The performance of N 6-6-1 model was compared with other existing models developed by Hadi [7], Yalciner et al [8], Diab et al [9], and the developed model using multiple linear regression. Data sets in each study were consolidated and used to test the prediction performance of each bond strength model. Fig. 3 shows the plotted points of the experimental data against predicted values provided by the aforementioned models. A 45° line, also called the perfect line, was drawn in the figure to clearly observe the fitness of the models in estimating the bond strength of a given set of input parameters. The better the prediction, the closer will be the point to the perfect line. The scatter plot diagram displayed large dispersion of collected data sets from different studies. The figure suggests that, in general, the models performed satisfactory only within the set of data in which the models were respectively calibrated. Most of the models provided significant deviations from the perfect line for values beyond the framework of their study. These undesirable attributes showed poor generalization of the models considered. It may be because of the ideal assumptions made in the modelling process that may not be the actual underlying behavior of the interactions involved in the system. The model developed by Yalciner [8] exhibited the largest recorded average error of 75%. While the model developed by Diab [9] included the largest number of parameters, the average prediction error was 49%. In fact, Hadi's [7] model involving four independent variables offered better approximations providing a mean error of only 48% in the predictions. This observation implies that the superiority of the model does not rely on the number of variables involved in the modelling process but by how significant is the contribution of each variable in the model. Looking closely on the plots of the proposed N 6-6-1 model, majority of the points showed relatively small deviations from the perfect line and obtained a correlation coefficient of 0.855. Among all the models considered in this study, the proposed ANN model gave the least average prediction error of only 29%. The maximum and minimum correlation coefficients were 0.855 and 0.062 respectively. About 72% of the consolidated data sets from various studies considered were captured by the ANN model with an error within ±20%.

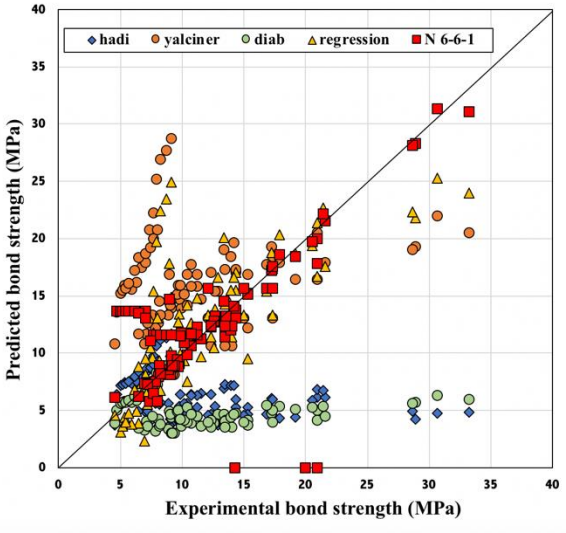

Fig. 3. Bond predictions using different models

CONCLUSIONS

Upon training various neural network architectures, N 6-6-1 model was found to be the best performing architecture having six input nodes, one hidden layer with five nodes, and one output node. The model was able to provide satisfactory prediction results capturing 72% of the data from experiments conducted and from various literatures with an error of at most 20%. Model comparison further showed that the proposed N 6-6-1 model provided the best prediction performance against other existing models considered in this study. The superiority was achieved since no simplified ideal assumptions were considered and only experimental results were used in the simulation process. This shows the power of artificial neural network in modelling highly complicated interactions using a limited source of experimental data.

The compressive and tensile strengths of concrete, concrete protective cover, and ultrasonic pulse velocity offered direct correlation with the bond strength behavior of reinforced concrete. The bond stress however decreases as the rebar diameter and embedment length of reinforcement increases. This observation was attributed by the lateral contraction of the rebar due to Poisson's ratio. The derived model

can be considered as rapid and convenient approach to estimate the bond strength of concrete. The results of the model can be used as baseline information in the design of reinforced concrete structures and other engineering applications involving bond strength.

ABSTRACT

In numerous mining process, tailing continue to be produced in large quantities and stored in massive ponds while posing environmental hazards. This paper presented the utilization of tailing as the substitution material of fine aggregate in the sand sheet of road construction. Several amounts of tailing are substituted to modify the gradation of the fine aggregate. The gradation analyses are conducted to evaluate the effect of the substitution of tailing on the gradation distribution of the mixed material. The Marshall tests are also conducted to asses the impact of tailing substitution on the strength of the hot rolled sand sheet. The gradation analysis shows that the substitution of 50% tailing has a significant effect on the distribution of mixed materials. The coefficient of uniformity, Cu, and coefficient of the curve, Cc of 4.82 and 1.72 are obtained, respectively. The mechanical test results using the Marshall test shows that the substitution of 50% tailing brings about a significant improvement in the strength of the hot rolled sand sheet. The strength of hot rolled sand sheet increase 100% or 2-fold higher compared than those without the tailing is obtained. The results of this study have indicated that the gold mining waste of tailing may be viable as the substitution material for road construction.

Keywords: Tailing, gradation analyses,marshall test, strength

INTRODUCTION

The development of infrastructure, especially road infrastructure in Indonesia in recent years, has increased. Since 2014, the Ministry of PUPR through the Directorate General of Highways has successfully completed the construction of 3432 km of national roads including roads on the borders of Papua, Kalimantan, and NTT. In addition, 941 km of new toll roads have been built with the final target of 2019 reaching 1,852 km [1]. In 2016, the total length of national roads that have been built was 47,017.28 km [2]. Hence, the material needs, especially asphalt constituents materials such as sand and gravel, also increase.

Until now, many the innovation of materials for roads, especially roads made from asphalt such as the use of resin as a substitute for conventional asphalt has been found by researchers [2]. Reclaimed asphalt (utilization of stripping and asphalt reprocessing materials) [7], utilization of used tire waste on asphalt [4], foam asphalt in road construction, and other innovative materials [6]. There are two conditions that must be considered in innovating road construction materials are the level of material effectiveness and sustainability. One alternative material that meets both of these criteria is tailings.

Tailings have the potential as an alternative material in construction materials such as mixtures of concrete and asphalt. Tailings, as a mixture of construction materials, has a good impact on the environment because tailings are waste from the rest of metal mining and minerals [5]. Aschuri and Yamin [1] show that the tailings on the base material and sub-base material gave an excellent effect on CBR values along with increasing use of 45% tailings. Whereas 5% by weight of cement replaced by tailings on mortar making will increase mortar compressive strength by 108.45% compared to more than compressive strength without tailings [5].

This paper aims to explain the ability of tailings as fine aggregate substitution and determine the optimum percentage of tailings in hot mix asphalt.

METHODOLOGY

Gradation Analysis

The strength and elegance of a pavement construction are very dependent on the aggregate quality, carrying capacity of the soil and the type of asphalt used as the primary material to bind the materials needed to obtain a hardened, durable, strong and rough hardening. The two types of pavement commonly used are flexible pavements that use asphalt as a binder and rigid pavements that use cement as an aggregate binder. With aggregate as the main component of the highway, pavement consists of coarse aggregates and fine aggregates that have each according to the specifications used the test is carried out by aggregate gradation test using fine and coarse aggregates using a shaker. The basic references used in this test are AASHTO T-27-74, and ASTM C-126-46. HRSS (Hot Rolled Sheet

Sheet). Requirements for gradation of the HRSS class with a filter size of 0.075 mm are 4-14% passed. Requirements for class HRRS B with a filter size of 0.075 mm are 8-18% escaped. The percentage of tailings used is 0%, 25%, 50%, and 75%. Experiments from this HRSS can require angularity to provide a mixture that is stronger and more resistant to deformation. While HRSS can be made with or not approved coarse aggregate, depending on the gradation of sand available.

Trial Mix

This examination is intended to determine the resilience (stability) of the plastic melt (flow) of the asphalt mixture, while the purpose of this test is to obtain an asphalt mixture that meets the requirements set out in the planning criteria. The procedure carried out in this experiment included: test specimen preparation, mixture preparation, and mixed preparation. In compaction procedures, the type of impact used is collision for light traffic.

Marshall Test

The Marshall test aims to determine the characteristics of a flexible tapper. The Marshall method consists of Marshall tests and Marshall parameters, which are explained as follows:

a.Marshall Test

Mixed design based on the Marshall method invented by Bruce Marshall. The Marshall test aims to measure the durability (stability) of an aggregate and asphalt mixture against the flow (plastic). Flow is defined as a change in deformation or strain of a mixture from no load, to maximum load. Marshall equipment is a press equipped with a Proving ring with a capacity of 22.2 KN (5000 lbs.) and flow meter. Proving ring is used to measure the value of stability, and a flow meter to measure plastic melt or flow. Standard cylindrical standard Marshall specimens with a diameter of 4 inches (10.16 cm) and a height of 2.5 inches (6.35 cm).

b. Marshall Test Parameters

The properties of paved mixtures, can be seen from the Marshall test parameters, including:

1. Marshall stability

According to The Asphalt Institute, Mudianto (2004), stability is the ability of asphalt mixture to withstand deformation due to load which works without permanent deformation like waves, groove or bleeding which is expressed in units of kg or lb. Value stability is obtained from the results of direct reading on the Marshall tool Test when doing Marshall testing.

Stability value too high will result in the pavement that is too stiff, so the durability is reduced.

2. Melt (Flow)

Like the way to obtain stability values, the flow value is the value of each indicated by the dial needle (inside mm) when doing Marshall testing. A mixture of those who have low melting will be more rigid and tend to experience early cracking at the age of service, while value high melting indicates the mixture is plastic.

3.Marshall quotient

Marshall Quotient is the result of a comparison between stability with the flow. The higher the MQ, the more it will be high stiffness of a mixture and the more vulnerable the mixture is against cracks. Here is the equation for the MQ value:

$$MQ = \frac{S}{F}$$

MQ : Marshall Quotient (kg/mm)
S : Corrected stability value (kg)
F : flow value (mm)

4. Asphalt / Void Filled with Asphalt (VFA)

Filled cavity Void Filled with Asphalt (VFA) is percent the cavity between the aggregate particles (VMA) filled by asphalt, not including asphalt absorbed by the aggregate.

5. Void in Mineral Aggregate (VMA)

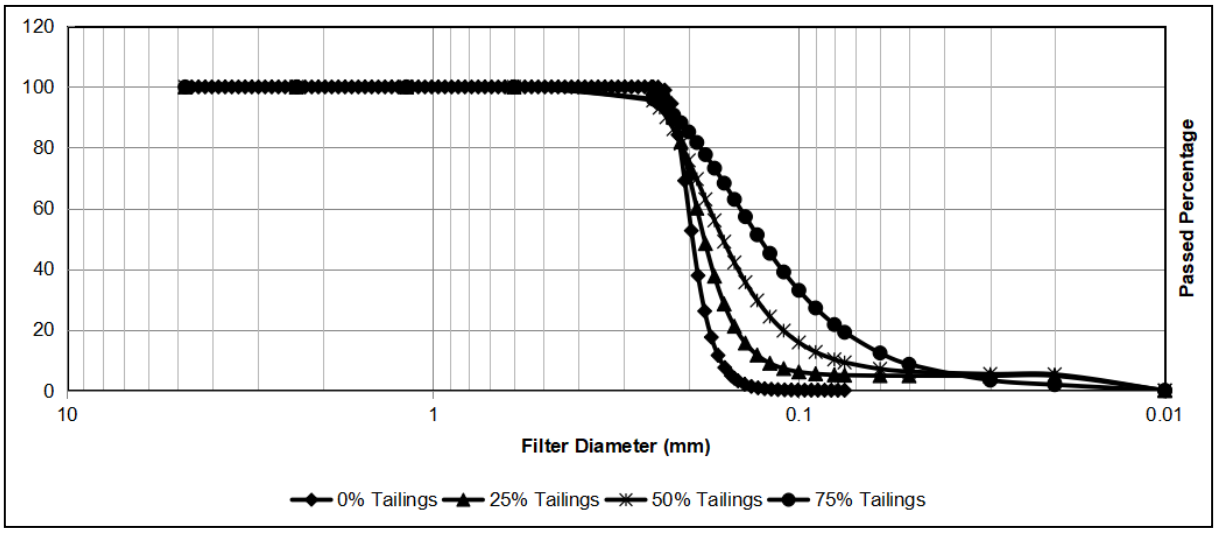
Intergroup cavity (VMA) is the cavity space between particles aggregate on the pavement, including air cavities and asphalt volumes effective (excluding aggregate absorbed asphalt volume).

6. Air cavity in mix / Voids in Mix (VIM)

The air cavity in the mixture (VA) or VIM in the paved pavement mixture consists of air space between the asphalt-coated aggregate particles.

RESULTS AND DISCUSSION

Manufacture of Hot Rolled Sand Sheet asphalt, starting with the determination of tailings content, namely 0%, 25%, 50%, 75%. The level indication is viewed from the increasing value of Cu (Coefficient Uniformity) and Cc (Coefficient Curve). Coefficient Uniformity, namely sand gradation coefficient, and Coefficient Curve, namely curvature cohesion on the graph obtained. At 0% tailing content Cu value of 1.32 and Cc is 0.96. At 25% tailings content Cu value of 2.65 and Cc is 1.74. The 50% tailings content of Cu is 4.83 and Cc is 1.72. At tailings content 75% Cu value is 4.19 and Cc is 1.60. This increase affects the size of the cavity in the mixture and determines the workability (ease of work) and the stability of the mixture. The following graph increases the graph of each level



After that, the test was carried out with an aggregate gradation test which used fine and coarse aggregates using a shaker. The basic reference used in this test is PB-0201-76, AASHTO T-27-74, ASTM C-126-46. HRSS (Hot Rolled Sand Sheet). At 0% percent tailing content escapes 0.075 mm diameter by 0.11% and does not meet the requirements as HRSS. In the tailings content, 25% escaped the 0.075 mm diameter by 9.97% and fulfilled the requirements as HRSS. The 50% tailings content escapes 0.075 mm diameter by 15.69% and meets the requirements as HRSS. At tailings levels of 75% escaped 0.075 mm diameter by 21.31% and did not meet the requirements as HRSS. Requirements for class HRSS A with a filter size of 0.075 mm are 4-14% passed. Requirements for class B, HRRS B, with a filter size of 0.075 mm are 8-18% escaped. The aggregate grading test results are presented in the following table 1:

The results of testing the asphalt with the trial mix method for pavement obtained the optimum level of 50% tailings with a doubling or 100% increase in strength with 0% tailings content as a control. The increase was marked by the marshal quotient value, at 0% tailing levels only reaching a value of 65.118 kg / mm. Whereas the 50% tailings content reached 136.7 kg / mm. The value of other test results also increases, such as the stability and flow that originally only reached 459.598 kg and 7mm, increasing to 872.69 kg, 6.5mm. According to SNI 03-6749-2008, the results have requirements as HRSS (Hot Rolled Sand Sheet) with a minimum value of marshal quotient and stability of 80 kg / mm and 200 kg.

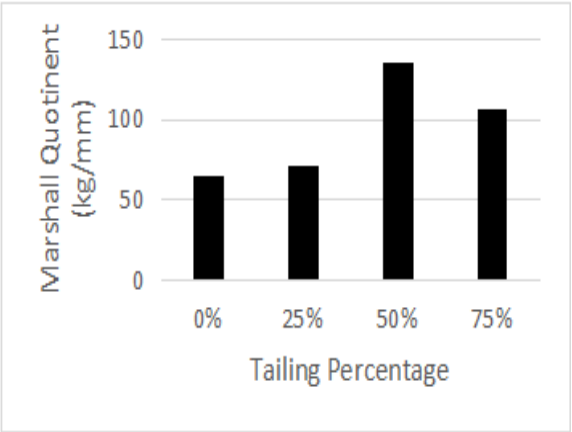


Figure 2 Marshall Test Results

The results of the study indicate that there is an effect of the coefficient of fine aggregate uniformity value (Cu) on road stability. The aggregate mixture with 50% tailings content has the highest stability value with the highest Cu value. This can occur because the value of Cu illustrates the distribution of the size of the grain in the aggregate. The higher the value of Cu, the higher the distribution of the size of the aggregate granules, the higher the aggregate density. In addition, after testing Marshall each level and tested for hardness. The optimum level of the tailing's mixture can be seen with the strong mixture sample holding the Marshall pavement test. The strongest level and the least damage compared to the other levels is 50% tailing substitution. The following samples are tested for each level of tailings.

HRSS is generally used for road planning with traffic that is not too high (≤ 500,000 SST), but can also be used for temporary maintenance or repair work in higher traffic.

Figure 3 Sample Condition after Marshall Test is Conducted, (a) Sample with 0% tailings (b) Sample with 25% tailings (c) Sample with 50% tailings (d) Sample with 75% tailings

CONCLUSION

The conclusions that can be taken in this study are:

1.The greater the value of Cu, the greater the size of the aggregate grain so that the aggregate density gets higher.

2.The value of Cu, Cc, stability, the highest quotient marshal and qualify as meeting the requirements as Hot Rolled Sand Sheet (HRSS) is a mixture of 50% tailings.

3.The optimum content of the tailing's mixture as 50% fine aggregate substitution with a 2-fold increase or a 100% increase

MICROMECHANICAL MODELING OF TENSILE STRENGTH OF SHORT RANDOM CARBON FIBER REINFORCED CONCRETE

Gilford B. Estores[1] and Bernardo A. Lejano[2]

[1]Faculty, Mapua University, Philippines; [2]Faculty, De La Salle University, Philippines

ABSTRACT

The accurate prediction on the response of the composite material is difficult to achieve due to the complexity of its mechanical properties. However, such complexity can be understood well using the micromechanical analysis. One of the most important goals of micromechanical analysis is to predict the failure and strength of the composite material on the basis of the geometries and properties of the matrix and the fibers. This study aims to develop a simplified micromechanical model that predicts the direct tensile strength of a randomly oriented short Carbon Fiber Reinforced Concrete (CFRC) using the modified rule of mixtures based on the assumptions that CFRC will fail by fiber failure mode and with the perfect interfacial bond between the matrix and the fibers. PAN-based High Tensile short carbon fibers distributed randomly in 3D with low fiber volume fractions (V_f) of 0.10%, 0.15%, 0.20%, 0.25% and 0.30% were used in this study. Fiber lengths (L_f) of sizes 19mm, 30mm, and 38mm were used. The designed compressive strength considered for each fiber volume fraction and fiber length was 21MPa, 28MPa, and 35MPa. There were three samples of specimens considered for each case. Each case was tested for cylindrical compressive strength and direct tensile test. Test results showed that the tensile strength of CFRC was optimum at V_f = 0.10% and L_f = 38mm. Finally, good agreement has been observed between the experimental tensile strength and predicted tensile strength using the micromechanical model.

Keywords: Micromechanical Analysis, Tensile Strength, Short Randomly Oriented Composites, Carbon Fiber Reinforced Concrete

INTRODUCTION

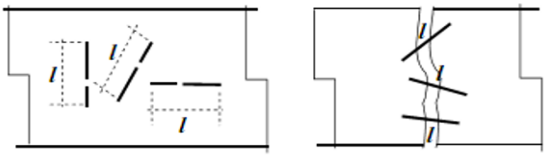
The micromechanical analysis is developed to understand well the complex mechanical properties of the combined materials known as a composite material. Within the composite material, it deals more on the stress and strain transfer within the fibers and the matrix. The inputs in the micromechanical analysis of composites are the fiber properties, matrix properties, a geometric configuration that would result in the uniaxial strengths and fracture toughness of the composite material. However, it is believed that the central parameter in micromechanical modeling is the fiber content and the matrix [1].

The fiber's length inclusion in composite material may be classified as continuous or short. Fiber is considered short if its length is less than its critical length. For increased fiber length, the strain difference tends to become smaller until equal strain can be attained between the fibers and the matrix. At this point of equality in failure strain, the fiber length is called the critical fiber length.

Unlike the continuous fiber composites, the mechanical properties of the short-fiber composites are very different due to their fiber's orientation. The orientation of short fibers may be aligned discontinuous, off-axis aligned discontinuous, and randomly oriented discontinuous. If the fiber's orientation in a composite is random, there are two considerations that must take into account. If the fiber length is less than the thickness of the part, the fibers are randomly oriented in 3D, but if the fiber length is greater than the thickness of the part, the fibers are randomly oriented in 2D. A random discontinuous fiber composite is indeed different from those of unidirectional continuous fiber-reinforced concrete. The tensile strength of the random discontinuous fiber is at its optimum as the content of the fiber increases and then tends to decrease [2].

According to Fu and Lauke [3], the modified rule of mixtures is usually used to estimate the direct tensile strength of short-fiber composites by presuming a perfect interfacial bond among the matrix and the fibers. The modified rule of mixture is actually the extension of the simple rule of mixture in which modification focuses on factors such as fiber length and fiber orientation.

It is believed that the accurate prediction of the failure and strength of composite materials is difficult to achieve. Thus, it is necessary that the failure mechanisms both on the fiber and matrix level should be understood. Fracture of the composite happens when either the fiber or the matrix fails. There are two possible failures for typical composites as shown in Fig. 1.



(a) (b)

Fig. 1 Typical failures for typical composite: (a) Fiber failure mode (b) Matrix failure mode

The first type is the fiber failure mode, where the failure strain of the matrix is larger than the failure strain of the fiber. This implies that the stress in the fiber portion at fracture must be larger than the stress in the matrix portion of the composite volume after the fracturing of all fibers so that the fibers will actually be reinforcing. On the other hand, the second type is the matrix failure mode, where the failure strain of the fiber is larger than that of the matrix. This assumes that the fiber has to carry the whole load when the matrix fails.

Some theories for unidirectional fiber-reinforced composites were derived from micromechanics simple rule of mixtures. However, the simple rule of mixtures does not apply for short randomly oriented fiber composites because it does not consider the fiber-matrix interaction effects and the fiber orientation at a given dimension (2D or 3D). From these considerations, a researcher like Curtis et al. modified the rule of mixtures by introducing factors such as fiber length efficiency factor and fiber orientation factor. The ultimate tensile strength of a short discontinuous and random composite can be calculated using the modified rule of mixtures developed by Curtis et al. [4].

METHODOLOGY

Materials

The composite material used in this study is Carbon Fiber Reinforced Concrete (CFRC). The carbon fiber type used was 0.111mm thick chopped PAN-based high tensile (HT) strength. The fiber lengths used in this study were 19mm, 30mm, and 38mm. The tensile strength (F_t), modulus of elasticity (E), specific gravity (SG) and other properties of the PAN-based HT carbon fibers considered are shown in Table 1.

Table 1 Properties of PAN-based HT carbon fibers

L_f (mm)	F_t (MPa)	E (MPa)	SG	Width (mm)
	4510	231000	1.8	3.0

The concrete matrix is consists of cement, fine aggregates, coarse aggregates, superplasticizer, and water. A Portland cement that meets ASTM standard specification C595 [5] was used. Crushed coarse aggregates with a maximum size of 19mm having an absorption of 1.01% and a mass density of 1592 kg/m^3 were used. Fine aggregates with a mass density of 1551 kg/m^3, and having a 3.01% water absorption and fineness modulus of 2.40 were used. A superplasticizer was added to ensure the workability of fresh CFRC mix. The water used was of good quality.

Specimens and Testing

The different cases of fiber volume fractions (V_f) and fiber lengths (L_f) combination used in this study are presented in Table 2. Three specimens were prepared for each case of CFRC composites both in compression and tension. All these CFRC specimens were tested and compared to the plain concrete specimen.

Table 2 Cases of the CFRC specimens

Case No.	L_f, mm	V_f, %	Case No.	L_f, mm	V_f, %
1	19	0.10	24	38	0.20
2	30	0.10	25	19	0.25
3	38	0.10	26	30	0.25
4	19	0.15	27	38	0.25
5	30	0.15	28	19	0.30
6	38	0.15	29	30	0.30

21	38	0.15	44	30	0.30
22	19	0.20	45	38	0.30
23	30	0.20			

The design mix of the CFRC composite was based on the compressive strengths 21MPa (Cases 1-15), 28MPa (Cases 16-30), and 35MPa (Cases 31-45) with a water-cement ratio of 0.68, 0.57 and 0.48,

respectively considering the slump requirement that ranges from 25mm to 100mm, and 2% entrapped air. Moreover, partial replacements of the sand by the carbon fibers are made in the design mix. Then the workability of each mix was checked using the slump test in accordance with ASTM C143 [6].

The compressive strength specimens were tested using 100mm x 200mm cylinders in accordance with ASTM C39-05 [7] after 28 days of curing period. Likewise, the tensile strength specimens employing a dumbbell form with a critical section of 75mm x 50mm, and a gauge length of 300mm were also tested on the same curing period. The set-up for the tensile strength test and its corresponding failure mode at the critical section are shown in Fig. 1.

Fig. 1 Tensile strength test set up and failure mode

Micromechanical Analysis

Since the composite material involved in this study is CFRC, its ultimate tensile stress is best determined by micromechanics equation. In this study, the fiber failure mode is considered because short carbon fibers were used for CFRC. Short fibers favor a fiber failure where the matrix failure strain is assumed to be greater than the failure strain of the fiber. On the practical point of view, fiber failure means composite failure. Such fiber failure mode is based primarily on the assumption that since PAN-based carbon fibers filament has a very small diameter despite their very high tensile strength, they tend to break first before the concrete matrix does upon the pull-out test.

The modified rule of mixtures by Curtis et al. is generally expressed as,

$$\sigma_{ult} = \chi_1 \chi_2 V_f \sigma_{fu} + \sigma_{mu} V_m \quad (1)$$

where χ_1 denotes the effect of fiber's orientation, χ_2 denotes the effect of fiber's length. V_f is the volume of fraction percentage of fiber's inclusion, V_m is the volume of fraction percentage of the matrix, σ_{fu} is the fiber's ultimate tensile stress, and σ_{mu} is the matrix ultimate tensile stress. For three-dimensional (3D) random fiber orientation, the value of χ_1 is 0.20 [8]. While χ_2 is computed as,

$$\chi_2 = 1 - \frac{s_c}{2s} \quad \text{when } s > s_c \quad (2)$$

$$\chi_2 = \frac{s}{2s_c} \quad \text{when } s < s_c \quad (3)$$

where s denotes the fiber aspect ratio and s_c denotes the critical aspect ratio. The critical aspect ratio is the ratio between the critical fiber length l_c and the fiber diameter d. The critical fiber length can be computed as,

$$l_c = \frac{\sigma_{fu} d}{2\tau_y} \quad (4)$$

where σ_{fu} is the fiber's tensile stress and τ_y denotes the interfacial shear stress. The diameter, d of the chopped PAN-based carbon fiber in tow is computed using the equivalent diameter equation [9] given by,

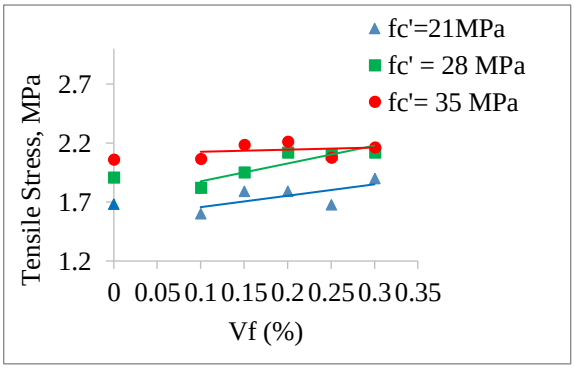
$$D_e = \sqrt{\frac{4m_f}{\pi l \rho_f}} \quad (5)$$

where m_f = mass of the chopped carbon fibers, ρ_f = mass density of chopped carbon fiber, l = total length of the sample carbon fiber used.

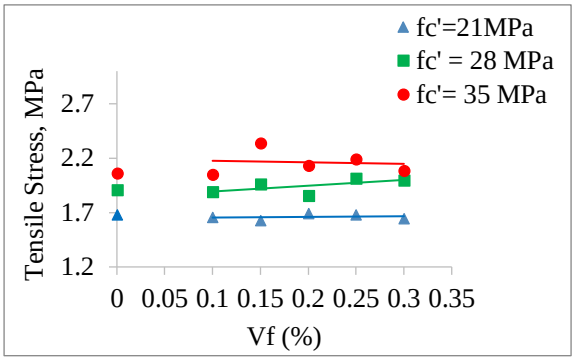
RESULTS AND DISCUSSIONS

Influence of Fiber Volume Fraction and Fiber Length to Tensile Strength of CFRC Composite

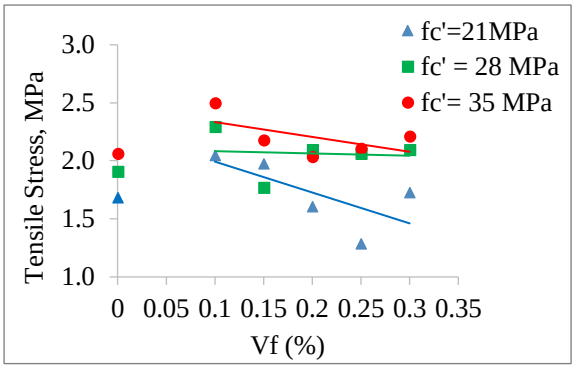
Generally, the fiber volume fraction strongly affects the tensile strength of the CFRC. Most of the cases of V_f and L_f mix have satisfied and significantly increased the tensile strength of CFRC in relation to their control specimens. The effect of fiber volume fraction to the tensile strength of CFRC at cases L_f = 19mm, L_f = 30mm, and L_f = 38mm are shown in Fig. 3(a), Fig. 3(b), and Fig. 3(c), respectively.



