, this study assumes an idealised three-dimensional horizontal trapdoor and that the propagation process is at the last stage where the cavity is big enough to cause a collapse failure.

Figure 1 presents a conceptual horizontal trapdoor problem underlying undrained homogeneous clay layer with constant unit weight (γ) and shear strength (S_u).

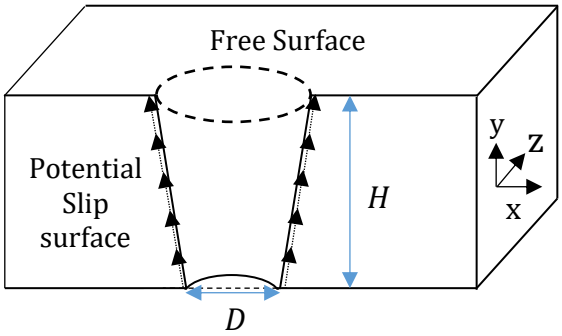

Fig. 1 An idealized sinkhole problem

The three-dimensional soil body is modelled as uniform Tresca material, which is the same as Mohr-Coulomb material when the soil friction angle (ϕ) is zero. The opening of the cavity is assumed to be horizontal, with the radius represented by (D) in the x direction and the height represented by (H) in the z direction.

An extensive range of depth ratios (H/D= 1 to 6) and shear strength ratios ($S_u/\gamma D$= 0.2 to 2) were selected for covering the wide range of parametric studies. Note that the shear strength ratio is defined following Taylor's method and the *FoS* can be defined as a function of the shear strength ratio ($S_u/\gamma D$) and the depth ratio (H/D). This relationship is shown in Eq. (2).

$$FoS = f\left(\frac{S_u}{\gamma D}, \frac{H}{D}\right) \quad (2)$$

MEDLLING TECHNIQUE

The trapdoor stability in undrained cohesive soil were examined using shear strength reduction method (*SSRM*) and 2D and 3D finite difference software. Built-in *FISH* scripts were also developed for the problem to facilitate the auto mesh generation, and hence allow parametric studies to be conducted efficiently. Internal verification and model validation of the solution revealed that results from full, half or quarter meshes were almost identical. This has greatly improved the level of confidence in the current 3D development.

Figure 2 shows the typical quarter mesh of circular trapdoor problem. Although the mesh shows perfect square cubes, *FLAC 3D* uses a mixed discretisation technique of various element shapes such as wedges, pyramids, bricks and tetrahedrons to form and solve the problem [12].

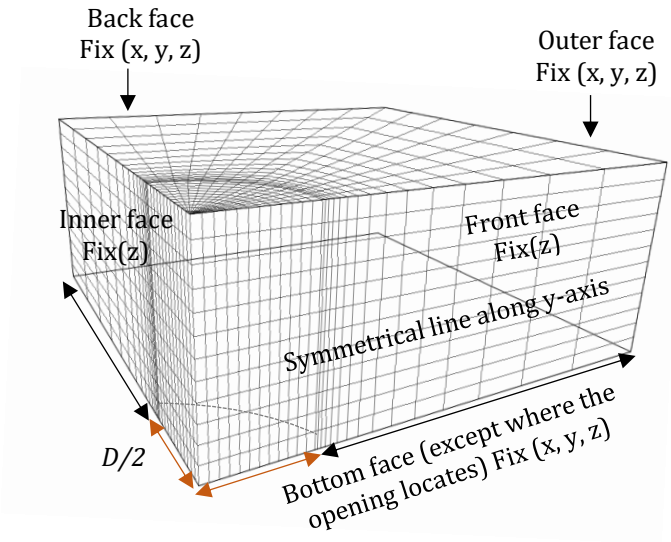

Fig. 2 Typical quarter mesh and boundary condition

This study conducted the stability analysis of three-dimensional circular trapdoor in undrained homogeneous layer of clay using the shear strength reduction method (*SSRM*). The velocity and displacement plots of the finite difference method represented to determine the surface subsidence due to collapse of the sinkhole. The results of the study are compared with other existing studies.

RESULTS AND DISCUSSION

A combination of wide range of depth ratio (H/D= 1-6) and strength ratio ($S_u/\gamma D$) utilizes to investigate all possible situations associated with the trapdoor stability. The factor of safety (*FoS*) results obtained by utilizing the shear strength reduction method in 3D finite difference method software which discussed previously. The factor of safety results of this investigation are presents in tables 1.

Figure 3 shows the comparison of the effect of shear strength rate ($S_u/\gamma D$) on factor of safety (*FoS*) with circular opening and various opening ratios (L/W) which were obtained from Shiau et al. [13]. The various range of the L/W ratio represent the square opening and the rectangular opening. The length (L) indicates the horizontal length of the cavity, the width (W) indicates the vertical length of the cavity.

Table 1 *FoS* results for *H/D*=1-6 and $S_u/\gamma D$=0.2-2.

H/D	FoS					
	SR =0.2	SR =0.6	SR =0.73	SR =1.0	SR =1.5	SR =2.0
1	0.84	2.51	3.06	4.19	6.28	8.38
1.5	0.81	2.43	2.96	4.06	6.08	8.12
2	0.75	2.26	2.75	3.77	5.64	7.53
2.5	0.69	2.09	2.52	3.47	5.12	6.94
3	0.64	1.92	2.33	3.20	4.72	6.43
3.5	0.59	1.75	2.15	2.97	4.38	5.94
4	0.55	1.66	2.02	2.77	4.16	5.53
4.5	0.52	1.53	1.89	2.59	3.89	5.19
5	0.49	1.47	1.79	2.45	3.66	4.89

6	0.44	1.32	1.61	2.20	3.30	4.41

*SR= $S_u/\gamma D$.

Figure 3 shows a linear correlation between *FoS* and shear strength ratio ($S_u/\gamma D$) for all values of square and rectangular opening (*L/W)* and circular opening. As expected, *FoS* increases as the shear strength of the soils $S_u/\gamma D$ increases.

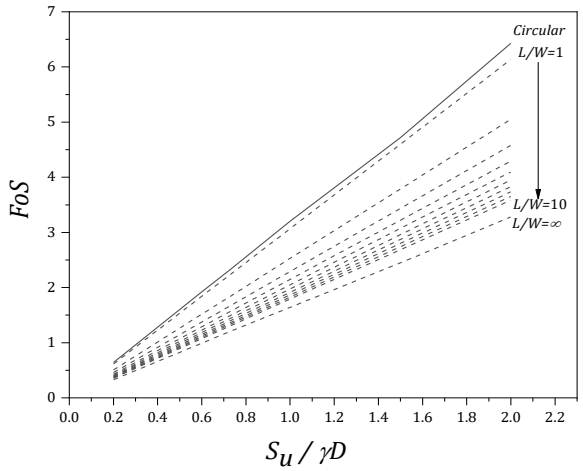

Fig. 3 Effect of $S_u/\gamma D$ (*H/D*=3)

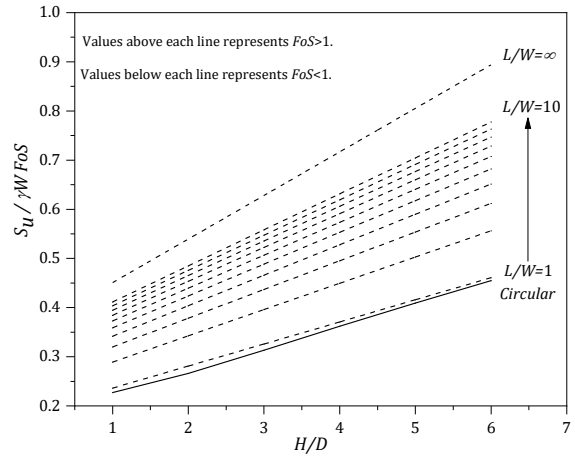

Fig. 4 Failure envelope (*L/W*=1 to *L/W*= ∞ and circular opening trapdoor)

Given the linear relationship in Fig. 3, a failure envelope or critical strength ratio ($S_u/\gamma DFoS$) is presented in Fig. 4. The shear strength ratio is normalised with respect to *FoS*, and therefore represents a critical condition where the *FoS* =1. Fig. 4 is particularly important for designers because it represents the critical value of each parameter. The values above each line indicate a safe working zone (*FoS* >1), while the values below indicate an unsafe zone (*FoS* <1). Closer inspection of the figure reveals that the value of ($S_u/\gamma DFoS$) increases as the depth ratio (*H/D*) increase. The line of the circular opening problem is below the all of the square trapdoor problems from Shiau et al. [13] study. It shows the similar trends as the square opening trapdoor problem as shown in Fig. 4.

A linear regression analysis was employed to develop a practical design equation covering geometrical parameter *H/D*. The linear function was used to yield an accurate curve-fitting of original *FoS* solutions with r^2 = 0.996. This is shown in Eq. (3).

$$\frac{S_u}{\gamma D \times FoS} = \left(\frac{0.0453H}{D} + 0.1812 \right) \quad (3)$$

Equation 3 can be used to obtain critical parameters such as undrained shear strength (S_u), depth (*H*) and opening radius (*D*).

Table 2 shows the used data for plotting circular trapdoor in Fig 4.

Table 2 Data used for Fig. 4 (Circular opening).

2	0.266
2.5	0.289
3	0.313
3.5	0.340
4	0.362
4.5	0.387
5	0.409
5.5	0.432
6	0.455

ARCHING MECHANISM

The arching effect is a phenomenon of redistribution of the stresses from yielding soil particles into non-yielded adjacent soil body. In general, the arching support can develop due to material property, geometrical shape or combination of both. In Mohr-Coulomb failure criterion, the shear stress (τ) is a function of normal stress (σ), the internal frictional angle (ϕ) and soil cohesion (c). Thus, the shear strength is represented by the following Eq. (4):

$$\tau = c + \sigma \tan \phi \quad (4)$$

For cohesive soils such as undrained clay where the friction angle (ϕ) is zero, the shear strength of the soil will be determined by soil cohesion (c) value. A better understanding of the arching support can be explained by studying the soil's failure mechanism. Fig. 5 presents vertical velocity contours for a shallow (H/D =4) and deep case (H/D =4.5).

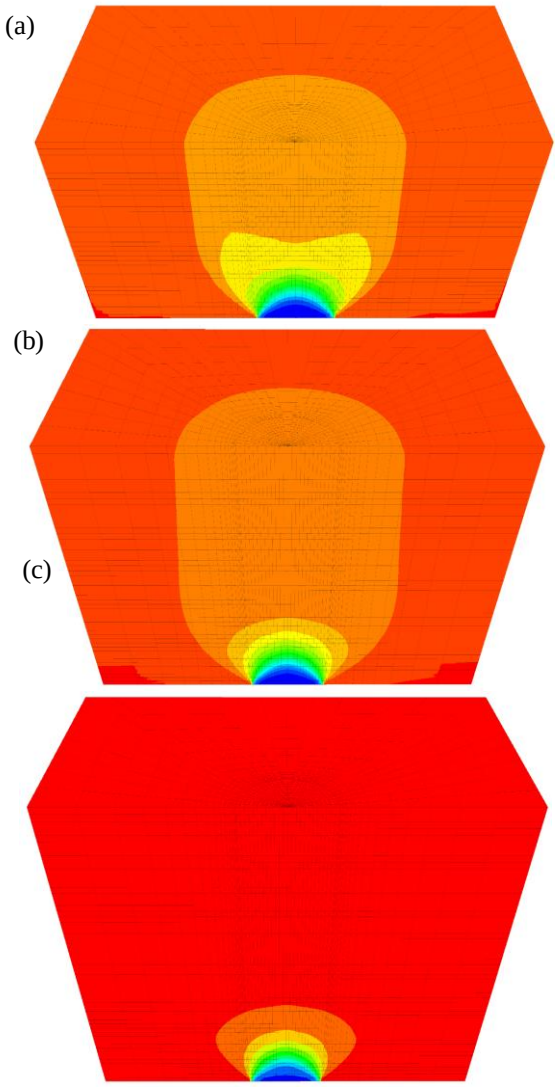

Fig. 5 Contour plots of the vertical velocity of *(a)* H/D=3, *(b)* H/D=4 and *(c)* H/D=5

As shown in Fig. 5, for deeper case (H/D=5), the failure does not extend to the ground surface. It implicates that the strong arching support is developed near the cavity in the deeper cases, resulting in a local failure.

The arching development also can be seen from the *FoS* results presented in Tables 1. It is noted that the rate of change of *FoS* starts to decrease for deeper cases. In addition, the stress distribution plot shown in Fig. 6, suggest that there is a change in vertical stress across the soil heights above the cavity.

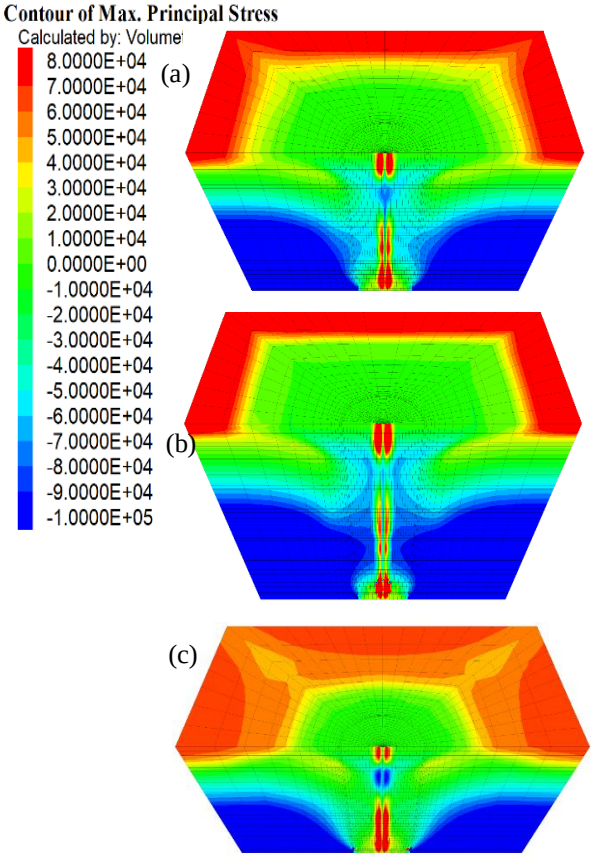

Fig. 6 Contour plots of principal stress of *(a)* H/D=3, *(b)* H/D=4 and *(c)* H/D=5

The transformation of compressive stress to tensile stress suggests that the vertical stress (σ_v) above the trapdoor is less than the total overburden pressure (γH) due to the load being redistributed in deeper case. This finding agrees with the observations in real engineering cases which assumes that the deeper tunnels are safer.

RESULT VERIFICATION

The use of *SSRM* and *FoS* is prevalent in slope stability analyses, however, this process is uncommon when it comes to estimating the stability of underground cavities. Owing to the lack of published literature for comparison, it was decided that the current 3D results obtained are to be compared with 2D and 3D *FDM* as well as 2D upper bound and lower bound solutions using the finite element limit analysis by Shiau et al. [13]. Fig. 7 shows such a comparison.

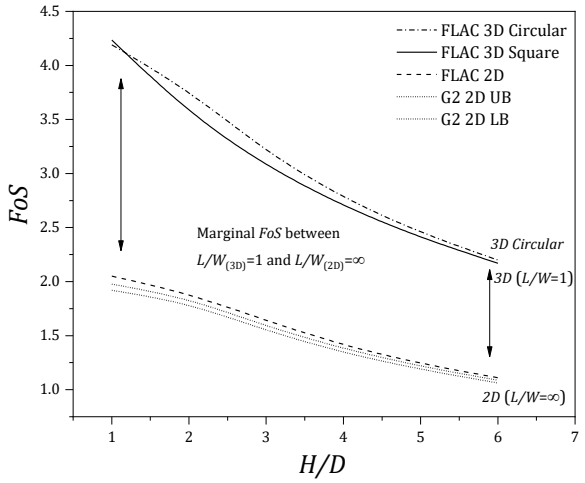

Fig. 7 Comparison of *FoS* results from 2D and 3D analyses (for $S_u/\gamma D$=1)

Fig. 7 shows that the results of 3D circular opening are similar to the 3D rectangular which has a significant variance between 3D and 2D. Table 3 shows the values used to plot Fig. 7.

Table 3 *FoS* results of *FLAC* 3D circular and rectangular, *FLAC* 2D and *FELA UB* and *LB* for $S_u/\gamma W$=1 [13]

H/W	FDM_{3D} Circular	FDM_{3D} Rectancular	FDM_{2D}	$FELA_{2D}$ LB [13]	$FELA_{2D}$ UB [13]
1	4.19	4.23	2.05	1.92	1.98
2	3.77	3.56	1.89	1.80	1.85
3	3.20	3.07	1.64	1.55	1.59
4	2.77	2.70	1.41	1.34	1.38
5	2.45	2.41	1.24	1.19	1.21
6	2.20	2.17	1.11	1.06	1.09

The results presented in table 3 shows that the *FoS* of 3D circular opening analyse is approximately two times higher than those 2D solutions. This is not particularly surprising, as a two-dimensional analysis will always yield conservative results when compared to a three-dimensional analysis. This finding can significantly reduce the estimation cost for practical purposes

DESIGN CHARTS AND EQUATION

The design charts and equations has been presented as a result of the factor of safety. A huge range of design charts for *H/D* = 1 to 6 are shown in Fig. 8.

The design chart is represented by the general equation to cover all possible depth ratios. Equation 3 which introduced earlier can be further transformed into Eq. (5) to determine *FoS* for known design parameters such as *H/D* and $S_u/\gamma D$.

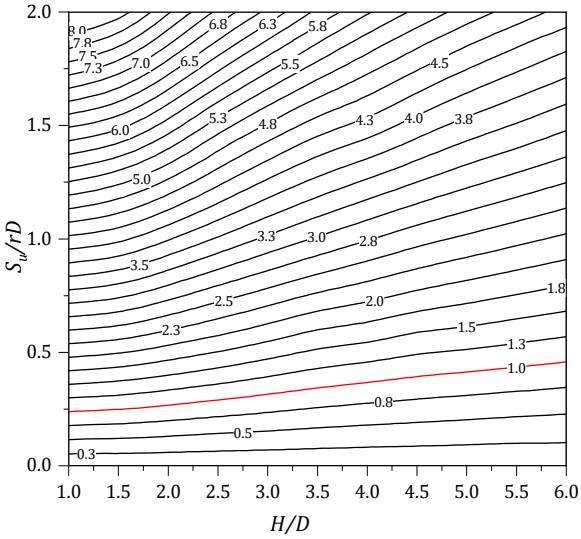

Fig. 8 Design chart for trapdoor stability.

$$FoS = \frac{S_u/\gamma W}{\left[\frac{0.0453H}{D} + 0.1812\right]} \quad (5)$$

Eq. (5) can be very useful in the early design stage for engineers because it allows them to determine the *FoS* when other parameters are available.

RPACTICAL EXAMPLES

Workability of the stability design charts and equations can best demonstrate through a number of examples, as follows.

Example 1 – determine the factor of safety (FoS)

Assume the sinkhole which has no internal pressure and no surcharge pressure, determine the factor of safety for the cavity. The following information is provided:

H=16m, *D*=4m, γ= 18 kN/m3 and S_u=72 kPa.

1. Given, *H/D*=4 and $S_u/\gamma D$=1, Eq. (3) returns a FoS approximately 2.76.

2. Using Fig. 8, a value of *FoS*=2.81.

3. An actual *FoS* value from the *FLAC* analysis is 2.77.

The results obtained from Eq. (5) and the Fig. 8 shows highly agreement with the actual analysis results.

Example 2 – determine the critical depth ratio (H/D)

In the case of the deep sinkhole, what would be the critical depth (H) required to maintain FoS of 1 with the following given parameters:

S_u= 162 kPa, D=30 m, γ= 18 kN/m3.

1. Given the parameter, $S_u/\gamma DFoS$ =0.3.

2. Using Eq. (3), the depth (H) is calculated to be 78.68m. Converting the result in terms of a depth ratio, H/D=2.62.

3. Using Fig. 4, H/D is estimated as a 2.8.

CONCLUSION

A series of 3D circular opening numerical models were investigated to analyse the stability of the trapdoors with various depth ratios in undrained cohesive soil. Numerical results were obtained by utilising the shear strength reduction method in the finite difference method software *FLAC* 3D. In order to efficiently perform parametric analyses, a *FISH* script was developed to enable auto mesh generation and solver. The following conclusions can be drawn based on this study:

- The *FoS* study showed that the 3D circular opening results were close to the 3D square opening (L/W=1).

- Strong soil arching was observed for deep trapdoors (H/D > 4.5) in the 3D circular trapdoor study, resulting in local failure mechanisms.

Although the study has investigated the stability in form factor of safety and the surface failure extent of sinkhole, there is certain limitation which is not considering the surcharge. Despite of the limitation, this study contributes to the understanding of the failure mechanism and arching effects in 3D circular opening problem. Further research is required to investigate the impact of surcharge load (σ_s) and support load (σ_t) for the development of sinkhole in undrained clay.

DETERMINATION OF CRITICAL TUNNEL HEADING PRESSURE

Fadhil Al-asadi[1] and Jim Shiau[1]
[1]School of Civil Engineering and Surveying, University of Southern Queensland, Australia

ABSTRACT

One of the main problems when constructing a tunnel is to ensure the stability of the tunnel heading. Many researchers have attempted to develop and elaborate the methods for tunnel stability calculation. In a similar form to traditional bearing capacity calculations, tunnel heading pressures can be analysed using the minimum supporting pressure σ_t, Such an equation is of the form: $\sigma_t = -cF_C + \sigma_s F_s + \gamma D F_\gamma$, where c and γ are the effective cohesion and the soil unit weight respectively, σ_s is the possible surcharge loading on the ground surface, D is the height of the tunnel and F_c, F_s and F_γ are the stability factors which are functions of soil frictional angle and tunnel depth ratio. For a series of tunnel diameter-to-depth ratios and material properties, this paper analyses the tunnel stability factors for the determination of tunnel supporting pressures σ_t. Both rigorous lower and upper bound solutions of stability factors are obtained by using novel finite element limit analysis techniques. For practical use, tunnel stability factors are presented in the form of figures and equations.