(a)



(b)



(c)

Fig. 3 Influence of fiber volume content to tensile stress of CFRC at (a) L_f =19mm (b) L_f = 30mm (c) L_f = 38mm

The addition of 19mm fiber length in concrete as shown in Fig. 3(a), the tensile strength tends to increase with increased fiber volume fraction particularly at f_c'=21MPa and at f_c'=28MPa.

With the addition of L_f =38mm as shown in Fig. 3(c), the tensile stress tends to decrease at increased fiber volume fraction in all cases of designed compressive strengths, while no trend was observed in the 30mm fiber length as shown in Fig. 3(b). However, 38mm fiber length at 0.10% fiber volume fraction has its tensile strength increased significantly to 2.047 MPa, 2.293 MPa, and 2.498 MPa by 21.63%, 19.99%, and 21.14% respectively as compared to their corresponding control specimens.

It is also noticeable from the findings that only the addition of L_f = 19mm at V_f = 0.30% and the addition of L_f = 38mm at V_f = 0.10% satisfy the compressive strength of CFRC, while most of the V_f cases for L_f = 19mm and V_f cases for L_f =38mm satisfy and significantly increased the tensile strength of CFRC. This indicates that the compressive strength of CFRC is relatively less affected by the addition of fibers as compared to the tensile strength of CFRC. This finding agrees to the report of ACI 544 [10] where the recommended fiber length of carbon fiber may vary from 5mm to 50mm, but preferably on 19mm or 38mm. In addition, Tezuka et al. [11] claimed that to achieve high strength in CFRC, use a chopped strand of carbon fibers with an average length based on the maximum aggregate size to be used as a minimum, but, more preferably not less than twice the maximum aggregate size. This refers to the fiber lengths 19mm and 38mm since the maximum aggregate size used in this study was 19mm.

Micromechanical Modeling

Assumptions

The micromechanics modeling of the ultimate tensile strength of the CFRC composites is based on the assumptions that the CFRC base material will fail by fiber failure mode during the tensile test and is linearly elastic until failure. It is also assumed that the fibers' strength is uniform, and the fibers and matrix are perfectly bonded at their interface. The errors are assumed to distribute normally with zero mean and variance.

In this study, the ultimate tensile strength of the CFRC composites was calculated by micromechanics analysis using the modified rule of mixtures. Although the ultimate tensile strength of a composite is difficult to achieve accurately, the modified rule of mixture is selected because it is the most appropriate for composite material at fiber failure mode. Figure 4 shows the fiber failure mode of different tensile strength specimens used in this study. It can be seen that most of the chopped carbon fiber breaks when the ultimate tensile strength of the CFRC specimens is reached.

Fig. 4 Fiber failure mode of tensile strength specimens

Modified rule of mixtures

The observed tensile strength was plotted against the cases of the specimens and compared with the modified rule of mixtures equation by Curtis et al. as shown in Fig. 5. The ultimate tensile stress of the CFRC composites using this model was computed by Eq. (1). Varying parameters are χ_2 and s. χ_2 is computed using Eq. (3), and s is the ratio of L_f and d. While L_f, V_f, V_m, and σ_{mu} are the experimental data. Constant parameters such as χ_1 = 0.20, τ_y = 2.3 MPa, σ_{fu} = 4510MPa, l_{fc} = 755.52mm, d = 0.771mm were also used as part of the micromechanics modeling.

The value of χ_1 is based on 3D random fiber orientation, τ_y = 2.3MPa and σ_{fu}= 4510MPa are the carbon fiber properties found in Table 1, and the l_c and d values are computed using Eq. (4) and Eq. (5), respectively.

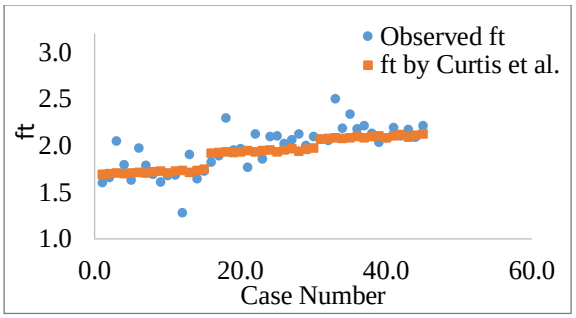


Fig. 5 Scatter plot of ultimate tensile stress for the observed and modified rule of mixtures model against cases of specimen

The Curtis et al. model was compared to the observed tensile stress as presented in the scatter plot above. Although there are cases where the tensile stress is extreme, its scatter is acceptable at the coefficient of variance (CV) of 12.23% which is less than the required maximum CV = 15%. Generally, the model appeared to have a good agreement. This only implies that the modified rule of mixture by Curtis et al. appeared to be an appropriate model for predicting the tensile strength of CFRC base material.

Modified Curtis et al. model

Despite good agreement observed from the plot as shown in Fig. 5, there are still some observed values that deviate largely from the modified rule of mixtures. However, most of these values increased significantly the tensile strength of CFRC. To address this increased effect, a tensile modification factor (k_m) that relates the observed and predicted values for tensile strength of CFRC was determined by

$$k_m = ft / \sigma_{ult} \tag{6}$$

In this study, the computed tensile strength of CFRC composite is denoted by f_{tc} and is expressed as

$$f_{tc} = k_m \sigma_{ult} \tag{7}$$

Equation 7 is considered in this study as the Modified Curtis et al. model, where k_m is the modification factor for tensile strength computed by Eq. (6) and σ_{ult} is the tensile strength derived from the modified rule of mixtures by Curtis et al. However, due to the difficulty in testing the direct tensile strength of the concrete matrix σ_{mu}, it is best expressed as a function of its compressive strength. The relation of the direct tensile strength to the compressive strength of the control specimens (f_{cm}) was denoted by k_t and expressed as

$$k_t = \sigma_{mu} / \sqrt{f_c} \tag{8}$$

The observed (σ_{mu}) values of the direct tensile strength were utilized to calculate the numerical value of k_t as shown in Table 3.

Table 3 Results of the estimated coefficient for direct tensile strength in plain concrete

Control Case	σ_{mu}	f_{cm}	k_t
0-21	1.6833	20.17	0.375
0-28	1.9111	27.82	0.363
0-35	2.0622	35.78	0.345
		mean	0.361

Consequently, the direct tensile strength of the concrete matrix is then expressed as

$$\sigma_{mu} = 0.361\sqrt{f_{cm}} \tag{9}$$

This estimated coefficient of compressive strength to determine the direct tensile strength of normal plain concrete is within the range cited in ACI Code 318-89 [12], where the coefficient of $\sqrt{f_c}$ ranges 0.247 to 0.412 for f_c in MPa.

With the inclusion of Eq. (9) to the Eq. (1), it becomes

$$\sigma_{ult} = \left[\chi_1 \left(\frac{L_f}{d} \right) \tau_y V_f + 0.361\sqrt{f_{cm}} V_m \right] \tag{10}$$

Substituting Eq. (10) to Eq. (7), the Curtis et al. model is modified to

$$f_{tc} = k_m \left[\chi_1 \left(\frac{L_f}{d} \right) \tau_y V_f + 0.361\sqrt{f_{cm}} V_m \right] \tag{11}$$

where k_m = 1.0245 computed by Eq. (6) using the data from Fig. 5, χ_1= 0.20 for 3D fiber orientation, τ_y = 2.3 MPa for UT70-20 PAN-based carbon fibers, and d = 0.771 mm computed from Eq. (5), and V_m = 1-V_f.

Residual Analysis

The residual output of tensile strength using the Modified Curtis et al. model is presented in Fig. 6. It is shown here the error between the observed tensile

strength and predicted tensile strength computed from the Modified Curtis et al. model given by Eq. (11). Using this modified model the CV was reduced from 12.23% to 8.24%. This means that the scatter for tensile strength using the modified Curtis et al. model is acceptable.

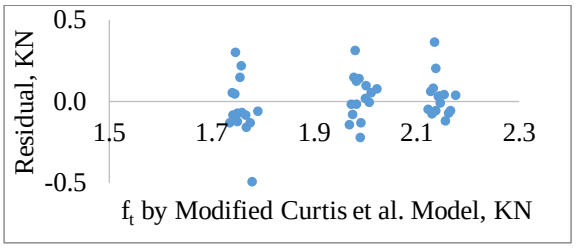

Fig. 6 Residual plot of tensile strength using a modified Curtis et al. model

The residual plot for predicted tensile strength of CFRC composites shown in Fig. 6 are clustered into three groups based on the three designed compressive strengths (21, 28, 35MPa) considered in this study, but the pattern appears to be fairly random. This means that in general, the errors are approximately normally distributed with constant variance. This implies that the modified Curtis et al. model use to predict the tensile strength of the CFRC composite follows a normal distribution and fits the observed data satisfactorily. It is noticeable that the residuals are ranging only from -0.495 to 0.364. This range of error is obviously small. This indicates that the tensile strength of CFRC composites can be predicted satisfactorily under given limitations of the Modified Curtis et al. model.

CONCLUSIONS

Test results show that the compressive strength of CFRC in each case of designed compressive strength are consistently satisfied with the addition of L_f = 38mm at V_f = 0.10%. Test results also show that the tensile strength of CFRC is optimum at V_f = 0.10% and L_f = 38mm.

A Modified Curtis et al. model to predict the tensile strength of CFRC composite is developed based on the micromechanics equation of Modified Rule of Mixtures by Curtis et al. model. This model is significantly acceptable and can be used to predict the tensile strength of the CFRC composites, but it is applicable only for UT70-20 PAN-based chopped carbon fibers distributed randomly in 3D with low fiber volume content ranging from 0.10 % to 0.30 %. This model also applies to CFRC composites with normal compressive strength. The fiber length in CFRC composite must be limited to 19mm, 30mm, and 38mm.

ACKNOWLEDGMENTS

The carbon fiber employed in this study was UT70-20 TORAYCA. The authors would like to thank Mapua University, DOST-ERDT, and Alphatec Chemical Corp. for their great support in this study.

PREPARATION OF GEOPOLYMER CEMENT FROM SIMULATED LUNAR ROCK SAND USING ALKALI FUSION

Kazuki Sakamoto[1], Takaaki Wajima[1]
[1]Graduate School of Science and Engineering, Chiba University, Japan

ABSTRACT

In this study, we tried to convert simulated lunar rock sand into geopolymer cement by alkali fusion with sodium hydroxide. Space development is currently being conducted in various countries. For construction on the moon, it is difficult to bring all the construction materials from the earth, and development of construction materials made from lunar resources is required. The authors have succeeded in making geopolymer cement from crushed stone dust using alkali fusion. Therefore, there is a possibility that geopolymer cement used for construction material can be made from lunar rock sand, abundantly present on the lunar surface, using the same method.

In this experiment, simulated lunar rock sand was fused with NaOH by changing the mixing ratio of the sand and sodium hydroxide, heating temperature, heating time in vacuum or air atmosphere, and the reaction in vacuum and air was compared and examined. As a result, it was found that the elution contents of Si and Al in the fused sand into acid solution increased with increasing the temperature, NaOH addition and heating time of alkali fusion, and the fused reaction in vacuum atmosphere is different from that in air atmosphere.

Keywords: Lunar Rock Sand, Alkali Fusion, Geopolymer Cement, Vacuum Atmosphere

INTRODUCTION

Space exploration with unmanned spacecraft for space development is currently active in various countries. The moon is satellite of the planet earth, the nearest astronomical object, and development as a base for space development is planned. In the development plan, when a large-scale base is built on the moon, it is difficult to transport all building materials from the earth. Therefore, the development of building materials made from lunar resources is required.

In this study, we focused on lunar rock sand (Regolith) which is abundant on the lunar surface. Regolith is the sand that covers the surface of the moon with a thickness of several meters and is mainly composed of SiO_2 and Al_2O_3 in the form of alumino-silicate minerals, such as anorthite and augite. In our previous studies, the authors have succeeded in making geopolymer cements from rock dust, discharged from a quarry, using alkali fusion [1, 2]. Although ordinary Portland cement is mainly solidified by the formation of needle-like calcium silicate hydrate (C-S-H), geopolymer cement is mainly solidified by the polymerization of silicate ions bridged by metal ions, such as Al^{3+}, Fe^{3+} and so on, which is similar to the reaction of zeolite synthesis [3, 4]. It would be possible to make geopolymer cement which can be used as a building material by using the same method for lunar rock sand abundantly present on the moon.

Therefore, in this study, we tried to make geopolymer cement by reacting simulated lunar rock sand with sodium hydroxide in air and vacuum. We prepared the precursor of geopolymer fused by changing the mixing ratio of sodium hydroxide, heating time and temperature in air and vacuum, and compare the reaction to make geopolymer cement.

EXPERIMENT

Sample

Simulated lunar rock sand (FJS-1, CSP Japan, Inc.) was used in this study. The chemical composition is mainly composed of 42% of SiO_2, 13% of Al_2O_3, 12% of CaO, 15% of FeO and 8% of MgO.

Preparation of fused dust

The sand and sodium hydroxide powder are mixed in a weight ratio of 1: 0.25 to 1: 2, put in a platinum crucible, and heated up to setting temperature (300 to 500 °C) in 10 min in air and vacuum atmosphere. After heating for 0 to 120 min, it cooled naturally at room temperature, recovered fused dust as a powder, and the mineral phase was identified by a powder X-ray diffractometer (MiniFlex 600, Rigaku).

In order to confirm the possibility of making geopolymer cement, the soluble elements, Si, Al, Fe, Mg and Ca, in the sample were examined. 0.1 g of the fused dust prepared under each condition is added into 20 mL of 1 M HCl solution, shaken at room temperature for 6 h, centrifuged, and the contents of Si, Al, Fe, Mg and Ca in the supernatant were measured by an atomic absorption spectrophotometer (Perkin Elmer, AAnalyst 200) to calculate the solubility (*S*) using the following equation;

$$S = C \times V/w \quad (1)$$

where C is the concentration of each element in the supernatant (mg/L), V is the volume of HCl solution, and w is the weight of the fused sand.

Preparation of geopolymer cement

Preparation of geopolymer cement was performed using the fused sand. The raw sand, water and the fused sand were mixed to prepare the mixtures of 5 g weight, and the mixing ratios used in this study are 1:1:2, 1:1:3 and 2:1:2. The mixture was formed into a mold (ϕ 25 mm $\times$5 mm) and allowed to stand at 80 ℃ in air atmosphere and cure for 1 or 7 days at 80 ºC.

Strength test

The obtained geopolymer cement were subjected to strength tests using a strength tester (ZT series ZTA-500N, IMADA). The sharp point attachment was inserted into the sample at a speed of 30 mm/min to measure the strength when the sample broke. Strength tests for the Portland cement were carried out to compare strength. Portland cement was prepared at water-cement ratio (W/C) = 40 %, formed in a mold and was cured at room temperature for 7 days.

RESULTS AND DISCUSSION

Mixing Ratio

The XRD patterns of the fused sands prepared by changing the mixing ratio in (a) air and (b) vacuum are shown in Fig. 1. The experimental conditions are a heating temperature of 500 ° C and a heating time of 60 minutes. In simulated lunar rock sand, the peaks of anorthite and augite were confirmed. In the sands after alkali fusion, the peaks of anorthite and augite in the sand disappeared and the peaks of sodium silicate were confirmed in both air and vacuum.

The solubility of each element dissolved from the fused sand prepared by changing the mixing ratio in (a) air and (b) vacuum are shown in Fig. 2. In both air and vacuum, as the amount of sodium hydroxide was increased, the solubilities of all elements increased and became almost constant above a mixing ratio of 1: 1. It is considered that almost all elements in the sand was converted into soluble phases by alkali fusion in air and vacuum.

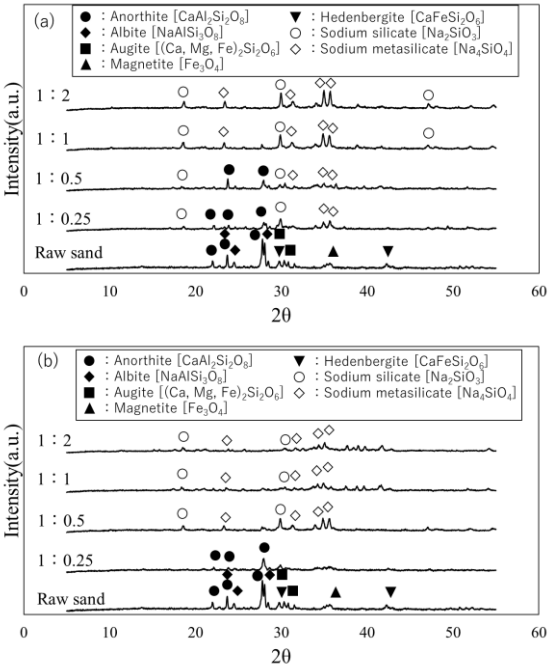

Fig. 1 The XRD patterns of the fused sand prepared by changing the mixing ratio in (a) air and (b) vacuum

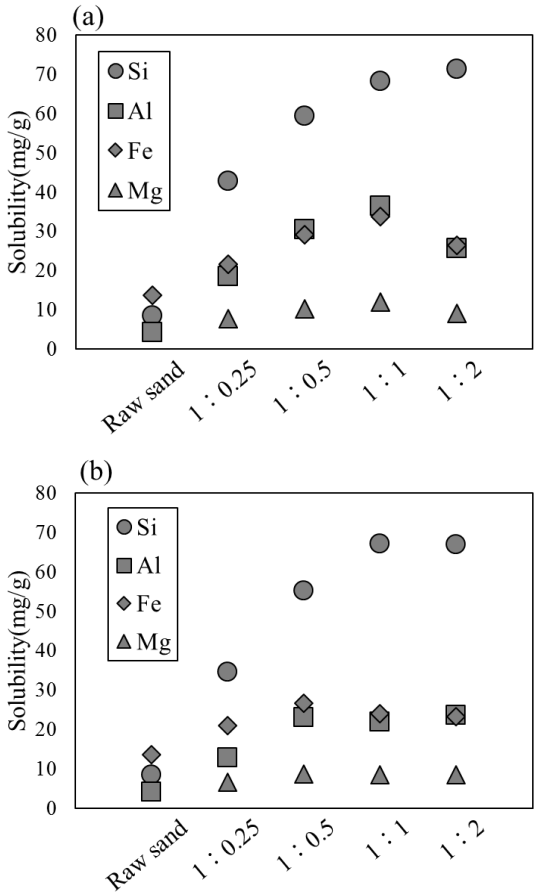

Fig. 2 The solubility of each element dissolved from the fused sand prepared by changing the mixing ratio in (a) air and (b) vacuum

Heating Time

The XRD patterns of the fused sand prepared by changing the heating time in (a) air and (b) vacuum are shown in Fig. 3. The fused sand was prepared at the ratio of raw sand: sodium hydroxide = 1: 0.5 at 500 ° C. In the air, as the heating time increased, the peaks of minerals observed in the sand disappeared, and the peak of sodium silicate was confirmed. In the vacuum, as the heating time became longer, the mineral peak observed in the sand disappeared except anorthite, the peaks of anorthite gradually decrease, and the sodium silicate peak was confirmed at more than 5 min.

The solubilities of each element dissolved from the fused sand prepared by changing the heating time in (a) air and (b) vacuum are shown in Fig.4. The solubilities of Si and Al rose and became constant in 10 min, in both air and vacuum. The soluble amounts of Si and Al from the fused sand in air are higher than those in vacuum, which would be caused by remaining anorthite. There was no change in the dissolved amount for Fe, Mg and Ca of all samples.

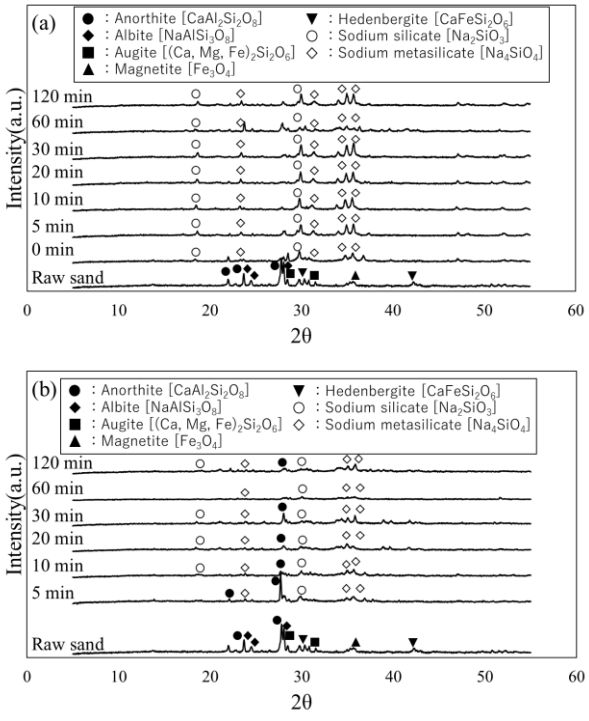

Fig. 3 The XRD patterns of the fused sand prepared by changing the heat time in (a) air and (b) vacuum

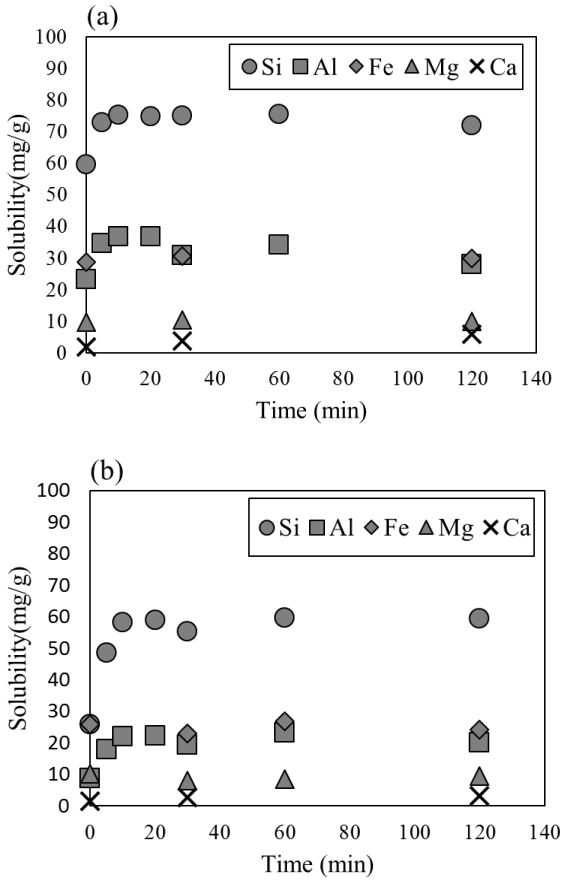

Fig. 4 The solubilities of each element dissolved from the fused sand prepared by changing the heating time in (a) air and (b) vacuum

Heating temperature

The XRD patterns of the fused sand prepared by changing the heating temperature in (a) air and (b) vacuum are shown in Fig. 5. The fused sand was prepared at the ratio of raw sand: sodium hydroxide = 1: 0.5 for 60 minutes. In both air and vacuum, the mineral peaks in the sand disappeared as the heating temperature was raised, and the peaks of sodium silicate were confirmed.

The solubilities of each element dissolved from the fused sand prepared by changing the heating temperature in (a) air and (b) vacuum are shown in Fig. 6. The solubilities of each element increased with increasing the heating temperature in both air and vacuum. At 300 °C, in the air, the fused sands have quadruple higher solubility than that of the raw sand, while in the vacuum, the fused sands have about double higher solubilities than that of the raw sand.

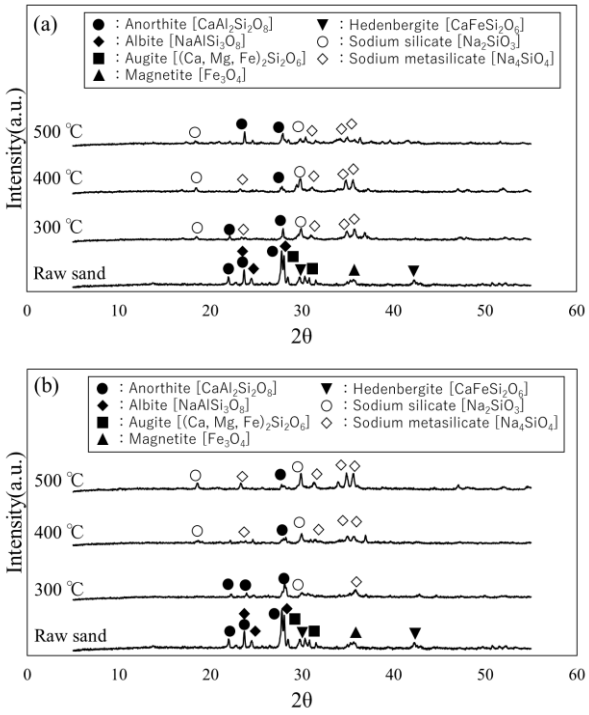

Fig. 5 The XRD patterns of the fused sand prepared by changing the heating temperature in (a) air and (b) vacuum

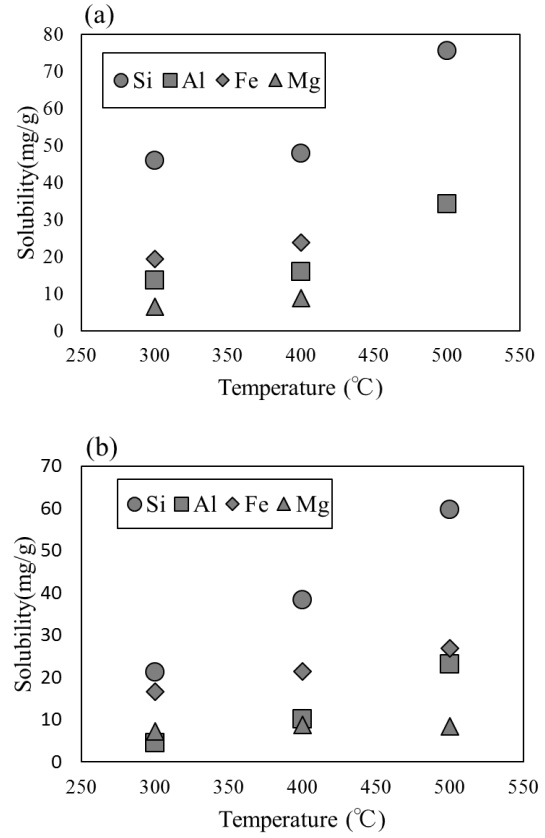

Fig. 6 The solubilities of each element dissolved from the fused sand prepared by changing the heating temperature in (a) air and (b) vacuum

From these results, it is possible to convert the sand into a soluble material including sodium silicate using alkali fusion in vacuum atmosphere, and a high soluble material can be prepared when the mixing ratio is 1:1, heating time is 10 min, and heating temperature is 500 ºC.

Preparation of geopolymer cement

The photograph of the product after 1 and 7 days from (a) fused sand in air and (b) fused sand in vacuum is shown in Fig. 7. After 1 day, hardened product was confirmed using the fused sand in the air, while the products from the fused sand in vacuum are slightly soft. After 7 days, all the products were hardened.

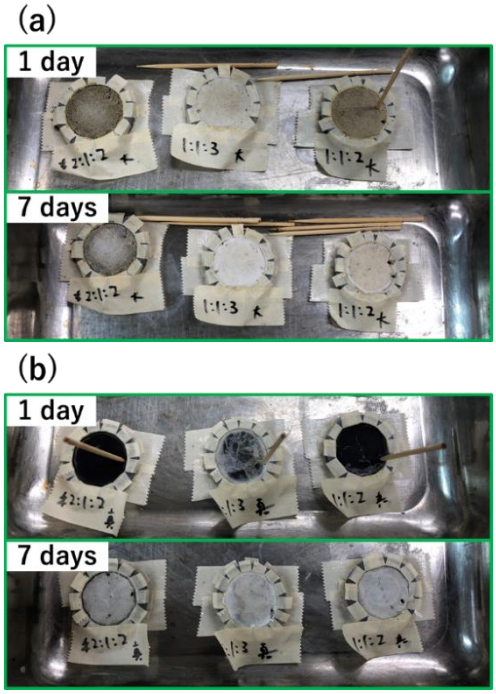

Fig.7 The photograph of the product after 1 and 7 days from (a) fused sand in air and (b) fused sand in vacuum

Strength test

The result of the strength test for the product prepared from (a) fused sand in air and (b) fused sand in vacuum is shown in Fig. 8. It was confirmed that the strength increased as the curing time was prolonged in all the products. The product with the highest strength was obtained using the fused sand prepared in the air atmosphere at the mixing ratio of 2: 1: 2.

The product using the fused sand prepared in a vacuum atmosphere at a mixing ratio of 2: 1: 2 had the highest strength (120 N) among the product from fused sand in vacuum.

Portland cement indicate higher strength (500 N) than the obtained products. The highest strength of the obtained product is 200 N, which is less than half as strong as the Portland cement.

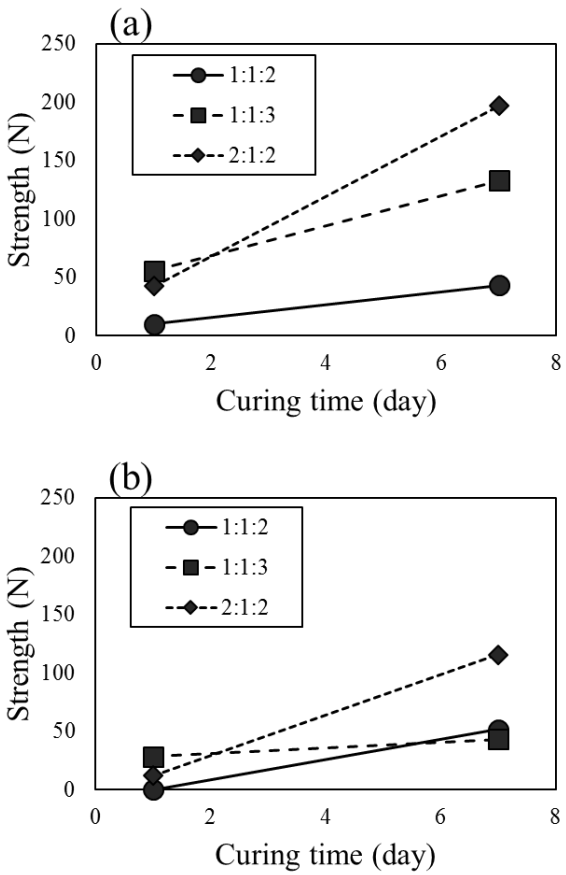

Fig. 8 The result of the strength test for the product from (a) fused sand in air and (b) fused sand in vacuum

CONCLUSIONS

An attempt was made to prepare geopolymer cement by alkali fusion of simulated lunar rock sand with sodium hydroxide. Alkali fusion with sodium hydroxide allows conversion to a highly soluble fused sand even under vacuum. It was found that a high soluble fused sand can be produced with a mixing ratio of 1: 1, a heating temperature of 500 ° C, and a heating time of 10 min.

We succeeded in making a hardened geopolymer cement by mixing the raw sand, water and fused sand. The strength of 200 N was confirmed with the geopolymer cement prepared at a mixing ratio of 2:1:2, using the fused sand prepared in the air atmosphere. Since this strength of the obtained product is about half the strength of the Portland cement, it is necessary to improve the strength.

FIELD PULL-OUT EXPERIMENTS OF FLIP-TYPE GROUND ANCHORS INSTALLED IN DRY SAND GROUND

Shota Yoshida[1], Tatsunori Matsumoto[2], Kazuki Komura[3] and Takayoshi Yoshida[4]
[1,2]Graduate School of Science and Technology, Kanazawa University, Japan; [3]Obayashi Corp., Japan; [4]Daisho Co., Ltd., Japan

ABSTRACT

The fundamental mechanisms of the pull-out resistance behaviour of flip-type anchors have not been fully understood enough to apply them on sites. In this research, pull-out experiments of 5 types of actual flip-type anchors were conducted in a field. Model ground was prepared in a test pit of 4 m in length, 4 m in width and 2.5 m in height. Sand was put into the test pit by layers of 0.25 m. Each soil layer was tamped to have a relative density of 80%. Flip-type anchors were embedded at different depths during the preparation of the ground. Anchor heads were set as "opened" or "closed". After the completion of the ground, flip-type anchors were also driven into the ground at different depths. The anchors were pull-out by means of a jack with measurement of pull-out displacement. As for the anchors buried with "opened" head condition, the maximum pull-out force, F_{max}, got larger as the embedment depth got deeper or as the anchor size got bigger. In contrast, the maximum pressure, p_{max} (F_{max}/project area of anchor), got larger as the anchor size becomes smaller. F_{max} of "closed" or "driven" anchors were about 80% of F_{max} of the corresponding "opened" anchor. The experimental results are presented in detail and discussed in the paper.

Keywords: Ground anchor, Field experiment, Pull-out experiment, Sand ground.

INTRODUCTION

Recently, easier and faster countermeasures for slope failures related to heavy rains are required.

Flip-type ground anchor (flip anchor, hereafter) is one type of end-anchors that are often used for reinforcing or stabilising slopes. As shown in Fig. 1, the flip anchor is driven directly into the ground with a driving rod to a designated depth. Then the anchor is pulled with a jack using a pulling rod connected to the flip anchor head. Hence, the flip anchor is an easy and fast solution for countermeasures of slope failures.

The biggest difference between soil nailing and the flip anchor is that there is no need to fill borehole with grout in case of the flip anchor, because pull-out force of the flip anchor does not depend on the friction resistance of the anchor rod, but on the pull-out bearing force acting on the anchor head from the ground above the anchor head.

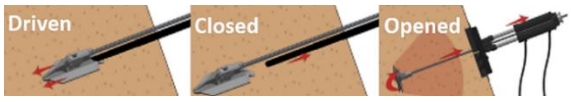

Fig. 1 Procedure of installing a flip-type anchor [1].

Although there are some previous laboratory experiments using model ground and model anchors as in [2]-[4], design guidelines of flip anchors have not been fully established in Japan due to a lack of experimental data and records. Therefore, pull-out experiments on various flip anchors with different installation methods and anchor head conditions were carried out in sand ground in a field, to provide performances of the flip anchors.

OUTLINE OF THE FIELD EXPERIMENT

Model Ground

Model sand ground was prepared in a test pit of 4 m in length, 4 m in width and 2.5 m in height in a field (Fig. 2).

Fig. 2 Test pit for model ground in field.

Table 1 shows the physical properties of river sand used for the model ground. The model ground consisted of 10 layers of 0.25 m thick. Each sand layer was compacted using a vibration tamper to have a relative density, D_r, of around 80% and a dry density, p_d, of around 1.745 t/m^3.

Two series of experiments were carried out in the model grounds named "Ground 1" and "Ground 2".

Table 1 Physical properties of sand used for the model ground

Density of soil particles, ρ_s (t/m^3)	2.688
Max. dry density, ρ_{dmax} (t/m^3)	1.833
Min. dry density, ρ_{dmin} (t/m^3)	1.463
Max. void ratio, e_{max}	0.837
Min. void ratio, e_{min}	0.466

Figure 3 shows the distribution with depth of the water content, w, of each ground. The water contents of the ground 1 and the ground 2 were similar having w around 5.5%.

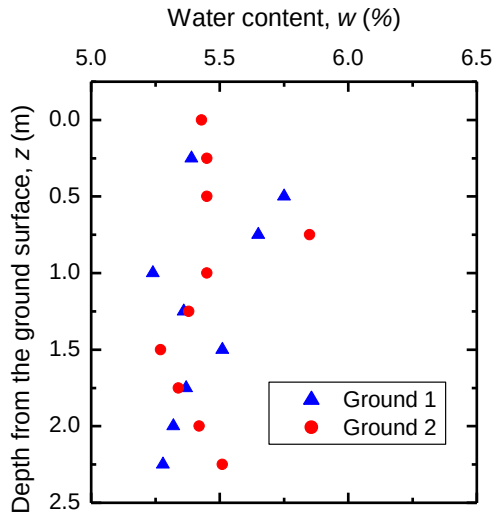

Fig. 3 Water contents of model grounds.

Figures 4 and 5 are distributions of total density, ρ_t, and dry density, ρ_d, of each ground. There is not a clear difference of the ground conditions between the ground 1 and the ground 2.

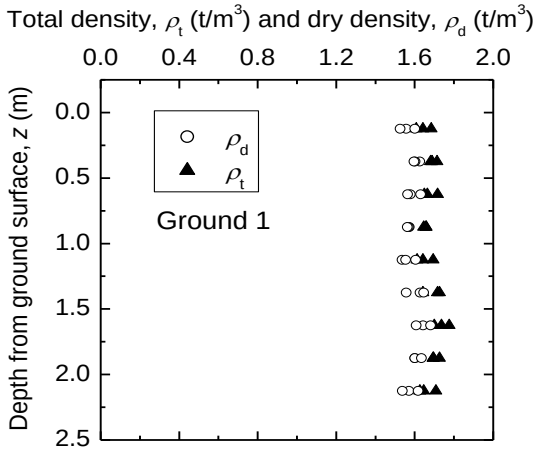

Fig. 4 Distributions of soil densities in the ground 1.

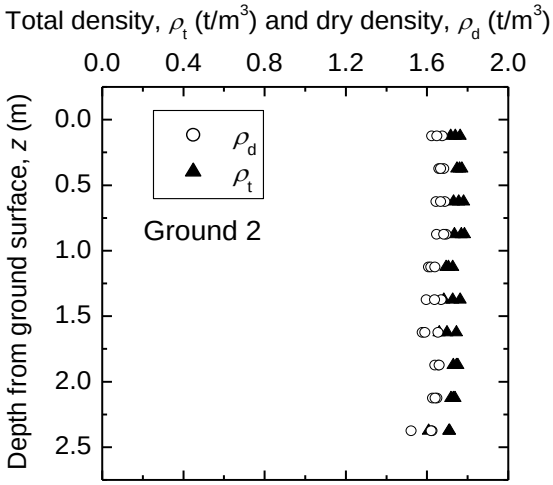

Fig. 5 Distributions of soil densities in the ground 2.

Portable dynamic cone penetration tests (DCPs) were also conducted in the model ground 1. In the DCPT, a cone having a diameter of 25 mm was driven with a hammer having a mass of 5 kg and a free-falling height of 500 mm.

Figure 6 is N_d-values of the ground 1. Here, N_d is the blow count required for the penetration of 100 mm of the cone.

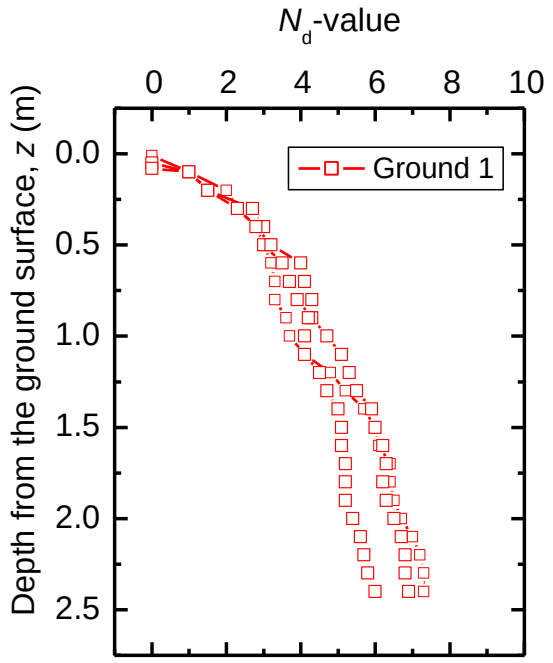

Fig. 6 N_d-values in the ground 1.

Although DCPT was not conducted in the ground 2, it could be judged that the conditions of the ground 2 are almost equal the conditions of the ground 1, based on the results of Figs. 3, 4 and 5.

Used Anchors

Figure 7 shows five flip anchors used for the experiments. They have different sizes and different projection areas, *A*.

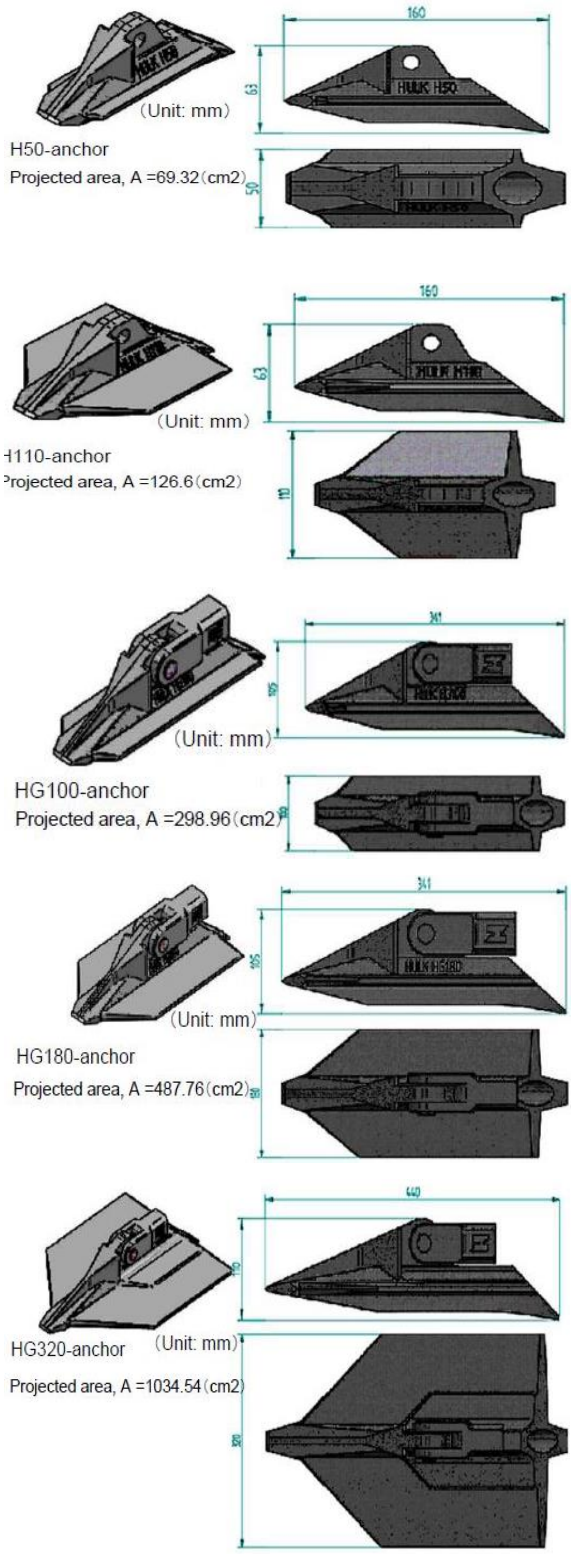

Fig. 7 Flip-anchors used in experiments [1].

Cases of Experiments

Table 2 and Table 3 list experimental cases in the ground 1 and the ground 2, respectively.

Experimental Procedure

First, anchors were set in the ground at designated depths with opened (OP) or closed (CL) anchor head condition while soil layers were being made (Figs. 8 and 9).

Each anchor was pulled out with a hydraulic jack, and the pull-out force, *F*, and the upward displacement, *w*, were measured with a load cell and an encoder (Fig. 10).

In case of the ground 1, five flip anchors were driven into the ground (G1_C10 to C14) after the completion of the pull-out experiments of G1_C01 to C09, and the pull-out experiments the driven anchors were carried out similarly.

In case of the ground 2, pull-out experiments of the buried anchors (G2_C01 to C10) were carried out .

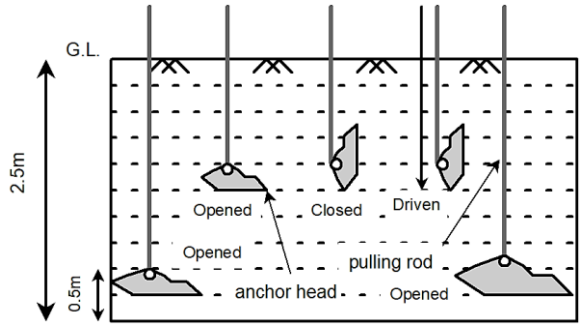

Fig. 8 Installed anchors in the ground.

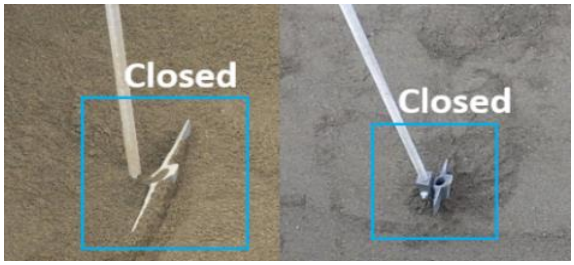

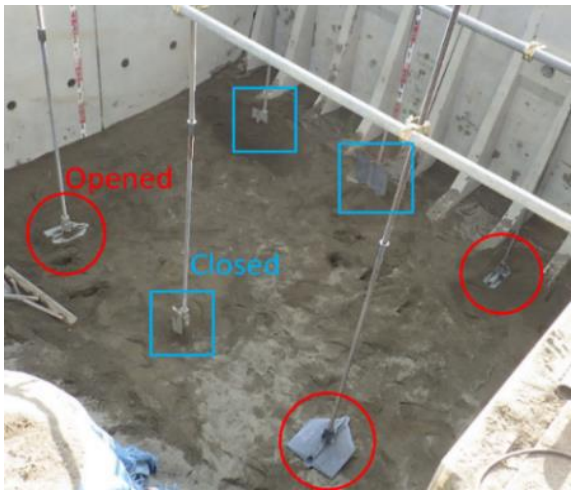

Fig. 9 Anchors set in the ground with opened or closed conditions.

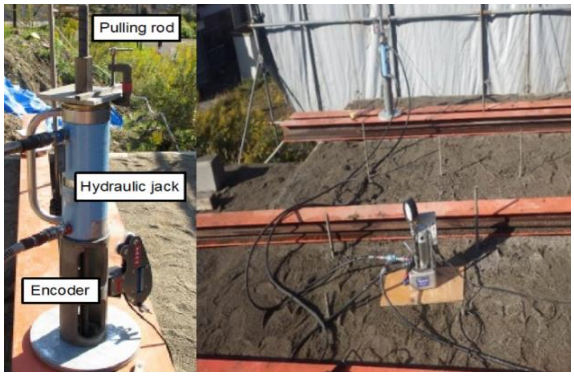

Fig. 10 Equipment for pull-out experiment.

EXPERIMENTAL RESULTS

Figures 11 and 12 show comparisons of relationships between the pull-out force, *F*, and the upward displacement, *w*, of each opened anchor. The pull-out force got larger as the size of anchors (projection area) got bigger. Similar tendency was observed for the closed anchors, as shown in Fig. 13.

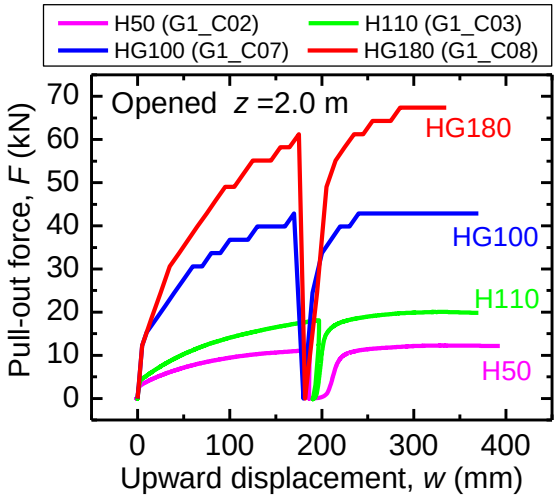

Fig. 11 Pull-out force versus displacement of each opened anchor buried at *z* = 2.0 m.

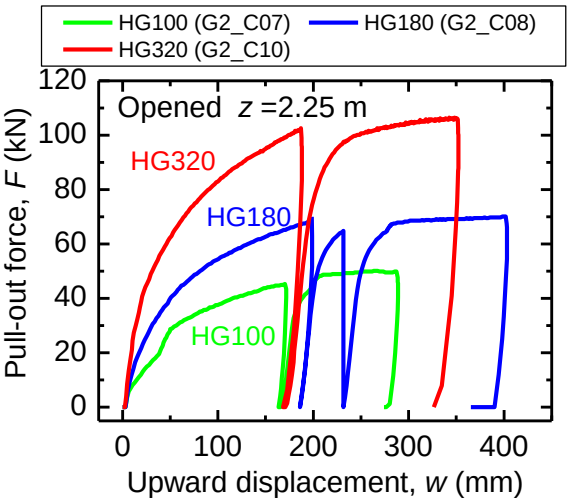

Fig. 12 Pull-out force versus displacement of each opened anchor buried at *z* = 2.25 m.

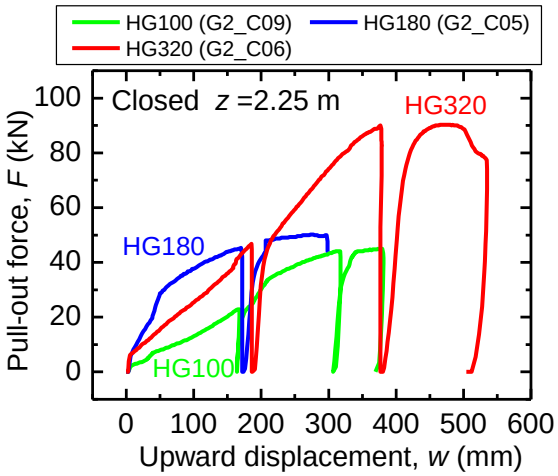

Fig. 13 Pull-out force versus displacement of each closed anchor buried at z = 2.25 m.

Figure 14 shows comparison of F versus w of opened HG100 anchor buried at different depths. As expected, the anchors got larger pull-out force when they were installed deeper in the ground.

Figure 15 is the relationship of maximum pull-out force, F_{max}, and embedment depth, z. F_{max} gets larger as the anchor size becomes larger at any depth.

Figure 16 shows the maximum pull-out stress, $p_{max} = F_{max}/A$, acting on each size of anchor at each depth. Contrary to the tendency of the maximum pull-out force, p_{max} becomes smaller as the anchor size becomes larger.

Figures 17 and 18 compare F versus w of flip anchors with opened and closed head conditions. It can be seen that although the stiffness ($\Delta F/\Delta w$) of the closed anchors are smaller than those of the opened anchors, the maximum pull-out forces of the closed anchors attain to about 80% of those of the opened anchors in both cases.

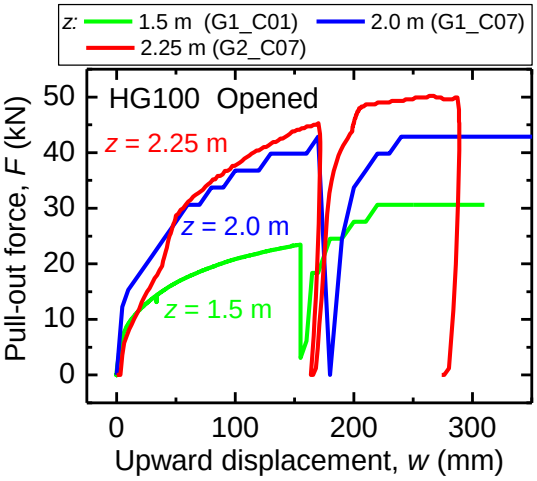

Fig. 14 Pull-out force versus displacement of opened HG100 anchor buried at different depths.

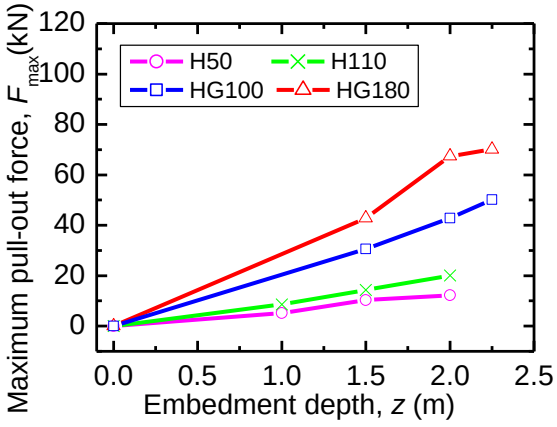

Fig. 15 Maximum pull-out force versus embedment depth of each anchor.

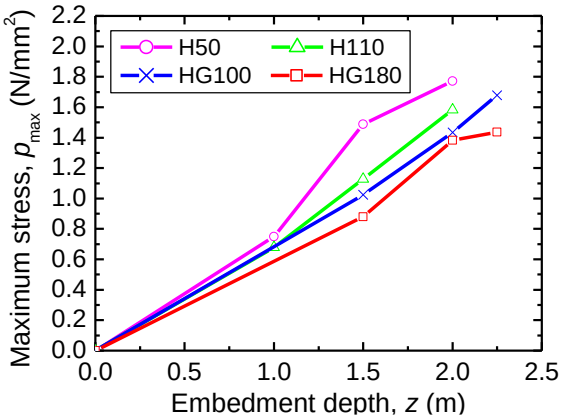

Fig. 16 Maximum pull-out stress of each anchor.

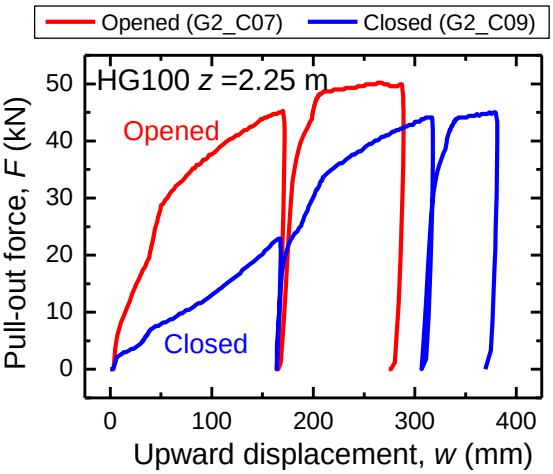

Fig. 17 Pull-out force versus displacement of opened and closed HG100 anchors buried at z = 2.25 m.

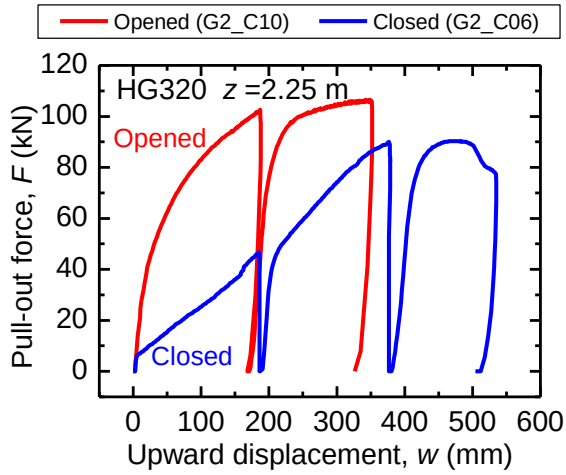

Fig. 18 Pull-out force versus displacement of opened and closed HG320 anchors buried at z = 2.25 m.

Figures 19 compares F versus w of opened and driven H50 anchors. Figure 20 is similar comparison for H110 anchor. Except for the early stage of loading, the stiffness of the driven anchors are comparable to that of the opened anchors, and the maximum pull-out force of the driven anchors attains to about 80% of that of the opened anchors.

In practical installation process, anchors are normally driven into the ground, not buried in advance. Therefore, how close the F_{max} of driven anchors approaches to the F_{max} of opened anchors, which is regarded as ideal values, is the most important concern in design of the flip anchors.

From these results, design values for F_{max} of the driven flip anchors could be around 80% of the ideal F_{max} of the corresponding opened anchors.