Keywords: Tunnel Heading, Upper Bound, Lower Bound, Finite Element Limit Analysis, Tunnel Stability Factors.

INTRODUCTION

Excavations for tunnel construction and underground mining in soft ground inevitably induces ground movement and may affect the existing underground infrastructure and surface structures. Ensuring tunnel face stability is directly related to the safety of the adjacent buildings and successful construction of a tunnel or mine.

Experimental tests and analytical approaches such as limit equilibrium methods and limit analysis methods are widely used in the analyses of tunnel face stability in cohesive-frictional soils. [1] was one of the first to propose a model for assessing the stability under drained conditions. He considered the limit equilibrium of a sliding wedge at the tunnel face. [2] proposed a 2D logarithmic spiral model. [3] derived the limit support pressure for tunnel face failure by assuming that the failure zone was a half sphere, a half circle, or a quarter circle. [4] applied the wedge model to calculate the limit support pressure in the homogeneous stratum. [5] extended the wedge model to a layered stratum. The other theoretical methods are the limit analysis methods

(Based on the upper and lower bound theorems of plasticity). [6] derived the limit support pressure for an unlined cavity in a dry cohesionless material. [7] derived upper bound solutions for the limit support pressure from assuming three failure mechanisms based on the movement of rigid blocks with conical shapes in frictional material. [8] investigated the stability of a plane strain circular tunnel in cohesive-frictional soils using finite element limit analysis methods.

The most recent publications are based on this new approach, and further developments have been produced on the stability of circular and square tunnels in cohesive-frictional soil subjected to surcharge loading [9-10].

The idea of considering drained stability based on a single equation was first suggested by [11] they proposed a formula for shield tunnels in dry sand as; $\sigma_t = \sigma_s F_s + \gamma D F_\gamma$.This formula was extended by [4] to cover cohesive-frictional soils by proposing an equation of the form: $\sigma_t = -cF_C + \sigma_s F_s + \gamma D F_\gamma$. However, the results produced were limited and were not ready for practical application. It is therefore the aim of this study to focus on finding the rigorous *UB* and *LB* values of the stability factors (F_c, F_s and F_γ) so that accurate minimum supporting pressure required to maintain the stability of the tunnel face in cohesive-frictional soils can be determined using a wide range of design charts and tables

PROBLEM DEFINITION AND METHODOLOGY

The layout of a plane strain heading stability problem is shown in Figure 1. The problem is similar to a long wall mining or any flat wall in an underground excavation. The heading has a height D and a cover C. The ground around the excavation is modelled as a uniform Mohr-Coulomb material with a cohesion c, friction angle ϕ, and unit weight γ.

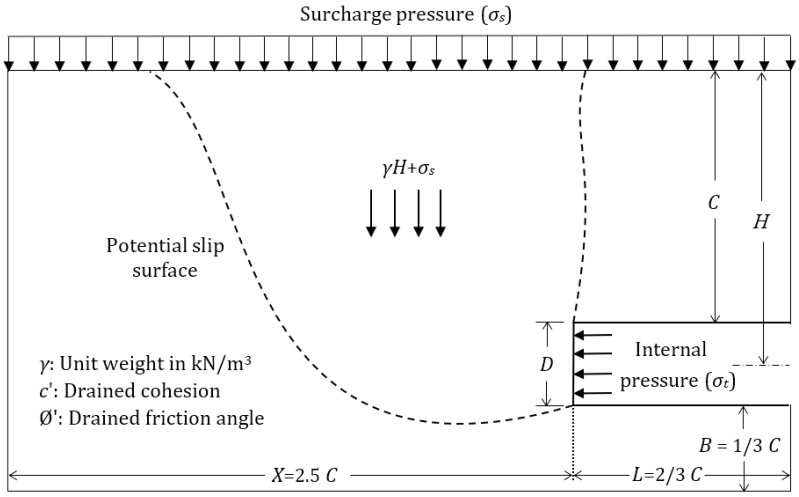

Figure 1. Problem definition

The face of the heading is free to move and is subject to normal stress representing an internal pressure σ_t. The ground surface is horizontal and subject to a vertical surcharge σ_s. The boundary condition of the problem was defined such that the bottom boundary of the model was fixed in both vertical and horizontal directions, while the left and the right boundary of the problem was allowed to move only in the vertical direction. Also, the rigid, smooth tunnel lining is achieved by constraining the movement in the vertical direction.

Figure 2 shows an example of the plane strain condition in *FELA* [12]. The soil mass was discretized as triangular elements. Three iterations of adaptive meshing with the number of elements increasing from 2000 to 5000 were used to obtain the solution. The size of the problem domains was chosen to be large enough that the plastic yielding zone was contained within the domain and did not intersect the boundaries. This would ensure that no influence of the domain size on the computed solutions.

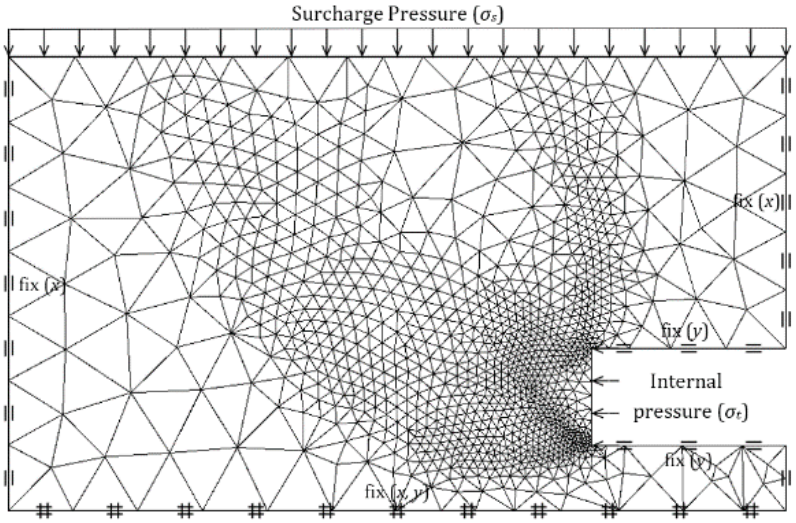

Figure 2. Adaptive mesh used for the problem

In *FELA* modelling, the solution is obtained by applying the load multiplier method, where a unit load is applied and amplified until a state of failure is induced. The internal pressure σ_t is optimised using both upper and lower bound simulations. To compute the bound solution of the stability factors (F_c, F_s and F_γ), zero value of the unit weight γ, the surcharge σ_s and the cohesion c are imposed respectively in the program runs. Similar to Terzaghi's bearing capacity equations, the three factors are functions of the depth ratio *C/D* and the soil friction angle ϕ. With the three factors, critical support pressures can be calculated by the method of superposition. The obtained results (F_c, F_s and F_γ) are compared and validated by using the existing published solution.

DISCUSSING THE TUNNEL STABILITY FACTORS (F_γ, F_s and F_c)

Numerical analyses were performed to calculate the upper bound (*UB*) and the lower bound (*LB*) limits of the stability factors (F_c, F_s, and F_γ) for various depth ratios *C/D* and angles of internal friction ϕ. Since the lower bound theorem offers a safe assessment of the limit pressure for a stability problem, the computed lower bound results of the stability factors were chosen in all equations and design charts. They can be used to assist designers and practising engineers in the evaluation of tunnel heading stability.

The stability factors for cohesion (F_c)

The *FELA* method used in this study produces different curves of F_c for different depth ratios *C/D*. In figure 3, F_c decreases as ϕ increases for all values of *C/D*. This indicates that the effect of soil cohesion diminishes as the soil friction angle increases. It is interesting to see that all curves merge into a single line at approximately ϕ = 30 degree. A double logarithmic regression analysis was employed to develop equation 1. The correlation coefficient r^2 = 0.996.

$$F_c = [-0.24 \times \ln(C/D) + 1.11] + [(-0.49 \times \ln(C/D) + 1.18) \times \ln(tan\emptyset)] \quad (1)$$

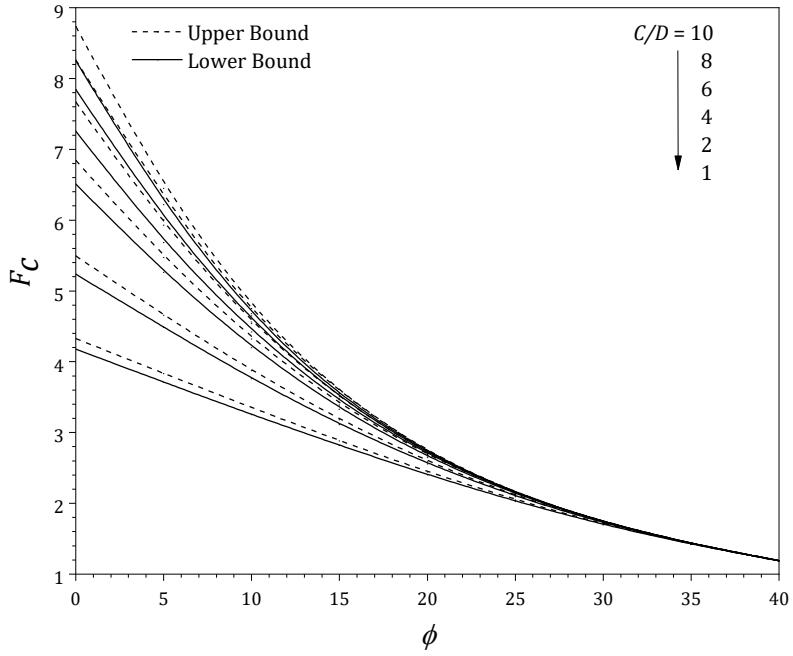

Figure 3. F_c vs ϕ for various depth ratios (*C/D* = 1-10).

The stability factors for surcharge (F_s)

Figure 4 shows that, for any given depth ratio, the maximum value of the surcharge stability factor (F_s) is one. When the internal friction angle (ϕ) of the soil is equal to zero, i.e. undrained condition, the value of F_s is equal to one. This indicates that, for the undrained condition without volume loss during shearing, the stability results is independent of the loading direction. With increasing angle of internal friction ϕ, the value of F_s decreases and merges into one line at ϕ = 35 degree. It is interesting to see that F_s approaches to zero for large values of ϕ, which indicates that surcharge loading σ_s has little contribution to the support pressure when the value of ϕ is large.

A double regression analysis (exponential and logarithmic) was employed to develop equation 2. The correlation coefficient r^2 = 0.991.

$$F_s = [0.056 \times (C/D) + 1.16] \times e^{[(-3.33 \times \ln(C/D) - 5.97) \times tan\emptyset]} \quad (2)$$

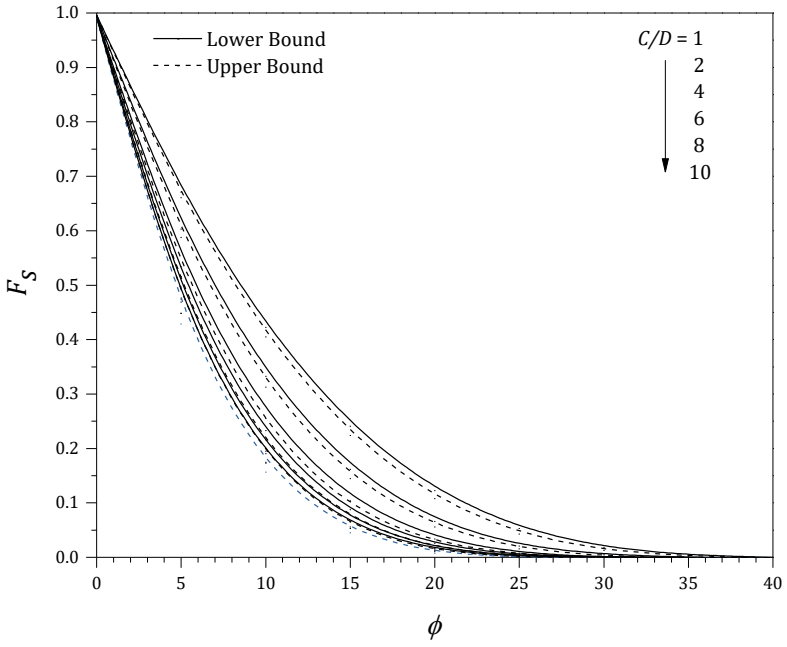

Figure 4. F_s vs ϕ for various depth ratios (C/D = 1-10).

The stability factors for unit weight (F_γ)

Tunnel stability factors based on theoretical analyses and numerical models results were discussed by Atkinson and Potts (1977), Atkinson and Mair (1981), Vermeer et al. (2002) and others. It was concluded that the values of F_γ depend only on the angle of internal friction (ϕ) and are independent of the depth of the tunnel. However, the present study produces different curves of F_γ for different depth ratios when the friction angle of the soil equal or less than 25˚. This is a significant finding for the current study based on the novel *FELA* approach.

In general, F_γ decreases as ϕ increases. A double regression analysis (Exponential and Logarithmic) was employed to develop equation 3. The correlation coefficient $r^2 = 0.983$.

$$F_\gamma = [-0.016 \times \ln(C/D) + 0.143] \times tan\emptyset^{[-0.347 \times \ln(C/D) + 0.994]} \quad (3)$$

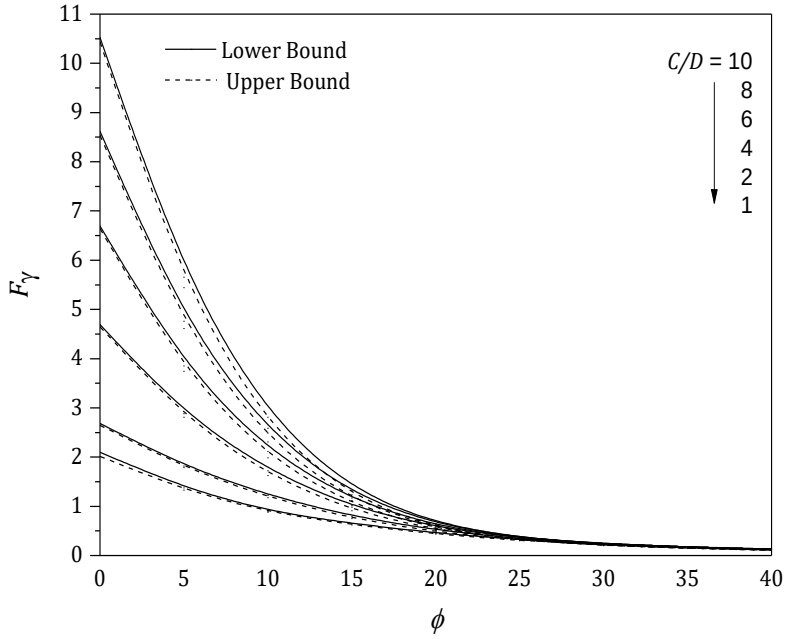

Figure 5. F_γ vs ϕ for various depth ratios (C/D = 1-10).

PRACTICAL USES AND EXAMPLES

The usefulness of the tunnel stability factors is best demonstrated through some examples. Since the lower bound theorem offers a safe assessment of the limit pressure for a stability problem, all stability factors and equations have been derived by double regression analysis based on *LB* results. The following examples demonstrated using *LB* results.

Example 1

Given soil cohesion (c) = 45 kPa, friction Angle (ϕ) = 0°, unit weight of soil (γ) = 18 kN/m^3, surcharge surface load (σ_s) = 40 kPa. The tunnel height (D) = 6m and the depth of the soil above the tunnel (C) =18m. It is required to determine the minimum support pressure at collapse.

Solution:

1. Using equations (1, 2 and 3) with C/D = 3 and ϕ = 0, F_c = 6.0, F_s = 1 and F_γ = 3.6.
2. $\sigma_t = -cF_c + \sigma_s F_s + \gamma D F_\gamma = -(45 \times 6.0) + (40 \times 1.0) + (18 \times 6 \times 3.6) = 158.8$ kPa
3. An actual *LB* analysis of this case gives a σ_t of 153.50 kPa.

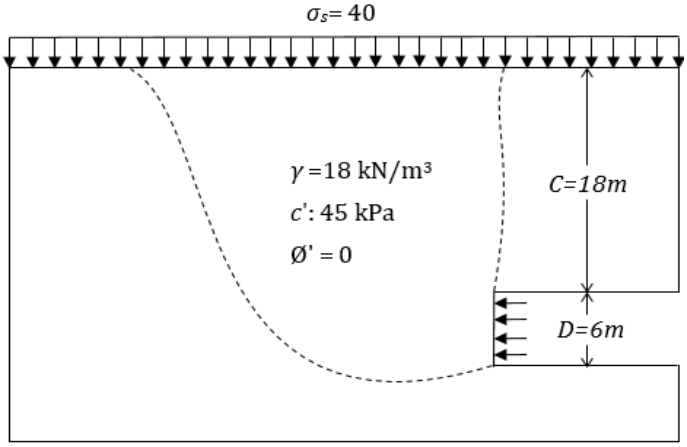

Figure 6. Statement of the problem for Example 1

Example 2

Given soil cohesion (c) = 0 kPa, friction Angle (ϕ) = 35°, unit weight of soil (γ) = 18 kN/m^3, surcharge surface load (σ_s) = 0 kPa. The tunnel height (D) = 6m and the depth of the soil above the tunnel (C) = 36m. It is required to determine the minimum support pressure at collapse.

Solution:

1. Using equations (1, 2 and 3) with C/D = 6 and ϕ = 35°, F_c = 1.43, F_s = 0 and F_γ = 0.171.
2. $\sigma_t = -cF_c + \sigma_s F_s + \gamma D F_\gamma = (0 \times 1.43) + (0 \times 0) + (18 \times 6 \times 0.171) = 18.47$ kPa
3. An actual *LB* analysis of this case gives a σ_t of 18.50 kPa.

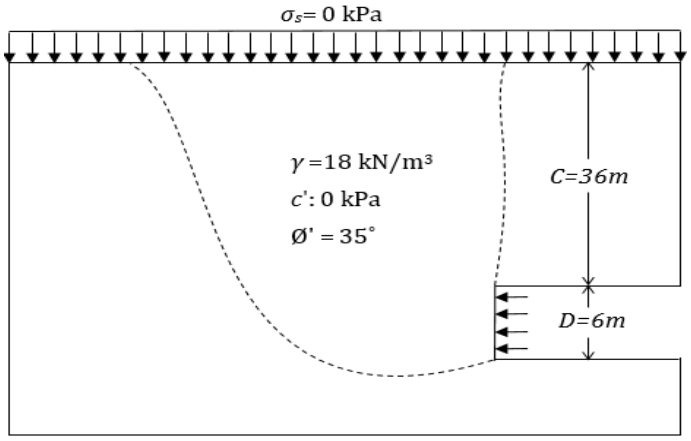

Figure 7. Statement of the problem for Example 2

CONCLUSION

In order to study the face stability of tunnel heading in cohesive-frictional soils, numerical simulations through finite element limit analyses were performed. The limit support pressure of the tunnel face for the limit conditions are of the main concerns. A series of numerical simulations in different soils (ϕ = 0 - 40) for various depth ratios (*C/D*) were performed to calculate tunnel stability factors (F_c, F_s, and F_γ). With the three factors, the minimum support pressures can be calculated using the principle of superposition ~ a similar approach to Terzaghi's bearing capacity equations. The current approach is convenient for practical engineers as it is user friendly in estimating the support pressure. Some future work may include the preparation of a comprehensive of design tables.

ADHESIVE STRENGTH OF INJECTABLE INORGANIC ANCHOR MATERIAL IN CONCRETE

Hidenori Tanaka[1], Hayata Yanagihara[2] and Nobuyuki Sasaki[3]
[1]National Institute of Technology, Gunma College, Japan; [2,3] Former students, Japan

ABSTRACT

We have used some organic materials to connect between steel anchors and concrete structures. They are very useful to repair the cracks in concrete and to glue the steel or another organic materials to concrete structures. But, we don't apply them in water or upward injection. Especially, we couldn't fill them sufficiently in case of the upward injection. Some crucial incidents are reported because of non-filling area in hole which have to be filled with anchor materials. And then, new inorganic anchor material has been developed as applications for construction under sea water level or upward injection. However, the adhesive strength of it to concrete or steel anchor hasn't been cleared sufficiently. We carried out the adhesive strength tests (punching out shearing) between steel anchor including anchor material and concrete by using amsler testing machine. The experimental factors are diameter of injection hole, injection length, type of steel anchor, axial eccentricity of steel anchor, treatment of side surface in hole. According to the results, we found that there were some fracture modes due to some experimental factors. In cases of short injection length and round steel anchor, Adhesive interfacial fracture between steel and anchor material or between anchor material and concrete tended to be occurred. Bond-splitting fracture including cone shape fracture was shown in treatment of side surface in hole.

Keywords: Adhesive strength, Inorganic material, Fracture modes, Numerical analysis, Damage Mechanics

INTRODUCTION

We have used organic material like epoxy and urethane resin to glue steel or plastic to concrete structures. Especially, epoxy resin is useful for cracking repair or injectable material. But, these materials have some flaws for example, deterioration by UV light, nonconformity under water construction, non-filling in case of the upward injection in hole.

We have tried to adopt the inorganic material which could make up for defects as the injectable anchor material to connect to a steel anchor and concrete structures in case of the thin thick structures.

Generally speaking, Adhesive strength has been easily defined by interfacial area of two materials or hypothesis of shear or diagonal fracture (45 degree). But, we have to consider fracture modes that defined Interfacial of material, shear fracture of injectable material and bond-splitting fracture of concrete [1].

In this study, we conducted some experiments to clear the adhesive strength between steel anchor and injectable material, or injectable material and concrete block considering fracture modes by punching out shearing test. Here, the experimental factors are diameter of injection hole, injection length, type of steel anchor, axial eccentricity of steel anchor, treatment of side surface in hole.