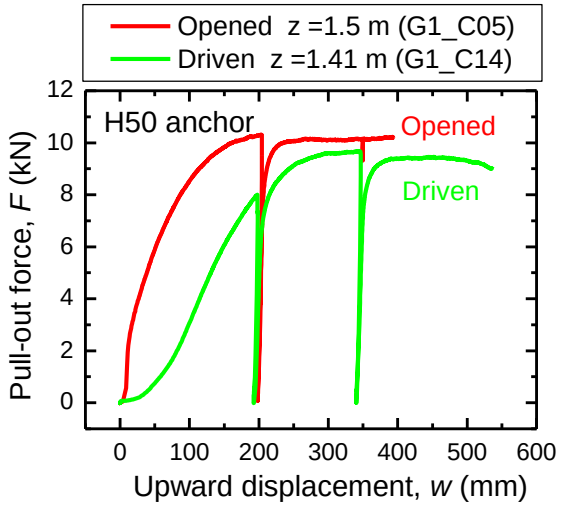

Fig. 19 Pull-out force versus displacement of opened and driven H50 anchors (z = 1.5 m and 1.41 m).

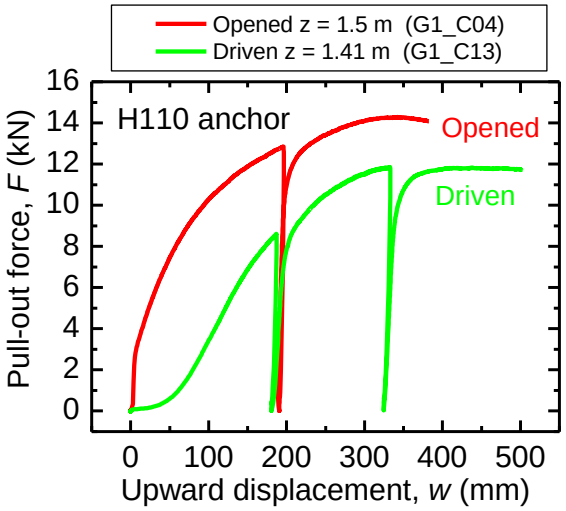

Fig. 20 Pull-out force versus displacement of opened and driven H110 anchors (z = 1.5 m and 1.41 m).

CONCLUSIONS

Pull-out experiments of flip-type anchors in sand ground in a field were carried out in this study. Main experimental parameters were embedment depth, anchor size, anchor head condition (opened or closed), installation method (buried or driven).

The maximum pull-out force, F_{max}, of buried opened anchor increases as the anchor size increases. Contrary to the tendency of F_{max}, the pressure, p_{max} (= F_{max}/A), becomes smaller as the anchor size becomes larger. So installing multiple smaller anchors is more effective than installing one big anchor.

Interestingly, stiffness ($\Delta F/\Delta w$) of buried closed anchors and driven anchors is smaller than that of buried opened anchors, but F_{max} of buried closed anchors and driven anchors attains to about 80% of F_{max} of buried opened anchors.

FINITE DIFFERENCE APPROXIMATION FOR SOLVING TRANSIENT HEAT CONDUCTION EQUATION OF THE BRICK

Dalal Adnan Maturi [1]

[1]Departement of Mathematics, Faculty of Science, King Abdulaziz University, P.O.Box 42664,Jeddah 21551, Saudi Arabia

ABSTRACT

In this paper, we studied the numerical approximation of transient heat conduction equation of the brick .Brick is a natural building material used in construction, usually shaped in parallel, made of clay, sand and water, with a small amount of hay (crushed and soft straw) added to the clay block before cutting bricks to dry it under the sun. The bricks are strongly resistant and are not easily affected by weather. We applied the Finite differences method to the thermal conductivity equation for bricks. The technique is described and illustrated with a numerical example. The obtained solutions are compared with the available exact solutions and the solutions obtained by Finite difference method Results showed that Finite difference method is a very promising method for obtaining approximate solutions to transient heat conduction equation of the brick. As evidenced by numerical results obtained from brick in resistance to external factors such as rain, air, sounds and others.

Keywords: Finite Difference Method,Transient Heat Conduction Equation, Brick, Matlab.

INTRODUCTION

Finite difference method is one of several techniques for obtaining numerical solution of partial differential equation. Finite difference method describe functions as discrete values across a grid and approximate their derivatives as differences between points on the grid. Knowing a little about how difference methods are formulated and in what regimes they are stable can help save a lot of time, both in the design of finite differencing algorithms, and in the time that they take to run, the finite difference approximations for derivatives are one of the simplest and of the oldest methods to solve differential equations.

We need a fast, realistic and reliable method to solve the heat conduction equation of the Brick.

Advantages of using clay brick:

• very lite:

Its weights are 40-55% less than other building materials, which reduces loads on concrete foundations for construction.

• Heatproof:

It consists of thermal insulating materials more than any other materials, which saves 40% of the electrical energy.

• High pressure:

It has a high pressure equivalent to three times the other building materials. It is used to build the bearing walls without columns.

• Fire resistance:

It is incinerated in ovens with a temperature of more than 1000 ° C, which gives immunity against fire and reduce its spread in buildings and facilities.

Resists moisture leakage:

It has a low water absorption rate of not more than 12% which prevents moisture leakage.

• Soundproof:

Features a high rate of sound absorption.

• Ease of work:

Helps in the ease of construction and electrical wiring and plumbing for light weight and the presence of spaces.

• Low maintenance costs:

Free of salt, which increases its age, prevents corrosion and maintains its color and shape and does not require maintenance.

FINITE DIFFRENCE METHOD FOR HEAT CONDUCTION EQUATION

The linear second order partial differential equation

$$Au_{xx} + 2Bu_{xy} + Cu_{yy} + Du_x + Eu_y + Fu + G = 0$$

as a parabolic equation if $B^2 - AC = 0$. A parabolic equation holds in an open domain or in a semi-open domain.

The partial differential equation governing the flow of heat in the rod is given by the

parabolic equation

$$\boldsymbol{u_t = c^2 u_{xx},\ \ 0 \le x \le l,\qquad t > 0.}$$

Where $\boldsymbol{c^2}$ is a constant and depends on the material properties of the rod.

The heat conduction equation of the Brick

$$\boldsymbol{u_t = (0.0038)u_{xx}}$$
$$\boldsymbol{u(0,t) = u(1,t) = 0, \forall t \in (0, t_F)}$$
$$\boldsymbol{u(x,0) = u_0(x),\quad \forall x \in [0,1],}$$

Where t_F Denotes the terminal time for the model. Here without loss of generality, we assume that the spatial domain is $[0, 1]$.
At first divide the physical domain $(0, t_F) \times (0, 1)$ by $N \times J$ uniform grid points

$$t_n = n\Delta t, \Delta t = \frac{t_F}{N}, n = 0, 1, \cdots, N,$$
$$x_j = j\Delta x, \Delta x = \frac{1}{J}, j = 0, 1, \cdots, J.$$

Then, we denote the approximate solution $u_j^n \approx u(x_j, t_n)$ .At an arbitrary point (x_j, t_n) . To obtain afinite difference scheme, we need to approximate the derivatives in (1) by some finite differences. (Explicit scheme)
Substituting

$$u_t(x_j, t_n) \approx (u_j^n - u_j^{n-1})/\Delta t,$$
$$u_{xx}(x_j, t_n) \approx (u_{j+1}^n - 2u_j^n + u_{j-1}^n)/(\Delta x)^2,$$

Into (1), another difference scheme for (1) can be constructed as:

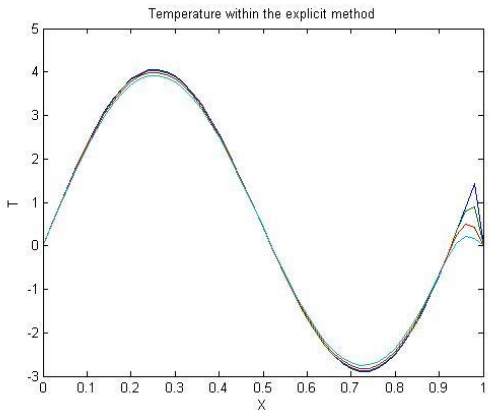
$$\frac{u_j^n - u_j^{n-1}}{\Delta t} = \frac{u_{j+1}^n - 2u_j^n + u_{j-1}^n}{(\Delta x)^2}, \quad 1 \le j \le J-1, 1 \le n \le N.$$

SEVERALS EXAMPLES

(i) Example1. Find the solution of the heat conduction equation of the Brick

$$u_t = (0.0038)u_{xx} \quad 0 < x < 1, \quad t > 0;$$
$$u(0, t) = u(1, t) = 0, \quad t > 0;$$
$$u(x, 0) = 2\sin(\pi x/2) - \sin \pi x + 4 \sin 2\pi x, \quad 0 \le x \le 1.$$

Applying the finite difference method using Matlab, then the result show as follows.



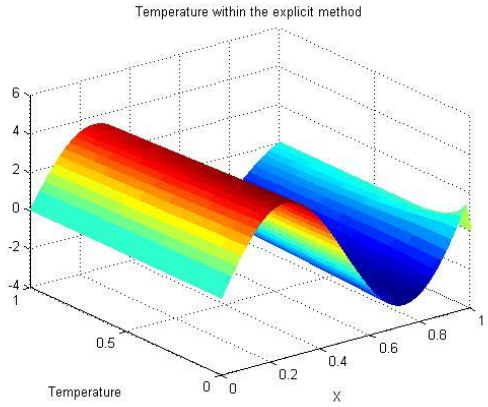


Fig.1 Temperature distributions at several times for the heat conduction of the Brick for example 1.

(ii) Example2. Find the solution of the heat conduction equation of the Brick

$$u_t = (0.011)u_{xx} \quad 0 < x < 1, \quad t > 0;$$
$$u(0, t) = u(1, t) = 0, \quad t > 0;$$
$$u(x, 0) = \sin \pi x, \quad 0 \le x \le 1.$$

Applying the finite difference method using Matlab, then the result show as follows.

CONCLUSION

In this paper, the calculations were performed by the MATLAB program for the programming and the corresponding evolutionary laws on the basis of the one-dimensional mathematical model of one-dimensional thermal conductivity using the Finite differences method of solving the heat-conduction equation for the bricks. All the examples show that the finite difference method is a powerful mathematical tool to solve the heat conduction equation for bricks. The graphic shapes we have provided to determine the higher resolution and simplicity of the proposed method. In addition, it should be noted that the method described can be easily circulated to build more heat for different materials. This work focuses on bricks because it is resistant to high temperatures, friction and various chemical effects. It is used in the construction of heaters and lining furnaces used in the iron and steel industry in the iron and steel industry and the non-ferrous industries such as copper, zinc and lead in the manufacture of cement, lime and glass.

POST-FIRE BEHAVIOUR OF CONCRETE-FILLED STEEL CIRCULAR TUBE COLUMNS UNDER AXIAL COMPRESSION

Kamonwan Prathumwong[1], Jaksada Thumrongvut[2*] and Cherdsak Suksiripattanapong[3]
[1,2,3] Department of Civil Engineering, Faculty of Engineering and Architecture,

ABSTRACT

This paper presents experimental studies on the post-fire behavior of concrete-filled steel tube (CSFT) columns under axial compression. The structural responses and axial load capacity of CSFT columns after exposure to elevated temperatures are investigated and discussed. All of the specimens are 750 mm in height, the nominal diameter of the circular columns is 150 mm, and have compressive strength of 18 MPa. The primary test parameters are wall thicknesses of the circular tubular (3.0 mm, 4.5 mm and 6.0 mm) and three different exposure to elevated temperatures (400°C, 600°C and 800°C). The results of these tests showed that the load-axial shortening relationship of the CSFT columns have a linear elastic response up to 80-90% of axial load capacity. After the axial load capacity is reached, the load-axial shortening curves are rarely becoming a nonlinear manner. The failure mechanism of CSFT columns is local buckling of the steel tubular walls and compressive crushing of the concrete core. It is also shown that the axial load capacity and ductility of the post-fire test columns are decreased significantly compared to the columns at ambient temperature, depending mainly on the elevated temperature and wall thickness of steel tubular. In addition, by comparing the axial load capacity of the experimental results with those obtained from the ACI design equation, the comparison results indicate that calculation formula in ACI code unconservative predicts the axial load capacity of the CSFT columns after exposure to elevated temperatures. Finally, the residual strength ratios are modified to both strength of concrete and steel tube under ambient temperature, and analyzed to evaluate the effect of post-fire behavior on the axial capacity of CFST columns.

Keywords: Concrete-filled tube columns, Circular tube, Axial compression, Post-fire behavior, Elevated temperature

1. INTRODUCTION

Concrete-filled steel tube (CFST) column is a type of composite columns in which the combined action of concrete and cold-formed steel circular and rectangular tubes leads to an exceptional structural behavior [1]. The axial load capacity of the CFST column increases due to the passive confinement that the steel tube generates on the concrete core [2]. Meanwhile, the local buckling failure of the steel tube is restrained by the concrete core which prevents it from suffering this phenomenon inwards. This fact reveals that the concrete retards the wall buckling and temperature rise of steel tube, and considerably enhances seismic resistance and inelastic deformation capacity in compression and combined loads [3]. Also, CFST members have many advantageous features at ambient temperature for structural applications, such as high stiffness and ductility, large energy absorption for earthquake-resistant properties, excellent fire resistance behavior without external prevention, the axial capacity of the CFST column is more than that achieved by reinforced (RC) columns with similar cross-section size, and reduced cost and time management in construction because formworks are not necessary for the construction process [4-11].

Over the last 20 years, the research and development on the mechanical behavior of CFST columns have advanced considerably in several countries [12]. Many research investigations have been conducted to study the structural response of CFST structural members under axial compression and flexure at the ambient temperature [13-20]. However, some attention has been reported on the fire behavior and performance of CFST columns or their residual properties after exposure to elevated temperatures [21-22]. Ordinarily, a deterioration in the properties of CFST columns occurs when it exposed to fire. In addition, the CFST members are loss in strength and ductility of the steel tube, reduction of compressive strength and modulus of the concrete core [23]. At elevated temperatures in case of fire, the assessment of CFST columns is much more complicated comparing to ambient temperature. Also, in order to create further confidence in the CFST columns after exposure to high temperatures, it is necessary to enhance knowledge of structural responses, particularly the post-fire behavior of CSFT columns subjected to axial compression. Consequently, this research aims to present the experimental results on post-fire behavior of CSFT columns, and to evaluate the axial load capacity of

test members after exposure to elevated temperatures. Eventually, comparisons with the prediction of axial load capacity by using ACI code provisions with consideration effect of residual strength of materials are also performed.

2. EXPERIMENTAL PROGRAM

2.1 Specimen Configuration

A total of 24 columns were prepared in the Department of Civil Engineering at Rajamangala University of Technology Isan. All circular columns had a height of 750 mm, the nominal diameter of the circular columns was 150 mm. The average 28-day compressive strength of concrete was 18 MPa. The main parameters were the wall thicknesses of the circular tube (3.0 mm, 4.5 mm and 6.0 mm) and three different temperatures. The maximum temperatures were 25°C, 400°C, 600°C and 800°C, respectively. The temperature of 25°C denoted the ambient temperature. Two specimens of each set were tested to determine the average axial load capacity. A summary of the nominal dimensions of CFST columns under different temperatures is presented in Table 1. The CFST columns were classified into 3 groups with thicknesses of steel tubular.

Table 1 Summary of test information

Specimen	t (mm)	D (mm)	L (mm)	T (°C)	D/t	Concrete		Steel Tube	
						A_c (mm^2)	f_c' (MPa)	A_{st} (mm^2)	f_y (MPa)

C18-6.0-600	6.0	150	750	600	25.0	18,942	18.2	3,001	366.7
C18-6.0-800	6.0	150	750	800	25.0	18,942	18.2	3,001	366.7

Each CSFT column is labeled according to its 28-days compressive strength of cylinder concrete, thickness of the steel tube and maximum heating temperature, respectively. For example, consider column C18-3.0-600; C represents the circular CSFT column, 18 is the compressive strength in MPa, 3.0 is the thickness of the steel tube in millimeter and 600 is the maximum heating temperature in Celsius. Also, the average mechanical properties of the compressive strength concrete at the age of 28 days and steel tube were performed according to ASTM procedures, and given in Table 1.

2.2 Fire Exposure and Test Setup

In the fire exposure process, heat treatment of CSFT columns was performed using the gas furnace at the Department of Ceramic Design in Rajamangala University of Technology Isan. The specimens were moved into position inside the furnace, as presented in Figure 1. Eight gas burners were set up in the furnace chamber and it can be adjusted individually to generate a uniform temperature. Dual thermocouples were fixed to the lower and upper inner furnace and were used to observe the furnace temperature. A heating rate was set at 10°C/min [24]. The furnace temperature was uniform increased to a target temperature (400°C, 600°C and 800°C). After the furnace temperature reached the target temperature, the furnace was maintained at a constant temperature phase for 3 hours to ensure that the CFST columns were heated equally and obtain a stable residual strength [25]. Then, the furnace was turned off and natural air cooling was used to cool down until ambient temperature.

Fig. 1 Exposure to elevated temperatures of column

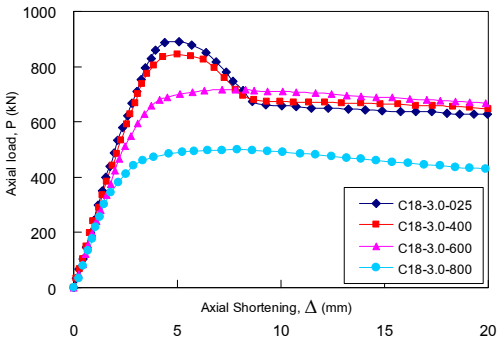
The CFST columns were tested under an axial compression load. A 2,000 kN capacity Universal Testing Machine (UTM) with displacement control was used to apply the compressive load monotonically until failure. The load arrangement and test setup can be seen in Figure 2. The column was set up in a vertical position and the steel bearing plates were placed between the column and the top and bottom crosshead of the UTM. Two linear variable differential transducers (LVDT) were used to monitor overall axial shortening. Before the beginning of each test, a preload of approximately 20% of the predicted axial load capacity of the columns was applied in order to reduce the friction between the steel bearing plates and the columns, and to balance the uneven top and bottom surfaces. The specimens were loaded at a very slow rate, was increased at a constant rate up to axial load capacity, such that the axial load, the axial shortening of the columns were automatically recorded by a KYOWA EDX-10 Series data acquisition unit. Additionally, the local tube wall buckling and the axial load capacity were carefully observed.

Fig. 2 Post-fire test of CFST member

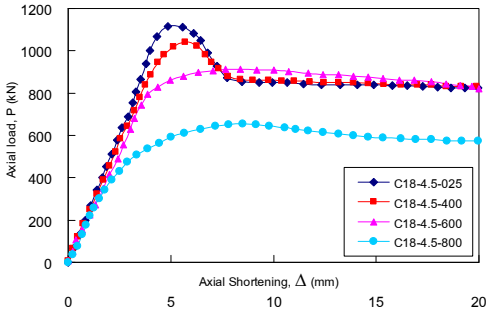
3. TEST RESULTS AND DISCUSSIONS

3.1 Behavior Curves and Failure Mode

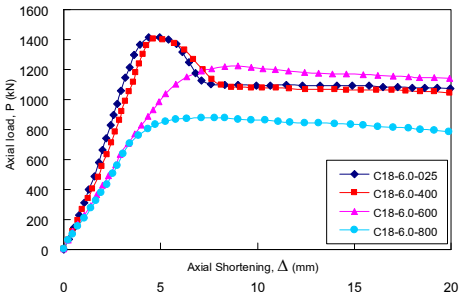
The term “short column” refers to a compression member which can attain its axial load capacity, known as the squash loads (P_{Test}), without buckling of the columns. The typical structural behavior of the tested CFST column at ambient temperature and after different elevated temperatures are obtained in Figure 3 by relations between the axial load and axial shortening. It can be seen that the CFST column at ambient temperature and after exposure to elevated temperatures showed a linear elastic behavior up to 80-90% of their axial load capacity. After that, as the load continued to increase and reached the ultimate load, the curves are gradually becoming nonlinear due to the start of the cracking of the concrete underneath the applied load and the local yielding of the steel tube [12].



(a) t = 3.0 mm



(b) t = 4.5 mm



(c) t = 6.0 mm

Fig. 3 Axial load-axial shortening curves of columns after exposure to elevated temperatures

According to the test results, the axial load-axial shortening curves of the CFST columns heated to 400°C are similar to the those CFST columns at ambient temperature (25°C). Thus, it is evident that there is no obvious deterioration of the mechanical properties of CFST columns at 400°C. In contrast, when the temperature increased to 600°C and 800°C, the ascending and descending line stages of the axial load-axial shortening curves became much less distinct, and the axial load capacity also decreased. This result is similar to that reported in previous research on the strength development of recycled

aggregate CFST stub columns [24]. Figure 4 shows a typical failure mode of the HSCFT column. The failure mechanism of the columns was identified as the crushing of concrete core and the yielding of steel tube. This indicates that the concrete core in these locations was contained by the steel tube, in turn providing large axial deformability to the columns [2].

Fig. 4 Failure modes of CFST columns after different elevated temperatures

3.2 Residual axial load capacity and comparison ACI

3.2.1 Residual strength of concrete

When concrete is exposed to an extreme heat sources, the physical and chemical responses occur at elevated temperatures, for instance, dehydration of cement paste, loss of moisture [26]. Figure 5 represents the residual strength ratio of normal strength concrete (ϕ_c) as a function of the elevated temperatures [27].

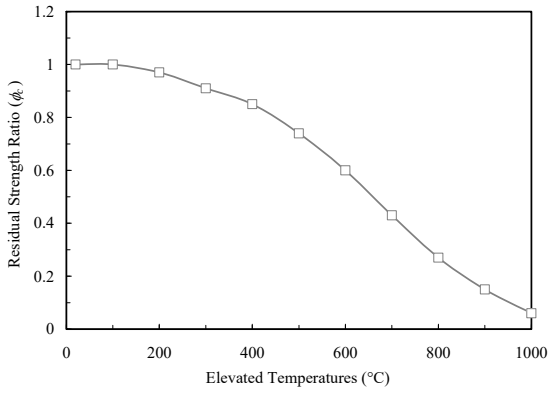


Fig. 5 Residual strength ratio versus elevated temperatures curve of concrete [27]

3.2.2 Residual strength of steel

In general, the residual strength ratio of steel after elevated temperatures can be estimated. The steel recovers most of its strength and stiffness natural air cooling [28]. Nevertheless, the higher elevated temperatures achieved in steel, the residual strength of steel is reduced, especially when the elevated temperatures in steel exceeds 500°C [29]. In this study, the residual strength ratio of steel is assumed to follow the test data reported by Neves *et al*. [28]. Figure 6 shows a residual strength ratio versus elevated temperatures curve of steel.

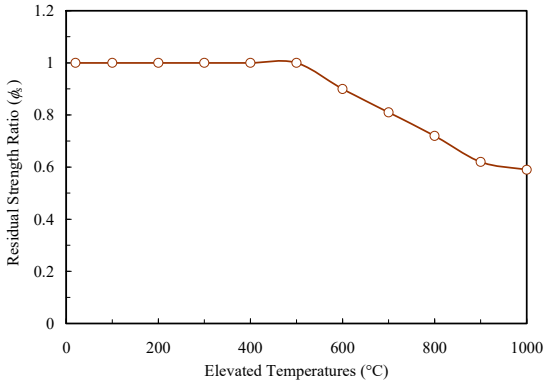

Fig. 6 Residual strength ratio versus elevated temperatures curve of steel [28]

3.2.3 Residual axial load capacity of CFST column

In the proposed approach, a simplified equation to assess the residual axial load capacity of post-fire CFST column is presented. The residual axial load capacity of CFST columns after exposure to elevated temperatures could be evaluated by using the composite design equation under ambient conditions, as recommended in the ACI code [30]. The residual strength ratio of concrete and steel will be multiplied by the strength of concrete and steel under ambient temperature, respectively. Consequently, the residual axial load capacity of CFST columns after exposure to elevated temperatures is given by:

$$P_u = \phi_c 0.85 f_c' A_c + \phi_s f_y A_s \quad (1)$$

where P_u is defined as the residual axial load capacity of CFST columns after exposure to elevated temperatures, ϕ_c is the residual strength ratio of concrete and ϕ_s is the residual strength ratio of steel tube.

From the analytical results, the comparison of residual axial load capacity of CFST columns between the test values and the modified the ACI design equation are presented in Table 2. The

comparison of results shows that modified ACI design equation closely predicts with a difference of 2-5%. This indicates that the modified ACI design equation with residual strength ratio can adequately predict the axial load capacity of the CFST columns after exposure to elevated temperatures.

Table 2 Comparison of the residual load capacity obtained from test and modified ACI Eq.

Specimen	P_{Test}	P_u	P_{Test} / P_u

C18-6.0-800	885.7	848.6	1.04

CONCLUSIONS

The conclusions from the experimental studies are summarized as follows.

1) The structural performance of CFST columns after exposure to elevated temperatures have a linear elastic behavior up to 80-90% of their axial load capacity. Then, the behavior of the columns is gradually becoming nonlinear with the strain-softening type. Failure mechanism of the CFST columns are identified as the crushing of concrete core and the localized buckling of steel tube.

2) There is no obvious deterioration of the mechanical properties of CFST columns at 400°C. In contrast, when the temperature increased to 600°C and 800°C, the ascending and descending line stages of the axial load-axial shortening curves became much less distinct, and the axial load capacity also decreased.

3) Good agreement is evaluated between the predicted residual load capacity using the modified ACI design equation and the experimental results.

EXPERIMENTAL STUDY ON INFILLING BEHAVIOR OF PLASTOC GROUT IN VOIDS WITH CHANGING HEIGHT

Hiroyasu Ishii[1]
[1]Technology Center, Taisei Corporation, Japan

ABSTRACT

The most effective measure to deal with underground voids is infilling with an engineering material; fluidized cement mixtures have been widely used due to easiness of placing, i.e. just pumping out to allow gravitational flow in voids. However, the mixtures spread mainly downwards in voids; they may spread to unintentional directions or spill out to adjoining land before infilling up in target areas. Then another engineering material, plastic grout, may contribute to improve work efficiency and infilling quality. Due to its characteristics in fresh state, plastic grout spread in voids under infilling pressure, and stay in place when infilling is stopped. In this paper, the author raises an attention to actual infilling behavior of plastic grout affected by change of void heights and shows simplified infilling tests with four model voids having 7.8 m in length, 0.3 m in width and 0.25 to 0.15 m in height. Each infilling was conducted from center of the model and allowed to spread in two directions along the length. It was experimentally demonstrated that; i) grout spreads uniformly in two directions when void height is uniform, ii) grout spreads more in direction with larger heights of voids. Also, the author proposed a simple estimation method to predict the infilling volume in each direction, and the validity of the method was confirmed by comparing with the testing results.

INTRODUCTION

Underground voids, created by human activity or natural phenomena, may cause land cave-ins or collapses at surrounding surface that may result in hampering construction activities or damage nearby structures. Underlying voids are also created beneath structures intentionally in some construction works as a part of efficient work processes.

In both the above cases, the most effective and popular measure to deal with voids is infilling with an engineering material; fluidized cement mixtures have been widely used due to easiness of placing; we may just pump it out to allow gravitational flow in voids [1], [2], [3]. However, the mixtures spread mainly downwards in voids; they may spread to unintentional directions or spill out to adjoining before infilling up in target areas.

Then another engineering material, plastic grout, may contribute to improve work efficiency and infilling quality in place of fluidized cement mixtures. Due to its characteristics in fresh state, plastic grout spreads in voids with infilling pressure, and stay in place when infilling is stopped even though gravitational force may work. Taking advantage of these characteristics, plastic grout have been already applied to some practices [4], [5], [6].

In case of practical application of plastic grout for void filling, execution details such as positioning of supply pipes, volumes from each supply pipe, order of infilling etc. have to be planned to complete the work effectively and efficiently. It is important that plastic grout behavior during infilling process should be well estimated in advance and reflected to the execution plans. For this purpose, numerical simulation based on fluid mechanics may be one of effective tools for this purpose and the author already conducted some applicability studies by dealing experimental results as verification data [7]. In mean time, it is clear that simple methods to estimate reaches of plastic grout under certain conditions can also be helpful for parametrical studies in practice.

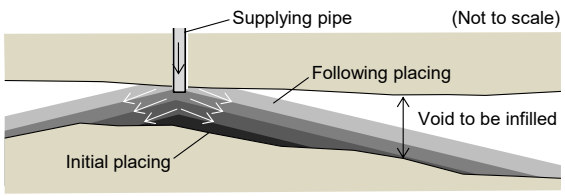
The present study aims to clarify engineering properties of plastic grout and to contribute to better achievement for infilling works. In this paper, a focus is put to basic infilling behavior of plastic grout in a simplified model considering changes of void heights. Firstly, two engineering materials, namely fluidized cement mixture and plastic grout, are reviewed. Secondly, four infilling model tests using plastic grout are explained. Finally, the tests results are shown and discussed to propose a simple estimation method to predict reaches of the plastic grout observed in the simplified model tests.