We also showed the results of basic numerical analysis about fracture by axisymmetric problem.

ADHESIVE STRENGTH TEST

In this research, we used cylindrical concrete specimen (outer diameter = 150 mm). And, the compressive strength is 50 (N/mm^2) of concrete and 55 (N/mm^2) of injectable material.

The specimen was shown in Figure 1. And, we adopted the displacement control method by amsler. The velocity was 2.0 (mm/min). The concept of loading (punching out) was shown in Figure 2.

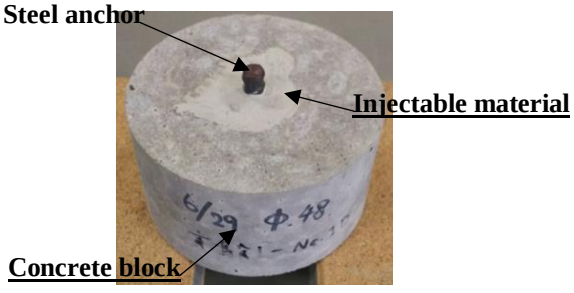

Fig.1 Specimen

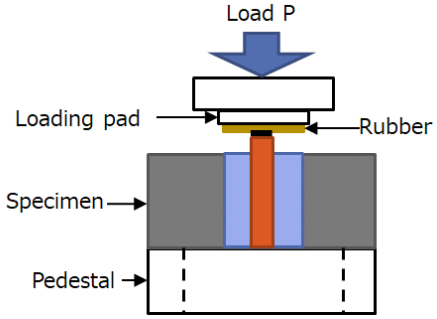

Fig.2 Loading method

Previous researches were carried out by the pulling off test which needed the special steel jigs and tools [1]-[3].Generally, The mechanism of adhesive was defined by shear behavior within a material or interfacial border between two materials. In case of isotropic material, we could apply punching out test to this research from point of theoretical and economical view. We found out that there were same fracture modes in pulling off or punching out. And, we targeted the concrete structure under 100 (mm) thickness. These were main difference between previous researches and ours.

Experimental factors

We focused on four experimental factors in this study. First, we used round and deformed bar as a steel anchor. Second, we changed the diameter and the length of injectable anchor material [2],[3]. Third, the eccentricity of steel anchor form center of hole which is equal to the center of injectable material. And fourth, we checked the influence to adhesive strength with or without side surface treatment of injectable material in hole.

The third and fourth factors also were difference between previous documents [2],[3].

Results of experiment

Influence of steel anchor

The load and displacement relation was shown in Figure.3. The maximun load of deformed bar was eleven times bigger than that of round bar. The interfacial fracture mode was occurred between round bar and injectable material (refer to Figure 4) .

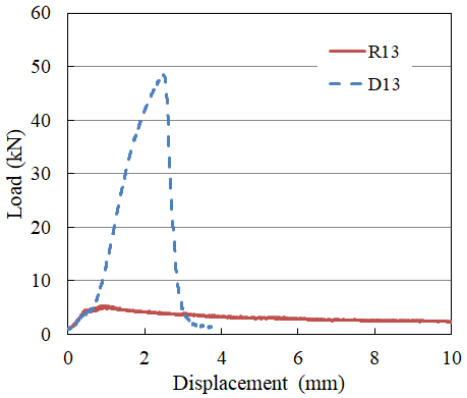

Fig.3 Load and displacement

On the other hand, The bond-splitting fracture mode was shown between deformed bar and injectable material including concrete block (refer to Figure 5). We used a deformed bar succeeding experimental cases as the steel anchor.

Fig.4 Bottom surface of specimen (R-bar)

Fig.5 Bottom surface of specimen (D-bar)

Influence of injectable diameter and length

We showed the influence of injectable diameter and length on the maximum load (refer to Figure 6).

We found out two main fracture modes whether the injectable length was less than 55 (mm) or not. It was bond-splitting fracture under 55 (mm) length. And then, In case of more than 65 (mm) length, it was founnd not only the bond-splitting but also the cone shape fracture. The cone shape fracture mode was shown in Figure 8 and 9.

The influence of injectable diameter on the maximum load has not been cleared. However, the maximum load in case of 60 (mm) diameter was the smallest, because the curve was bifurcated two peaks under 55 (mm) length (refer to Figure 7) .

The maximum load trended to be in inverse proportion to the injectable dimameter in cases of more than 65 (mm) length.

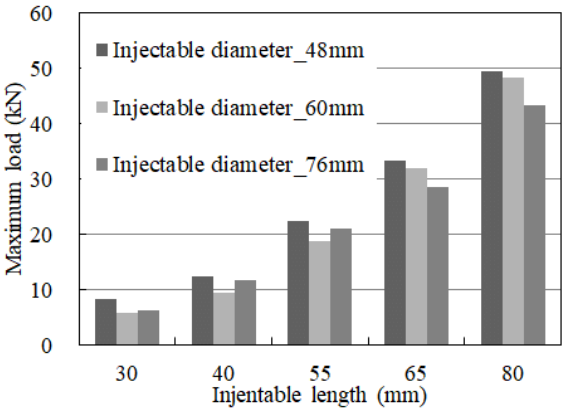

Fig.6 Maximum load and injectable length, diameter

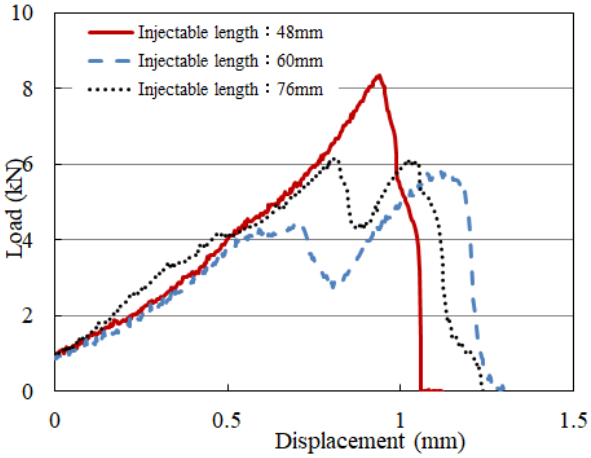

Fig.7 Load and displacement (length=30 (mm))

Becase the height of cone shape became lower in inverse proportion to the injectable diameter, the total area against the load got smaller (refer to Figure 8 and 9) . We thought that was main reason.

Fig.8 Cone shape fracture (ℓ=65 (mm),d=60 (mm))

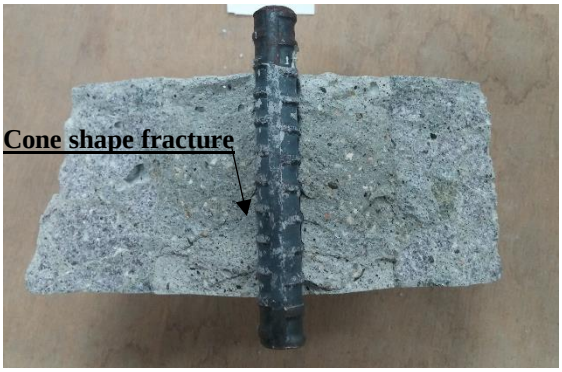

Fig.9 Cone shape fracture (ℓ=65 (mm),d=80 (mm))

Influence of the eccentricity of steel anchor in hole

We had to check the influence of the eccentricity of steel anchor on adhesive strength in order to avoid the inconsistency of steel anchor position in hole.

The e of legend in Figure 10 notes that the eccentricity value from center of hole.If there were 8 (mm) eccentricity from center, The maximum load was about 30 percent smaller than that of center and the bifurcation was occurred in the curve (refer to Figure 10).

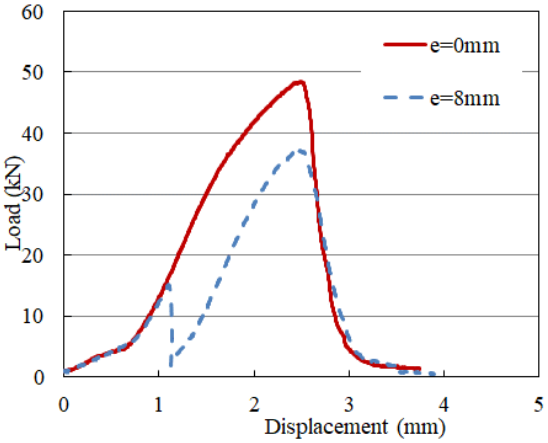

Fig.10 Load-displacement curve (eccentricity of bar)

I thought that it was caused by the shift from bond-splitting to cone shape fracture. At first, the bond-splitting was occurred and next, the mechanism of fracture was shifted to the cone shape mode (refer to Figure 11). The standard case was bond-splitting mode in Figure 12.

Fig.11 Bottom surface of specimen (e=8 mm)

Fig.12 Bottom surface of specimen (e=0 mm)

Influence of treatment of side surface of hole

Most of the time, The suface treatment in hole

was carried out by brush to improve the adhesive strength between injectable material and concrete [4]. In this research, we did the surface treatment by brush and checked the influence of that. There were about 17 percent difference with or without treatment on maximum load in Figure 13.

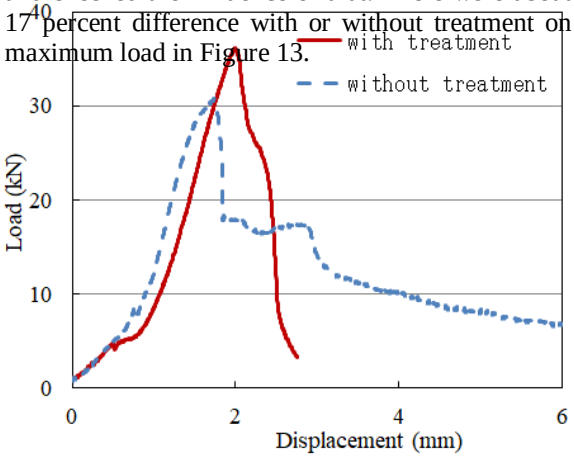

Fig.13 load and displacement (treatment)

Fig.14 Without treatment

Fig.15 With treatment

The fracture modes were shown in Figure 14 and Figure 15 respectively. The interfacial fracture was occurred between injectable material and concrete without treatment. On the other, the bond-splitting fracture was occurred with treatment. It was found that the fracture mode was shifted with or without treatment of surface in hole.

NUMERICAL ANALYSIS (FIRST VERSION)

In this section, we showed the results of numerical analysis that was applied to damage mechnics [5]. And, we conducted numerical analysis by finite element method considering axisymmetric problem to evaluate the basic fracture mode which was so called the interfacial border fracture.

Constitutive equation

It was important to evaluate the equivalent stress and strain of material in numerical analysis. The constitutive equation was defined as followed [6].

$$F = F_p(\bar{\sigma},\gamma,D) + F_D(Y;p,D) = \bar{\sigma}_{eq} - \gamma - \sigma_y + \frac{S_1}{(S_2+1)(1-D)}\left(\frac{Y}{S_1}\right)^{S_2+1} \quad (1)$$

Where, F_p is the potential for the growth of plastic strains, which is a function of the effective stress $\bar{\sigma}$, the plastic hardening parameter γ and the scalar damage variable D.

F_D is the potential for the evolution of damage which is a function of the strain energy release rate Y, the equivalent plastic strain and the damage variable p.

In the formulation of the constitutive equation, the yield function is assumed as follows:

$$f = F_p = \bar{\sigma}_{eq} - \gamma - \sigma_y = 0 \quad (2)$$

$$\bar{\sigma}_{eq} = \sigma_{eq}/(1-D) \quad (3)$$

$$\sigma_{eq} = \alpha I_1 + \left(J_2^{'}\right)^{1/2} \quad (4)$$

Where the following notations are used. $\bar{\sigma}_{eq}$;effective Drucker-Prager's equivalent stress, σ_y ;the yield stress, ; α material parameter, I_1 ;the first invariant of stress and $J_2^{'}$;the second invariant of deviatoric stresses.

$$dD = \left(\frac{Y}{S_1}\right)^{S_2} dp \qquad Y = \frac{\sigma_{eq}^{\ 2}}{2E(1-D)^2} \quad (6)$$

$$d\sigma = (1-D)d\bar{\sigma} - \bar{\sigma}dD = D_{epd}d\varepsilon$$

$$\mathbf{D}_{epd} = \left[(1-D)\mathbf{C} - \left\{(1-D)\mathbf{C}\frac{\partial F_p}{\partial \bar{\boldsymbol{\sigma}}} + \bar{\boldsymbol{\sigma}}\frac{\partial F_D}{\partial Y}\right\}\frac{\left(\frac{\partial F_p}{\partial \bar{\boldsymbol{\sigma}}}\right)^T\mathbf{C}}{H + \left(\frac{\partial F_p}{\partial \bar{\boldsymbol{\sigma}}}\right)^T\mathbf{C}\frac{\partial F_p}{\partial \bar{\boldsymbol{\sigma}}} - \frac{\bar{\sigma}_{eq}}{1-D}\frac{\partial F_D}{\partial Y}}\right] \quad (7)$$

D_{epd} meant elasto-plastic and damageable stiffness tensor, C is general elastic tensor.

We used the same relationship between equivalent stress and strain both injectable material and concrete. Because the compressive strength and these mechanical properties were almost same value. The basic prameters were shown in Table 1.

Figure 16 showed the compressive stress test of concrete specimen comparing with the numerical constitutive equation (MODEL in Fig.16).

Table 1 Material parameters

Parameter	Value
E (Young Modulus)	30.0 (kN/mm^2)
ν (Poisson's ratio)	0.17
α (equivalent stress)	0.72
σ_y (yield stess)	0.75 (N/mm^2)
K (plastic hardening)	40.0 (N/mm^2)
n (plastic hardening)	0.215
S_1 (damage paremeter)	0.000215 (N/mm^2)
S_2 (damage parameter)	1.55

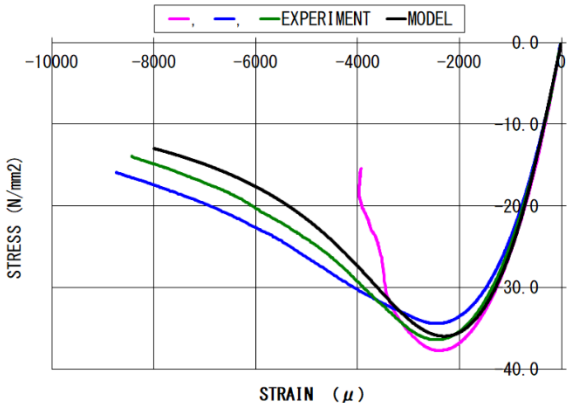

Fig.16 stress-strain cure (concrete)

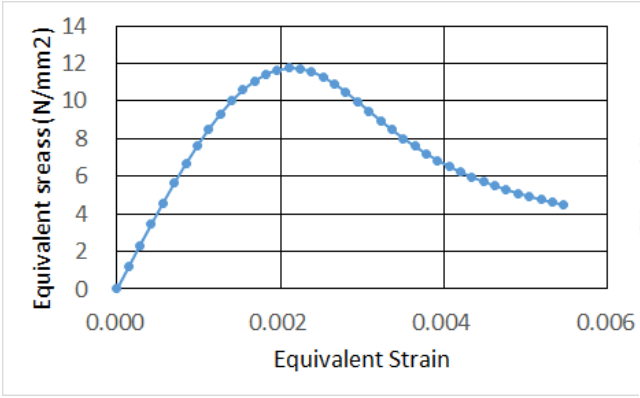

Fig.17 Equivalent stress-strain curve

Examle of analysis

We took the specimen without steel bar as the example of analysis. Because it was needed to confirm the basic fracture mode between injectable material and concrete. The final state was shown in Figure 18.The analysis model was half considering axisymmetric (refer to Figure19) .

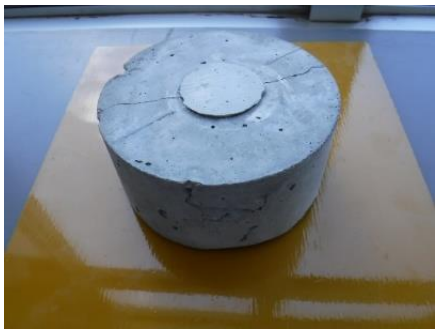

Fig.18 Bottom of specimen (example)

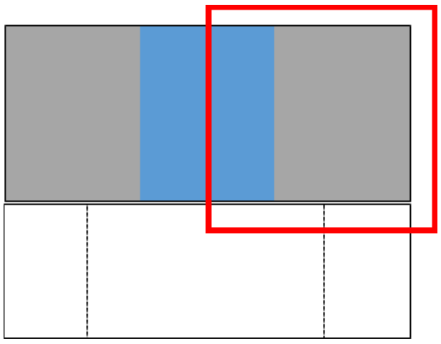

Fig.19 Analysis area (1/2model)

The analysis was based on elasto-plastic problem [7]. We used Von Mises type as the yield function.

Result of analysis

The distribution of equivalent stresses were shown in Figure 20. The analysis was carried out to controll the displacement at the top of injectable material. We showed each distribution of stresses from the top to the bottom in proportion to controlled displacement (refer to Figure 20,Numit:(N/mm^2)).

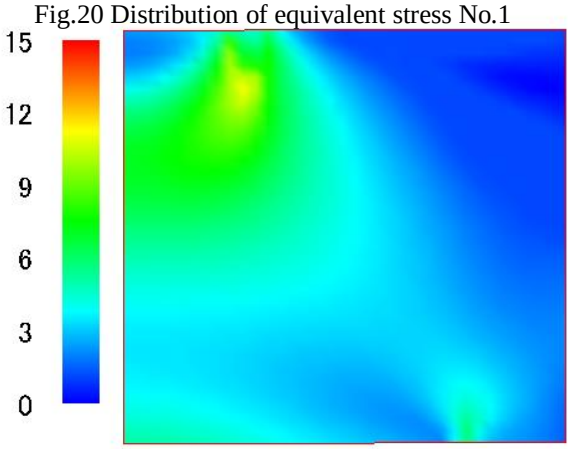

Fig.20 Distribution of equivalent stress No.2

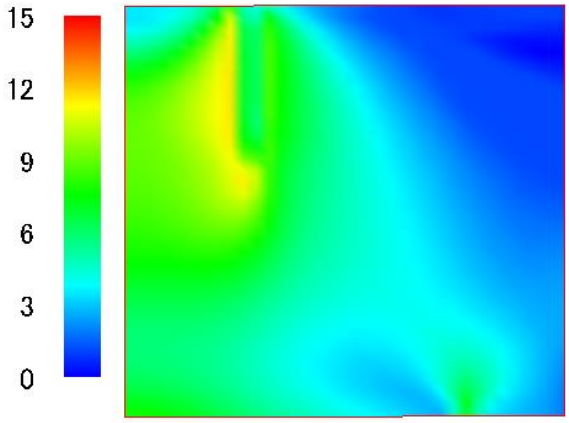

Fig.20 Distribution of equivalent stress No.3

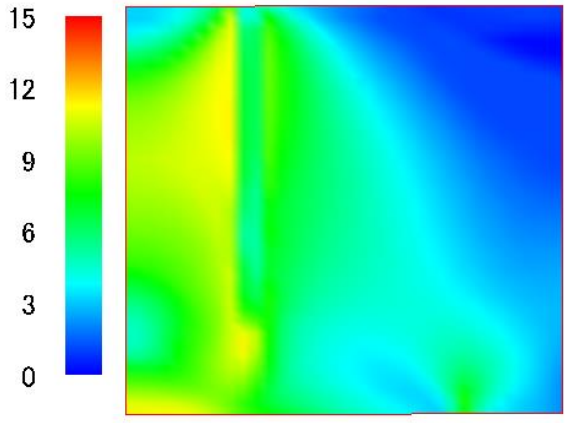

Fig.20 Distribution of equivalent stress No.4

CONCLUSIONS

The knowledge found in this research were as below.

(1) The mixed fracture modes of bond-splitting and cone shape were found over 65 (mm) length of injectable material.

(2) The maximum load was decreased about 30 percent because of the eccentricity of steel anchor.

(3) The fracture mode was shifted from the interfacial to the bond-splitting with or without the treatment of surface in hole. And, the maximum load of with the treatment was 17 percent bigger than that of without.

(4) The crack was occurred along the border of injectable material and It had good response to the experimental result.

(5) We have the plan to change the strength of concrete and the shape of side surface in hole.

(6) It needs to improve the relationship between equivalent stress and strain about concrete and injectable material.

(7) We will try to carry out the analysis including steel anchor and various strength of concrete.

ACKNOWLEDGMENTS

Authors appreciate Sumitomo Osaka Cement Co.,Ltd. for providing the injectable inorganic anchor material so called “Ceme-force Anchor “.

ABSTRACT

Concrete's strength is derived by the hydration of cement particles which requires sufficient moisture. Curing can be considered as a way of moisturizing the concrete for the hydration process. The principal objective of this study is to find the effect of curing period on the properties of concrete. The curing period of concrete has been kept variable through this study. The properties of materials are determined according to ASTM specification and only one mix proportion is used. In this study, a series of concrete cylinders have been cast and cured for 0, 3, 7, 14, 21 and 28 days. Each specimen has been tested after 28-days and basic properties of concrete such as compressive strength, tensile strength and modulus of elasticity have been determined. Mix proportion of concrete has been considered as 1:2:4 by volume and ratio of water cement has been used 0.5 by weight. Specimens have been immersed in fresh water for curing process. It has been observed from the study that the compressive and tensile strength both increases linearly and gradually with the increase of curing periods respectively. Also increasing rate of tensile strength is slower for short period rather than long period.

Keywords: Curing; Concrete strength; Hydration; Compressive and Tensile strength.

INTRODUCTION

Concrete is a mixture of cement, water and aggregate which produces firm and hard mass making it durable. The quality and durability of concrete depend both on the quality and properties of ingredients and method of preparation, placing, curing and environmental conditions to which it is exposed over its service life.