EINGINEERING MATERIALS FOR VOILDS FILLING

Fluidized cement mixture

A fluidized soil-cement mixture normally consists of surplus soils, water and cement with which mix

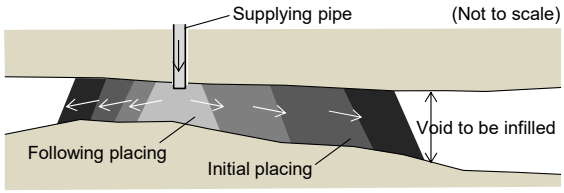
(a) Spread in table flow test (*C.F.* = 200 mm)



(b) Schematic behavior in sectional view

Fig. 1 Characteristics of fluidized cement mixture.

(a) Spread in table flow test (*C.F.* = 120 mm)



(b) Schematic behavior in sectional view

Fig. 2 Characteristics of plastic grout.

proportion is designed to secure fluidity as well as to prevent material segregation (see Fig.1(a)).

Fluidity is normally confirmed by cylinder flow tests in which i) sample is prepared in casing with the diameter and the height of 80 mm set on a flat plate, ii) then the casing is vertically lifted up to allow sample to spread in circle on the plate, iii) diameters of sample are measured in two directions and iv) a cylinder flow index (*C.F.*) is identified by averaging. Typical range of *C.F.* for fluidized soil cement mixtures are 180~300 mm to secure good flowability.

When it is utilized for void filling, fluidized cement mixture is normally dumped in place, or supplied through supplying pipes. Then, it gravitationally flows to cover wider area of subjected voids as depicted in Fig 1(b). While this contributes better work efficiency, there are some demerits of fluidized cement mixtures under certain construction conditions, as described in the followings:

- Due to gravitational flow, fluidized cement mix flows downwards; it may spread to unintentional directions or spill out to adjoining land before infilling up in target areas.
- After placing, fluidized cement mix gets solidified in conical shape with flow angle. It is usually 3~10%, which creates unfilled space immediately below void ceiling.

Plastic grout

A typical plastic grout consists of cement, water and plastic agents, such as a sodium silicate or clay minerals. Such grouts have recently been used in construction works as an effective method for infilling in place of fluidized cement mixtures. As shown in Fig. 2(a), typical *C.F.* of plastic grout is 80–120 mm in contrast with 180 mm or more for conventional flowable mixtures. As illustrated in Fig. 2(b), the plastic grout is pushed forward by the following mass when injected into voids, which is different from flow behaviors seen with conventional gravitational placement. As a result, the voids can be filled to full height with a lower probability of leaving major voids.

Plastic grout is first prepared in separate solutions, namely cement solution and plastic solution. These are pumped separately from batching plant to infilling work places, then mixed together in line type mixers immediately before infilling. This procedure enables delivery of the solutions by pipes over a long-distance and suggests us a major advantage in comparison with fluidized cement mixtures.

During maturing period after infilling, plastic grout hardens with the help of cement hydration to reach an unconfined compressive strength of approximately 1 MN/m^2 or more according to mix design.

Void filling behavior of plastic grout

While the above merit of plastic grout during infilling work, the author points out a particular infilling behavior to which a certain attention needs to be paid during practical application. As depicted in Fig.2 (b), plastic grout tends to extent infilling areas where void height is relatively large. This highlights

an importance of proper execution plans for infilling works which requires a number of supply pipes to cover infilling areas. It is inferred that improper plane arrangement of supply pipes and wrong order of placing work may leave some areas not to be infilled. This leads us to recognize importance of knowledge about actual behavior of plastic grout subjected to infilling works.

METHODOLOGY OF INFILLING TEST

Outline

The aim of the present model testing is to clarify basic behaviors of plastic grout when implemented for simplified model voids with changing height. The results are also referred to for verification of a simple calculation method to predict the reaches of plastic grout in the simplified model voids.

Considering simplicity of testing conditions and easiness of preparation, model voids were prepared in commercially available U shape drain concreates as shown in Fig.3 and 4. 13 drain concretes were connected in line to create a space with 7,800 mm in length, 300 mm in width and 300 mm in height. Infilling was conducted from center of the model, and allowed plastic grout to spread in both right and left side along the length.

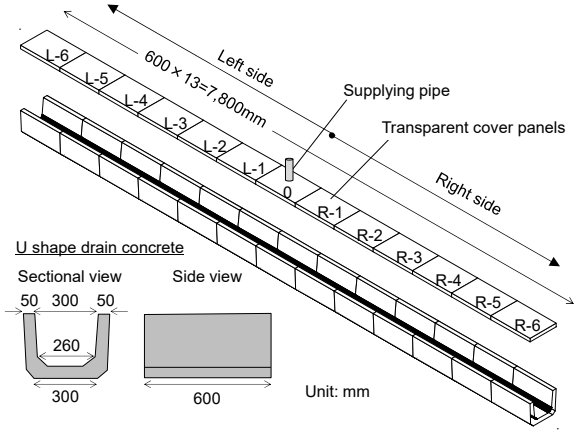


Fig. 3 Model void fabricated using 13 U shape drain concretes.

Fig. 4 Model void preparation

Testing conditions and procedure

Four model voids, as illustrated in Fig. 5, were prepared. Case 1 has a uniform height, Case 2 and 4 have shrinking heights and Case 3 has an enlarging height, respectively. By laying the 10~25 mm size gravel on the bottom of U shape drain concretes, the heights of the void were changed from 150 to 250 mm. While the first case was to observe balanced reaches in both the sides, the other cases let grout reaches more in the right or left side. Accordingly, the positions of the infilling pipe was set on the center

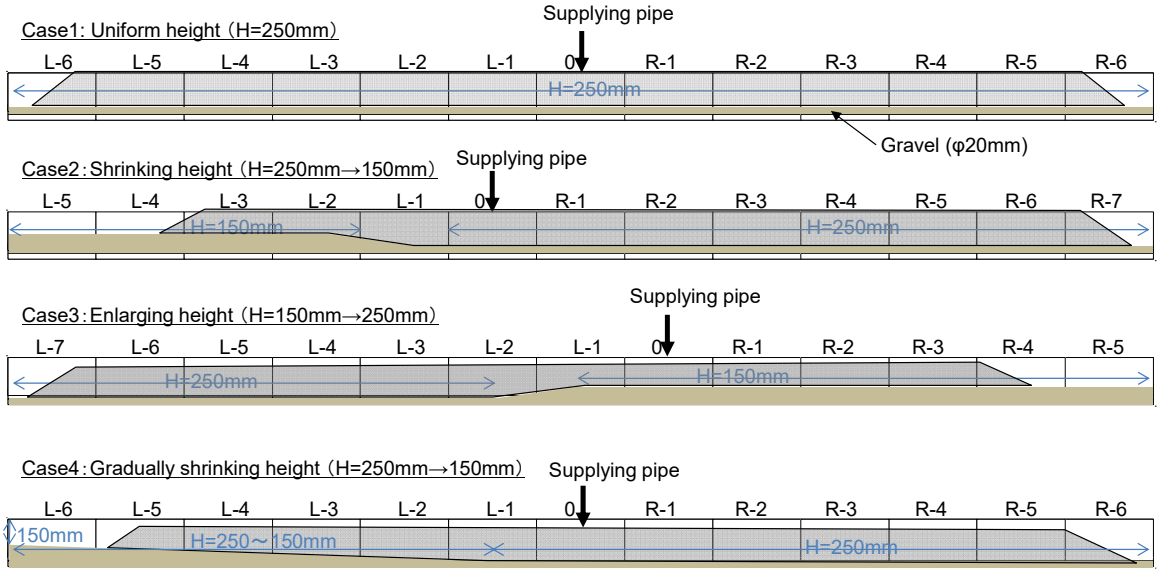

Fig. 5 Sectional view of model voids.

Table 1 Mix proportion of plastic grout used for filling tests (per 1,000L)

Solutions	Materials	Mix description	
A	Cement	320kg	390L
	Solution B	60L	
	Retarder	2L	
	Water	226L	
B	Bentonite	47kg	590L
	Water	571kg	
C	Sodium silicate	20L	

Measured properties:
C.F. = 130-145mm
Vane shear resistance = approximately 200N/m^2
(measured by miniature vane shear apparatus)

unit or neighboring ones according to each condition.

Table 1 shows the mix proportion of plastic grout used for the tests. Among various mix proportions proposed by researchers and practitioners, the mix proportion in Table 1 has been proposed by the author in which two plastic agents, namely clay and chemical type, are utilized. The author recognizes that the simultaneous use of the plastic agents helps plastic properties in fresh state kept longer, contributing better applicability for large scale infilling works in which significant amount of plastic grout needs to be supplied from one infilling pipe.

While plastic grout is often used for infilling in submerged condition, the present tests were conducted without water to allow us to observe the behavior of plastic grout very clearly and easily. During the infilling with the rate of 120 L/min, the grout reaches were recorded by the following methods.

i) The area where the plastic grout reached were confirmed through the transparent cover panels and were marked directly with 2 minutes interval.
ii) Thermocouples placed on the bottom gravel monitored changes of temperature to confirm the arrival of grout by sensing sudden change of temperature.

Finally in each case, infilling was terminated when the plastic grout reached one end wall.

RESULTS AND DISCUSSION

Test results

Fig. 6 shows the plastic grout observed through the transparent cover panels. The area where the plastic grout closely contacted the transparent cover panels was easily identified and horizontal moves of the area were successfully recorded.

Fig. 7 shows the temperature changes recorded during Case 1. In this case, the atmospheric temperature, approximately 23 degrees Celsius, suddenly decreased to below 20 degrees Celsius which allow us to confirm arrival of plastic grout. Comparing the left and right-side results, the times of temperature change are almost simultaneous at the record points with same distance from the infilling

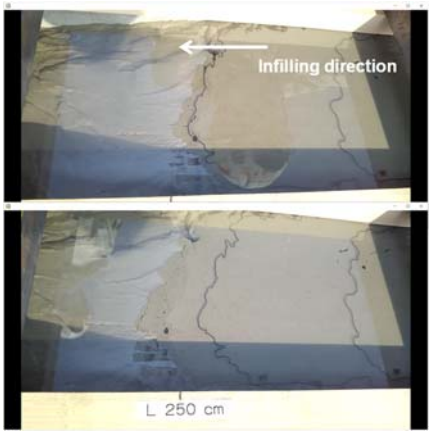

Fig. 6 Observation of grout spread through transparent cover panel (30 seconds gap between the top and bottom photos).

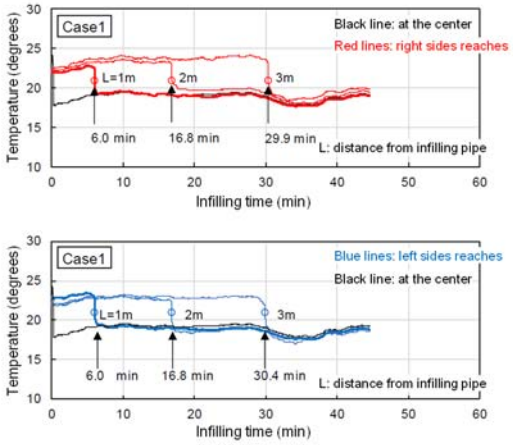

Fig. 7 Temperature changes recorded with thermocouples in Case 1.

Fig. 8 Plastic grout after test (left side of Case 1).

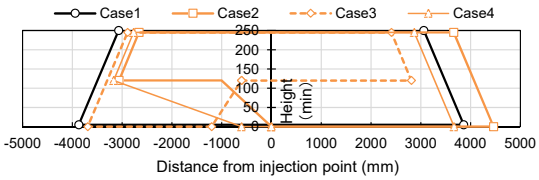

Fig. 9 Shapes of supplied plastic grout after tests.

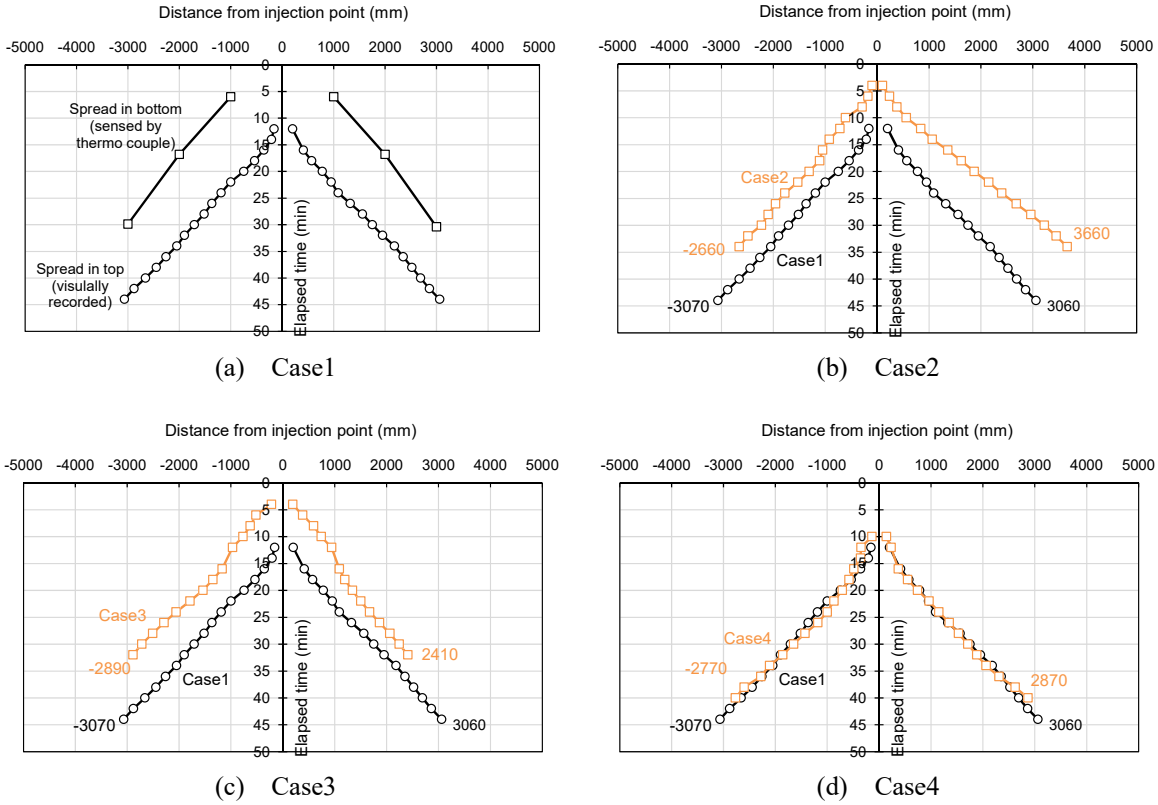

Fig. 10 Observed right/left side spread of plastic grout.

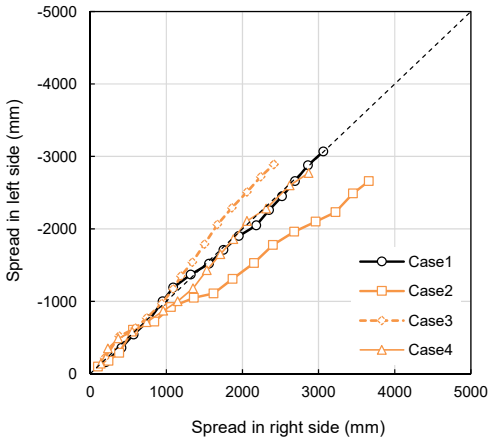

Fig. 11 Relationships between reaches in right and left side obtained from infilling tests.

pipe. This demonstrates that the plastic grout was equally spread in left/right side.

After each test, the transparent cover panels were removed to observe the reaches of the plastic grout as shown in Fig.8, and the observational results were summarized in Fig. 9. While left/right reaches in Case 1 are equal in length from the infilling pipe, the right side reaches in Case 2 ~ 4 are larger or smaller than the left ones.

To examine the filling process in more detail, the elapsed changes of reach which the plastic grout achieved are depicted in Fig. 10. Here, the result from Case 1 were compared in Fig. 10(a) with the estimation based on the temperature change sensed by thermocouples and other results of Cases 2~4 were compared in Fig.10(b)~(d) with those of Case 1. Consequently, relationships between reaches in left and right side were compared in Fig. 11. From these results, it is confirmed that:

- From the comparison between results of Case 1, it is confirmed that the gap of reaches in bottom and top tends to decrease. This infers that tip gradient of the plastic grout got steeper as the infilling proceeds.
- In Case 2 and 3, the infilling of plastic grout proceeded equally in left/right side till 10 minutes in Fig.10 (till approximately 800 mm reach in Fig. 11) and unequally afterwards. This demonstrates that changes of void height clearly affected the advance rate of the plastic grout reaches.
- In Case 4 where the void height gradually changes, the deference between left/right side reaches were not significant.

Simple estimation

Fig. 12 shows a schematic view of the simple calculation model to predict plastic grout reaches in left and right side. The basic principle is to identify the reaches so that each reach generates an equivalent pressure at the infilling pipe. Here, pressure distributions are calculated based on the following

assumption:

a) When a mass of plastic grout advances in void, shear resistance reacts on a surrounding area touching with void surface.
b) The magnitude of shear resistance is identified by shear resistance measured by miniature vane shear apparatus.
c) The amount of pressure generated in a calculation element (*dP*), is calculated as the shear resistance divided by the sectional area of the element.
d) A pressure distribution is calculated by integrating *dP* among the reach of plastic grout.

To estimate the present 4 cases, the differences of void height were referred to in calculations and relationships between left and right reaches were summarized in Fig.13. It is notified that the simple calculation reasonably represents the unbalanced reaches observed in the tests. Even though influence of gravity force should be considered especially in the cases when void foundation is inclined, the present simple model is expected to be utilized in practical works.

CONCLUDING REMARKS

Through the present test results and discussion, the following conclusions are obtained.

- By conducting a series of simplified infilling tests using U shape drains, the influence of changing heights of void on plastic grout reaches was successfully demonstrated.
- The proposed simple calculation model is effective to predict reaches of plastic grout observed in the tests.

The author recognizes that that the present study of the simple calculation is just the first step based on two directional advances of plastic grout. The extension of the model to multi-dimensional behavior is the next step of the research aiming at developing a tool for infilling works in practice.

ABSTRACT

Due to the negative environmental impacts of concrete production, several studies have explored other concrete materials, specifically plastic aggregates and fly ash. However, previous studies have focused on evaluating the alternative concrete for its strength properties and none for its performance during extreme events, such as a fire. Thus, this study sought to further validate the feasibility of alternative concrete by investigating its strength properties in conjunction with its post-fire performance. The concrete specimens were made by replacing sand with HDPE pellets by volume of fine aggregates, and cement with class F fly ash by weight of the binder. The parameters investigated were compressive strength (fc'), post-fire relative residual strength (RRS) and fire resistance rating (FRR). The compressive strength tests were done on cylindrical specimens at varying curing periods (7, 14, 28, and 120 days), while fire performance tests were done on specimens cured for 28 days. The specimens were fired on one surface in a small-scale furnace. The fired cubes were then tested for compressive strength to obtain the RRS. The results show that to have comparable or increased strength than conventional concrete. Using the optimization model, response surface method, the optimum mix was garnered. This study is a stepping stone towards acceptance of the alternative concrete in the Philippines.

Keywords: Plastic, Fly Ash, Fire, Post-Fire Performance, Philippines

INTRODUCTION

The Philippines is considered one of the developing countries and, currently, one of its priorities is to develop its infrastructure, thus, it is noticeable that more projects are being constructed. More construction project entails more concrete is being used. Concrete is among the widely used structural materials due to its versatile properties, however, it has a negative environmental impact due to the production of some of its components, such as cement. Cement production is energy-intensive and emission-intensive because of the amount of heat needed during manufacturing. Moreover, the production of a ton of cement requires 4.7 million BTU of energy or 400 pounds of coal, which has an effect on the environment [1].

Many studies have been conducted locally in the use of waste materials as a substitute for some of the construction materials [2-8], such as fly ash. An option towards more sustainable concrete production is replacing energy-intensive cement with supplementary cementitious materials (SCM) that are industrial by-products. Apart from economic and environmental benefits, SCMs enhance the strength and durability of concrete [9-11]. Being comprised of cement and aggregate, both of which containing inert materials, concrete is virtually non-combustible [12]. However, despite such attributes, concrete exposed to elevated temperatures still undergoes significant changes in its mechanical properties. Also, the inclusion of fly ash in the concrete mix can improve the performance of concrete at elevated temperatures or its fire performance [13].

Aside from fly ash, another way to make concrete more sustainable is by substituting natural aggregates with less energy-intensive and sustainable materials, such as plastic. Currently, a growing number of researches have examined the feasibility of using waste plastic in concrete. Different plastic types have been investigated for their feasibility as aggregate, fibre, or filler for concrete, including polyethylene terephthalate (PET), polyvinyl chloride (PVC), high density polyethylene (HDPE), low density polyethylene (LDPE), expanded polystyrene (EPS), glass-reinforced plastic (GRP), polycarbonate (PC), and polypropylene (PP) [14]. In this study, the focus is on using HDPE as fine aggregates. This is due to the limited number of studies on that type as compared to PET and EPS, as well as the vast usage of HDPE in the Philippines.

In light of these two approaches towards sustainable concrete material, the researchers recognized that there is a gap in the current studies. Most published literature on the use of HDPE as fine aggregates has dealt with testing the mechanical properties only. Little has been done to assess other properties.

Based on the 2015 Annual Accomplishment Report of the Bureau of Fire Protection, fire incidents

in the country increased from 15,879 to 17,138, where 8,501 were related to structural fires. Estimated property damage of 3.62 billion was reported in the same year. Additionally, in 2012, the annual worldwide economic and human costs of fire-related casualties were estimated to amount to billions of dollars due to damaged property. Though no recent fire has been classified as a disaster, fire makes structures dangerous to public welfare due to hazards posed by structural failure, which is caused by the weakening of its materials. This has led to numerous efforts such as emergency responses and disaster risk reduction, but these may still not be enough to reduce the unpredictable effects of fire. As such, the disastrous impact of fire on livelihood and properties poses the need to investigate the fire resistance of concrete as the structural material.

As one of the primary objectives, the study evaluated the fire-resistance rating of alternative concrete. With the intended use as non-load bearing exterior walls, the specimens were not loaded during fire testing and only one face was exposed to fire. To save on material while still enabling comparison with the standards, the fire-resistance rating was determined for an effective wall thickness of 50 mm only, which has a standard fire rating of 30 minutes [15].

The researchers sought to integrate the growing body of knowledge from the two approaches in promoting concrete's sustainability, with the ultimate goal of producing a structural material that maximizes the use of waste materials without compromising its fire resistivity and strength. Since the addition of fly ash has been proven to enhance the fire performance of conventional concrete, it was anticipated that it would improve the fire resistance of the alternative concrete, thus permitting a higher plastic percentage replacement while still having an acceptable fire resistance and strength.

By determining the fire-resistance rating and post-fire residual strength of the concrete, the researchers were able to assess the fire performance of the alternative concrete as compared to conventional concrete. This provided information on the effects of fire on the structural integrity of this alternative material. Since the risk of fire is inevitable in any structure, studying the fire performance of building materials is relevant in the present and the future. The investigation of these properties is valuable in ensuring the safety of occupants in concrete structures and progressing towards sustainable concrete production.

The results lay the groundwork for future studies that aim to improve the performance of the alternative material. These add to existing literature that investigated the feasibility of concrete with HDPE aggregates, and of using fly ash to improve fire performance. It served as a stepping stone towards accepting HDPE concrete as a building material, particularly in the Philippines where fire incidence is high. The goal of reducing plastic waste and the negative impacts of fire on structures was also fulfilled.

METHODOLOGY

The study dealt with the investigation of the strength performance of concrete with fly ash and recycled HDPE plastic aggregates through an experimental method of research. This was done by assessing the effect of varying amounts of substitution of fly ash and HDPE on the compressive strength of the concrete and fire performance.

There were 2 independent variables: the percentage of HDPE substitution and the percentage of fly ash substitution. The percentage of HDPE substitution were 0%, 5%, 10% and 15% by volume of fine aggregates. The level of substitution cannot be increased further due to the adverse effect of HDPE on the compressive strength of concrete.

Second, the percentage of fly ash substitution were 0%, 30%, and 60% by weight of the total binder. From past studies on concrete, fly ash was found to increase the residual strength of concrete at high levels of substitution – ranging from 20% to 60% by weight of the binder.

The main parameters that were investigated in this study were the compressive strength (fc'), post-fire relative residual strength (RRS), and the fire-resistance rating (FRR). Cylindrical specimen with 100 x 200-mm dimension were tested for compressive strength after curing for 7, 14, 21, 28, and 120 days. For the fire performance, 50-mm cube specimens that were cured for 28 days were tested for compressive strength, while a corresponding mix subjected to fire exposure was used to determine RRS and FRR. The results with and without fire exposure were compared to evaluate the relative strength loss. The specifications of the materials used are shown in Table 1.

With 2 independent mix design variables, fly ash and HDPE percent substitution, at 3 and 4 levels, respectively, giving a total of 12 types of mixes.

The preparation of the samples was divided into 3 batches based on the amount of fly ash substitution (0%, 30%, 60%). The concrete specimens were mixed and cast in accordance with ASTM C192 and ASTM C39 in the form of 100 x 200-mm cylindrical specimens and 50-mm cube specimens. After 24 hours of being cast, the specimens were removed from the molds and placed in a water bath at room temperature.

Compressive Strength

The cylindrical specimens were used to assess the compressive strength of the alternative concrete. Before placing in the cylindrical molds, the freshly mixed concrete was tested for the slump in

accordance with ASTM C143 and adjustments were made to achieve a workable concrete mix. The hardened concrete was tested for their compressive strength in accordance with ASTM C39, at different curing days, namely, 7, 14, 21, 28 and 120 days. The 28th-day strength was the basis for assessing the effect of the substitutions on the compressive strength of concrete.

Table 1. Specifications of Materials Used

Gravel	Gravel from Montalban, PH with max. size of 19 mm.
Sand	Natural sand from Pampanga, PH.
HDPE Plastic Pellets	Pellets approx. 3 mm in length and diameter, recycled from various HDPE products like post-consumer plastic.
Cement	Cement Type 1P Portland Cement
Fly Ash	Class F Fly Ash. As per ASTM C618, Class F has pozzolanic properties, less than 5% of CaO and more than 50% of SiO2+Al203+Fe2O3.
Water	Clean tap water.

Fire Resistance Rating

For the standard fire tests, the 50-mm cubes were used. After curing for 28 days, the cube specimens underwent fire testing in a small-scale test furnace, as shown in Fig. 1. The specimens were placed in the furnace starting from ambient temperature and heated through the ASTM E119 time-temperature curve. With a thermocouple attached to the unexposed surface of the specimen, the temperature of the specimen was monitored until the temperature was 139°C greater than the initial temperature, signifying the end of the test. This time in minutes was taken as the fire-resistance rating (FRR) of the specimen. Afterward, the specimen was taken out from the furnace to cool for 24 hours at room temperature before undergoing compression testing.

During the fire resistance test, physical observations were noted during and after the test. This includes hearing any explosive spalling of the samples during the test and investigating the physical appearance of the fired samples, such as the occurrence of cracks and shrinkage.

Optimization

Further analysis was made through the graphs of the strength development, fire-resistance rating, and the individual effect of each substitution on the response variables. With the objective of finding the optimum amount of percent substitutions, the response surface method (RSM) analysis was carried out. A response surface model equation was developed for each response variable.

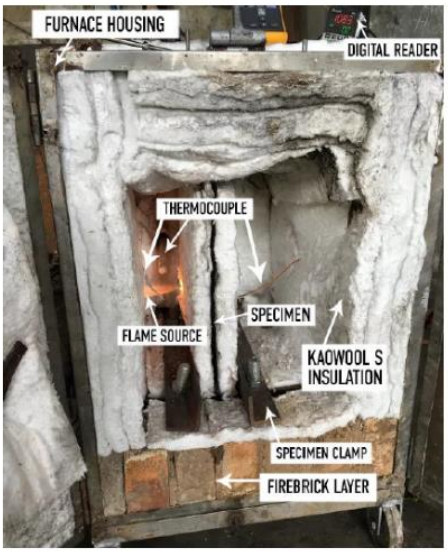

Figure 1. Small-scale furnace for fire testing [16]

RESULTS AND DISCUSSIONS

Compressive Strength Tests

A large portion of the concrete strength developed in the first 14 days of curing, ranging from 12.95% to 54.65% increase from 7th-day strength, the data is shown in Table 2. It was observed that the concrete with higher fly ash content had a higher percentage increase in the strength after 28 days. The addition of fly ash improved long-term strength. The rate of strength increase of Portland cement concrete slows down, the opposite happens to fly ash concrete due to the continued pozzolanic reaction with water in the later ages.