In the practical, higher water-cement ratio is used where the concrete remains open to atmosphere. The water used in the concrete evaporates and quick surface drying of concrete results extraction of moisture from the concrete mix. Remaining water in the concrete is not sufficient for effective hydration. Extra water must be added for the proper hydration during a specified period to replenish the loss of water by absorption and evaporation. (Shetty, 2005)

The strength of concrete starts developing immediately after settling is completed which continues for an indefinite period at a rate gradually diminishing with time. 80-85% of the strength is attained within first 28 days and hence this strength is considered to be the design criterion. Submerged method is the most effective method of curing during laboratory tests.

Objectives

- Study the effect of curing period on the compressive strength of concrete.
- Find the effect of curing period on the modulus of elasticity of concrete.

MATERIALS AND METHODOLOGY

The Second Level Headings

The strength of concrete is greatly influenced by the properties of ingredients in the concrete mix. Cement, Fine Aggregate, Coarse Aggregate and Water are generally used in concrete:

Cement

Holcim is one of the world's leading cement, for this study Holcim ordinary Portland cement has been used. Its specific gravity ranges from 3.12 to 3.16 and weight 1208 kg/m3 (94lb/ft3). The specific gravity of cement used in this study is 3.15.

Fine Aggregate

Fine aggregate passes through a 4.75 mm IS sieve and contains material permitted by the specifications. The fine aggregate that has been used in this study was mix of 50% Sylhet sand and 50% local sand. The value of F.M of combined fine aggregate is 2.59 where the F.M of fine sand is 1.86 and coarse sand is 3.32

Coarse Aggregate

Most of the coarse aggregate are retained on the 4.75mm IS sieve and contain material permitted by specifications. Generally, brick chips are used as coarse aggregate. Brick chips are prepared by crushing

first class bricks and 3/4" down grade chips are selected for this study.

Table 1: Properties of brick

Compressive strength	35.1 (MPa)
Absorption capacity	8.45% (by weight)

Properties of Coarse Aggregate
The test method for sieve analysis of coarse aggregate conforms to the ASTM standard requirements of specification C136. Maximum size of coarse aggregate was 3/4".

Table 2: Properties of coarse aggregate

Common properties	Brick aggregate
Dry unit weight	18.62
Absorption capacity (%)	12.47
Bulk specific gravity (S.S.D)	1.92
F.M	6.54

Water

Water is essential for concrete to initialize chemical reaction with cement, to wet the aggregate, and to lubricate the mixture for workability. Since the quality of water effects the strength it is necessary to ensure fresh water. Normally, drinking water is used for mixing. Water having harmful ingredients such as contamination, salt, oil, sugar or chemical is deleterious to the setting properties of cement. It can damage the affinity between the aggregate and cement paste also adversely affect the workability of mixture.

PREPARATION OF TEST SPECIMENS

Quality of concrete requires careful care exercised at every stage of concrete manufacturing. The various stages of casting test specimens are batching, mixing, placing and compacting, and curing.

Batching

The correct method of measuring the materials is weigh batching. For important concrete, invariably, weigh batching system is should be adopted. In this study weigh batching has been used for measuring water cement ratio and volume batching is used for measuring the materials.

Mixing

Tilting type mixer machine has been used for the study to mix up the concrete. After loading the mixer machine, the mixing process should be continued till a thoroughly and properly mixed concrete is obtained. Speed of this mixer machine was about 15-20 rpm. Mixing time was 5-6 minutes.

Placing and Compacting

After mixing the concrete is placed in a cylindrical mold in three layers. Each layers compacted by a 25mm bar with rounded end. Compaction is accomplished by doing external work on the concrete. In this study compaction was done by manually. In the process of placing and mixing, air might have been trapped in the concrete. If the air is not removed entirely, the strength of concrete will decrease significantly.

Curing of Concrete

During the first few days and weeks, fresh concrete gains strength rapidly. Structural design is usually based on the 28-days strength, about 70 percent of which is reached at the end of first week after casting. The final concrete strength depends largely on the conditions of moisture and temperature during this initial period.
In this study water curing method was used for curing of concrete. Test specimens have been immersed in curing tank for 3-days, 7-days, 14-days, 21-days, 28-days. Some specimens have been immersed for 25-days which have not been immersed in water for first 3-days after casting. Some specimens have been immersed for 21-days which have not been immersed in water for first 7-days after casting. Some specimens have allowed for no curing totally.

TESTING OF CONCRETE SPECIMENS

Testing of harden concrete plays an important role in controlling and confirming the quality of cement concrete work. Following tests have been commonly used to determine the properties of hardened concrete.

Test for Compressive Strength

Compression test is the most common test on hardened concrete. In this study cylindrical specimens have been used. The size of the cylinder specimens is 6 in. dia. and 12 in. height. Universal testing machine has been used for loading which is illustrated in Fig 1. Capacity of the testing machine 1000 KN and rate of loading is 250 KN/minute. The test method conforms to the ASTM standard requirements specification C39 for cylinder. The compressive strength of test specimens of concrete has been determined at 28-days but different curing periods have been used for different specimen.

Fig 1: Photo view of set up of compressive strength

Test for Modulus of Elasticity

The modulus of elasticity is determined by subjecting a cylinder specimen to uniaxial compressing and measuring the deformation by means of dial gauges fixed between certain gauge lengths showing in Fig 2. Dial gauge reading divided by gauge length will give the strain and loads are divided by area of cross section will give the stress. A series of reading is taken and stress-strain relationship is established. Thus, the modulus of elasticity Ec (N/mm2), that is, the slope of the initial straight portion of the stress-strain curve, is seen to increase as the strength of concrete increases. The modulus of elasticity values obtained will usually be less than moduli derived under rapid load application (dynamic or seismic rate, for example) under slow load application (extended load duration) provided another test condition have been kept the same.

Fig 2: Photo view of set up for modulus of elasticity test

RESULTS AND DISCUSSIONS

Compressive Strength of Concrete

The compressive strength of concrete varies with the change of curing period. In this study it has been obtained that the variation is linear (**Error! Reference source not found.**). The result of compressive strength of concrete are summarized in **Error! Reference source not found.**.

Table 3: Test result of compressive strength

Curing Period (day)	Compressive Strength (MPa)
No curing at all	15.67
3	17.68
7	17.25
14	20.08
21	22.46
28	24.31

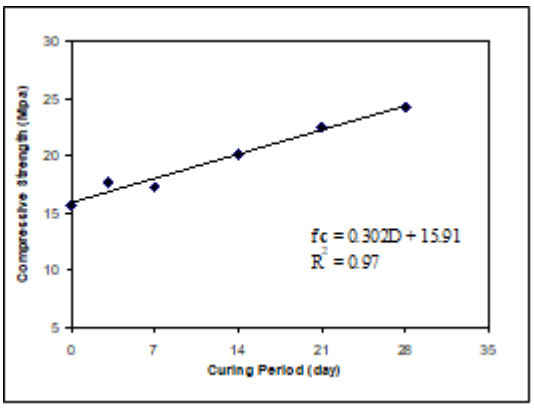

Fig 3: Relation between the compressive strength and curing period.

The following equation is suggested to express the relationship

$$f_c^{'} = 0.302D + 15.91 \quad (1)$$

Where, f_c'= Compressive strength of concrete in Mpa, D= Curing period in day.

From the test results we obtain that the specimen which were cured for 0, 3, 7, 14, 21 days attained 65%, 69%, 74%, 82%, 91% strength as compared to the strength of 28 days cured specimen. The strength of concrete increases almost linearly with the curing period, so from the experimental data it can be say that proper curing up to a specified period is must be required for attaining the desired strength of concrete.

Modulus of Elasticity of Concrete

The modulus of elasticity is determined by the formula, $f_c^{'} = \frac{2P}{\pi LD}$ (Hossain. N, Concrete structure)

The modulus of elasticity is affected by curing period but no relationship can be defined with such limited number of experimental data. The variation of modulus of elasticity is shown in

The result of modulus of elasticity is summarized in **Error! Reference source not found.**.

Table 4: Test result of modulus of elasticity

Curing Period (day)	Modulus of elasticity (Mpa)
No curing at all	45,880
3	42,700
7	44,350
14	42,610
21	45,630
28	44,400

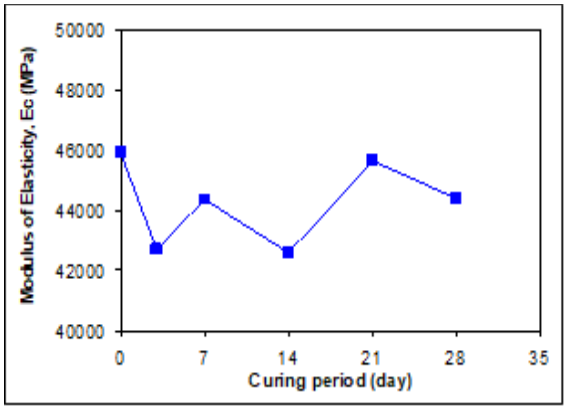

Fig 4: Variation of modulus of elasticity with curing period.

RELATION BETWEEN COMPRESSIVE STRENGTH AND TENSILE STRENGTH

Depending on the curing variation the relation between compressive strength and the tensile strength is established. The relation is shown Fig 2

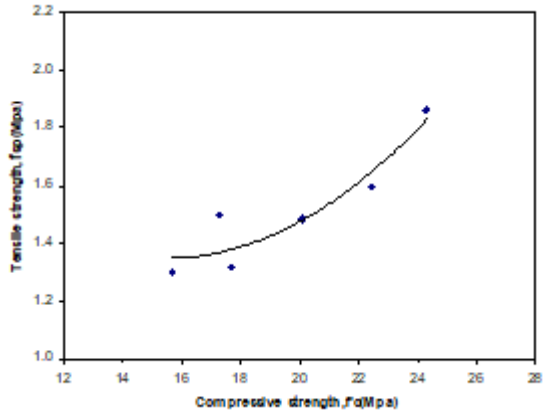

Fig 2: Relation between Compressive strength and Tensile strength in different curing period

Result show that the tensile strength is increasing with the increasing of compressive strength. This rate of increasing is lower than the increasing rate of compressive strength. The curve shows that the rate of increasing of tensile strength is lower in less compressive strength and higher in larger compressive strength.

$$f_{sp} = 0.0061f_c'^2 - 0.188f_c' + 2.8 \quad (2)$$

Where,
f_{sp}= Tensile strength of concrete (MPa)
f_c'= Compressive strength (MPa)

CONCLUSIONS

Concrete is the most widely used construction materials. When other factors remain same the quality control is the main factor to get good concrete. Curing of concrete is crucial to attain the desired strength of concrete. Concrete hardens and gains strength as it hydrates. The hydration process continues over a long period of time. It happens rapidly at first stage and slows downward trend as time increases. However, hydration occurs only if water is available and if the concrete temperature remains within an appropriate range. During the curing period initially, concrete surface needs to be kept moist to permit the hydration process. So, it is clear that for attaining desired strength, the concrete must be cured sufficiently up to a specified time period.

The main objective of this project work is establishing a relationship among curing period and different properties of concrete. Analysing the result, it has been figured out that

(i) Compressive strength increases linearly up to 28 days with the increasing in curing periods and compressive strength can be determined by using the equation

$$f_c^{'} = 0.302D + 15.91$$

(ii) Tensile strength increases gradually with the increasing in curing periods, the increasing rate is lower in short curing period becomes higher in longer period and the tensile strength can be determined by using a two-degree equation

$$f_{sp} = 0.0061f_c'^2 - 0.188f_c' + 2.8$$

ACKNOWLEDGMENTS

At first authors are grateful to almighty Allah for giving the strength and courage that we have completed the study successfully. The completion of this study involves contribution and assistances from many individuals. First of all, we would like to express our invaluable profound gratitude to our supervisor Dr. M.A. Rashid, Professor, Department of Civil Engineering, Dhaka University of Engineering and Technology (DUET) for his valuable continuous guidance, helpful suggestion and constant encouragement throughout the thesis. His generous suggestions and directions during this period have led to the completion of this thesis. We are also grateful to him for acquainting us with the world of advanced technology.

Finally, the authors would like to convey their thanks to the Department of civil Engineering. They also express their sincere gratitude to Dhaka University

of Engineering and Technology (DUET), Gazipur, for providing the necessary fund to fulfil the entire project.

ABSTRACT

In efforts to generate sustainable concrete, alternative mixing constituents are used. In this study, the use of powdered eggshells as partial cement replacement and seawater as freshwater replacement were explored. The experiment consisted of two phases. First phase was the investigation of 50-mm mortar cube specimens to determine the effect on the compressive strength of mortars with 5% cement replacement with powdered eggshells that were heated at varying temperatures and duration. In the preparation of powdered eggshells, the heating duration was varied at 3, 6, and 12 hours while the temperature was varied at 100^{O}C and 200^{O}C. Base on the compressive strength test results, it was determined that heating of powdered eggshells at 100^{O}C for 12 hours achieved the highest compressive strength. Results of Scanning Electronic Microscope (SEM) showed that there was formation of fiber-like structures for mixes with powdered eggshell. This is believed to be the cause of increase in strength. For the second phase, the better heating method of powdered eggshells that was determined from the first phase was adopted and was used as mixing guide for the cylindrical concrete specimens. The three water-cement ratios used in making the concrete cylinders were 0.4, 0.5 and 0.6. All water-cement ratios of concrete cylinders cured for 28 days exhibited increased compressive strength as powdered eggshells were added as partial cement replacement. It was also determined that the compressive strength further increased when both seawater and powdered eggshells were utilized in concrete. An increase up to 36.4% was observed.

Keywords: Cement Replacement, Compressive Strength, Concrete, Eggshells, Seawater

INTRODUCTION

The versatility of eggs as food and other usage resulted to large volume of production which in turn produces a lot of eggshell waste. In poultry hatchery plants alone, huge volume of eggshells is produced. Currently the most viable disposal is throwing them into landfill sites. Eggshells are composed of 97% calcium carbonate [1], one of the main components of cement. Hence, several researches have been conducted regarding the utilization of powdered egg shells as a partial replacement for cement in concrete. These eggshells were either, air-dried, sun-dried or oven-dried before being grounded into powder. Although there are contradicting reports, results of some researchers [2]-[4] have shown that concrete with powdered eggshells have produced higher compressive strength than conventional concrete.

Another aspect of this research is the water used in concrete. Currently, the use of seawater in concrete is not allowed as stipulated in most building codes worldwide. However, shortage of freshwater is already experienced in certain areas even though they are close to the seashore. In addition, the increasing demand for water and the rising global temperatures also increase the cases of freshwater shortage. Thus the use of seawater in concrete production is worthy to investigate. Concrete with seawater as ingredient may be possible to use in structural application [5].

With the foregoing statements, this study is conducted to determine whether the utilization of eggshells and seawater are suitable alternative materials in the production of concrete; powdered eggshells as partial replacement for cement and seawater as a substitute for freshwater. The specific objectives are the following: (a) To determine the temperature and duration of heating of powdered eggshells that will produce mortar with the highest compressive strength; (b) To determine the effects of powdered eggshells and seawater on the compressive strength of concrete; and (c) To determine whether the concrete with powdered eggshells and seawater will be cost efficient.

The possible use of eggshells and seawater would be beneficial in protecting the environment. Partially replacing cement with powdered eggshells will not only address eggshell waste disposal but also reduce cement consumption. Cement production is one of the largest sources of carbon dioxide emissions, thus reduction of cement consumption will result to reduction of carbon

dioxide emissions. Ultimately, the use of eggshells and seawater would also address the sustainability of environmental resources. This is also in line with other researches utilizing other waste materials like fly ash, powdered mussel shells, and others as possible partial cement replacement [6].

METHODOLOGY

The experimental program was divided into two phases. The first phase is the test of mortar specimens while the second phase is the test of concrete specimens.

The production of mortars had different duration and temperature of heating of powdered eggshells. The duration and temperature of heating that yielded the highest compressive strength of mortar was used in the mix design of concrete.

Preparation of Eggshells

The chicken eggshells that were used were obtained from an egg hatchery plant. The hatchery plant produced eggs from a specific type of chicken called Gallus Domesticus or also known as Broiler chickens. The eggshells were subjected to initial disinfection process. This process involved cleaning with water until unnecessary substances are removed, especially the soft membranes. The eggshells were air dried for 24 hours. Then they were crushed, grinded, heated and sieved through a 100 μm sieve, similar to previous research in preparing powdered mussel shells [6]. The crushed eggshells were then placed inside the oven having two different heating temperatures, 100°C and 200°C, and three different duration of heating, particularly 3, 6, and 12 hours. Heating the crushed eggshells was done to determine the optimum duration and temperature to enhance the strength of the mortar specimens.

First Phase: Test of Mortar Specimens

The mortar samples used for compressive test were 50 mm cube specimens. The mortar cubes had a sand to cement ratio of 2.75 to be mixed at a water-cement ratio (W/C) of 0.5. All proportions are by weight. Furthermore, a 5% constant partial replacement of the total weight of cement with powdered eggshell was adopted based on the findings of previous researches [2], [3].

Thirty two (32) cases of mortar cubes were prepared to evaluate effects of the four parameters considered. For each case, 5 specimens were tested, for a total of 160 specimens. Shown in Table 1 are the codes used for naming the different cases of mortar specimens. The name of the specimens was based on the parameters in the following order: heating temperature of eggshells, type of water, curing age, and duration of heating of eggshells.

Table 1 Codes for naming the mortar specimens

Temperature (^{o}C)	Water Type	Curing (days)	Duration (Hours)
100	F=freshwater	7	III=3
200	S-seawater	28	VI=6
			XII=12

The code names were based on the four parameters. For example, the mortar specimens with code name 100F7-III is identified as follows: the first code "100" refer to 100^{O}C heating temperature, the second code "F" means that freshwater was used, the third code "7" refers to specimens cured for 7 days, and the last code "III" means the heating durations was 3 hours. There were also specimens without cement replacement. The codes used for these specimens were only the water type and curing age, that is, F7, F28, S7, and S28. For the specimens with powdered eggshells that were not heated, "0" was added for the heating duration, that is, F7-0, F28-0, S7-0, and S28-0. It should be noted that specimens F7 and F28 served as the control specimens for 7-day and 28-day curing, respectively.

Scanning Electron Microscope (SEM) analysis was done to the mortar specimens to determine the microscopic structural changes that occurred due to the presence of powdered eggshells and seawater.

Second Phase: Test of Concrete Specimens

Concrete cylindrical specimens measuring 100 mm in diameter by 200 mm in height were prepared with the following parameters considered: water-cement ratio, W/C (0.4, 0.5 and 0.6); type of water (freshwater or seawater), and with or without cement replacement. Table 2 shows the codes used in naming the specimens. For example, a specimen named 0.4FX refers to concrete specimen with W/C=0.4, "F" for freshwater, and "X" for no partial replacement of cement.

Table 2 Codes for naming the concrete specimens

W/C	Water	Cement Replacement
0.4	F=freshwater	X=None
0.5	S=Seawater	E=With
0.6		

The adopted percentage of partial cement replacement with powdered eggshells was also 5%. The preparation of powdered eggshells used in this phase was one that produced the highest compressive strength in the mortar test in phase 1. For the parameters considered, 12 cases of concrete mixes were prepared. Five concrete cylinders had to be made for the compression strength test, for a total

of 60 concrete cylindrical specimens.

After mixing the concrete, fresh concrete properties (slump, wet density and air content of the concrete) were evaluated. Curing of concrete was done for 28 days. Freshwater was used in curing concrete. After curing the specimens were subjected to compressive strength test.

RESULTS AND DISCUSSION

The main output of this research is the evaluation of the effects of powdered eggshells and seawater on the strength of mortar and concrete. In addition, other data and experiment results will be presented in this section.

Properties of Materials Used

Table 3 shows the properties that were obtained from the raw materials used in this research. The raw materials are Portland cement, fine aggregates (sand), coarse aggregates (gravel), and water. These properties were needed in designing the mix proportion of mortar and concrete.

Table 3 Properties of materials used

Material Properties	Values
Specific gravity of Cement	3.16
Specific gravity of CA	2.804
Specific gravity of FA	2.353
Absorption of CA (%)	1.18
Absorption of FA (%)	3.80
Dry-rodded density of CA (kg/m^3)	1813
Fineness modulus of FA	2.76
Density of seawater (kg/m^3)	1025.8
Salinity of Seawater (%)	3.7

Note: FA=fine aggregates, CA=coarse aggregates

Table 4 Properties of powdered eggshells

Classification of Powdered Eggshells	SG
Air-dried eggshells for 24 hours	2.466
Heated at 100^{o}C for 3 hours	2.393
Heated at 100^{o}C for 6 hours	2.466
Heated at 100^{o}C for 12 hours	2.505
Heated at 200^{o}C for 3 hours	2.495
Heated at 200^{o}C for 6 hours	2.486
Heated at 200^{o}C for 12 hours	2.534

Note: SG=specific gravity

The material property of eggshell was measured in terms of the specific gravity. Shown in Table 4 are the values of the specific gravity of powdered eggshells as affected by heating temperature and duration. It may be noticed that the specific gravity increased as the heating temperature and duration were increased.

Results of Tests of Mortar Specimens

The variation of temperature and duration of heating of the powdered eggshells for the mortar cubes affected their compressive strength. The compressive strength data were statistically analyzed using the software ANOVA in order to determine whether the differences within the each case are significant or not. The result of the analysis says that the strengths of the specimens in each case (5 specimens per case) are statistically similar. Furthermore, the average strength per case is statistically different from the other cases. This statistically verifies that the addition of powdered eggshells and use of seawater have an effect on the strength of mortar specimens.

Compressive strength of mortar specimen at 7 days

Shown in Table 5 is the summary of the average compressive strengths of the mortar cubes and their corresponding percentage difference with respect to the control specimens (F7).