Table 2. Compressive strength of the specimen

MIX	Compressive Strength, MPa				
	7	14	21	28	120
0F-0H	29.65	33.49	34.02	34.20	34.38
0F-5H	15.69	18.41	20.91	28.57	28.63
0F-10H	23.69	34.87	38.52	38.60	38.89
0F-15H	23.76	27.48	31.14	30.89	31.32
30F-0H	20.42	27.91	31.76	33.73	34.34
30F-5H	15.76	21.43	26.79	27.09	28.19
30F-10H	13.54	19.16	21.00	24.92	26.47
30F-15H	14.41	20.68	22.29	22.91	25.40
60F-0H	8.22	12.71	17.17	17.39	19.94
60F-5H	10.48	14.75	17.82	20.50	22.45
60F-10H	8.06	11.77	16.03	17.54	19.79
60F-15H	9.40	14.08	16.96	20.47	21.95

It is possible that the strength of the 30F and 60F samples may still increase significantly beyond 120 days.

Concrete cylinder samples with 60% fly ash show failure in columnar vertical cracking from top to bottom of the concrete, the crack started from the top

cap down to the bottom cap without forming well-defined cones on either end. With concrete samples that fail due to shearing means that the concrete is likely to have a high sand content.

0F, 30F-0H and 30F-5H samples characterized as a failure with side fractures are visible at the top. This failure pattern occurs commonly in samples subjected to compression tests with unbonded caps, which is the case for this study.

It can be observed that as the percentage of fly ash substitution increases, the failure pattern is more severe. For samples with no fly ash substitution, the failure is only caused by the unbonded caps used in the compression test. Hence, there is a strong bond between the aggregates. For samples with 60% fly ash substitution, the failure pattern illustrates a columnar failure, similar to a system of continuous parallel cracks in the direction of compression.

It is clear that replacing cement with fly ash had an adverse effect on the 28th day compressive strength, regardless of the HDPE content. Since the graph displays the 28th-day compressive strength which is considered early strength, this trend is consistent with the study conducted by Johari et. al (2011), where fly ash was found to reduce the early strength of concrete but improves the long term strength.

Relative Residual Strength (RRS) and Fire Resistance Rating (FRR)

The relative residual strength (RRS) represents the remaining strength after fire exposure, relative to equivalent unfired samples. The fire-resistance rating is the time before failure as defined in ASTM E119. It represents how fast the heat can conduct through the concrete. The results are shown in Table 3.

Table 3. Relative residual strength (RRS) and Fire resistance rating (FRR) Results

Mix ID	RRS, %	FRR, min.
0F-0H	77.07	15.75
0F-5H	81.88	6.28
0F-10H	66.12	8.66
0F-15H	86.2	9.49
30F-0H	52.36	12.16
30F-5H	70.83	10.64
30F-10H	82.74	8.38
30F-15H	64.77	10.68
60F-0H	47.22	9.28
60F-5H	70.23	15.06
60F-10H	62.96	15.28
60F-15H	53.59	9.05
Minimum	47.22	6.28
Maximum	86.2	15.75

According to the International Building Code (2012), the standard fire-resistance rating for 50-mm thick concrete specimens is 30 minutes. The FRR that was attained in the test was only half of this value (15.753 minutes). A possible reason for this low value is due to the smaller scale testing equipment that was used. Since the test furnace has already been used several times since its fabrication, the quality of the results could not have been as accurate as its initial testing.

For concrete with 0% HDPE, only charring occurred and surface spalling was negligible.

However, for concrete with 5% and 10% HDPE, there was a small part that melted away. For concrete with 15% HDPE, there was a significant reduction in the size of the concrete and a large part of the cube was burnt.

It can be inferred that the surface spalling of concrete depends on the amount of HDPE. The higher the HDPE content, the more concrete was melted or stripped off. This was probably due to the melting of the plastic pellets that comprise the concrete matrix. Since the furnace temperature was observed to reach 400-600°C at failure, this was sufficient to melt the HDPE

The effect of fly ash on the RRS was quite similar to the effect on fc'. All mixes except for the 10H samples decreased in RRS when fly ash replacement was increased from 0% to 30%. By contrast, the 10H mix had a peak RRS at 30%. Notably, all combinations decreased in RRS at 60% fly ash substitution. Overall, the fly ash negatively affected the concrete except for 10H samples which benefited from 30% fly ash substitution.

For the 0H samples, increased fly ash substitution resulted in a decrease in FRR. It was at its highest when no fly ash was present in the mix. It was the opposite for the 5H and 10H samples, where increased fly ash resulted in a higher fire-resistance rating.

Although the 5H samples attained a greater FRR at 30F, both 5H and 10H samples obtained similar FRR at 60F. For the 15H samples, however, the fly ash content did not significantly affect the FRR.

Overall, the control concrete attained the highest FRR and adding fly ash to the 0H concrete adversely affected the FRR. However, when the concrete was mixed with HDPE at 5% and 10%, the fly ash improved the FRR of the alternative concrete.

In light of both the RRS and FRR, it appears that the 30F-5H and 60F- 5H samples were the best performing alternative mixes in terms of fire performance.

Response Surface Methodology

One of the main objectives of this study was to build a model that would be useful in predicting the compressive strength, given the mix proportion of HDPE and fly ash as well as finding the optimum mix proportions for a given response criterion. Shown in Figure 2-4 are the 3D-surface plots generated for the

compressive strength (fc'), post-fire residual strength (RRS), and fire resistance rating (FRR), as a function of the percent substitution of FA and HDPE.

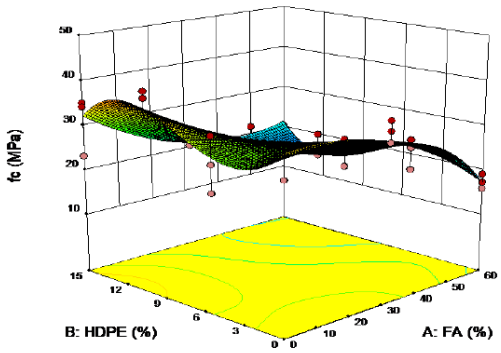

Figure 2. 3D surface plot showing the 28th-day compressive strength as a function of fly ash and HDPE percent substitution

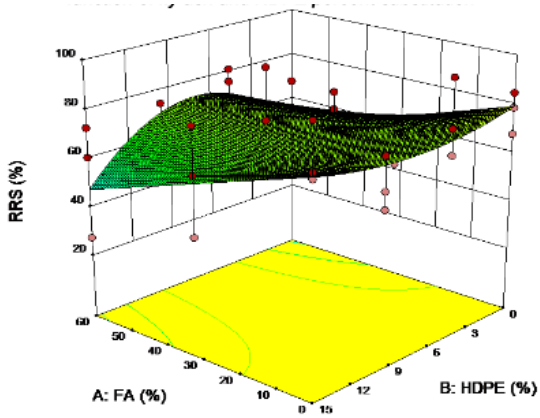

Figure 3. 3D surface plot showing the relative residual strength as a function of fly ash and HDPE percent substitution

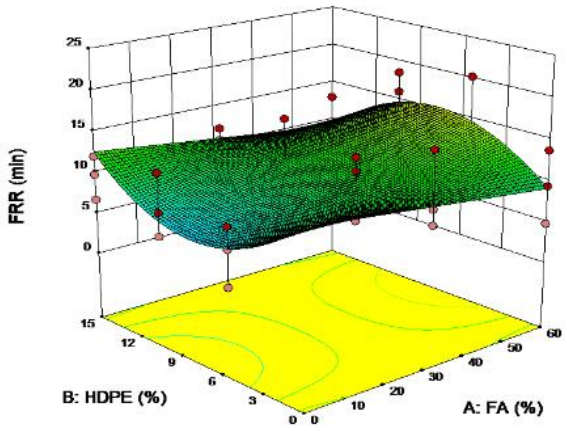

Figure 4. 3D surface plot showing the fire-resistance rating as a function of fly ash and HDPE percent substitution

Different models were investigated, but based on the adjusted r-squared, the quadratic model was found to be the most suitable. The backward elimination analysis was used to increase the precision of the model.

Before proceeding to optimization, the fitted models were examined to ensure that they give sufficient approximation of the results obtained in the experimental conditions.

The fitted models were examined to ensure that they give sufficient approximation of the results obtained in the experimental conditions.

Validation

The actual and predicted values of the responses obtained using the three model equations are graphically presented in Figures 5a-5c, where the predicted values were plotted against the actual values later and a 45-degree line was used as a reference of equality between the two values.

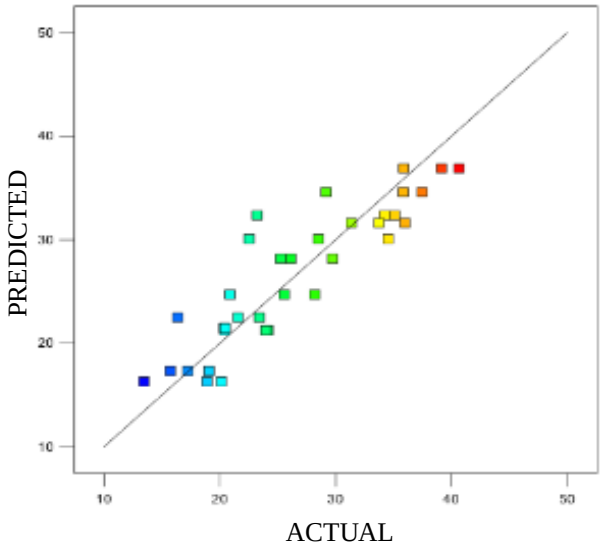

Figure 5a. Predicted vs. actual plots of compressive strength

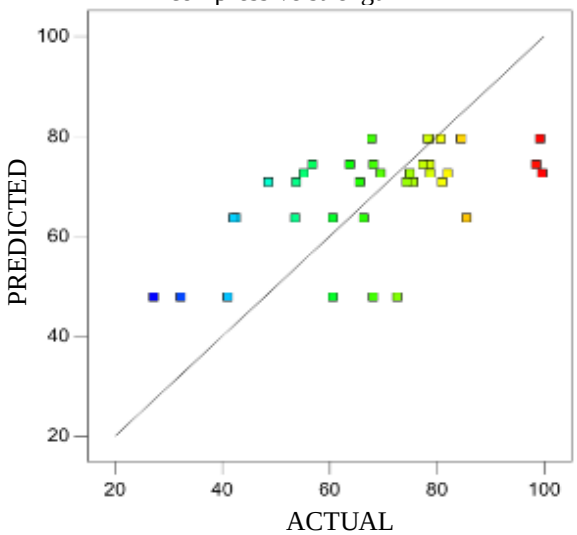

Figure 5b. Predicted vs. actual plots of relative residual strength

It could be noted that due to the large variation in the responses for the RRS and FRR, the predicted values may be far off some of the actual values, which explains the low adjusted R-squared values. In Fig. 5a-5c, this was illustrated by the scattered behavior of the values around the equality line. For the fc', the points lied close to the equality line, which means the model has high accuracy in predicting the fc'.

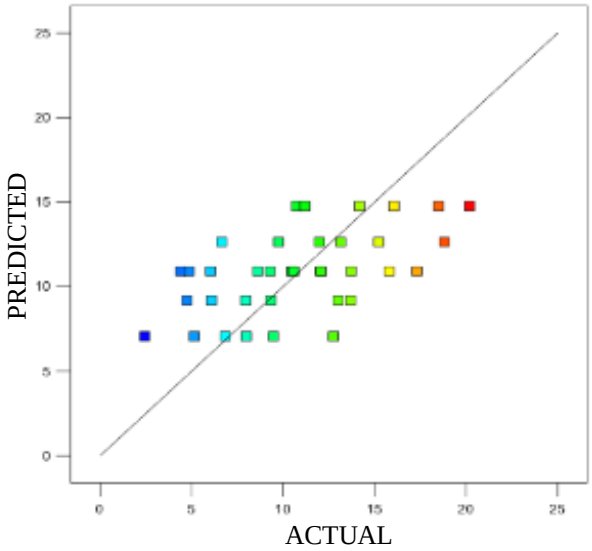

Figure 5c. Predicted vs. actual plots of fire-resistance rating

CONCLUSIONS

The majority of the concrete strength development occurred in the first 14 days of curing, with percentage increases relative to 7 days ranging from 12.95% to 54.65%. After 28 days, concrete with higher fly ash content showed a higher rate of increase due to delayed pozzolanic reaction of fly ash with water. The control concrete exceeded the target compressive strength of 25 MPa with an average strength of 34.20

MPa. Among the alternative concrete mixes, 0F-10H attained the highest strength with 38.60 MPa while 60F-0H attained the lowest strength with 17.39 MPa. HDPE as fine aggregate replacement slightly increased or did not have a significant effect on the strength. This may be attributed to the size of the HDPE pellets which were larger than sand - thus leading to a strength increase in spite of their lower density. By contrast, fly ash as cement replacement decreases the strength, which was consistent with previous studies that observed Class F fly ash to be detrimental to the 28th-day compressive strength.

Cubes with 60% fly ash substitution were observed to be vulnerable to explosive spalling, whereas cubes with higher HDPE content were more vulnerable to surface spalling, as exhibited by a large reduction in size after fire exposure. Replacement of up to 5% HDPE increased the RRS. By contrast, fly ash generally decreased the RRS except for 10H samples which increased at 30% fly ash. At HDPE levels of 5%, 10%, 15%, the peak RRS was at fly ash levels of 60%, 30%, and 0%, respectively. It was surmised that at higher HDPE content, lower fly ash content was more favorable for the RRS. The control concrete attained the highest FRR with 15.75 minutes. Among the alternative concrete mixes, the 60F-5H and 60F-10H performed best with 15.06 minutes and 15.28 minutes, respectively. Similar to the RRS, the effect of fly ash on the FRR varied according to the HDPE content. Generally, the fly ash improved the FRR of 5H and 10H samples, while decreased those of 0H samples and did not affect those of 15H samples.

Using the response surface method, model equations were developed for use in predicting the compressive strength, relative residual strength, and fire resistance rating of concrete at different levels of HDPE and fly ash percent substitution. A quartic model was formed for fc' while cubic models were formed for the RRS and FRR. All models were validated for the assumptions of response surface methodology.

EFFECTS OF ANTI-CRACKING AGENT TO ASPHALT COMPOSITE USING CONTINUOUS CONSTRUCTION METHOD

Aisha Marie Castillo[1], Joshua Mendoza[1], Franchette Coleen Presto[1], John Paul Villa[1] and Albert Griño Jr[2]
[1]Graduate Student, Adamson University, Philippines; [2]Faculty, Adamson University, Philippines

ABSTRACT

Reflective cracks is one of the most common types of distress failure in the cement treated base(CTB) in pavement. These cracks can be seen as a reflection from the base to the surface layer which can affect the performance and durability of hot-mix asphalt pavement. The base layer can be treated with lime, however, this process is not effective to eliminate the reflective cracks. This paper presents the effects of gypsum, potassium sulfate and silicate mineral powder as anti-cracking agent in asphalt composite used in continuous construction method. The anti-cracking agent was composed of 65% silicate mineral powder, 20% gypsum, and 15% potassium sulfate. The cement mixture was mixed with varying weight fractions (0%, 3%, 6%, 9%) of the anti-cracking agent. The initial, final setting time and compressive strength of the asphalt composite with anti-cracking agent (0%, 3%, 6%, 9%) were determined in accordance to American Standard for Testing and Materials (ASTM). The Vicat needle test result showed that the anti-cracking agent increased the final setting time up to 29.17% when the weight fraction of the anti-cracking agent was 3%. On the other hand, the compressive strength test showed increase in the strength by 21.27% for the 6% mixture in comparison to that of the control. The optimum percentage of anti-cracking agent is 6% since it gained the maximum compressive strength which implied a higher quality of cement treated base.

Keywords: Anti-Cracking, Asphalt Pavement, Gypsum, Continuous Construction Method, Silicate Mineral Powder

INTRODUCTION

Asphalt concrete pavements are not simply a thin covering of asphalt concrete over soil— they are engineered structures composed of several different layers. Because asphalt concrete is much more flexible than Portland cement concrete, asphalt concrete pavements are sometimes called flexible pavements [1]. Reflective cracking of asphalt concrete (AC) overlays is one of the most extensive pavement distress and damage mechanisms in composite pavement structures [2].

Reflective cracking is one of the most common failure modes of roads and is mainly caused by traffic loading and thermal variations [3]. Reflective cracks allow water to penetrate the surface and migrate into the aggregate base and subgrade, weakening those layers. Reflective cracks are more than an aesthetic concern; they eventually weaken the overall pavement structure and reduce ride quality [4]. These kinds of cracks are difficult to prevent, thick overlays or reconstruction is the usual solution.

Several approaches have been made to properly address the problem of reflective cracks in pavement with cement-treated base. One of these is by using or adding an anti-cracking agent. This study used gypsum, potassium sulfate and silicate mineral powder as an anti-cracking agent in asphalt mixture.

Another approach used in this study was the implementation of new construction method, Continuous Construction Method (CCM). This new method differs from the traditional construction method mainly in the construction process. Traditionally, the Cement Treated Base (CTB) need to be cured for 3 to 7 days after paving to secure strength, this procedure was canceled in CCM and the asphalt mixture was paved immediately after the construction of CTB. This study is significant to the construction industry since the addition of anti-cracking agent can be used to improve the quality of the pavement and to increase the structural capacity of the road.

BACKGROUND OF THE STUDY

Last 2009, an anti-split agent for materials such as lime and coal ash was invented by Kaiyan Tan, Junqi Chen, Zhiyuan Chen, Yongjun Song, Runxi Cheng and Wei Zeng [5]. This agent mainly comprises of silicate mineral powder, gypsum or chemical engineering waste residue phosphogypsum and an alkali metal substance containing SO_3, wherein the tri-calcium silicate content of the silicate mineral

powder is more than 55%. Usually, these limes and coal ash materials' early strength are significantly low making the anti-cracking performance of the material poorer. However, after mixing the said anti-split agent, the researchers have come up with positive results that improved the anti-crack performance of the material and thereby lowering the construction cost and obtaining good economic benefits.

Five years later, Jia Li, Jianmin Zi, Lei Mao and Tao Hu developed a low-cost anti-cracking agent by using the chemical waste phosphogypsum. According to their research, the principle is to stimulate pozzolanic reaction to occur between the phosphorus gypsum (calcium sulfate dihydrate) and lime by using alkaline binder lime. Shrinkage caused by the temperature and humidity change reduced significantly because of the certain amount of expansion and densification generated by the substances in the pozzolanic reaction, Aft ($3CaO•Al_2O_3•3CaSO_4•32H_2O$) and AFm ($3CaO•Al_2O_3•CaSO_4•32H_2O$). Having said that, the researchers achieved the purpose of reducing road base cracking, therefore, prolonging roadway service life.

The aforementioned studies were the basis in reinventing an anti-cracking agent, which comprises of 65% silicate mineral powder, 20% gypsum and 15% potassium sulfate.

METHODOLOGY

Research Design

This experimental study tackled the effects of using anti-cracking agent and continuous construction method in asphalt composite with cement-treated base to minimize reflective cracks.

The experimental factor in this study was the anti-cracking agent, comprised of 65% silicate mineral powder or talc powder, 20% gypsum and 15% potassium sulfate. The criterion for the effectiveness of anti-cracking agent and continuous construction method in asphalt composite with cement-treated base are as follows: setting time test and compressive strength test.

The researchers produced four batches each for setting time test and compressive strength test. Batch 1-4 contained 0%, 3%, 6% and 9% respectively. Each batch for setting time test and compressive strength test comprised of three trials per anti-cracking addition. The asphalt composites were tested on the 7th, 14th and 28th day after the construction.

Research Procedure

Preparation of anti-cracking agent

The anti-cracking agent used in this study was composed of 65% silicate mineral powder or talc powder, 20% gypsum and 15% potassium sulfate. The locally available form of gypsum was Plaster of Paris which had 75% of its water evaporated. Thus, gypsum was reproduced by adding 75% of water in Plaster of Paris. The chemicals were mixed evenly in a container using a stirring rod.

Preparation of cement-treated base

The mix proportion used for mechanical property Test was 4 parts Type 1 Portland cement, 16 parts Class F fly ash and 80 parts gravel. Batch formulation for 12 trials were composed of 4 kg of cement, 6 kg of fly ash and 91 kg of gravel. The gradations of gravel used were G1, ¾ and ¼ with a proportion of 30:25:45.

Preparation of CCM Constructed Asphalt Composite

Hot-mix asphalt mixture comprised of 79% sand, 19% 3⁄8 gravel, 2% hydrated lime and 5.7% asphalt cement with a compressive strength of 200 psi. The asphalt composite was consisted of hot-mix asphalt mixture, tack coat and cement-treated base. The following series of steps were used for CCM constructed asphalt composite: (1) A 20 cm cement-treated base was placed in a cylindrical mold, (2)The layer was consolidated by rodding 25 times around the layer, (3) The sides of the mold were tapped 10-15 times with the mallet after each layer in order to close any insertion holes formed by the rod, (4) The tack coat was then applied after compaction, and (5) Before the initial setting time of the base, the 6.5cm hot mix-asphalt mixture was paved and compacted immediately. Compaction for asphalt concrete was also 25 blows using hammer.

Setting time test

The setting time test was conducted in accordance with the ASTM C191-08 "Standard Test Methods for Time of Setting of Hydraulic Cement by Vicat Needle" [6]. A vicat apparatus was used to test the setting time of the samples with varying amount of anti-cracking agent. The role in set-retarding and water-reducing of the anti-cracking agent in cement are tested by following these procedures: (1) 300g of cement was mixed with 30% of water and varying amount of anti-cracking agent, (2) The mold was filled with cement paste. The top of the specimen if necessary was smoothed with one or two light touches of the pointed end of the trowel. The specimen remained in the conical mold supported by

the glass plate throughout the test period, (3) The specimen was set in the moist cabinet for 30 minutes after molding without being disturbed (4) The penetration of the 1mm needle at this time and every 15 minutes thereafter was determined until a penetration of 25mm or less was obtained (5) The needle of the rod was lowered until it rest on the surface of the cement paste for the penetration test. The setscrew was tightened and the initial reading was obtained (6) The rod was released quickly by loosening the setscrew and allowed the needle to settle for 30 seconds. No penetration test shall be made closer than 6.4mm form any previous penetration and no penetration test shall be made closer than 9.5mm from the inside of the mold.

Compressive strength test

It was performed on the 7th, 14th and 28th day after construction of asphalt composite. The following series of steps were used for compressive test: (1) The hot-mix asphalt was separated from the cement treated base by means of cutting (2) Cement treated base was weighed and measured before it was then placed on the Universal Testing Machine (3) The load was applied until the specimen fails, and recorded the maximum load carried out by the specimen during the test. The compressive strength can be calculated using Eq.1.

$$\sigma = \frac{P}{A} \quad (1)$$

where:
σ = compressive strength, psi (kPa)
F = maximum load carried by the batch, lbf (kN)
A = cross-sectional area of the batch, in^2 (m^2)

RESULTS AND DISCUSSION

Setting Time Test Results

Table 1 Setting Time Results

Anticracking Content(%)	Initial Setting Time(mins)	Final Setting Time(mins)
0	165	240
3	241	310
6	180	265
9	177	255

As seen in Table 1 the result of setting time test obtained for all of the samples with varying amount of anticracking agent. Relative to the control, all of the samples were higher for both initial and final setting time. This only indicates that the anticracking agent can extend the setting time of the cement in the concrete mix. The highest initial and final setting time were obtained at 3% with a value of 241 minutes and 310 minutes, respectively. At 3% in comparison to the control there is a substantial increase of 46.06% for the initial and 29.17% for the final setting time.

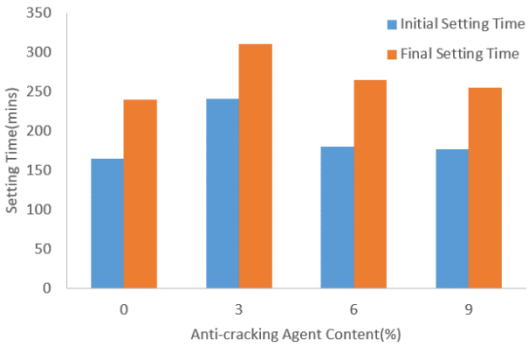

Fig. 1 Setting Time Test Results

The delay in setting time of these batches as seen in Figure 1 was caused by the reaction formed between the anti-cracking agent particularly gypsum and tricalcium aluminate that is already present in cement. Suryakanta [7] affirms this study in which gypsum reacts with tricalcium aluminate quickly to generate calcium sulfoaluminate hydrate which deposits and forms a protection film on the cement particles to hinder the hydration of tricalcium aluminate and delay the setting time of cement. Prolonged setting time of cement implies that the longer it is for the cement to set, the longer the time for the continuous construction to be executed.

Although, the results showed inconsistent increment as the anti-cracking mixture addition increases. From zero to three percent, the initial and final setting time increased but partially decreased from three to nine percent. This, on the other hand, was particularly caused by the potassium sulfate and talc powder in the anti-cracking agent. Hewlett [8] proved this result in his study that determined the effect of potassium sulfate in the setting time of cement paste. The results in his study showed that adding 0.88% of potassium sulfate would give 66.67% and 32.56 % decrease in the initial and final setting time respectively while adding 1.48% potassium sulfate would lead to 91.67% and 90.70% decrease in the initial and final setting time respectively.

Moreover, Woo and Ryu [9] examined the potential use of talc as a substitute for cement and found out that the setting time for all the specimens were shortened compared to the one without talc powder. This implies that talc and potassium sulfate

could increase the setting time of cement thereby making it difficult for the continuous construction method to be performed.

The batch that showed the most significant result based from the setting time test was the cement with 3% anti-cracking agent addition. Among all the batches with agent addition, this batch gained the highest increase in setting time compared to the control that has 0% addition.

Compressive Strength Test Results

Table 2 Compressive Strength Test Results

AC Content (%)	Compressive Strength (MPa)		
	7th day	14th day	28th day
0	4.594	5.025	7.084
3	4.722	5.188	8.357
6	4.875	5.277	8.591
9	4.707	5.217	8.334

As seen in Table 2 the result of the compressive strength test obtained for all of the samples with varying amount of anticracking agent. It was found out that all the batches with varying amount of anti-cracking agent implied a significant increment relative to the control batch. Higher strength results implied higher quality of cement treated base.

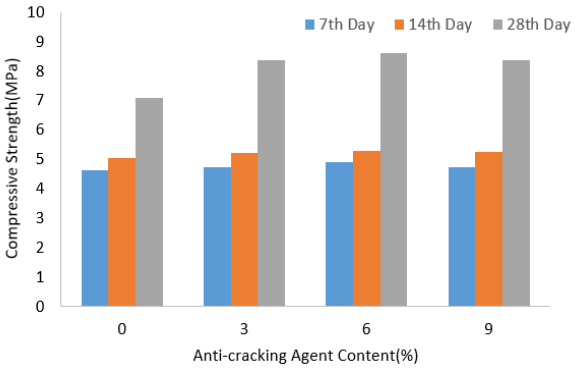

Fig. 2 Compressive Strength Test Results

Also, the test results have shown that an increase in compressive strength by 21.27% for the 6% mixture relative to the control as shown in Figure 2. It can be noted that 6% anticracking addition gained obtained the highest increment with 4.875 MPa, 5.277 MPa and 8.591 MPa on its 7th, 14th and 28th day.

According to Lim and Zollinger [10], most specifications require the minimum design strength of CTB in the range of 350 to 500 psi (2.4 to 3.4 MPa). On the other hand, Portland Cement Association [11] stated that typical cement contents that range from 3 to 10 percent will have a resulting 7-day compressive strength of 300 to 800 psi. But, since the researchers adopted the design mix used in the study of Li, Zi, Mao and Hu [12], the resulting compressive strength of their control was set as the standard which is 650 psi (4.48 MPa) on the 7th day.

A study was conducted by Halaweh [13] on the effect of potassium sulfate in the compressive strength of different cements and concluded that specimen with 5% potassium has a slightly higher strength compared to the control from 0-60 days. But beyond 60 days, it appeared that the sulfate content of 3.6% generated the highest strength.