Table 5 Compressive strength of mortar at 7 days

Specimen Case	Compressive Strength (MPa)	Percentage Increase
F7 (control)	12.42	0.0%
F7-0	15.33	23.4%
100F7-III	13.38	7.7%
100F7-VI	16.43	32.3%
100F7-XII	15.73	26.7%
200F7-III	13.62	9.7%
200F7-VI	13.88	11.8%
200F7-XII	13.35	7.5%
S7	11.08	-10.8%
S7-0	15.83	27.5%
100S7-III	9.86	-20.6%
100S7-VI	15.37	23.8%
100S7-XII	12.32	-0.8%
200S7-III	9.86	-20.6%
200S7-VI	11.77	-5.2%
200S7-XII	16.49	32.7%

The partial replacement of air-dried powdered eggshells (F7-0) resulted to a stronger mortar cubes by 23.4% compared to the control specimen at 7 days. It was also noticed that the strength decreased by 10.8% when seawater was added by comparing F7 and S7. Among the mortars mixed with freshwater, the highest increase was for 100F7-VI,

which was 32.3% greater than the control mortar (F7). As for the mortars mixed with seawater, the highest increase was for 200S7-XII, which was 32.7% greater than the control mortar (F7).

Although, the strength of mortar cubes has increased in the freshwater group, there was a decrease in strength in some mortar cubes in the seawater group. This may mean that the certain combinations of seawater and powdered eggshell tend to decrease the strength development at 7 days.

Compressive strength of mortar specimen at 28 days

Shown in Table 6 is the summary of the compressive strength of 28-day mortar specimens.

Table 6 Compressive strength of mortar at 28 days

Specimen Case	Compressive Strength (MPa)	Percentage Increase
F28 (control)	18.09	0.0%
F28-0	20.24	11.9%
100F28-III	18.92	4.6%
100F28-VI	19.53	8.0%
100F28-XII	23.86	31.9%
200F28-III	20.60	13.9%
200F28-VI	21.22	17.3%
200F28-XII	24.64	36.2%
S28	20.26	12.0%
S28-0	19.58	8.2%
100S28-III	23.87	32.0%
100S28-VI	26.46	46.3%
100S28-XII	26.90	48.7%
200S28-III	21.77	20.3%
200S28-VI	23.17	28.1%
200S28-XII	16.76	-7.4%

The compressive strength gathered from the 28-day mortar cubes had generally exhibited increase in strength compared to the 7-day age mortar cubes. In contrast to the 7-day mortar cubes, the use of seawater increased the strength by 8.2% by comparing F28 and S28. Powdered eggshells exposed to longer duration of heating resulted to higher strength, except for the seawater group with the powdered eggshells exposed to 200^{O}C. This may indicate that overheating the powdered eggshells results to quality degradation. This is further manifested in 200S28-XII, which resulted to strength lower than the control specimen.

For better visualization of the trend of the 28-day compressive strength as affected by powdered eggshell and seawater, the data in Table 6 are plotted in Figure 1 as bar graph.

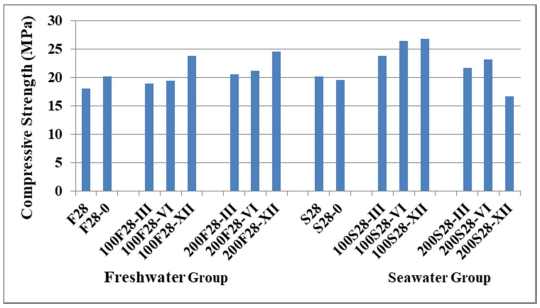

Fig. 1 Plot of 28-day compressive strength of mortar specimens

A trend of increasing strength can be seen in the Fig.1. The freshwater and seawater groups, show in increasing strength with the increase in heating duration for those exposed to 100^{O}C. Also, using seawater as substitute to freshwater further increased the strength of the mortar cubes. Furthermore, 100S28-XII produced the highest strength, an increase of 48.7%. Based on the test results, the most promising preparation of powdered eggshells is by heating at 100^{O}C for 12 hours.

Results of Tests of Concrete Specimens

Mix designs based on 0.4, 0.5 and 0.6 water-cement ratio were made for the experimental program. The designed mix proportions are shown in Table 7. The powdered eggshells that were used were heated at 100^{O}C for 12 hours.

Table 7 Mix proportion per cubic meter of concrete

W/C	Water (kg)	Cement (kg)	Gravel (kg)	Sand (kg)
0.4	221	553	1126	451
0.5	218	432	1090	471
0.6	205	342	1131	620

The resulting fresh concrete properties of the different mixes were almost the same. The average values obtained were as follows: slump=74mm, air content=2.4%, and wet density=2363kg/m^3. It appears that the powdered eggshells and seawater have little effect on the properties of fresh concrete.

Shown in Table 7 is the summary of the average compressive strength of concrete specimens as affected by seawater and powdered eggshells. Also indicated in the Table 7 are the percentage increases with respect to the control specimens (0.4FX, 0.5FX, and 0.6FX). Statistical analysis was also done similarly to what was done in the mortar. The results also validated the similarity of results of strength test per case, and the significant different

between cases. To have a good visualization of the results, a graphical representation of Table 8 is presented in Figure 2.

Table 8 Compressive strength of concrete

Specimen Case	Compressive Strength (MPa)	Percentage Increase
0.4FX	30.38	0.0%
0.4FE	34.96	15.1%
0.4SX	37.51	23.5%
0.4SE	38.42	26.5%
0.5FX	27.28	0.0%
0.5FE	29.31	7.4%
0.5SX	34.00	24.6%
0.5SE	37.21	36.4%
0.6FX	24.73	0.0%
0.6FE	25.07	1.4%
0.6SX	25.28	2.2%
0.6SE	28.53	15.4%

Note: F=freshwater, S=seawater, X=no replacement, E=cement replacement with powdered eggshells

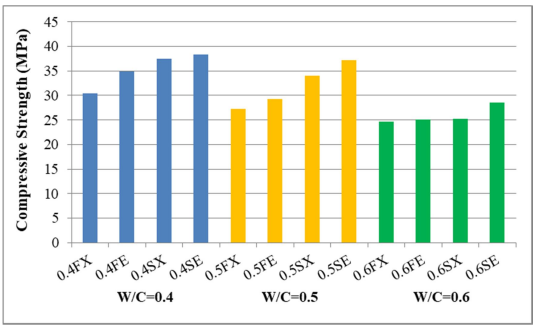

Fig. 2 Plot of 28-day compressive strength of concrete specimens

The results validated the known concept that as the W/C decreases, the strength of concrete increases. In general, the use of powdered eggshell increased the concrete strength. It seems that it is more effective at lower W/C (0.4 and 0.5). Furthermore, the use of seawater in mixing of concrete resulted to a higher strength. Among the concrete specimens, the highest increase was for 0.5SE at 36.4%. For concrete mixed with freshwater, the highest increase was for 0.4FE at 15.1%.

Results of SEM Analysis

Mortar samples were subjected to the scanning electron microscope (SEM) analysis. Typical results are presented in Fig.3. The picture at the top in the Fig.3 is a 3500 magnification of the mortar without eggshells, mixed with freshwater, and cured for 28 days. The picture at the bottom of Fig.3 is a 3500 magnification of the mortar with powdered eggshells, mixed with seawater, and cured for 28 days. Comparison of the two pictures showed fiber-like microscopic structures that were found only on specimens containing powdered eggshells. These fiber-like structures were formed on grain surfaces like needles with sharp ends and were seen gathering in void spaces. It is believed that the increase in strength is caused by these fibers. More of these fibers were observed to be present when seawater was used.

(b) Mortar specimen 100S28-XII at 3500 magnification

Fig. 3 SEM comparison of mortars without and with powdered eggshells

Cost Analysis Results

Determining the effect of seawater and powdered eggshells on the cost of concrete is necessary for commercial and economical applications. The unit cost of each material used is tabulated in Table 9. Since seawater can be freely obtained from the seaside, the assumed cost was zero. Powdered eggshells can be assumed to cost zero but since it involved the process of cleaning, crushing, grinding and heating, it was estimated to cost 4.30 Php/kg.

Table 9 Unit cost of materials used

Material	Cost per Kilogram
Portland Cement	5.250 Php/kg
Sand	0.530 Php/kg
Gravel	0.661 Php/kg
Freshwater	0.035 Php/kg
Seawater	0.000 Php/kg
Eggshell Powder	4.300 Php/kg

Table 10 Cost analysis of concrete

Specimen Case	Cost /Volume (Php/m^3)	Cost Efficiency (Php/MPa)
0.4FX	3885	128
0.4FE	3859	110
0.4SX	3893	104
0.4SE	3867	101
0.5FX	3236	119
0.5FE	3212	110
0.5SX	3244	95
0.5SE	3220	87
0.6FX	2870	116
0.6FE	2854	114
0.6SX	2878	114
0.6SE	2861	100

With the unit cost of the materials known, the cost of concrete per cubic meter can be easily calculated. Table 10 shows these values for the different specimen case. Lower W/C resulted to more expensive concrete. However, the addition of powdered eggshells and seawater lowered the cost of concrete. Enumerated also is the cost-efficiency which can be calculated by simply dividing the cost with the measured strength of the specimen. The lowest value is the most cost- efficient. Among the specimen considered, the specimen with W/C=0.5, using seawater, and with powdered eggshells (0.5SE) is the most cost efficient.

CONCLUSIONS

The use of powdered eggshells as partial replacement for cement and seawater as a substitute for freshwater were found to be suitable alternatives for conventional concrete materials. However, certain combination of powdered eggshells and seawater tends to delay the strength development as manifested in the results of strength test of 7-day mortar specimens. On the other hand, the 28-day mortar specimens generally resulted enhanced strength due to the addition of both powdered eggshells and seawater. It was also observed that the powdered eggshell produced the highest mortar strength (among those tested) when heated at 100^{O}C for 12 hours.

The strength of concrete increased when powdered eggshell were used, especially when W/C is low. The strength further increased when using both seawater and powdered eggshells. Among those tested, the highest obtained is for concrete with W/C=0.5, using seawater, and with powdered eggshells. The increase was 36.4%.

Utilizing seawater and powdered eggshells in concrete was determined to be cost-efficient, and most cost-efficent at W/C=0.5.

ACKNOWLEDGMENTS

The authors express their gratitude to the faculty and staff of the Civil Engineering Department of De La Salle University (DLSU) for all their help and support. The authors also acknowledge the support of the other DLSU offices. Special appreciation is also due to the parents of the students who participated in this research.

ABSTRACT

In Egypt, conventional clay bricks produced from clay with a high firing temperature is a common construction materials. The clay bricks industry consumes a significant amount of energy and releases a large quantity of gases to the atmosphere leading to environmental and economic problems. The stabilized clay bricks are an unfired clay bricks produced from mixture of clay, stabilizing materials and wastes. The current study evaluates the feasibility of using waste materials such as electric arc furnace slag (EAF slag) and calcrete dust (CD) with Miocene clay deposits for production of stabilized clay bricks. The use of waste materials can achieve economic benefits (reduction in raw material and energy required) and environmental benefits.

Experimental investigations were carried out to explore the effect of wastes addition in different clay-based mixes at different ratios. Ordinary Portland Cement (OPC), gypseous hydrated lime (GHL) and sands were added in the studied formulations. The ingredients of each mix were molded in a cylindrical metal mold under compression of 100kg/cm^2 then cured in a plastic container for 14, 28, and 60 days. As the curing days increase, the gypsum transformed into ettringite and the calcium-silicate-hydrate (C-S-H) phase well-formed as shown from the X-ray diffraction (XRD) analysis and Scanning Electron Microscopy (SEM). That can be visualized also on the enhancement of the physico-mechanical properties. The results show that the pozzolanic reaction and cation exchange played an important role in particles agglomeration and stabilization. Also, the addition of EAF slag as an additive material enhances the durability of stabilized clay specimens more than the addition of calcrete dust.

Keywords: Miocene clays**,** Unfired bricks, EAF slag**,** Pozzolanic reaction

INTRODUCTION

In Egypt, clay deposits are widely distributed. One of these deposits is the Miocene clay which is widely exposed especially at the east of Western Desert. The traditional application of clays is many, but one of the most is clay bricks making. The increasing consumption of suitable clay deposits may lead to the decrease in their resources. Therefore, the improvement of some useless clays should be target. This may be carried out through some additives and /or treatments. The common and most of building bricks in the world are conventional fired bricks which produced when clay particles bond to one another at high temperatures, forming a glassy material, which, upon cooling, displays high strength and durability properties. High temperatures required to melt SiO_2 which mean high energy cost associated with brick production. In addition to cost, challenges facing the modern brick industry include shortages of raw material and environmental impacts of production due to the generation of a significant amount of carbon dioxide (CO_2) to the environment, which accounted for around 5% of global man-made CO_2 emissions [1]. The catastrophic consequences of the greenhouse gas emission from the traditional brick industry have considerably contaminated the surroundings with smog, fog, acid rains, global warming and climate change. These dangerous impacts of the bricks manufacture have been encouraged to find new building technologies which have a low environmental impact. The use of stabilized unfired clay bricks for masonry construction may solve these problems [2]. Due to problems with shrinkage and swelling of clays and changes in material properties, it is tried to stabilize the mixtures realized with clay using cement, lime and sand as binder, and also the addition of some industrial waste materials.

Stabilization which characterized by pozzolanic properties can bind soil particles together as the pozzolanic reaction is the reactions between lime, water, soil silica and alumina that form various cementing-type materials such as calcium-silicate-hydrates (C-S-H) and calcium-aluminate-hydrates (C-A-H) which can bind soil particles together and at the same time reduce water absorption by clay particles [3]. The clay minerals and amorphous materials are the only important sources of calcium-silicate-hydrates (C-S-H) and calcium-aluminate-

hydrates (C-A-H) in most soils. The same hydrates are formed during the hydration of Portland cement.

Now in the worldwide, there is a sizeable body of research completed on the possibility of utilizing unfired clay bricks for masonry building wall construction. These researches concern with the use of some secondary materials and wastes types (environmental approach) as partial substitutes for primary clay (economical approach) and stabilizing agents for the manufacture of unfired clay bricks. Yin sung, [4] produced bricks from reservoir harbor sediment mixed with fly ash. Oti [2] produced unfired clay brick by recycling a Ground Granulated Blast Furnace Slag (GGBS) activated with an alkaline lime and Portland cement combined with clay soil. Vinai [5] studied the production of bricks using coal combustion residues together with cement, lateritic clayey soil and sand. Smeu [6] tried to stabilize the mixtures made from clay by using cement, lime and sands as a binder, and also added sawdust in each batch made. El- Mahllawy [7] studied the activation of granulated blast-furnace slag on the properties of unfired eco-friendly clay brick. It is observed from his study that the addition of quick lime and cement kiln dust (CKD) to the granulated blast-furnace slag improved the investigated engineering properties of the unfired stabilized specimens due to the pozzolanic reaction. Tao [8] studied the possibility of using sandy soil as the main raw material in making unfired bricks. The results show that unfired brick specimens with the addition of Ground Granulated Blast Furnace Slag (GGBS) tend to achieve better mechanical properties when compared with the specimens that added cement alone. El-Mahllawy [9] evaluated the feasibility of stabilizing clay bricks with application added cement alone. marble cutting waste (MCW). The results demonstrate that the utilization of MCW incorporating up to 15% hydrated lime for the stabilized clay brick production is feasible.

So, this work aims to investigate the using feasibility and characteristics of selected Egyptian industrial and quarry waste in clay-based mixes for producing eco-friendly clay brick. This is to provide technical solution that will enable the brick industry to develop commercially and using wastes in a useful application.

MATERIALS AND METHODS

Materials

The materials used for the current research consisted of clay and sand, from wadi El Natrun area (wadi El-Farigh depression). The wadi el Natrun area is covered by Miocene sediments (Moghra formation, Raml member). Facies of Raml member are represented by, ferruginous quartz arenite, calcareous subarkosic arenite and shales. Loose sands dominate the examined sequence and commonly pale yellow and frequently stained by iron oxides. They are fine to coarse grained, moderately well sorted and vary from subrounded to subangular.

Clay of Raml member are grey, greyish to light green and moderately hard occasionally contain streaks and spots of gypsum. The clay minerals of the clay include montmorillonite, illite and kaolinite in a decreasing order of abundance [10].

Also, Ordinary Portland cement (OPC), gypseous hydrated lime (GHL), electric arc furnace slag (EAF slag) and calcrete dust (CD).

Methods of Investigation

Laboratory methods

The physical properties of clay samples (Water content, Grain size analysis Atterberg Limit, Unit weight and Specific gravity) are determined according to ASTM. Also, Unit weight and Grain size analysis of the sand samples were determined.
Ordinary Portland cement (OPC), gypseous hydrated lime (GHL), calcrete dust (CD), and electric arc furnace slag (EAF slag) were crushed and ground, if necessary, then passed through 0.5 mm sieve diameter.

The prepared specimens were tested for water absorption, bulk density and compressive strength at the end of curing periods (14, 28 and 60 days) according to ASTM standards and evaluated in accordance with The Egyptian Code for the Building by the stabilized and compressed earth soil [11].

The used material and the made unfired clay specimens were analyzed by powder X-ray diffraction (XRD) for mineralogical characterization. The chemical composition (major oxides) of the starting materials was determined by X-ray fluorescence (XRF). Scanning electron microscope (SEM) technique was used to investigate micro structure and morphological feature of the tested samples.

Mix compositions and specimen preparation

In order to investigate the effect of the used stabilizers on the properties of the unfired stabilized clay specimens, three system were studied: reference sample, calcrete dust system and steel slag system. Seven suggested mixtures from the three systems were studied namely C (Control mix), L1, L2, L3 (Calcrete system) and S1, S2, S3 (Slag system) as shown in Table 1.

The prepared mixtures were homogenized for 5 min, and then mixed with a suitable amount of water about (15%) to reach a wetting mixture. The water/solid ratio was adjusted to achieve ease molding as to match processing technology for the

clay brick manufacturing in Egypt. Immediately after mixing, the materials were compressed into steel mold cylinders by using a hydraulic compaction machine under pressure of 100kg/cm^2.The compacted cylinder was left in the mold under pressure for about 5 second in order to allow for dissipation of pore pressure, thus enabling test specimen stability and/or relaxation. The specimens were then extruded using a steel plunger. Thereafter, the demolded prepared specimens were labelled and placed in sealed plastic box. The specimens were moist (cured) for 14, 28 and 60 days in a plastic box at temperature of about 35^{o}C ± 2 and humidity about 83% ± 2. This was done to avoid sample carbonation that is common with most stabilized soil-based systems, where lime reacts with carbon dioxide to form calcium carbonate instead of forming cementitious reaction products (C-A-H, C-A-S-H, C-S-H among other complex compounds).

Table 1 Composition, proportion (wt.%) and pH of the studied mixes

Mix code	Clay(C)%	Sand (S)%	GHL%	OPC%	CD%	EAF slag%	pH
C	50	25	15	10	----	-----	13.0
L1	50	20	15	10	5	-----	13.4
L2	50	15	15	10	10	-----	13.3
L3	50	20	15	5	5	-----	13.1
S1	50	20	15	10	----	5	13.3
S2	50	15	15	10	----	10	13.4
S3	50	20	15	5	----	5	13.2

RESULTS AND DISCUSSION

Characteristics of the used materials.

The results of grain size analysis indicated that the percentage of clay particle size is approximately 47 % in the clay sample used in this work. This percentage met the required guideline for the minimum clay contents required for the production of red clay bricks [12]. Moisture content ranges between 7.76 and 9.7%. Specific gravity ranges between 2.76 and 2.91. The unit weight of the clayey soil ranges between 1.60 and 1.72 gm/cm^3. Depending on the obtained data of moisture content, unit weight, and specific gravity, the void ratio of the clay samples ranges between 0.82 and 0.93. The porosity (η) ranges between 45 and 48%. Sand samples are classified according to the Unified Soil Classification into poorly graded sand (SP).

XRD analysis show the predominance of montmorillonite over the other clay minerals. On other hand, the kaolinite and illite minerals, as well as the non-clay minerals such as quartz and hematite, were present as trace amounts. Also, The XRD pattern shows that the gypseous hydrated lime composes of gypsum, anhydrite and portlandite [Ca $(OH)_2$], while EAF slag compose mainly of calcium iron oxide, wustite (FeO), and calcium silicate ($CaO.SiO_2$). The XRD pattern of (CD) shows that it is composed of calcite and dolomite and a minor amount of quartz. The chemical composition and loss on ignition (LOI) of the used materials are depicted in Table 2.

Table 2 Chemical composition in terms of oxide content, loss on ignition (wt.%).

Oxide %	GHL	OPC	EAF Slag	CD
SiO_2	4.06	20.59	16.00	18.90
Al_2O_3	1.01	4.02	4.85	2.06
Fe_2O_3	0.13	3.31	34.80	1.28

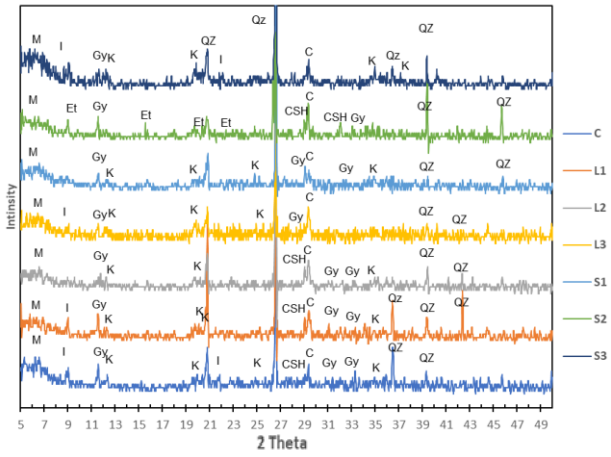
Cr_2O_3	Nil	Nil	0.64	Nil
Cl^-	Nil	Nil	Nil	0.10
L.O.I	27.10	3.81	0.25	30.50

Characteristics of the Cured Specimens

i) Control system (C): It is observed from the XRD pattern as shown in figure 1,2, that the examined specimens of mix C for 14 day have illite, gypsum, quartz, calcite and calcium silicate hydrate (C-S-H) phase. Also, with increasing the curing days from 28 up to 60 days, gypsum ($CaSO_4.2H_2O$) begins to decrease due its consuming in the formation of ettringite ($3CaO.Al_2O_3.3CaSO_4.32H_2O$) until it is completely disappeared at 60 curing days. Furthermore, the quartz peak intensity decreased with increasing curing day, which may be due to its sharing in (C-S-H) formation or agglomeration of particles in the mix.

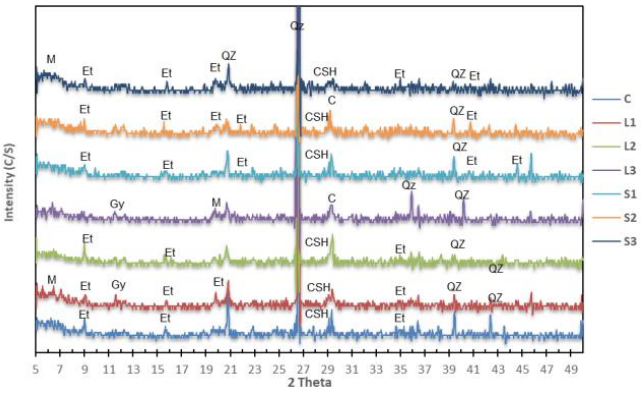
ii) EAF Slag system (S1, S2 and S3): It is observed that ettringite phase is formed earlier in mix S2 as compared to the other mixes (S1 and S3) at 14 curing days. C-S-H is detected at 14 and 28 curing day at (10% OPC) while it is not detected at 60 curing day at (5% OPC). The appearance of kaolinite mineral in mix S3 means that it does not share with any cementitious phase formation. It is expected that mix S2 will show superior physico-mechanical properties as well as the all mixes in slag system.

iii) Calcrete dust system (L1, L2 and L3): It is observed that ettringite phase is not detected at 14 day but with progressing curing days, gypsum consumed to form ettringite. Also, C-S-H phase is not formed in mix L3 (5% OPC) this may be due to the shortage of OPC content and related hydration phase $Ca(OH)_2$ while it detected at 14 and 28 curing days at (10% OPC). It is observed that with increasing calcrete dust, C-S-H decrease. This is may be due to that Ca^{+2} found in $CaCO_3$ is not easy to be solubilized in the media so the calcrete dust acts as a filler rather than a pozzolanic material.



(Et: Ettringite, M: Montmorillonite, Qz: Quartz, Gy: Gypsum, I: Illite, C: Calcite and CSH: Calcium silicate hydrate).

Fig. 1 XRD patterns of the 14 days cured specimens of different mixes.



(Et: Ettringite, M: Montmorillonite, Qz: Quartz, Gy: Gypsum, I: Illite, C: Calcite and CSH: Calcium silicate hydrate).

Fig. 2 XRD patterns of the 60 days cured specimens of different mixes.

The results of SEM technique of the lab specimens (C, L1, L2, S1, S2 and S3), cured for 60 days which are more representative for the formation of cementitious material and ettringite phase show, a well cemented structure and the quartz grain is surrounded by a matrix composed of a mix of clay particles and the formed phases (ettringite and C-S-H) as shown in figure 3. On the other hand, pozzolanic reaction will promote a more compacted microstructure with less pores, and fractures, resulting from the stronger bonds formed during the hydration process and the possibility of additional pozzolanic C–S–H, and therefore deliver better mechanical and physical properties and durability to the bricks. While mix L3 cured for 60 days shows a poorly-cemented structure and a number of unfilled pores as shown in figure 4. The gypsum is appeared as radiated needles on the surface and around the clay particle (matrix).

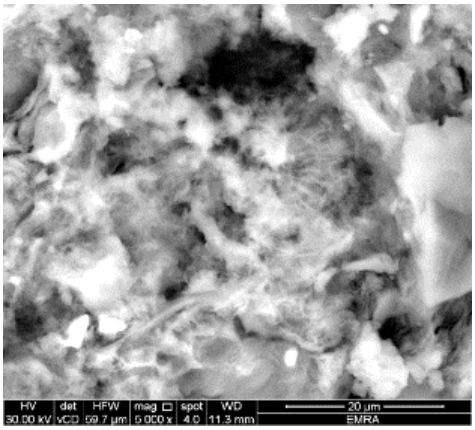


Fig. 3 SEM images of mix S2, show C-S-H gel and ettringite (needle -like structure) phase at high magnification.

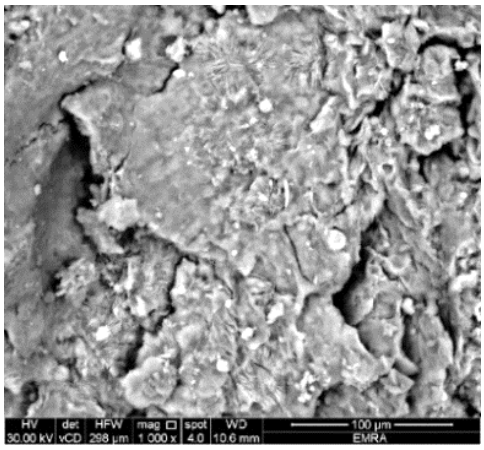

Fig. 4 SEM images of mix L3 shows a poorly cemented structure and gypsum (radiated needle -like structure).

Physico-mechanical properties of the lab specimens

Compressive strength

It is observed generally that compressive strength increases significantly with prolongation of curing days. Figure 5 show that highest compressive strength is gained by the (C, L1, L2, S1 and S2) cured specimens due to the addition of cement (10%) that has a positive effect on the strength. This is attributed to the continuous hydration forming more C-S-H as binding agent. Also, the results explained that the loss of strength in mix L3 and S3 is due to the low content of OPC. It is noticed that the strength of mix S2 has the highest compressive strength which attributed to pozzolanic activity of slag. Furthermore, cation exchange between the soil and the steel slag was identified as the major factor that influenced the modification of the engineering properties of the clayey soil by the addition of steel slag [13]. Also, the progressive increase in the compressive strength can be explained by the formation of ettringite on the expense of gypsum content. It is observed that when industrial waste gypsum is combined with Portland cement to solidify soil, the strength of the solidified soil will be much higher than that when Portland cement is used only, because of the effect of ettringite on filling pores.Indeed, the increase in compressive strength values is particularly important when the amount of $CaSO_4.2H_2O$ increases to an extinct limit [14]. Based on the test results, all stabilized specimens cured for 14, 28 and 60 days achieved the ECBS requirements.

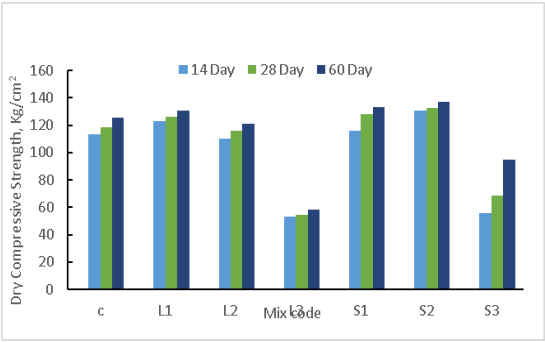

Fig. 5 Dry compressive strength of specimens at various curing days.

Water absorption

In all case, water absorption decreases with increasing in curing days of the cured specimens as shown in figure 6. The results show that amount of the absorbed water decreased as the cement (OPC) content increased (10%) giving evidence that the cement (OPC) plays a significant role in the impermeability of the tested specimens. The best value was found in the S2 specimens (10% EAF slag) cured for the 60 days. This is probably due to the pozzolanic reaction development as detected previously in the XRD patterns which leads to the formation and accumulation of cement phases that close some of the open pores then decreases their affinity to absorb water and also may be due to the formation of ettringite which fill pores.

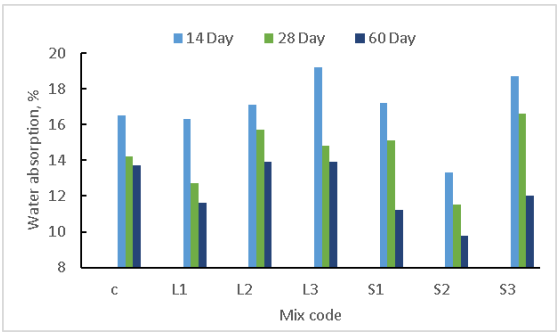

Fig. 6 Water Absorption of specimens at various curing days.

Bulk density

In terms of bulk density of the unfired stabilized clay specimens, it is increased with curing days as shown in figure 7. The highest value was achieved by specimens of the mixture S2 at the end of 60 curing days. The specimens of the mix L3 show the lowest density rather than the other mixes. The bulk density increases are indicative for the pozzolanic reaction progressing and phases formation. In other words, as the Portland cement content increases, the bulk density increases giving evidence for densification.

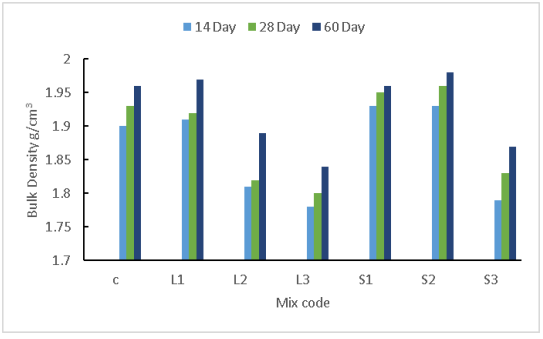

Fig. 7 Bulk density of specimens at various curing days.

CONCLUSIONS

The current study evaluates the feasibility of using waste materials (electric arc furnace slag EAF slag), calcrete dust CD) for production of stabilized clay bricks. From the present work, it can be concluded that:

1- With increasing curing days, the calcium silicate hydrate phase well-formed and increased, gypsum transformed into ettringite and the peak intensities of quartz and kaolinite decrease due to its contribution towards the formation of C-S-H phase as well as quartz particles agglomeration which reflected on the physico-mechanical properties that enhanced with increasing the curing days which attributed to the formation of calcium silicate hydrate (C-S-H) gel which act as a binding material and also due to the formation of ettringite which fill the open pores .

2- The decreasing in OPC affected negatively on the significant properties of the unfired stabilized montmorillonite clay specimens.

4- Calcrete dust has no pozzolanic activity and it act primary as a filler in the mix. Increasing the addition of CD on the expense of sand at mix L2 has a negative effect on specimen properties, while slag has more pozzolanic activity rather than calcrete dust and reference mix. This is reflected on the mechanical properties of S specimens especially S2 (10% EAF slag)

ABSTRACT

The durability of concrete is the ability to withstand induced damages over a long period of time. It can be measured by sorptivity, or rate of water absorption, and resistance to sulfate attack (RSA). Concrete with larger voids is more susceptible to deterioration through absorption of chemicals, such as sulfate found in soil and seawater, which forms gypsum and ettringite. Gypsum and ettringite cause reduction of strength, cracking, and expansion of concrete. To improve the durability of concrete exposed to sulfate, the National Structural Code of the Philippines (NSCP) suggests increasing the strength of concrete to 31 MPa, which would require more cement; thus, increasing the cost of concrete. This study aims to investigate the effects of partially replacing cement with coconut shell ash (CSA) in terms of its compressive strength, sorptivity, and RSA. CSA in this study was classified as a Class N pozzolan, a cementitious material that will make a cheaper substitute for ordinary Portland cement (OPC). Results showed that the sorptivity of all concrete with CSA is within the acceptable limit. Based on the relationship of compressive strength with the CSA content, the optimum percentage replacement of OPC with CSA is 10%. From statistical analysis, it was determined that there is no significant difference in the compressive strength and expansion of concrete between the conventional and 10% CSA concrete. The strength of 10% CSA concrete is 92.10% of the strength of conventional concrete. The study reveals that CSA at 10% cement replacement is an effective pozzolan, which neither compromises the compressive strength and RSA of concrete.

Keywords: Coconut Shell Ash, Compressive Strength, Sorptivity, Resistance to Sulfate Attack

INTRODUCTION

The durability of concrete is the ability to withstand induced damages over a long period of time. There are multiple parameters in which the durability of concrete can be measured, two of which are sorptivity and resistance to sulfate attack (RSA). Sorptivity, or rate of water absorption, is when water undergoes capillary suction within the pore spaces of concrete. Durability is highly dependent on the capacity of concrete microstructure to absorb water [1]. This implies that concrete with greater voids between particles is highly susceptible to chemicals, such as sulfate ions. Sulfate ions that penetrate the concrete and incorporated with free lime and alumina would yield gypsum and ettringite, which causes expansion and deterioration of concrete. Most soils in the ground contain the element sulfate in different forms [2]. Since most of the concrete structures, like foundations, are exposed to the soil in its entire lifespan, protection against sulfate attack is important to ensure that reduction of strength, cracking, and expansion of the concrete does not occur especially on concrete exposed to soil with high salinity level. To improve the durability of concrete exposed to sulfate, the National Structural Code of the Philippines (NSCP) suggests increasing the strength of concrete to 31 MPa, which would require a smaller water-cement ratio. Hence, more ordinary Portland cement (OPC) is required, increasing the cost of concrete. A lower water-cement ratio leads to a decrease in total porosity and pore median of concrete [3]. Thus, decreasing water-cement ratio decreases voids and increases strength and durability due to less water penetration but increases also the cost of concrete. One way to lessen the cost of concrete without sacrificing the strength or durability is to partially replace OPC with a cheaper cementitious substitute. Several studies make use of waste materials that contain pozzolanic property as a substitute for cement in concrete. Fly ash [4], rice husk ash [5], palm oil fuel ash [6], and coconut shell ash [7] are some examples of viable substitute for cement.

The partial replacement of OPC with coconut shell ash (CSA) in concrete was found to be effective in reducing the cost of concrete and environmental pollution due to the accumulation of agricultural wastes as it incorporates recycling of wastes [8]. This study aims to investigate if the effects of substituting OPC with CSA will produce acceptable results in terms of concrete compressive strength, sorptivity, and resistance to sulfate attack.

COCONUT SHELL ASH

The Philippines is one of the major suppliers of coconut in the world, producing more than 15 million tons of coconut annually or 26.4% of coconuts worldwide [9]. There are currently 500 million coconut trees in the Philippines that contribute to 10.4 million tons of biomass annually [10]. An estimated area of 178,180 hectares is allocated for approximately 23,329,000 coconut trees in Quezon province. The coconut shells used for the study were collected from a local farm in this province. The shells underwent calcination to produce CSA in uncontrolled combustion which lasted for 4 hours. The calcined coconut shells were then crushed and ground to produce CSA. To control the effect of fineness on the performance of CSA, only samples that passed through the No. 200 sieve was used for experimentation. The material was oven-dried for 24 hours prior to experimentation to maintain moisture content less than 3% as required by ASTM C618.

EXPERIMENTAL PROGRAM

Mixing and Curing of Concrete Test Specimens

In this study, CSA was used as partial replacement of cement in the concrete mix. The CSA content used for experimentation were 10%, 20%, 30% and 40% of cement by weight. The concrete material will be termed as the CSA concrete. Specimens without CSA were also prepared which serves as the control specimen and represents the conventional concrete. Concrete materials were proportioned in accordance with ACI 211.1. The water-cement ratio of 0.6 was maintained in all concrete mixes. Table 1 shows the concrete batch mix proportion for cylindrical specimens while Table 2 shows the mortar batch mix proportion for mortar prisms. The mixing, curing, and molding of the concrete specimens was in accordance with ASTM C192.

Table 1 Concrete mix proportion

CSA content	Water (kg)	Cement (kg)	CSA (kg)	Gravel (kg)	Sand (kg)
0%	3.76	6.67	0.00	19.45	14.61
10%	3.76	6.37	0.30	19.45	14.61
20%	3.76	6.03	0.64	19.45	14.61
30%	3.76	5.64	1.02	19.45	14.61
40%	3.76	5.20	1.47	19.45	14.61

Table 2 Mortar mix proportion

CSA content	Sand (g)	Cement (g)	Water (g)	CSA (g)
0%	3850.0	1400.0	952.0	0.0
10%	3850.0	1337.1	952.0	62.9
20%	3850.0	1265.9	952.0	134.1
30%	3850.0	1184.9	952.0	215.1
40%	3850.0	1091.7	952.0	308.3

Compressive Strength Test

To determine the compressive strength of CSA concrete, a total of 150 cylindrical specimens with dimensions of 100 mm diameter and height of 200 mm were prepared and subjected to a uniaxial compression test in accordance with ASTM C39. The uniaxial compression test was conducted after the 7th, 14th, 21st, 28th, 50th, and 90th curing age. The 50^{th} and 90^{th} curing periods were conducted to determine the long-term compressive strength of CSA concrete.

Sorptivity

Sorptivity of CSA concrete was determined using cylindrical concrete specimens with a diameter of 100 mm and a height of 50 mm in accordance with ASTM C1585. The sorptivity test was done after the 28^{th}-day curing period. This was done by submerging 1mm to 3mm of the samples in water and computing the absorption using the mass difference at different intervals until 9 days. Linear regression analysis was applied to experimental results to measure the initial (1st day of testing) and secondary sorptivity (2nd to 9th day of testing) of the specimens.

Resistance to Sulfate Attack

Resistance to sulfate attack (RSA) was done by measuring the length change of mortar prisms with dimensions of 25 mm by 25 mm x 275mm in accordance with ASTM C1012. RSA was also measured through a mass change of cube specimens with a side dimension of 100mm following the procedure described in the study of Wang, Zhou, Meng, and Chen (2017) [11]. The specimens were submerged in a sulfate solution after the 28^{th}-day curing period. The sulfate solution has a 5% concentration where 50g of anhydrous sodium sulfate was diluted for every 950g of water. Hence, the exposure class, based on the concentration of the sodium sulfate, is classified as S3 [14]. The measurement of expansion through length and mass were conducted once a week until 9 weeks.

TEST RESULTS

Pozzolan Classification

To determine the pozzolan classification of CSA, the chemical composition, obtained using Energy Dispersive X-Ray Analysis (EDX), was compared with the chemical requirements for calcined natural pozzolan in accordance with ASTM C618. The oxides formed in calcinating the raw materials of OPC such as calcium oxide, silicon oxide, aluminum trioxide, and iron oxide, are also found in CSA. As shown in Table 3, CSA contains 80.02% of a combined chemical compound of SiO_2, Al_2O_3, and Fe_2O_3. Hence, it signifies that the pozzolanic activity is greater. Silicon dioxide in OPC, commonly known as silica, is the main component that is responsible for the strength of concrete and mortar at an early age; thus, the abundance of silica in CSA denotes that it is a cementitious material and it can be used as a substitute of OPC. Based on chemical properties requirements as stated in ASTM C618, CSA can be classified as Class N pozzolan. The loss on ignition is below the 10% criteria for Class N pozzolan. This denotes that the amount of unburnt carbon in CSA is very minimal. This is a desirable property of Class N pozzolan because if the percentage of loss on ignition is greater than 10%, it indicates that the pozzolan has an abundance of unburnt carbon that could decrease the pozzolanic activity [7]. A decrease in pozzolanic activity can lead to a decrease in the strength of the concrete. On the other hand, the moisture content of CSA is greater than the minimum requirement for Class N pozzolan; thus, oven drying before use of CSA is recommended.

Table 3 Chemical properties of CSA

Chemical Compound	CSA %	Class N Pozzolan* %
Silicon dioxide (SiO_2)	60.91	
Aluminum trioxide (Al_2O_3)	17.38	
Iron Oxide (Fe_2O_3)	1.72	
SiO_2 *plus* Al_2O_3 *plus* Fe_2O_3	80.02	70 min.
Sulfur trioxide (SO_3)	0.5	4 max.
Calcium oxide (CaO)	0.84	
Moisture Content	4.58	3 max.
Loss on Ignition	5.54	10 max.

*Standard requirements as per ASTM C618

Compressive Strength of CSA Concrete

The CSA concrete samples were subjected to a uniaxial compressive test to obtain their corresponding strengths on the 7th day until the 90th day of curing. This test was done before conducting sorptivity and RSA tests to verify whether the CSA concrete samples passed the required compressive strength. Figure 1 shows the collective compressive strength results from the 7th to 90th-day curing period. It can be observed that the compressive strength of the samples increases with the curing time. However, as the CSA content increases in the concrete, the compressive strength tends to decrease.

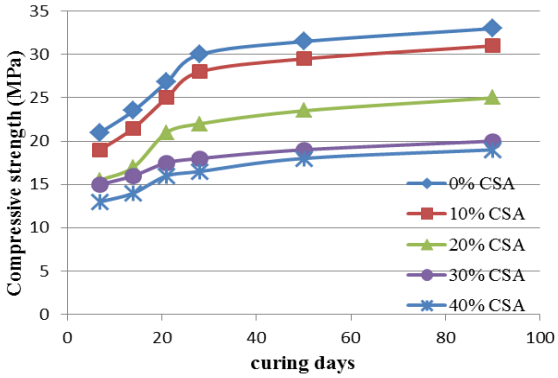

Fig. 1 Compressive strength of CSA concrete

Statistical Analysis of Compressive Strength

The Two-Tailed T-test is applied to the compressive strength test results of the concrete cylinders. Comparing the compressive strength of CSA concrete specimens with that of the control specimens, the computed T-critical value is 1.8331; while the *p*-value is below 0.5, which implies that the probability of the observed results due simply to chance is very low. The T-values of specimens with 10% CSA from 7 to 90 days curing period is less than the T-critical; hence, the compressive strength of concrete with 0% CSA and 10% CSA concrete is statistically the same and the replacement of OPC with 10% CSA did not affect the compressive strength. Thus, increasing the CSA content until 10% would significantly decrease the cost of concrete while retaining the identical strength performance it has to the conventional concrete.