Meanwhile, Sabouang, Mbey, Liboum, Thomas and Njopwouo [14] made a study about the effect of talc powder as a potential raw material for the formulation of cementitious materials in the year 2014. The compressive strength test results of their study varied from 3.35 MPa (cement with 0% added talc) to 4.50 MPa (cement with 20% added talc). According to them, the addition of talc powder in cement causes more cement phase formation and thereby leading to strength increment.

In line with this, Woo and Ryu [9] also proved the significant strength improvement of concrete by replacing plain mix with fine grains of talc at the rate of 10%, 20% and 30%.

The implementation of continuous construction method to the batches with anti-cracking agent addition also greatly contributed to its strength increment. Li [12] added phosphogypsum as anti-cracking agent and obtained 0.89% and 5.30% increase on the 7th and 28th day of the CCM constructed pavement respectively. Meanwhile on our results, the maximum increase we have attained are 6.12% on the 7th day, 5.01% increase on the 14th day and 21.27% increase on the 28th day.

However, strength of the mixture gradually decreased from six to nine percent. This was caused by excessive amounts of gypsum and potassium sulfate in the mixture. Studies conducted by Halaweh [13] and Sabouang [14], mentioned above had already clarified certain limitations in the dosages of the chemicals used. In addition to that, Suryakanta [7] also mentioned that if the content of gypsum exceeds the limit of 3-5% of the cement's mass, it would certainly lower the strength of cement and lead to poor dimensional stability.

CONCLUSION

Several approaches has been made to effectively eliminate the cracks in asphalt pavement with cement-treated base, one of these is by adding lime in the base. In line with this, the production of gypsum,

silicate mineral powder and potassium sulfate as an anti-cracking agent in asphalt mixture using continuous construction method has shown great potential in eliminating or minimizing cracks significantly because of the certain properties that these chemicals have. The Vicat needle test result showed that the anti-cracking agent increased the final setting time up to 29.17% when the weight fraction of the anti-cracking agent was 3%. On the other hand, the compressive strength test showed increase in the strength by 21.27% for the 6% mixture in comparison to that of the control. The optimum percentage of anti-cracking agent is 6% since it gained the maximum compressive strength which implied a higher quality of cement treated base. For further studies, the researchers recommend to perform bonding property test between the asphalt mixture and cement treated base in order to further determine the effectiveness of continuous construction method.

RESISTIVITY AGAINST SULFATE ATTACK OF CONCRETE WITH HDPE AS PARTIAL SUBSTITUTE FOR FINE AGGREGATES

Richard De Jesus[1], Grant Yves M. V. Borbon[2], Kenrick F. Go[2], and Rockwell M. G. Jardiniano[2]
[1]Faculty, De La Salle University, Philippines; [2] De La Salle University, Philippines

ABSTRACT

High-Density Polyethylene (HDPE) when used as partial substitute of fine aggregates in concrete is investigated to determine if it addresses sulfate attack in concrete. Since HDPE is known to be resistant against chemical compounds including sodium sulfate, it is hypothesized in this study that sulfate attack problems in concrete will be lessened by incorporating HDPE in concrete mix. Mechanical properties of concrete were determined to ensure that HDPE is limited to an amount where there will be no serious compromise to strength, hence, compressive, and split tensile test are included in the study. To determine the influence of HDPE in addressing sulfate attacks, length change of mortar specimen is investigated using ASTM C1012 (length change of mortar exposed to sulfate solution). Scanning Electron Microscopy (SEM) is also employed to qualitatively assess the microstructure of concrete with HDPE exposed to sulfate attacks. Mechanical test results showed that increasing HDPE did not adversely affect the compressive strength. However, there was a decrease observed in tensile strength. To achieve balance between mechanical properties, HDPE replacement of fine aggregates was set at 10% by weight of fine aggregates. The mortar bar test demonstrated that increasing HDPE resulted to an increased resistivity against sulfate attacks. SEM have also shown reduction in voids and ettringite with increasing HDPE content.

Keywords: HDPE in concrete, Sulfate attack, Mortar bar test, Ettringite, Alternative concrete

INTRODUCTION

Among the causes of deterioration in concrete is sulfate attack [1]. In coastal regions, sulfates from groundwater seeps through the pores in concrete and reacts with cement mix. These sulfate ions react with aluminates in concrete which forms gypsum and ettringite that causes concrete expansion [2]. Concrete exposed to environment with high sulfate compounds are vulnerable to sulfate attacks and so are concrete in contact with soil abundant with sulfate contents. Aggregates may also contain sulfuric compounds that may initiate sulfate attacks if such aggregates are used in the production of concrete. Sulfate attacks is a potential problem in concrete hence, it must be addressed.

Sulfate attack may be caused externally, when sulfate-containing water seeps through concrete, or internally, when sulfate-rich aggregates are used. When sulfate ions react with aluminates in concrete, ettringite and gypsum are formed. These two cause a reaction that involves cracking, expansion, loss of bond between cement paste and aggregates, and/or alteration of paste composition. When cement paste is altered, monosulfate is converted into ettringite then into gypsum [3]. This takes up calcium from CaOH and CSH hence affecting the mechanical properties of concrete [4] & [5]. Consequently, the formation of ettringite causes expansion and cracking in concrete [4].

Other than contributing to helping save the environment by utilizing waste materials such as HDPE, high density polyethylene (HDPE) has been shown to have combative properties against sulfate attacks. ISO 10358 [6] stated that HDPE possesses higher chemical resistance compared to other polymers, particularly against sulfuric acid. Polymer impregnation was also shown to enhance the chemical resistance of concrete [7]. HDPE are plastics made up of polymer molecules linked together. Hence, when used in concrete as partial substitute for aggregates, HDPE can aid in lessening the deterioration brought about by sulfate attacks.

Study of [8] used PET bottles as component of concrete and had shown that the reduction brought by sulfuric acid to crushing load, and weight loss was lessened. Moreover, [9] showed that the use of PET as aggregates in concrete improved acid resistance of concrete. And [10] employed HDPE as coarse aggregates replacement in concrete and showed that with 10% and 20% replacement, compressive strength is comparable to that of normal concrete. Thisstudy investigated the impact of using HDPE in concrete to combat the effects of sulfate attacks in concrete using mortar-bar test (ASTM C1012) reinforced by spectron electron microscopy (SEM). Additionally, it will seek to establish the desirable amount of HDPE as partial replacement of fine aggregates in concrete without compromising the mechanical properties.

MATERIALS AND METHODS

The HDPE used in this study was in pelletized form bought commercially. It was checked with sieve No. 4 to determine its' suitability as a fine aggregate material. It has a specific gravity of 0.80, as provided by the supplier. Coarse and fine aggregates were sourced from a local hardware store. Upon checking experimentally, the specific gravities of fine aggregates and coarse aggregates are 2.34, and 2.81 respectively. Type I Portland cement was utilized in the preparation and making of concrete in this research. Utilization of HDPE as fine aggregates substitute were done in 5% to 20% by weight at 5% interval. For each strength test, three (3) specimens were prepared. Cylinders of size 100mm x 200mm was used for both compression and split tension test. Two sets of strength tests were conducted – the first set involves strength tests for concrete specimens cured in water while the second set involves the same strength tests but for concrete specimens submerged to sulfate solution. The duration of curing in water and in sulfate solution is 28 days.

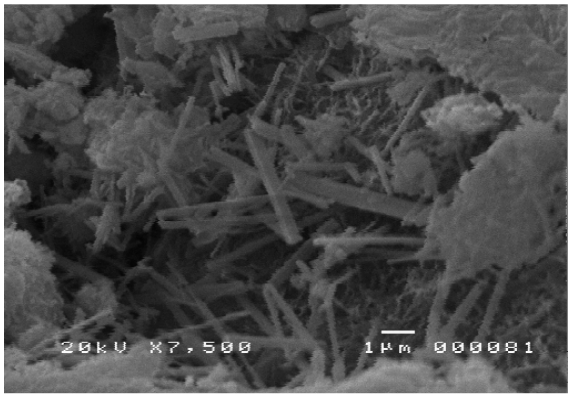

Figure 3. SEM of mortar with 10% HDPE (10HDPE)

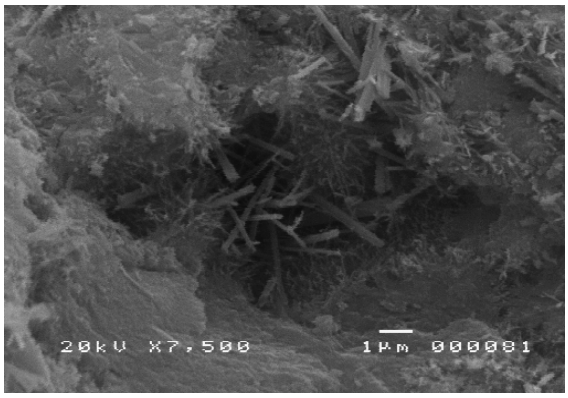

Figure 4. SEM of mortar with 15% HDPE (15HDPE)

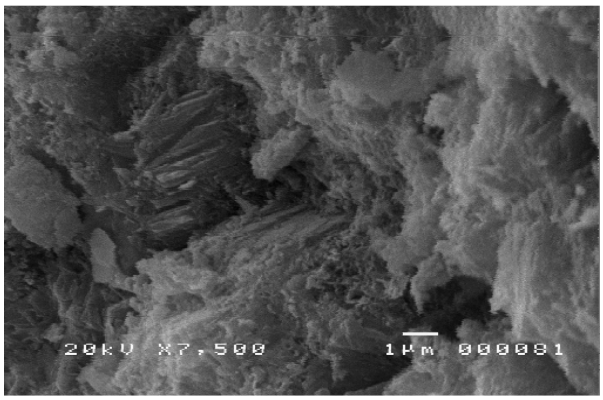

Figure 5. SEM of mortar with 20% HDPE (20HDPE)

Table 1. Concrete design mix (as per ACI 211.1)

Component (kg)	00HDPE	05HDPE	10HDPE	15HDPE	20HDPE
Water	205.00	205.00	205.00	205.00	205.00
Cement	379.63	379.63	379.63	379.63	379.63
Coarse Aggregates	1009.20	1009.20	1009.20	1009.20	1009.20
Fine Aggregates	691.30	656.73	622.17	587.60	553.04
HDPE	0.00	11.80	23.60	35.30	47.20

Table 2. Average compression and split tension strength (in MPa) of samples exposed to sulfate solution

% HDPE	Compression (MPa)		% reduction (pre to post-sulfate)	Tension (MPa)		% reduction (pre to post-sulfate)
	Pre-Sulfate	Post-Sulfate		Pre-Sulfate	Post-Sulfate	
00HDPE	36.43	32.45	11.0%	2.37	2.05	13.5%
05HDPE	39.15	37.80	3.4%	2.31	2.16	6.5%
10HDPE	35.53	34.66	2.4%	2.27	2.21	2.7%
15HDPE	44.48	40.11	9.8%	2.21	2.18	1.3%
20HDPE	42.36	41.07	3.0%	2.17	2.14	1.3%

The mortar bar test involves measurement of length change of mortar specimens in accordance with ASTM C1012 [11]. Three mortar specimens, in rectangular prism of size 25mm x 25mm x 285mm, were prepared in varying HDPE content, from 0% to 20% at 5% interval. One set of all mortar samples were prepared with 3 specimens per mix. Initial length reading was done before curing the specimen to sodium sulfate solution. Measurement of final length change was conducted after 28 days of curing. Concrete mix design was made in accordance with ACI 211.1 and the design mix is shown in Table 1. Mortar mix was designed in accordance with ASTM C305 [12].

DATA AND ANALYSIS

Strength Test Results

The result of strength tests for compression and tension is shown in Table 2. Reduction in strength is observed for concrete exposed to sulfate solution (post-sulfate samples) compared to unexposed ones (pre-sulfate samples). As mentioned earlier, the formation of gypsum during sulfate attacks takes up calcium from CaOH and CSH in hydrated cement paste hence, affecting the strength of concrete. It can be observed from test results that for both compression and tension tests, these drops in strength caused by exposure to sulfate solution decreases as HDPE increases. Post-sulfate samples have demonstrated an increase in strength properties, both in compression and tension, with increasing HDPE.

Length Change Of Mortar Bars

After immersing mortar bars to sulfate solution for 28 days, the final length is measured using a length comparator. The table below shows the average length change per mix. Mortar mix includes a control sample (i.e. 00HDPE) and samples with varying HDPE (from 5 to 20%).

Table 3. Length change of mortar bars

% HDPE	Average length change
00HDPE	0.0209
05HDPE	0.0213
10HDPE	0.0144
15HDPE	0.0103
20HDPE	0.0063

It is apparent from this test that HDPE influenced the resistance of mortar bar specimens against length expansion attributed to sulfate attack. This result supported the hypothesis of the study that HDPE, when mixed into concrete, will provide resistance against sulfate attacks.

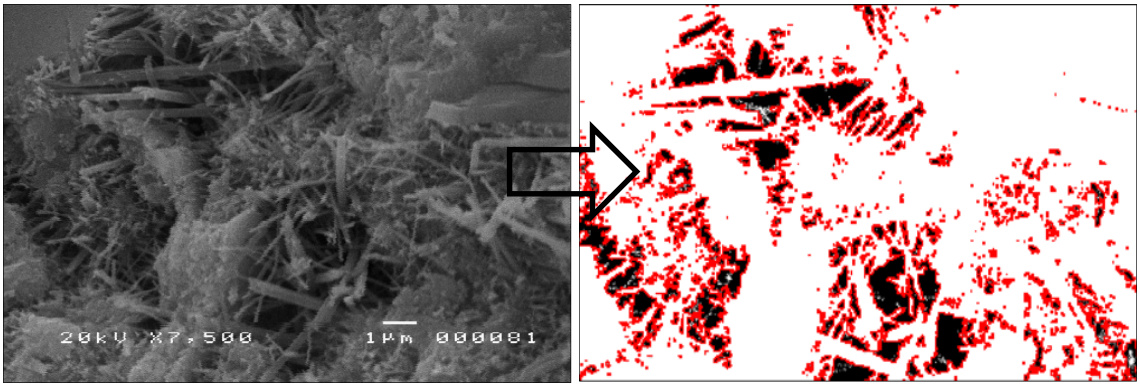

Figure 6. Conversion of SEM micrographs into 'imageJ' image to calculate area of voids (00HDPE)

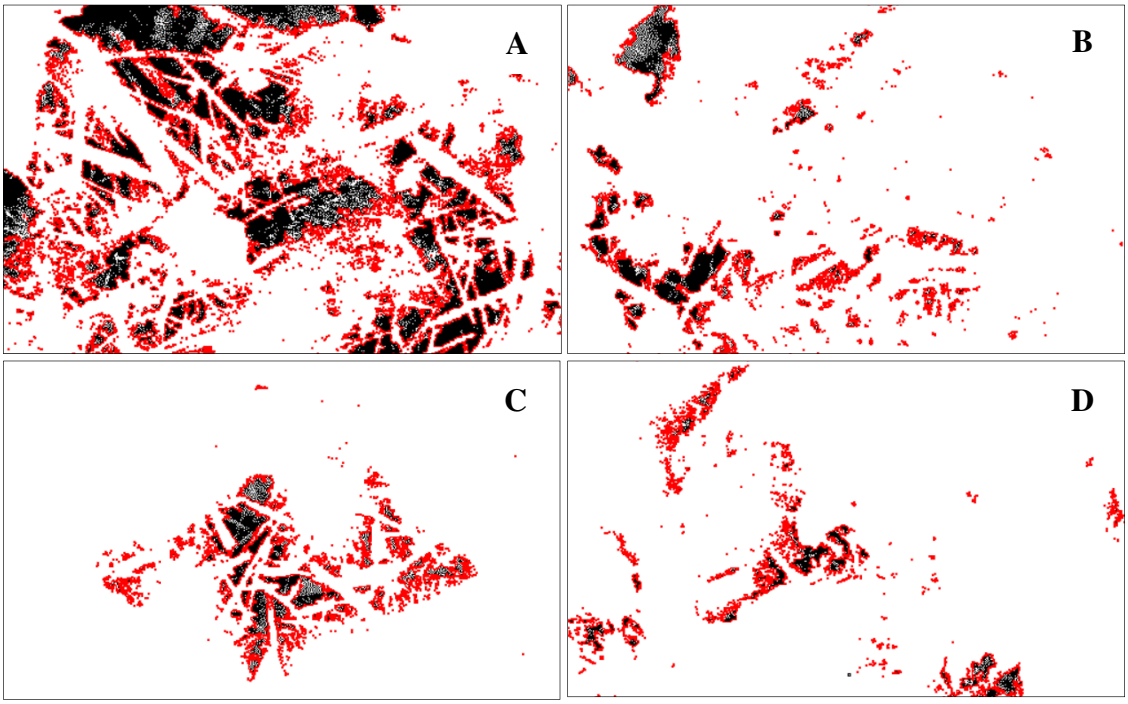

Figure 7. 'ImageJ' image for (a) 05HDPE, (b) 10HDPE, (c) 15HDPE, and (d) 20HDPE

Spectron Electron Microscopy

As earlier mentioned, sulfate attacks in concrete happens when sulfate ions react with aluminates to form ettringite and gypsum which are responsible for concrete expansion leading to cracking. This study attempted to look for the formation of ettringite after exposing concrete specimens to sulfate solution for 28 days. Formation of ettringites are expected to be more common on areas with wide spaces, like cracks and voids, as the formation of ettringite crystals require space. Figures 1 to 5 show ettringite formation (needle-like crystals in the micrographs) typically along the void regions. These micrographs also exhibited lessening amount of ettringite formation with increasing HDPE amount. It can also be noticed that voids were reduced with increasing HDPE.

These micrographs support the results of length expansion by mortar bar test which implies that increasing HDPE contributes to the reduction of ettringite and correspondingly, reduction in voids and size resulting to reduced length expansion as shown by mortar bar tests. Using ImageJ, a platform for processing scientific images, quantification of area of ettringite and voids from SEM images were computed and shown in Table 4. This table provides number to support the study claim that SEM results showed reduction in the amount of ettringite and voids as a consequence of increasing HDPE in concrete. Figures 6 and 7 were the result of ImageJ reduction of SEM images into calculable areas for voids. Images in black are the voids while red spots mark the boundaries. Similar procedure was done to calculate the ettringite areas. Ettringite and voids calculation show that with increasing HDPE, both areas of ettringite and voids decreases.

Table 4. Computation of ettringite and void area using ImageJ

% HDPE	Ettringite Area (μm^2)	Void area (μm^2)
00HDPE	91.962	23.689
05HDPE	113.345	37.646
10HDPE	74.306	8.883
15HDPE	37.731	6.668
20HDPE	10.184	4.680

CONCLUSIONS

In order to address the potential deterioration that can be brought about by sulfate attacks in concrete, the use of HDPE in concrete was explored. This study investigated the mechanical properties of concrete with varying HDPE used as partial substitute for fine aggregates. Concrete mix with 5% to 20% HDPE at 5% interval were assessed. HDPE significantly reduces the tensile strength of concrete but in compression, no impact was observed for the compressive strength property. Exposure to sulfate solution, to simulate sulfate attacks, revealed that both compressive and tensile strength properties decreased but HDPE in increasing amounts, have shown to have the potential to arrest the impact of sulfate attacks.

Length change of mortar bars exposed to sulfate solution were also evaluated. The change in length decreases as the amount of HDPE increases. To explain this further, SEM images of concrete samples with varying HDPE were taken. From SEM micrographs, the formation of ettringite and development of voids (or cracks) in concrete have decreased with increasing HDPE. These are significant demonstration of HDPE providing resistance against sulfate attacks.

ASSESSMENT OF TESTING PROTOCOLS FOR BAMBOO FOR TENSION PARALLEL TO FIBER

Martin A. De La Cruz[1], Luis F. Lopez[2], Richard M. De Jesus[3], and Lessandro E. O. Garciano[3]
[1, 3]De La Salle University (Manila), Philippines; [2] Base Bahay Inc., Philippines

ABSTRACT

To determine tension parallel to fiber properties of Bamboo, one can employ ISO 22157. However, several studies highlighted some challenges in using the method such as premature failure of testing due to force at clamping and slipping failure at the grips. Hence, this study aims to look for a solution to address these challenges. This study investigated, both qualitatively and quantitatively, three testing protocols in determining bamboo's tensile strength parallel to fiber – (1) ISO 22157, (2) a modification of ASTM D143, and (3) Pittsburgh Method. The success rate, test duration, load rate and transmission, specimen preparation, equipment fabrication, and execution of the three protocols were compared. The physical properties of bamboos, such as moisture content, density, and shrinkage, were also measured in the study. The results of the study showed that the modified ASTM D143 test is the most viable method to use in testing the tensile strength parallel to fiber of bamboos. Modified ASTM D143 produced the highest tensile strength with value equal to 100.36 MPa, compared to specimen tested under ISO 22157 with tensile strength only reaching 94.11 MPa, while Pittsburgh Test produced the lowest tensile strength of 76.78 MPa. Modified ASTM D143 also yielded the lowest confidence interval which implied good consistency. Modified ASTM D143 is the recommended test protocol based on the results of this study as it gained the highest success rate during testing, lowest testing duration and the easiest to execute.

Keywords: Bamboo, Tensile strength parallel to fiber, ISO 22157, ASTM D143, Pittsburgh method

INTRODUCTION

Bamboo is used as an alternative to wood and it has been considered as "poor man's timber" [1]. Its reputation changed in recent times with the technological developments and researches [2] and [3] which led to different uses of bamboo such as ceilings, floorings, cabinetry, furniture, and even, a base of a bicycle ([4]-[8]). Bamboo is a renewable material, being one of the fastest growing plants in the world. It can be harvested at an age as early as 3 years compared to timber which takes about 25 years to mature and be harvested [9]. Since bamboo is technically a grass, thus it regenerates faster. In 2004, ISO published ISO 22157-1 (Bamboo - Determination of physical and mechanical properties) with 2 parts: Requirements, and (2) Laboratory Manual. Also, it has published ISO 22156 Bamboo - Structural Design. One of the properties that [10] determines is the tension parallel to the fiber. However, this test method exhibited some notable shortcomings: specimen clamped at the grips failed due to the force of gripping, and slipping at the grips [1] & [11].

Study of [12] also observed similar issues and additionally noticed that it also has problems with specimen orientation noting that reduction should be made in the tangential direction of the specimen so as not to remove the extreme inner and outer culm wall fibers from the test coupon.

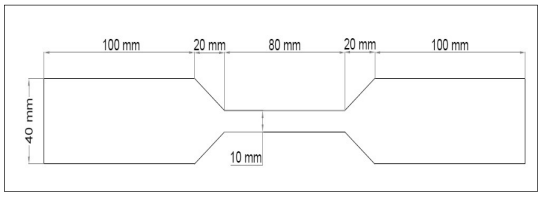

Figure 1. ISO 22157 (TP1) specimen

According to [13], adjustments should be made to ISO 22157 in determining properties of bamboo to make sure that the cause of failure is tension and not failure due to compression because of the grip issues. Study of [14] recommended the adaptation of [15] ASTM D143 for tension parallel to fibers test.

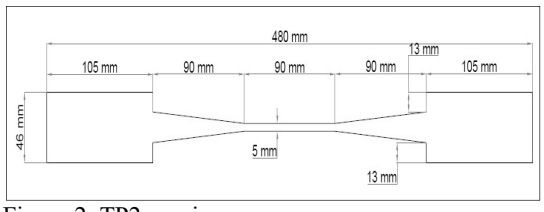

Figure 2. TP2 specimen

It is evident that there is a need for modifications in ISO 22157 to address concerns about testing of tension parallel to fiber. Since before making any recommendation to ISO 22157, verification of a new test protocol is needed, it is the aim of this study to

Table 1 Tensile strength (parallel to fiber) summary of test results

Test Protocol	Average Tensile Strength, MPa	R_k, MPa	Moisture Content, %	Density ρ (kg/m^3)	Shrinkage, %
TP1	94.11	44.86	10.95	682.48	1.40
TP2	100.36	62.67	10.95	682.48	1.40
TP3	76.78	43.45	10.95	682.48	1.40

assess three testing protocols: (1) ISO 22157 itself, (2) a modification of ASTM D143, and (3) Pittsburgh Method - a test adopted from [1]; in determining bamboo's tensile strength parallel to fiber.

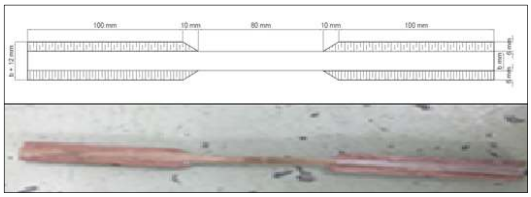

Figure 3. TP3 specimen

MATERIALS AND METHODS

Materials and Equipment

The material used in the study is a homegrown bamboo known as "kawayang tinik" (*Bambusa blumeana)* which was sourced from Tarlac, Philippines. The specimen came from several culms of the said specie. Testing was done using a Shimadzu UH-1000kNI universal testing machine equipped with finely-tuned control loading rate settings and is available locally. The number of specimens tested for each protocol is 25.

Testing Protocols (TP)

TP1: ISO 22157

For this protocol, the specimen used has a measure of the gauge area of 10 mm in width, and a length of 80mm (Fig. 1). The ends of the test specimen were shaped to ensure failure at the gauge portion. The node of the bamboo is taken to be exactly at the middle of the gauge length. Notably, the whole specimen is slightly curved. The specimen was cut using a handsaw. In this test, the load was applied constantly at a constant rate of 2.0 mm/min.

TP2: Modified ASTM D143

The second testing protocol is a modification of ASTM D143 which, without modification, is specifically for test of tension parallel to grain for small clear specimens of timber. The modification comes in the form of special grips which is attached to the testing machine to lessen failures. The specimen was cut using a table saw because the specimen profile requires high precision (Fig. 2). Load rate of 1 mm/min is applied for this test.

TP3: Pittsburgh Method

Pittsburgh method is a test protocol adopted from [1]. The specimen (Fig. 3) of the method have a rectangular cross section dimension with breadth equal to the culm wall thickness (t), and width (b) equal to one-half the culm wall thickness or less. The specimen width did not exceed 20 mm and included one node in the gauge section. The gauge length was set at 80 mm. The gripped ends of radially oriented test pieces have softwood tabs laminated to the breadth dimension using a coconut lumber with a thickness 6mm. The load rate of the test was set at 5mm/min.

RESULTS AND DISCUSSION

Table 1 shows the tensile strength of each protocol and the average value of moisture content, density, and shrinkage of all specimen. Pittsburgh Method has the least tensile strength average while the modified ASTM produced the highest tensile

strength. Table 2 summarizes all tensile strength test results, characteristic value, allowable stress and confidence interval.

Modes of Failure

TP1: ISO 22157

For the ISO test, there were five mode of failures observed during testing: bearing, shear, premature cracking or cracking in grips, tension (parallel to fiber) failure on node or brittle tension, and splintering tension (parallel to fiber) failure. Out of 25 specimens, 17 (68%) failed in tension (parallel to fiber) while 8 (32%) failed in non-tension mode.

TP2: Modified ASTM D143

There were three mode of failures observed in the test: tension brittle, splintering tension parallel, and

Table 2 Tensile strength (parallel to fiber) values for three (3) testing protocols

Test Protocol	Range (MPa)	Average (MPa)	Rk (MPa)	Allowable Stress (MPa)	Confidence Interval (MPa)	Confidence Interval Range@ 95% confidence level, MPa
TP1	51.72-145.18	94.11	44.86	9.97	12.89	81.22-106.99
TP2	49.65-131.84	100.36	62.67	13.93	10.09	90.27-110.45
TP3	42.71-102.36	76.78	43.45	9.66	13.59	66.22-93.40

Table 3 Qualitative comparison of three (3) testing protocols

Testing Protocol	Success Rate	Test duration < 5 min?	Specimen Preparation Difficulty	Needs accessory?	Test Difficulty
TP1	68%	Yes	Mid	No	Mid
TP2	76%	No	High	Yes	Easy
TP3	48%	Yes	Mid to High	No	Mid

shear failure. Out of 25 specimens, a total of 19 (76%), failed in tension (parallel to fiber), 6 specimens (24%) failed in shear.

TP3: Pittsburgh Method

There were two failures observed in the test: tension (parallel to fiber) failure on node, and bearing failure. Out of 25 specimens, 12 (48%) failed in tension parallel, 13 specimens (52%) did not fail in tension (parallel to the fiber) but instead, failed in bearing failure mode.