Response surface methodology (RSM) was used to determine the optimum CSA replacement based on the compressive strength obtained at all curing days. The statistical method revealed that 10% CSA generated the highest compressive strength among all the other concrete design mixtures while the 40% CSA mix obtained the lowest compressive strength. It can be inferred that the optimal CSA content based on compressive strength is 10%. Empirical model as shown in Eq. (1) was derived from RSM in order to predict the compressive strength of concrete with CSA at any curing period. Using the formulated model, the compressive

strength of 10% CSA concrete is 92.10% of the strength of the conventional concrete at 28th-day curing period.

$$fc = 15.81 - 0.111(x) + 0.70(t) - 7.020\times10^{-3}(x)(t) - 0.022(x^2) - 9.758\times10^{-3}(t^2) - 2.173\times10^{-5}(x^2)(t) + 5.956\times10^{-5}(x)(t^2) + 4.096\times10^{-4}(x^3) + 4.45\times10^{-5}(t^3) \quad (1)$$

where:
fc = compressive strength of concrete at x% CSA, in MPa
x = CSA replacement in decimal (i.e. 10% is 0.1)
t = curing days of concrete, in days

Sorptivity of CSA Concrete

The slope of the linear trendline of the initial and secondary absorption versus the square root of time is the sorptivity of the specimen. A typical test result is shown in Fig. 2. In all test trials, the initial rate of water absorption, which was taken on the 1st day of experimentation, is greater than the secondary sorptivity, which was taken at the 2nd to 9th day of experimentation, because the empty pores of the sample are being filled with water more rapidly. However, at the stage of the secondary sorptivity, the pores are already filled with water which causes the sample to have a lower sorptivity as time progresses. Figure 3 shows the collective sorptivity results for all CSA concrete samples. It can be observed from the graph that the sorptivity increases as the amount of CSA in concrete increases at the stage of initial sorptivity. This implies that conventional concrete absorbs less water for a certain duration that it is exposed to water. The sorptivity for all samples is acceptable since all concrete specimens passed the acceptable limit which is 6 mm/hr$^{1/2}$ [12].

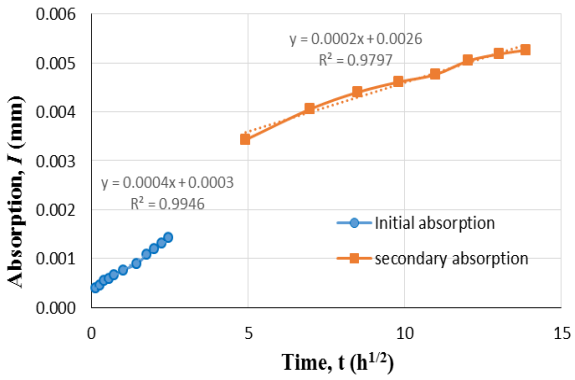

Fig. 2 Typical absorption result of CSA concrete

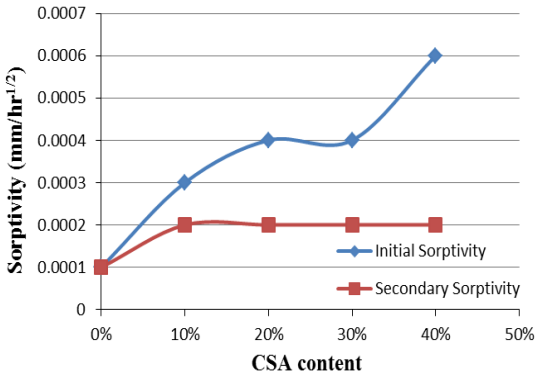

Fig. 3 Sorptivity of CSA concrete

Resistance to Sulfate Attack of CSA Concrete

Gypsum, a form of sulfate, is usually added to the production of cement to prevent the flash setting and improve the performance of concrete; furthermore, it is composed of hydrated calcium and sulfate. On the other hand, sulfate combined with alumina and calcium produces ettringite, which is normally present in concrete at early ages of the concrete [13]. However, an excessive amount of ettringite on the void spaces of the concrete cause deterioration, in the form of expansion, in concrete and mortar.

The length change or expansion of CSA mortar prisms was obtained to determine if the samples would not go over the NSCP limit for concrete susceptible to sulfate attack. Since the solution wherein samples were submerged contains 5% sodium sulfate (exposure class S3), the limit is 0.1% in 18 months [14]. Figure 4 shows the relationship of the length change of CSA mortar prisms with the time when it is immersed in a sodium sulfate solution. It can be observed that as the time of immersion increases, the expansion increases as well. Moreover, the expansion of mortar also increases as the CSA content increases. It can be observed that at the 9th week, the mortar with 0% and 10% CSA surpassed the acceptable limit while the expansion of other CSA content exceeded the limit at the 7th and 8th week. Previous research showed that it took 49 days for the conventional concrete mortar to reach 0.1% expansion when submerged in a 5% sodium sulfate solution [15]. In this study, the limit of 0.1% expansion is attained sooner than 18 months even for mortar without CSA.

The expansion of CSA concrete cubes in terms of mass change was obtained to determine the effect of sulfate attack on the exposure of concrete to saline soil and groundwater or saltwater containing sodium sulfate in its aqueous state. The test results are presented in Fig. 5. It can be observed that the

mass change is directly proportional to its time of exposure. As the CSA content increases, the expansion in terms of mass change also increases as time progresses.

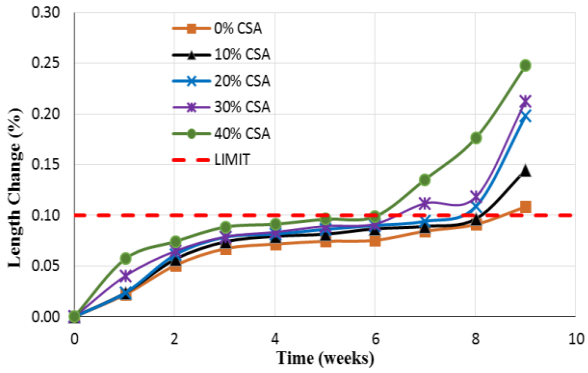

Fig. 4 Length change of CSA mortar prism

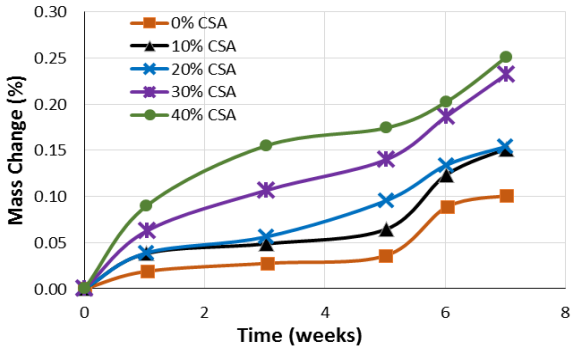

Fig. 5 Mass change of CSA concrete

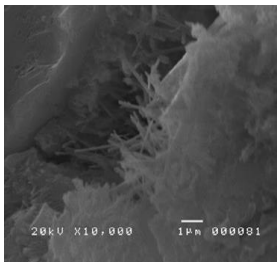
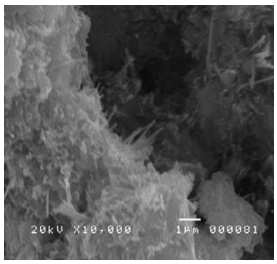
The microstructure of CSA concrete after exposure to sulfate solution

The microstructure of CSA concrete after exposure to sulfate solution is shown in Fig. 6. Since sulfate can only be detrimental to concrete in its aqueous form, sulfate will only cause deterioration if it seeps through the void spaces and bond with the excess calcium oxide, also known as lime, and alumina in the concrete. It can be observed that there is needle-like particles, ettringite, between the void spaces of CSA concrete. Ettringite is a compound composed of calcium, sulfate, and aluminate. The sulfate interacted with the free lime and alumina in the concrete, from the OPC and CSA, which resulted in ettringite that was displaced into the intergranular and trans-granular voids and caused expansion of the concrete. This expansion in the concrete can be detrimental and cause spalling, onion peeling, or scaling. Furthermore, ettringite is expansive; hence, if it expands, it can lead to the cracking of the concrete, which ultimately decreases its strength [16].

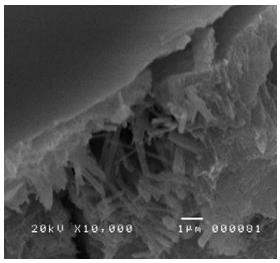
Gypsum is also present in the concrete together with ettringite in between the voids, which was produced when the free calcium ions in the concrete mix reacted with the sulfate ions. Gypsum is expansive and has a softening effect that can cause strength loss [16]. However, the cause of the expansion of the concrete immersed in the sulfate solution is not exclusive to the expansive property of gypsum and ettringite. The tensile stresses that may have accumulated in the concrete could have also caused the expansion. The cracking of concrete could lead to bigger void space wherein the sulfate could penetrate the concrete and cause more expansion due to ettringite and gypsum.



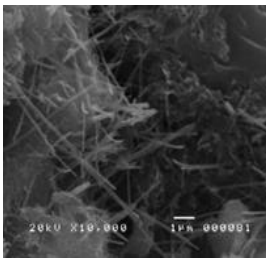
a.) conventional concrete (0% CSA)



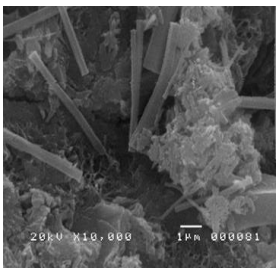
b.) 10% CSA



c.) 20% CSA



d.) 30% CSA



e.) 40% CSA

Fig. 6 Microstructure of CSA concrete after exposure to sulfate solution.

CONCLUSIONS

Based on the experimental results, the following conclusions can be drawn:

Coconut shell ash (CSA) contains 80.02% of the combined silicon dioxide, aluminum trioxide, and iron oxide classifying it as Class N pozzolan. The high pozzolanic activity makes it suitable to be used

as a replacement for ordinary Portland cement (OPC).

Increasing CSA content increases sorptivity and makes it more susceptible to sulfate attack. The sorptivity of the conventional concrete and all CSA concrete mixture up to 40% CSA is deemed to be acceptable and is less than the limit which is $6mm/hr^{1/2}$.

There is no significant difference between the conventional and 10% CSA concrete in terms of compressive strength at all curing ages. The compressive strength of concrete with 10% CSA is 92.10% of the compressive strength of the conventional concrete.

The microstructure of the CSA concrete after immersion in the sulfate solution shows the presence of ettringite and gypsum, which causes softening and expansion effect in the concrete. The limit of 0.1% expansion was attained sooner than 18 months even for mortar without CSA.

The results obtained proved that CSA is suitable to replace OPC because it passed the criteria to classify it as a cementitious material, however, the optimal percentage of replacement of OPC that will not affect the durability and strength of concrete should be observed. The optimum level of CSA content as replacement of OPC is 10% wherein the durability and strength are acceptable. CSA concrete can be used as an economical approach in having an acceptable level of durability of concrete structures without increasing the cement usage in any construction project; however, it is recommended that further study on the long term behavior of hardened concrete, specifically on its resistance to sulfate attack, be conducted.

EFFECTS OF MINERAL AND CHEMICAL ADMIXTURES ON THE RHEOLOGICAL PROPERTIES OF SELF COMPACTING CONCRETE

Nolan C. Concha[1] and Melito A. Baccay[2]
[1]Faculty, FEU-Institute of Technology, Philippines
[2]Faculty, Technological University of the Philippines, Philippines

ABSTRACT

One of the most significant innovations on the workability of concrete that was achieved in recent years is self-compacting concrete (SCC). This desirable performance can be attained through the addition of admixtures to enhance its properties. In this study, superplasticizers were blended with fly ash and air entraining admixtures and were tested for Slump Flow, V-Funnel, L-Box, U-Box, and Screen Stability tests based on the European Federation of National Associations Representing for Concrete (EFNARC) specifications and guidelines for SSC. Based on the results of the study, Fly ash with spherical smooth texture enhances the lubrication between the concrete particles while the air-entrainer provides microscopic bubbles acting as ball bearings between aggregates. The best result was obtained in the specimens containing 5.0% superplasticizers due to its dispersibility effect and reduced flow resistance. In general, the air entraining agent blended with 3.7% superplasticizer exhibited the best performance in all workability test conducted.

INTRODUCTION

The introduction of chemical and mineral admixtures in the fundamental components of self-compacting concrete (SCC) has been used to enhance further the desirable properties of the freshly mixed concrete. SCC is a special concrete mixture exhibiting superior material homogeneity and workability requiring less to no form of external compaction [1]. Even without the aid of a compactor, a concrete is able to pass through corners of forms through its own mass. Such condition is essential in developing designs of SCC mixture. However, there is a limited number of study as to this area of concrete technology and thus require further research to completely describe the behaviour of SCC [2]. In the preparation of SCC, the material proportions of the mix are an essential component [3-6]. The compactness of concrete attributed by well distributed aggregates imparts strength to the concrete. The efficiency of the concrete in flowability is affected much by tuning the coarse aggregates spacing that depends on sizes and volume of cement in the mixture.

The rheological performance of SCC is much affected by the proportioning of the material components in the preparation of the mixture [7]. All normal concrete fine aggregates including crushed or rounded either siliceous or calcareous fine aggregates can be used in SCC. In order to develop a self compacting concrete of desirable quality, the moisture content of sand must be carefully checked and must be regarded into account. The volume of sand less than 0.125 mm must be taken as powder and is essential for the consistency of SCC. The small quantity of accumulated powders, resulting from the binders and the used of fine aggregates, must be achieved to avoid segregation with a recommended value of 500-600 kg/m3 [8]. Almost every type of coarse aggregates is appropriate for the production SCC, where the angular coarse aggregates develop the mechanical interlocking performance of the particles resulting to better strength, whilst rounded aggregates enhanced the flowability attributed by the lesser build-up of frictional stresses. The average largest aggregate size is normally 16-20 mm but particle sizes of 40 mm and up have been utilized in SCC. Well-graded aggregates are of vital importance in the production of SCC, while gap graded aggregates may exhibit more internal resistance and provide flow reduction. The volume content of the coarse aggregates usually varies between 50 to 60% of the total volume of solids in concrete [9]. When the amount of coarse aggregates in concrete go beyond the recommended limit (50-60%), the chance between aggregate particle contact or collision develop quickly and may result in higher susceptibility to blockage when the concrete move through gaps between rebars [10]. Mineral admixtures were incorporated as well in the SCC mix to further enhance the desirable properties of concrete. Rice husk ash can improve the resistance to

segregation and plastic viscosity of the mixture [11]. The concrete also exhibited chloride ion resistance and drying shrinkage with the addition of ground granulated furnace slag in the design mix [12]. The use of waste marble powder of up to 0.60 in ratio with cement produced better workability and compressive strength in the development of eco-efficient SCC [13].

To investigate the effects of blending admixtures on the rheology of self-compacting concrete, various concrete mixtures with different dosages of admixtures was prepared. The results can be used as baseline information for the identification of the most appropriate proportion for self-compacting concrete, decrease the duration of construction, and minimizes the use of external vibrators.

EXPERIMENTAL PROGRAM

Materials and Specimens

The primary objective of this research is to measure the rheological properties of self-consolidating concrete using the EFNARC criteria and examine the influence of added admixture in the concrete mix. All locally available concrete materials were tested to meet the structural standards established by the American Society for Testing and Materials (ASTM). In order to meet the requirements for SCC, superplasticizer was added to the concrete mix in gradual amounts. Adjustments as recommended by the EFNARC trouble shooting guide was carried out correspondingly to develop the desired SCC mix. The workability performance of the freshly mixed concrete having 3.7 % and 5.0% superplasticizers blended binary with Fly ash, Retarding, and Air-entraining admixtures were tested for V-Funnel, Slump Flow, L-Box, U-Box, and Screen Stability tests. Two SCC proportions with different amounts of superplasticizers was derived using the recommended material design proportions provided by the American Concrete Institute (ACI). These design mixes were used as benchmark proportions to investigate the influence of various admixtures when blended with superplasticizers. Using the general criteria for Self-Compacting Concrete, test specimen with varied admixture dosage was designed and tested in three trials for viscosity and flowability performance. Linear regression analysis was implemented to develop various linear models describing the correlation of the variation of mineral and chemical admixtures on the workability of concrete.

EXPERIMENTAL RESULTS

Rheological Tests of Blended Superplasticizer and Fly Ash

Typical quantity of fly ash ranging from 15-25% was used to partially replace the cement in the concrete mixture. This amount is found to be sufficient without providing undesirable effects in the mechanical properties of hardened concrete. Various experimental tests were carried out to evaluate the performance of the samples in passing, filling, and resistance to segregation abilities with the results reflected in Table 1. The design proportions in the table contains an increasing volume of fly ash and it is apparent from the measured values that the greater the quantity of this additive in the design proportion, the better will be the filling ability of the resulting SCC mix. Fig. 1 shows a direct correlation between fly ash volume and the flow spread of freshly mixed concrete. The addition of fly ash in the mixed resulted to better flowability performance of SCC.

Table 1 Test Results of SCC with Blended Fly Ash

Fly Ash (kg/m^3)	FILLING ABILITY				PASSING ABILITY				SEGREGATION RESISTANCE	
	Slump Flow (550-850 mm)		V-Funnel (0-8 sec)		L-Box (0.8-1.0)		U-Box (0-30mm)		Screen Stability (0-15%)

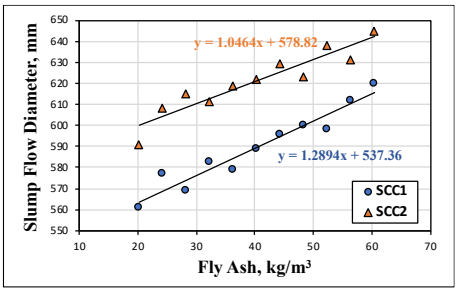

Fig. 1 Fly Ash vs Slump Flow

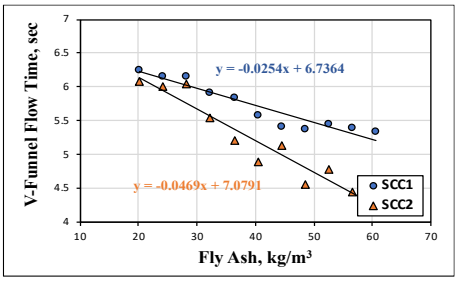

Fig. 2 Fly Ash vs V-Funnel

All samples satisfactorily met the minimum standard flow of 550 mm with SCC2 having the highest amount of fly ash registered the highest flow diameter. This observation is being justified by the time-based parameter considering a decrease in time of the concrete to move in the V-Funnel test. It is also evident and important to note that under the V-Funnel test, each SCC proportion consistently provides a declining flow time values having a strong correlation coefficient as shown in fig. 2. The dominating rounded structure of the particles of fly ash associated with mainly glassy texture and composition of its surface as shown in fig. 3 has significantly affected the flow time values of the concrete containing fly ash. Fly ash in rounded and particulate geometry can enhance flowability by its ball bearing effect between aggregate particles [14]. The increased ball bearing effect of the particle imparts better lubrication and reduces the cohesion between particles allowing it to flow freely and provides lesser recorded time.

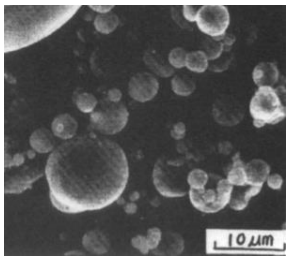

Fig. 3 Fly Ash under Scanning Electron Micrograph [14]

Ouchi et al. [15] had established the correlation between the flowing ability of fresh concrete and the amount of superplasticizer. It has been reported that the ratio of flow diameter and V-Funnel flow time could be an index of dispersibility of the concrete components. The dispersibility values of the samples tested increases with the amount of fly ash introduced in the mix with a remarkable correlation coefficient. The particulate form of the fly ash has glassy texture and are charged negatively. With this, it has lesser capacity in absorption relative to the particles of Portland cement. The quantity of adsorbed superplasticizer in the cement mixed with fly ash varies largely on the substituted fraction of the Portland cement with fly ash [16]. Superplasticizers tend to increase the dispersing effect between solid particles and since fly ash is weak to adsorb it, the adsorption effect has been given to the cement particles allowing a higher dispersibility. Fly ash can also reduce the water requirement of the mortar mixtures since porous particles can be attributed to the absorption of water. This property has a substantial effect on the behavior of the fresh concrete.

The coarse aggregates sizes were limited to a maximum of 20 mm in diameter to improve the passing ability of the mixture. Each passing ability test showed impressive results indicating a well-achieved self-compacting concrete proportion. Fig. 4 shows the behavior of the design mixes in relation with L-box and U-box tests and both regression lines demonstrate a consistent concrete behaviour in the two sample groups. As the distance between the particles decreases, the potential for blocking increases due to the particle collisions and internal stresses. The presence of excess water developed in the mixture due to the amount of fly ash and the considerable powder content maintained sufficient gap between aggregates thereby reducing interparticle interaction and build up. The aggregates in the samples having the least amount of fly ash developed a less spaced particles that is highly susceptible to collision, thus obtaining the most undesirable values.

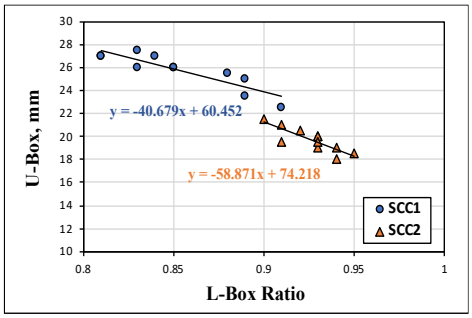

Fig. 4 L-Box vs U-Box

The viscosity of concrete dictates its segregation resistance and the more viscous the resulting mixture, the lesser will be the likelihood of its components to segregate. Fig. 5 provides a picture of the behavior of the mixture when tested using the screen stability. The given data established evident correlation between the values obtained and the quantity of fly ash blended in the concrete. Most of the calculated percentages in the mixtures indicates a susceptible chance to material segregation. Consistency is essentially related on the thickness and cohesiveness of the mixture of concrete. These properties can be enhanced by lessening the excess amount water and increasing the volume of cement. The SCC samples having the greatest amount of fly ash excessively increased the free water content and reduced cohesiveness of the mixture.

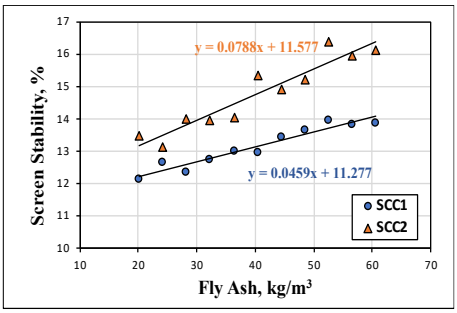

Fig. 5 Fly Ash vs Screen Stability

Rheological Tests of Blended Superplasticizer and Air Entraining Admixtures

This section discusses the final set of SCC designed samples with the addition of varying amounts of air entraining admixtures. Similar proportions of concrete components and superplasticizer were prepared and tested for filling ability, passing ability, and segregation resistance requirements as shown in table 2. The mixture in each SCC design contains an increasing amount of air entraining admixture. In the slump flow test, the spread of the concrete in each sample satisfactorily met the acceptance criteria and this shows that the blending promotes better and smooth horizontal free flow of the mixture. As observed in the table, the increasing amount of air entrainer corresponds to a better slump flow result and is consistently exhibited in the two SSC design groups as shown in fig. 6. Stabilizing the air void system in the fresh concrete would permit relatively free motion of fresh concrete in shear. The drastic change in the air bubbles as contributed by the increase in the air-entraining dosage resulted to desirable effect on the flow efficiency of SCC. The entrained air also increases the paste volume and tends to increase the distances between solid particles. This in turn reduced the interparticle friction and interaction allowing the fresh concrete to flow easily in the slump flow test.

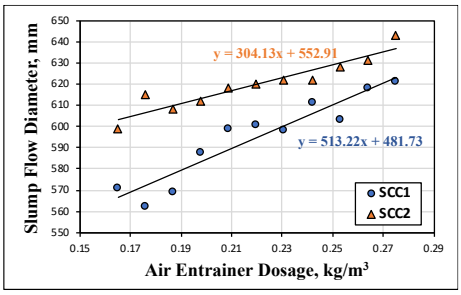

Fig. 6 Air Entrainer vs. Slump Flow

With the low results in the recorded data of the time-based V-Funnel test, the samples displayed better fluidity and efficient flow ability. Fig. 7 shows the declining flow time with the increasing dosage of air entrainer. This implies that the fresh concrete was able to flow easily due to low flow resistance and minimal frictional stresses developed between concrete particles.

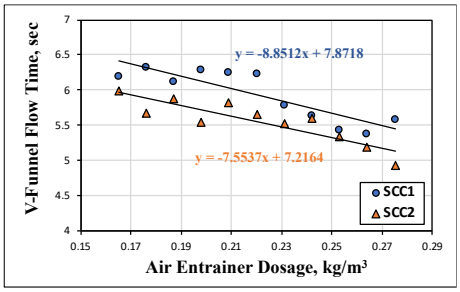

Fig. 7 Air Entrainer vs V-Funnel

The entrained bubbles in the mixture considerably modified the flow characteristics of the mixture yielding a well-performed SCC. It can be seen in fig. 8 the relationship between the increased dosage of the admixture and the dispersibility of the mixture. The addition of superplasticizers in the mixture as well imparts dispersion effect in the particles creating a significant dispersibility results. The entrained bubbles allowed deformation under compression and slippages of neighboring particles offering smooth translation of the concrete particles.

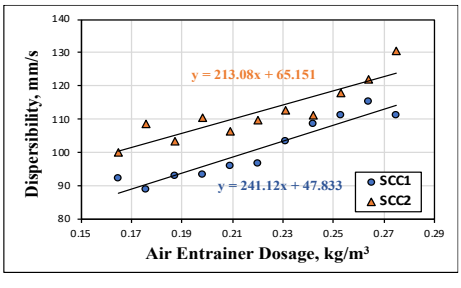

Fig. 8 Air Entrainer vs. Dispersibility

Table 2 Test Results of SCC with Blended Fly Ash

Air Entrainer (kg/m^3)	FILLING ABILITY				PASSING ABILITY				SEGREGATION RESISTANCE	
	Slump Flow (550-850 mm)		V-Funnel (0-8 sec)		L-Box (0.8-1.0)		U-Box (0-30mm)		Screen Stability (0-15%)

Legend: ■ - Passed ■ - Failed

When the entrained air content is increased, the effect of further increased in the electrostatic attraction between the cement and other small particles was counteracted by greater reduction in the mechanical interlocking due to the lubricating effect of the bubbles. The group of samples was also tested for passing ability requirements. According to Chia [1] entrained air bubbles were able to perform effectively as deformable and elastic ball bearings, reducing internal friction in the fresh concrete. It can be seen that the samples having the highest amount of air entrainer registered the best results among the samples. The augmented ball bearing behavior of the bubbles imparts better lubrication and reduces the friction between particles allowing it to flow freely and pass over the apparatus. The impressive ability of the concrete to flow over complex forms is described by the results in the L-box and U-box tests depicted in fig. 9. Again, the lubrication and minimal development of friction due to the ball bearing behaviour of the entrained bubbles enable the freshly mixed concrete to flow and pass successfully over the L-Box and U-Box apparatus.

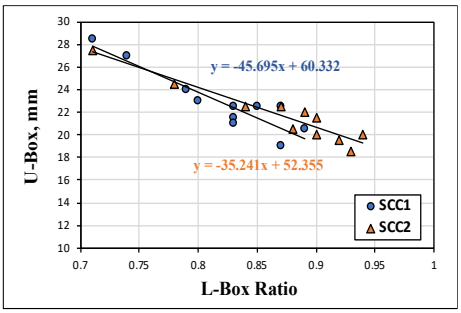

Fig. 9 L-Box vs. U-Box

Fig. 10 presents the increasing values in the screen stability test with the amount of air entrainers mixed in the concrete. This has been regularly observed in each SCC design groups. It can be seen that a less stable distribution in the composition of concrete was provided by the corresponding increase in the dosage of the admixture. Among the design proportions prepared, SCC2 having the most amount of air entrainer exhibits a possible chance to segregation.

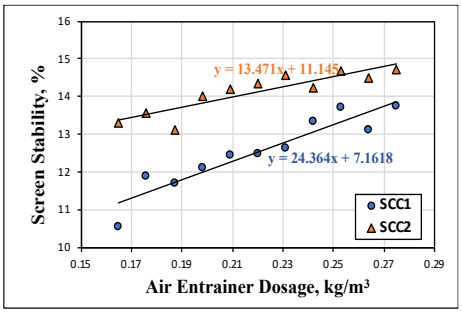

Fig. 10 Air Entrainer vs Screen Stability

CONCLUSIONS

The blending of fly ash and superplasticizer demonstrates a remarkable performance in the filling ability and passing ability of the self-compacting concrete. This is due to the roller bearing effect of the smooth spherical surface of the fly ash. Most of the tests conducted for these workability parameters were fulfilled establishing a concrete with high flowability. Consequently, the blending significantly reduced the viscosity of the mixture producing a concrete susceptible to segregation. It is advisable to blend these two admixtures in their minimum recommended amounts to maintain the overall workability performance of SCC.

To produce SCC having a uniform material distribution, one of the two admixtures is sufficient for the purpose. With the increasing amount of air entrainer in the production of self-compacting concrete, the design mixes performed efficiently in

the three workability parameters. The blending of air entraining admixture and superplasticizer significantly enhanced the ability of the concrete in passing, filling and resistance to segregation. The blending should be done such that the proportions of each admixture fall within the middle range of the recommended dosage.

AN IMPROVED PREDICTION MODEL FOR BOND STRENGTH OF DEFORMED BARS IN RC USING UPV TEST AND ARTIFICIAL NEURAL NETWORK

Nolan C. Concha[1] and Andres Winston C. Oreta[2]
[1]Faculty, FEU-Institute of Tech., Philippines
[2]Faculty, De La Salle University, Philippines

ABSTRACT

The composite action of reinforcement in the surrounding concrete involves a complex and non-linear mechanism. Inadequate understanding of the underlying interactions may lead to designs with insufficient amount of bond resistance of reinforcing bars in concrete structures. To investigate the effects of various parameters on the bond strength of steel bars in concrete, 54 cube samples with varying embedded reinforcements and strengths were prepared. The samples were cured for 28 days and tested using ultrasonic pulse velocity (UPV) test for sample homogeneity and single pull out test for bond strength. Data gathered in the experiment were used in the development of bond strength model as a function of compressive strength, concrete cover to rebar diameter ratio, embedment length, and UPV using artificial neural network (ANN). Of all the bond strength models considered from various literatures, the neural network model provided the most satisfactory prediction results in good agreement with the bond strength values obtained from the experiment. The UPV parameter was found to be one of the most significant predictors in the neural network model having a relative importance of 20.57%. This suggest that the robust prediction performance of the bond model was attributed to this essential component of the model. The proposed model of this study can be used as baseline information and rapid non-destructive assessment for zone wise strengthening in reinforced concrete.

Keywords: Bond strength; Artificial neural network; Ultrasonic pulse velocity; Parametric analysis

INTRODUCTION

One of the essential components that must be achieved for structural design is the bond strength of the steel reinforcement to the enveloping concrete. The resistance of the rebar against slipping from embedment due to pulling force is defined as bond strength. The composite action between steel and the enveloping concrete may be may be destroyed by the inadequate bond resistance and may result to concrete brittle failure [1]. The bond does not only ensure the composite action but also controls structural behavior of the reinforced concrete. There are numerous number of researches embarking on bond behavior of steel bars in concrete are available in the literature. Results recorded from experiments of these studies were used to develop analytical and empirical models. Due to the complex non-linear relationships that exist in the rebar and concrete, several ideal assumptions were adopted to simplify the systems involved in the development of the models. These estimates however insufficiently represent the existing underlying mechanism of bond strength in reinforced concrete. As a result, the derived bond equations provided estimates that are in good agreement only within the framework of their study. It is therefore indispensable to consider other modelling techniques that are powerful enough to generally adopt with the complex behavior of bond strength in reinforced concrete.

A convenient and precise way to model the complex interactions in such intricate systems is by means of artificial neural network [2-6]. There is no need to consider ideal assumptions to simplify the modelling approach as the neural network process raw data from actual experiments. Through the aid of a set of input-output data, a system of interconnected neurons can be developed that is capable of predicting variables from a certain set of inputs. In this work, novel prediction model of bond resistance of reinforcing rebars in reinforced concrete using neural network will be developed. A greater number of variables will be considered in the modeling including concrete compressive strength, tensile capacity of concrete, homogeneity of concrete using ultrasonic pulse velocity, rebar diameter, embedment length and concrete cover. The performance of the model will be compared to other available bond strength models in the literature. Multiple regression model will also be derived for comparison.

BOND STRENGTH MODELS

The bond strength of reinforced concrete members depends on many different variables such as compressive strength, rebar size, length of embedment, type of loading (dynamic or static), development length, and bar spacing. The use of pull out test played a vital role in the development of bond strength model. In the study of Hadi [7], 14 simple pull out tests were performed in measuring the bond strength of 500 MPa grade steel embedded in a 70 MPa concrete compressive strength. Different bar diameters from 12 mm to 36 mm were used having concrete cover of 120 mm and 150 mm. The derived model using regression analysis is given in eqn 2. The equation is dependent on the compressive strength of concrete (f'c), concrete cover (c), diameter of the rebar (d_b), and the length of embedment (L_d). The bond strength equation was compared with other established models and comparison showed that among the models considered, the proposed model provided the best prediction values in agreement with the experimental results.

$$u = 0.08305\sqrt{f'c}\left(22.8 - 0.208\frac{c}{d_b} - 38.212\frac{d_b}{L_d}\right) \quad (1)$$

Unlike any other studies that focus on bond strength, the study of Yalciner et al [8] made use of multiple linear regression in order to model an equation for the ultimate bond strength(τ_{bu}) that is dependent to compressive strength (f'c) of concrete and the cover (c) to bar diameter (D) ratio. An increase in concrete compressive strength and concrete cover would also result to an increase in bond strength. Moreover, it was found out that an increase in the compressive strength with constant concrete protective cover resulted to higher bond strength than a constant compressive strength with increasing the concrete protective cover. Using multiple linear regression, the following equations with high correlation coefficient values were established:

$$\tau_{bu} = -2.7143 + 0.3621 f'c + 2.3296\left(c/D\right)\left(R^2 = 0.96\right) \quad (2)$$

A larger number of variables were considered in the study of Diab et al [9] on bond performance and ultimate design of bond stress of normal and high strength concrete. Samples having different compressive strength (f_{cu}), concrete cover (c), size of the bar (d_b), length of embedment (L_d), rib height (h_r), and rib spacing (s_r) were tested using single and double pull out tests. The bond stress equation of samples having compressive strength of 80 MPa was developed using multiple regression as shown in eqn 3. The reliability of this equation was validated using values recorded from experiments and compared with forecasted values provided by other available models. There is a satisfactory agreement of the proposed equation as described by the average value of actual to predicted bond strength ratio of 0.89.

$$\tau_{pr} = \sqrt{f_{cu}}\left[0.08262 + 0.09234\left(c/d_b\right) + 1.6038\left(d_b/L_d\right) + 0.6318\left(h_r/s_r\right)\right] \quad (3)$$

In most of the studies enumerated for bond strength models, other equally important factors were not considered such as tensile strength and homogeneity of concrete. Thus, the results of the studies do not provide a substantial and complete discussion of the composite action between steel and concrete. Further, the derived models can only be applied to specific cases of bond strength to which the models were calibrated. In most of the studies involving non-linear relationships of multiple variables like bond stress, several ideal assumptions were usually adopted to reduce the complexity of the system in the modeling process. In order to avoid these simplifications that may reduce the reliability of results, a more powerful modelling approach such as artificial neural network must be used.

EXPERIMENTAL PROGRAM

Materials and Specimens

In designing the correct proportion of concrete, raw materials need to exhibit desirable properties to ensure beneficial effect to the design mixture. With the advent of available standard testing procedures and duly accepted gaging criteria, this study was able to measure the physical properties of the materials used and found to be in good conditions for the production of concrete. Water used in the mix was in good quality and free from contaminants. The density and water absorption of the coarse aggregates used were 1572.028 kg/m^3 and 0.402% respectively. These values were measured in accordance with ASTM C127-04. Using ASTM C127-04a and ASTM C136, the density, water absorption, and fineness of fine aggregates were respectively measured to be 1533.801 kg/m3, 3.2 %, and 2.673. Three distinct designs of concrete mixtures were prepared based on target compressive strengths of 21 MPa, 28 MPa, and 35 MPa. Using a slump interval between 25mm and 100mm, 2% entrapped air, and estimated water cement ratios of 0.68, 0.57, and 0.47, three design mixes shown in table 1 were obtained. A total of 54 cube samples having side length of 200 mm with embedded reinforcement were prepared for the conduct of pull out test. Variation in rebar diameter (16mm, 20mm, and 25mm), concrete cover (60mm, 70mm, and 80mm), and embedment length (50mm, 75mm, and 100mm) were used in this study.

Table 1 Concrete design proportions and strengths

Design Mix	W kg/m^3	C kg/m^3	CA kg/m^3	FA kg/m^3	f'c (MPa)	ft (MPa)
1	189	301	1018	866	22	2.08
2	189	359	1018	806	29	2.61
3	190	436	1018	726	36	3.14

Testing of Specimens

Immediately after molding and finishing, cube and cylindrical specimens were cured by immersing the samples in water for 28 days (ASTM C31). The dimensions of the cylindrical samples were 6 inches in diameter and 12 inches in height. After the specified age of curing period have been reached, the cylindrical samples were tested in three trials for compressive strength (ASTM C39) and tensile strength (ASTM C496) of concrete using the universal testing machine. To assess the quality of concrete, ultrasonic pulse velocity test was carried out to all the cube samples (ASTM C597). All lateral faces of the specimen were applied with liquid coupling material for better contact between the coupler and surface of the sample. The transducer and receiver of the UPV apparatus was placed in direct set up. Lastly, standard single pull out test (ASTM C234-91A) was conducted in all the concrete cube samples to measure the maximum force necessary to pull the rebar from the concrete as shown in fig.1. Bond strength between the rebar and enveloping concrete was obtained by taking the ratio of the stress load and the surface area of steel bar which is in contact with the concrete.

Fig. 1 Concrete cube sample under pull out test

EXPERIMENTAL RESULTS

Experimental Data Statistics

The statistics of 54 samples tested for ultrasonic pulse velocity and pull out tests were determined. The statistical description includes the mean, standard deviation, sample variance, maximum value, and minimum value of the geometric attributes and measured strengths of the samples. The maximum pulse velocity was 4537 km/s while the minimum velocity was 4009 km/s. These values were measured from samples having 36 MPa and 22 MPa compressive strengths respectively. The observed values were reasonable since higher compressive strengths imply more solid or compact internal structure of the sample. The signal generated by the UPV apparatus travels faster in solid medium thus providing larger values of pulse velocity. The UPV standard deviation of 128.56 km/sec suggests that the measured UPV values of the samples were roughly close to the average UPV value of 4355 km/sec. Less variability in the measured values were also observed as describe by a relatively small COV of only 3%. In the bond strength however, a larger dispersion in the measured values were observed as indicated by large SD of 6.376 MPa and COV of 46.7%.

NEURAL NETWORK MODELLING

Framework of the Neural Network Model

The bond strength model was a function of 6 independent variables namely compressive strength (f'c), tensile strength (ft), embedment length (ld), rebar diameter (ϕ), concrete cover (cc), and ultrasonic pulse velocity (UPV). These variables were individually represented by 6 distinct nodes in the input layer of the neural network. To develop a simple ANN model, only one hidden layer was used with varying number of hidden nodes between 3 to 6. A single node in the output layer represents the bond stress in the model. Neural network architecture having 6 input nodes, 2 hidden layer neurons, and 1 output node was represented as N 6-2-1. Four ANN structures were developed having different number of nodes in the intermediate layer. The variation in the nodes was carried out to explore a better neural network topology. Feedforward backpropagation algorithm was used as the learning algorithm in the derivation of the models with hyperbolic tangent sigmoid function $f(n)=2/(1+e-2n)^{-1}$ as the neural activation function. This transfer function calculates a layer output that returns value between -1 to 1. Threshold criteria of 100000 cycles or an error tolerance value of 0.001 were used to terminate the simulation process. A few number of nodes in the hidden layer was considered to avoid overfitting in the development of the model. Early stopping in the testing phase was also carried out to further improve the generalization of the model.

ANN Model Experimental Data and Simulations

The least number of training data pairs that will provide unique approximation must not be less than the number of weights and biases associated with the neural network model [10]. Carpenter and Hoffman [11] further suggest that 20-50% overdetermined

ANN model tends to provide satisfactory prediction performance. The bond strength model in this study involved six predictors, one hidden layer, and one output node. This neural network structure (N 6-5-1) with five nodes in the hidden layer and using 20% overdetermined network required a minimum number of input-output data pairs between 42 to 50 [12].

The correlation coefficient (R) and the mean squared error (MSE) were used as performance metrics in selecting the best bond strength model. The best neural network structure among the variations considered will have the least MSE and the closest R value to 1.0. As shown in table 2 were the results of MSE and R of the four distinct ANN model architectures having different number of nodes in the hidden layer. It is evident that N 6-6-1 model provided the best performance among all the models considered in the simulation. After all the data in the output layer were transformed in their corresponding physical attributes, the errors can be calculated by subtracting the experimental values from the estimated values provided by each model. The measured errors in the predicted values of N 6-6-1 model were the least errors relative to the other neural network architectures inasmuch as the model obtained the least MSE of 1.491. Further, a better agreement between the experimental and predicted values of N 6-6-1 model was expected owing to its high Pearson correlation coefficient R equal to 0.981. Having these desirable results, the developed model successfully learned from the simulation given a limited number of experimental data.

Table 2 Variation of ANN models

Model	Number of hidden nodes	Performance criteria	
		MSE	R
N 6-3-1	3	5.247	0.938
N 6-4-1	4	3.413	0.957
N 6-5-1	5	2.287	0.972
N 6-6-1	6	1.491	0.981

Connection Weights and Biases of N 6-6-1 Model

After a series of simulations of different ANN architectures, the N 6-6-1 model emerged as the best performing architecture. The model has six normalized nodes in the input layer representing compressive strength of concrete (f'c), tensile strength of concrete (ft), embedment length (Ld), rebar diameter (ϕ), concrete cover (cc), and ultrasonic pulse velocity (UPV). The weights and biases of this network model upon simulation were shown in table 3. Using the causal inference procedure developed by Garson [13], the relative importance of each parameter was also reflected in the table. Apparently, the rebar diameter was the most significant predictor in the model having a relative importance of 29.29% followed by compressive strength (16.78%), and concrete cover (16.63%). This was reasonable since the bond strength in reinforced concrete is largely influenced by the change of these three parameters. The least significant predictor on the other hand was the UPV having a relative importance of only 8.32%.

Table 3 Connection weights and biases of N 6-6-1 model

Hidden Nodes	**Input Layer**						**Output Layer**
	f'c	**ft**	**L_d**	**ϕ**	**cc**	**UPV**	
1	1.2359	0.97265	-3.488	-0.7465	0.8836	0.7632	0.8562

Prediction Performance of N 6-6-1 Model

Fig. 2 shows the comparison of the N 6-6-1 model predictions to the experimental values for both training and test data. The results obtained in both data sets were significantly correlated as described by their respective Pearson's correlation coefficients of 0.99 and 0.90. A vast majority of the plotted points was very close to the measured bond strength. Based almost lied on the perfect line with an average prediction error of 6.86%. Roughly 90% of the predicted values of the model lied within the 10% error. Maximum and minimum errors of 64% and 0.01% respectively were observed in the estimated values. An average ratio between the experimental and predicted values of 0.998 was further obtained. This result suggests that the estimated bond strength on these desirable results, the derived ANN model

exhibited a robust prediction performance