Qualitative Analysis

Table 3 shows the success rate of the testing protocols. The most successful testing method is TP2 with 76% (19/25). The least successful method is TP3 with 48% (12/25).

It is observed that TP2 has the fastest average testing time with 258 seconds. TP1 and TP3 take 534 and 682 seconds, respectively, to complete the test. This is attributed to the difference in load rates between test protocols. Additionally, for TP1 and TP3, it was observed that the load-displayed values were fluctuating and is attributed to the clamping at the grips. During test, the grips compressed the specimens and when the specimen gets thin as a result of compression, slipping at the grips happen, thus, the fluctuation of values. At the beginning of the tests for TP1 and TP3, it took time for the load to increase as the clamps need to grip the specimen firmly. Qualitative observations for all test protocols were summarized in Table 3.

The preparation of specimen is very important to obtain the expected failure. For TP1, the preparation of the specimen is the easiest since its specimen's width is larger compared to the other TPs. The specimens for TP2 were the most difficult to prepare since it needs precise and careful preparations as it demands that the part where the gadget and the specimen comes into contact must be parallel to make sure the load distribution is equal. For TP3, preparation was rated between medium and high. It is easier than TP2 test since it is much easier to cut but tedious due to the addition of tabs.

TP1 and TP3 did not require additional grips as the testing machine's grip is sufficient to conduct the tests. For TP2, however, extra grips were fabricated for better clamping. TP2 is the easiest test to execute as the additional grips made the setup for clamping easy. TP1 and TP3 made the setup for clamping extra difficult as the testing machine's grip requires manual adjustment for the specimen to be perfectly aligned with the load direction.

CONCLUSIONS

Among three testing protocols investigated, modified ASTM D143 Test (TP2) produced the highest tensile stress reading at 100.36 MPa compared to ISO 22157 (TP1) with 94.11 MPa, and Pittsburgh Method (TP3) with 76.78 MPa. TP2 also produced the most consistent results with the lowest confidence interval.

From the results summarized above, it is concluded that the Modified ASTM D143 test (TP2) is the most recommended method to use. It has the highest success rate, lowest test duration, and the easiest to execute. The only downside is the demand for careful attention during the preparation of the specimen. The second recommended protocol is the ISO 22157 (TP1) based on its success rate, test duration, and specimen preparation. The least recommended method is the Pittsburgh method (TP3) because of the lowest success rate, long test duration, and tedious specimen preparation.

UTILIZATION OF PHILIPPINE GOLD MINE TAILINGS AS A MATERIAL FOR GEOPOLYMERIZATION

Erica Elice S. Uy[1], Mary Ann Q. Adajar[1], Hannah Eunice V. Beltran[1], Camille Allysa L. Calicdan[1], Tony Rose E. Duran[1] and Caryl David G. Ramos[1]

ABSTRACT

Mining minerals results to a waste material called mine tailings. In the Philippines, these waste materials are considered as valueless and are just stored at tailing dams. The increasing demand of gold minerals in the country can cause an increase in production of these waste materials. This can lead to a shortage in storage facilities. With this, this study used Philippine gold mine tailings as a material for geopolymerization. The process of geopolymerization produces a cementitious material with properties substantially comparable to those of a conventional cement. It occurs after an aluminosilicate material reacts with an alkali hydroxide or silicate solution. In this study, gold mine tailings was mixed with the alkaline solution, or the combination of the 10-molar sodium hydroxide solution (10M NaOH) and the water glass solution (WGS), to produce the geopolymer. A total of four-mix proportion of WGS-to-10M NaOH and alkaline solution-to-mine tailings (AS-to-MT) was tested in this study. The compressive strength of each mix proportion were compared. Based on the results, highest compressive strength has a mix proportion of AS-to-MT ratio of 0.35 and the WGS-to-10M NaOH solution ratio of 2.5. X-Ray Diffraction was also performed to determine the chemical compound present in the gold mine tailings used. The results show that aluminum and silicon compounds are present in the material, hence, making the gold mine tailings viable for geopolymerization.

Keywords: Gold Mine Tailings, Geopolymerization,Geopolymer Binder, Waste Material

INTRODUCTION

The increase in mining of minerals such as gold and copper resulted to the growth of waste materials such as mine tailings. These materials are considered as valueless and are always stored in tailing dams. Shortage in storage facility can be a problem due to the increase in mine tailings. As a result, several studies proposed the application of mine tailings for embankment material [1]-[3]. Another promising application is by utilizing mine tailings as a material for geopolymerization which can result to a geopolymer binder. Geopolymerization is a process that produces a cementitious material with properties substantially comparable to those of conventional cement. In a study done by Hardjito, Wallah, Sumajouw, and Rangan (2004), they used geopolymer paste instead of cement paste, but applied the usual methods of creating concrete in manufacturing a type of geopolymer concrete [4]. Based in their results, the geopolymer paste works similarly to a normal cement paste as it binds all the other ingredients together, such as the coarse and fine aggregates, to form the geopolymer concrete. There are several researches that already claimed that mine tailings can be used as a material geopolymerization. Rösner (1999) investigated the geotechnical, mineralogical, and geochemical parameters of gold mine tailings found in South Africa was investigated in the research [5]. A semi-quantitative X-Ray Diffraction (XRD) method was performed. This method is a common technique which identifies the phase and structural characteristics of crystalline solids [6]. Based on the result of the analyses of Rösner, gold mine tailings have high quartz content with an average of 78%. After thorough investigations, it was also revealed that the major chemical element of gold mine tailings found in the East Rand area was silica or SiO_2, with an average of 81.6%. Ahmari, J. Zhang, and L. Zhang (2011) also investigated the feasibility of fly ash modified mine tailings-based geopolymer concrete as an alternative construction material [7]. They discovered that mine tailings have significantly high silicon to aluminum ratio (Si-to-Al) and can be adjusted by using fly ash (ASTM Class F). In the study, the chemical composition of mine tailings and fly ash was compared. It was observed that mine tailings have more SiO_2 content and have less Al_2O_3 content than fly ash, thus, resulting to a greater Si-to-Al ratio. More of their test results revealed that the properties of the mine tailings-based geopolymers were intensively affected by the Si-to-Al ratio and alkalinity of the material, as well as its curing time, especially during the first week. Nevertheless, Ahmari et al. (2011) came to the conclusion that mine tailings may be used as the base material in creating a geopolymer concrete [7].

Moreover, Ahmari and Zhang (2012) tested the feasibility of environment-friendly bricks made through the geopolymerization of copper mine tailings [8]. Unlike the conventional method of brick production, but similar to the production of geopolymer concrete, these environment-friendly bricks were produced by combining the tailings sample with an alkali solution. These bricks were tested under water absorption and unconfined compression tests. The results showed that the use of copper mine tailings in the production of environment-friendly bricks using geopolymerization technology met the ASTM requirements. It is therefore the objective of this study to investigate the potential of the gold mine tailings form the Philippines as a material for geopolymer. Specifically, establish the most appropriate ratio of the alkaline reagent and gold mine tailings to be able to create a geopolymer binder.

GEOPOLYMERIZATION

Geopolymerization occurs after an aluminosilicate material reacts with an alkali hydroxide or silicate solution [9]-[10]. Aluminosilicate materials are minerals composed of compounds with aluminum and silicon; examples of this type of materials include fly ash and mine tailings [11]. Likewise, examples of an alkali hydroxide or silicate solution would be sodium hydroxide (NaOH), and sodium silicate (Na_2SiO_3) solutions, respectively. The mixture of the alkali hydroxide and silicate solutions is collectively known as the alkaline solution or alkaline reagent. The chemical reaction between the wet (alkaline solution) and dry (aluminosilicate material) constituents causes an amorphous gel to harden and condense into a geopolymer binder.

GOLD MINE TAILINGS

The gold mine tailings sample was from a mining site at the Northern Province of Luzon, Philippines. The index properties of the sample were first established based in ASTM standards. The results are tabulated in Table 1. X-Ray Diffraction (XRD) analysis was performed in order to identify the presence of crystalline compounds in the mine tailings sample. The result is shown in Fig. 1. The peaks on the XRD graph suggest that the material is crystalline, while if the lines are somehow flat, the material is amorphous. Based on Fig. 1, the gold mine tailings contain crystalline compounds. Additionally, illite, kaolinite, montmorillonite, and quartz were present in the mine tailings sample. Quartz has a chemical composition of SiO_2 which shows the presence of silicon compounds in the sample. However, no aluminum compound of Al_2O_3 was identified; thus, the aluminum may be amorphous which is desirable for geopolymerization. The XRD results of the mine tailings used in this study shows that aluminum and silicon compounds are present in the material, hence, making the gold mine tailings viable for geopolymerization. To further investigate if the material is amorphous X-Ray Fluorescence (XRF) was also performed. It is a non-destructive procedure that performs the quantitative analysis of elemental composition in which the amount of aluminum (Al) and silicon (Si) present in the mine tailings sample can be found [12]. This was done by displacing the electrons from their atomic positions through a discharge of energy from the apparatus. This energy is identified by the detector to categorize the material by element [13]. The XRF analysis identified the major elemental components of the mine tailings. The top two major elemental components found in the mine tailings sample are silicon (Si) with 61.848% and aluminum (Al) with 12.867%. Since the XRF shows the presence of aluminum, it confirms with the XRD result that this aluminum oxide is amorphous.

Table 1. Index Properties of Gold Mine Tailings

Material	Properties	Values
Gold Mine Tailings	Specific Gravity	2.63
	Liquid Limit	27
	Plastic Limit	22
	Plasticity Index	3
	Linear Shrinkage	3
	Uniformity Coefficient	2.47
	Coefficient of Curvature	1.93
	Soil Classification	Uniformly graded ML

GEOPOLYMERIZATION OF GOLD MINE TAILINGS

The gold mine tailings was first stored in dry condition before the preliminary experiments and the production of the geopolymer binder. The sample was dried in an oven for 24 hours then placed in a plastic container to prevent the absorption of moisture in the atmosphere. Compacted lumps of mine tailings that resulted after the oven-drying were crushed using the mechanical crusher to ensure uniformity of the particle sizes. The texture of the sample after crushing was soft and fine, with physical properties similar to that of cement powder.

Gold Mine Tailings and Alkaline Reagent

An alkali solution was needed to initiate the geopolymerization process of gold mine tailings. A combination of the water glass solution (WGS) and the 10M NaOH was established as the alkaline reagent to create a geopolymer. For the geopolymerization of the gold mine tailings, an alkaline solution-to-mine tailings (AS-to-MT) ratio is also needed to ensure that the geopolymer can develop a capacity to hold compressive stress. The WGS used in this study was composed of 14.65% of Na_2O, 34.13% of SiO_2 and 51.22% of water. The 10M NaOH solution was made from 97%-98% pure sodium hydroxide pellets that were dissolved in distilled water. The ratio of the alkaline solution-to-aluminosilicate material affects the strength of the geopolymer. As the ratio increases, the strength also increases [15]. Based on previous researches, in order to form a geopolymer the WGS-to-10M NaOH ratio can be 1.0 or 2.5 [14]-[15]. Hence, the WGS-to-10M NaOH ratios that were used in this study were 1.00 and 2.50 to ensure that geopolymerization can occur. The alkaline reagent produced by combining the 10M NaOH and WGS is recommended to be prepared at least 24 hours before use [16]-[18]. For the alkaline solution-to-mine tailings (AS-to-MT) ratio, a value of 0.35 and 0.45 was implemented. These ratios were based on previous researches from Aleem and Arumairaj (2012), Patankar, Ghugal, and Jamkar (2014a) and Patankar, Ghugal, and Jamkar (2014b) where they used 0.35 as the AS-to-MT ratio; while Patankar, Ghugal, and Jamkar (2014b) used 0.35, 0.40 and 0.45 as their AS-to-MT ratio, and the results of their study showed that the ratio 0.45 resulted to the samples with the greatest compressive strengths [14], [15], [19].

Preliminary Experiment

A preliminary procedure was made to determine whether the gold mine tailings would react with the alkaline reagent to form a geopolymer and hence, if it would harden, Fig. 2. This is due to the fact that, although some studies have shown to use copper mine tailings to successfully produce geopolymer bricks, it cannot be guaranteed that the same reaction would happen to the gold mine tailings used in this study considering it was obtained from a different source and could possibly be of a different composition, especially the level of aluminum and silica content, both of which are vital to the geopolymerization of the material [8].

Five 50x50mm cubes of geopolymer binders were produced as seen in Fig. 2. The geopolymer binder was produced through the combination of the aluminosilicate material and the alkaline solution. This is analogous to cement paste or the product of the combination of water and cement powder. The geopolymer binder specimens were hand mixed to ensure a uniform consistency of the mixture, since the use of mechanical mixer did not effectively mix the ingredients well. The addition of water was limited to observe medium workability. As a result, four trial mixtures were successfully produced from the combination of the WGS-to-10M NaOH and AS/MT ratios. A minimum of ten 50-mm mortar cubes for each trial mix were made; therefore, an estimated total volume of $1.25x10^{-3}$ m^3 of geopolymer binder per trial was produced. The summary of the materials needed is tabulated in Table 2.

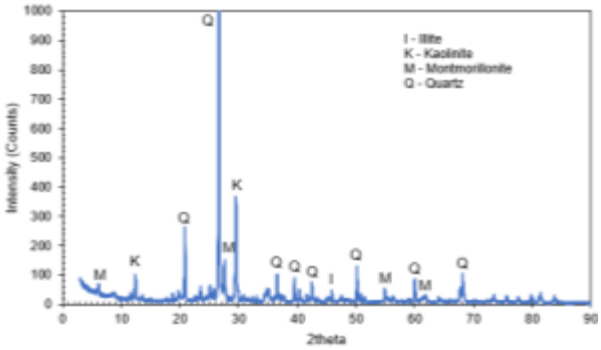

Fig. 1 XRD Results of Mine Tailings.

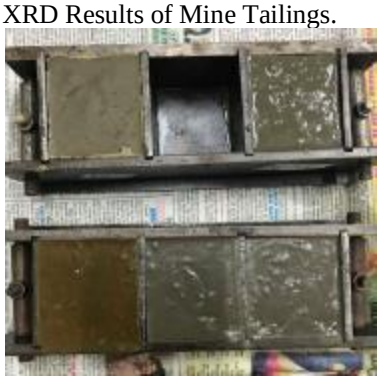

Fig. 2 Preliminary of Geopolymer Binder Samples

Table 2. Mix Proportions of Geopolymer Binder

Materials	Weight Proportions (kg)			
Trial	1a	1b	2a	2b
WGS-to-10M NaOH	1.00		2.50	
AS / MT	0.35	0.45	0.35	0.45

These specimens were heat cured for a temperature of 60ºC for 24 hours after casting in cube molds for at least 5 days, since the specimens were still moist after few days of production. The total number of created specimens for geopolymer binders was 42, wherein at least 10 cube samples were made for each ratio (Fig. 3). The cubes were tested in an unconfined compression test to determine the compressive strength of the geopolymer binder. Five samples for each ratio were first tested on the 7th day, while the remaining

samples were tested on the 28th day.

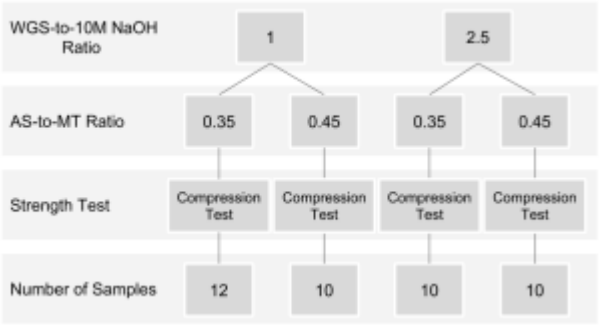

Fig. 3 Actual Number of Samples

Fig. 4 Testing of Geopolymer Binder

RESULTS AND DISCUSSION

The WGS-to-10M NaOH ratios used in this study were 1.00 and 2.50. The WGS, also known as sodium silicate solution, used in this study was composed of 14.65% of Na_2O, 34.13% of SiO_2 and 51.22% of water. Meanwhile, the 10-molar concentration of the NaOH was produced by mixing 400 grams of NaOH micropearls per 1L of the solution. Furthermore, the AS-to-MT ratios used were 0.35 and 0.45. The alkaline solution was mixed a day prior to the mixture of the wet and dry ingredients [17]. Consequently, four trial mixtures were produced based on the combination of the given ratios. Ten 50-mm mortar cubes of each trial were produced whose mix proportions may be found in Table 3. The specimens were heat cured at a temperature of 60ºC for about 24 hours after casting and setting in the cube molds for 5 days. Based on the results of the unconfined compression test, Binder 2a possessed the highest unconfined compression strength both on the 7th and 28th days, with a value of 1.541 MPa, and 1.636 MPa, respectively. These results may be seen in Table 4 and Fig. 4. Binder 2a has an AS-to-MT ratio of 0.35, and WGS-to-10M NaOH ratio of 2.5. Comparing the two ratios for AS-to-MT of 0.35 and 0.45, it shows that the amount of alkaline solution, that is 35% of the amount of mine tailings, is enough to produce a binder. However, increasing the amount of solution to 45% decreases the strength of the binder. WGS, which is used as a binder or adhesive, is required to have a greater amount than the 10M NaOH. This is to ensure the adhesivity of the binder and its ability to set.

Table 3. Mine Tailings-Based Geopolymer Binder Mix

Sample ID	MT (g)	AS (g)	H_2O (g)	AS-to-MT	WGS-to-10M NaOH
Binder 1a	2834	992.5	114.8	0.35	1
Binder 1b	2224	1000	96.6	0.45	1
Binder 2a	2224	778.2	90	0.35	2.5
Binder 2b	2444	1100	106.3	0.45	2.5

On the other hand, 10M NaOH is also used to increase the strength of the binder, but excessive 10M NaOH may result to the occurrence of efflorescence as observed in the preliminary investigation for the production of geopolymer binder (Fig. 5).

Fig. 5 Occurrence of Efflorescence

Table 4. Summary of Compression Test Results

Sample ID	Unconfined Compression Strength, MPa			
	Day 7	Std. Dev.	Day 28	Std. Dev.
Binder 1a	1.225	0.291	1.626	0.380
Binder 1b	0.831	0.413	1.362	0.137
Binder 2a	1.541	0.207	1.636	0.304
Binder 2b	1.155	0.478	1.237	0.201

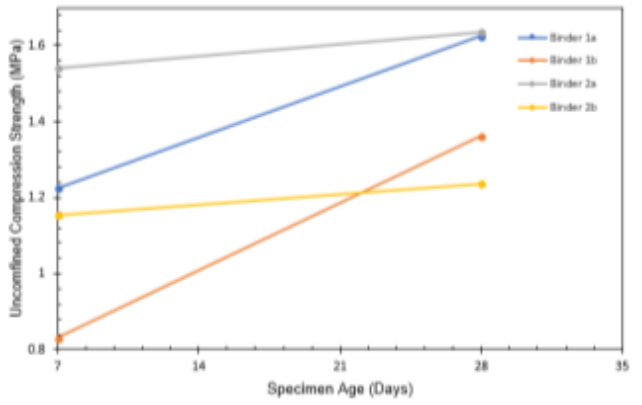

Fig. 6 Relationship between Unconfined Compression Strength and Specimen Age

This is the result of some of the sodium hydroxide solution not reacting completely with the mine tailings. A study by Zhang et al. (2014) suggests that the presence of efflorescence in geopolymers could pose negative effects to its compressive strength development especially when exposed to humid environments [20]. The test results of their study show that the geopolymer binder samples subjected to the occurrence of efflorescence have lower strength values compared to the samples without efflorescence products. Moreover, Zhang et al. (2014) explained that the specimens produced with a higher amount of additional water might have a higher porosity which may lead to the formation of higher efflorescence products within the pores, which then translates to a higher inner stress [20]. They proposed that this eventuality could account for the low strength of the geopolymers with efflorescence. The load-deformation curve of the mine tailings-based geopolymer binder may be seen in Fig. 6.

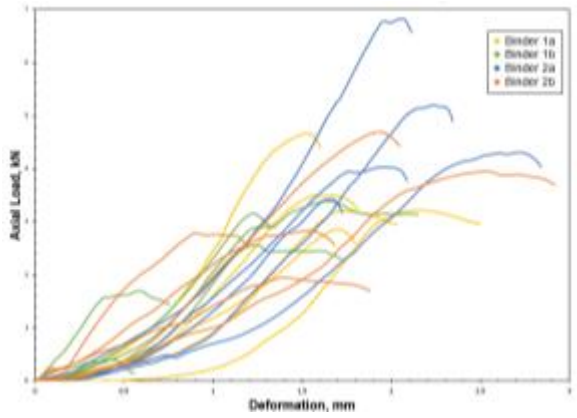

Fig. 7 7th Day Compressive Test

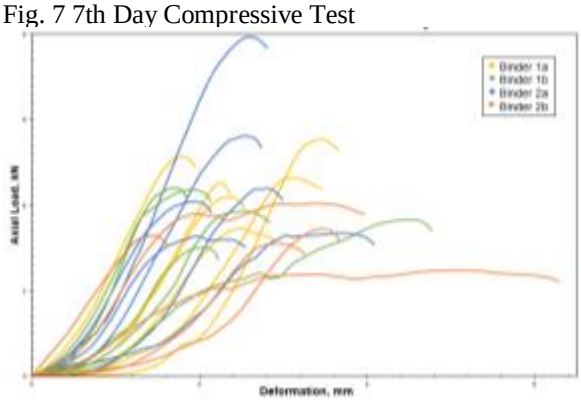

Fig. 8 28th Day Compressive Test

This shows the relationship between the applied axial load and the corresponding deformation at the 7th day of binders 1a, 1b, 2a, and 2b. Binders 1a, 1b, and 2b show steeper slopes than binder 2a. This means that there is gradual deformation as the axial load is applied. However, binder 2a is more flexible in handling the axial load and can still resist greater magnitudes. Binder 2a also produced the greatest unconfined compressive strength at the age of 7 days as seen in Fig. 7. For the 28th day unconfined compression test found in Fig. 8, the load-deformation curve has steeper slope than that of the 7th day. Binders 1b and 2b show a lesser value of maximum applied axial load thus lesser unconfined compressive strengths. These two mixes, binders 1b and 2b, with the AS-to-MT ratio of 0.45 showed that too much alkaline solution may result to a more workable mixture, but binder specimens with lesser compressive strength. The amount of alkaline solution must be adequate to produce the geopolymerization. Binders 1a and 2a presented lesser steep graphs, but, binder 2a resisted a greater load. Thus, the ratio combination that will be used for the mine tailings-based geopolymer concrete is binder 2a, which consists of 0.35 as AS-to-MT ratio and 2.5 as WGS-to-10M NaOH. The summary of these compression strengths is found in Table 4 with its corresponding standard deviation.

CONCLUSIONS

Gold mine tailings were used to produce a geopolymer. Preliminary investigations on the mine tailings sample revealed that the gold mine tailings obtained was a fine-grained, poorly-graded soil having particles with roughly the same sizes or shapes, and may then be considered as uniformly graded inorganic silt with low plasticity (ML) with a specific gravity of 2.63. The average liquid limit of the gold mine tailings was found to be 27, while the average plasticity index was 3; on another hand, the plastic limit and linear shrinkage were found to be 22 and 3, respectively. Furthermore, the XRD analysis showed that the gold mine tailings sample is viable aluminosilicate material for geopolymerization since it has aluminum and silicon compounds in their crystalline forms. This was further verified when the XRF analysis was conducted. This also revealed that the two major elements present in the mine tailings specimen are silicon (Si) with a percentage quantity of 61.85%, and aluminum (Al) with 12.87%. The results show that aluminum and silicon compounds are present in the material, hence, making the gold mine tailings viable for geopolymerization. For the production of the geopolymer binder, four proportion combinations of WGS-to-10M NaOH and AS-to-MT ratio were used to create ten 50mm x 50mm cubes for each ratio combination. After 5 days of setting in the molds, the cubes underwent heat curing for 24 hours using an oven temperature of 60^{o}C. An unconfined compression test was conducted to determine the compressive strength of the geopolymer cubes. The highest compressive strength obtained among the tested binders had a WGS-to-10M NaOH ratio of 2.5 and a AS/MT ratio of 0.35, with a value of 1.541 MPa on the 7th day, and 1.636 MPa on the 28th day. Based on the

results, gold mine tailings has a potential to be used as a material for geopolymerization which can result to a geopolymer binder. For further studies, the binder can be mixed with concrete. The mixture is limited to non-load bearing structures based on its compressive strength.

THE INFLUENCE OF UTILIZATION OF FLY ASH AND RECYCLED COARSE AGGREGATE TO THE STRENGTH OF PERVIOUS CONCRETE

Eva Arifi[1], Evi Nur Cahya[2]
[1]Civil Engineering Department, Brawijaya University, Indonesia;
[2] Water Resources Engineering Department, Brawijaya University, Indonesia

ABSTRACT

This paper investigates the strength performance of pervious concrete which utilizes recycled coarse aggregate and fly ash to promote sustainable pavement construction. Recycled coarse aggregate was obtained from parent concrete with around 225 kg/cm2 of compressive strength. Fly ash was used as supplementary material for cement, while to evaluate the strength of pervious concrete using recycled coarse aggregate, 0%, 50%, and 100% of recycled aggregate was prepared to replace natural coarse aggregate. Result shows that fly ash improves compressive strength and tensile strength of pervious concrete for natural coarse aggregate. Moreover, it also shows that utilization of recycled aggregate indicates significant influence to replace specific natural coarse aggregate to the strength of pervious concrete.

Keywords: Pervious concrete, fly ash, recycled coarse aggregate, compressive strength, splitting tensile strength

INTRODUCTION

Pervious pavement is made so that water can flow through the pavement structure as it has more pores than normal concrete [1]. As the development of urban areas has significantly increased and caused change of land use, resulted increasing surface runoff. As a green alternative to conventional pavements with high void content, pervious concrete allows water to infiltrate through the pavement thus reducing the runoff [2]. The void content of pervious concrete closely relates to the strength of concrete [3]. The advantages of pervious concrete using as road pavement are lower density, lower cost due to lower cement content, lower thermal conductivity, relatively low drying shrinkage, no segregation and capillary movement of water. It also has better insulating characteristics than conventional concrete because of the presence of large voids [4].

As natural aggregate continue to deplete in the recent years, while demolition of old building also increases, the utilization of recycled aggregate offers sustainable construction. Many research have been recorded that recycled aggregate have lower quality than natural aggregate. Recycled aggregates are more porous due to containing mortar from their parent concrete compare to natural aggregate. McGovern [5] has been reported that recycled aggregate has a water absorption rate of between 5-6%, whereas recycled fine aggregate has a water absorption rate of 9-10%, while natural aggregates has a water absorption rate of about 1-2%, therefore the application of recycled aggregate are commonly for low quality concrete [6].

In the other hand, with the increased amount of fly ash generated each year as an environmental pollutant, the utilization of fly ash has drawn researchers interests. In fact, it is proved the most effective of utilization fly ash is in concrete and cement [7], [8]. It is well documented that fly ash as cement replacement improves durability and workability of concrete [9]-[12]. Furthermore, in recycled aggregate concrete, the utilization of fly ash reduces drying shrinkage of concrete [13]. Thereby, the experiment on the influence of utilization of fly ash and recycled coarse aggregate on the strength of pervious concrete is conducted.

EXEPERIMENTAL METHOD

Material Used

To investigate the strength of pervious concrete, recycled coarse aggregate were reclaimed from crushed concrete with 225 kg/cm2 as parent concrete average compression strength. The natural coarse aggregate and recycled coarse aggregate are presented in Fig. 1 dan Fig. 2, respectively. Table 1 showed the physical properties of natural coarse aggregate and recycled coarse aggregate used in the experiment. It is clear that natural coarse aggregate used in the experiment has higher oven-dry density compared to recycled coarse aggregate. However, the water absorption indicated that natural coarse aggregate more porous compared to recycled coarse aggregate. Portland pozzolan cement was used in the experiment with water-to-cement ratio was set to 0.3.

Fly ash Type C also used in the experiment as partial replacement of portland pozzolan cement.

Mix Proportion

The mix proportions of pervious concrete in this study are described in Table 2. The cement-to-aggregate ratio of pervious concrete was set to 1:4 with 0% of fine aggregate used in the experiment. The recycled coarse aggregate replaced 0 %, 50% and 100% of natural aggregate while 0%, 15% and 25% of fly ash were used to replaced Portland pozzolan cement by weight.

Compressive and Splitting Tensile Strength Test

Compressive strength test and splitting tensile strength were conducted at age 28day to evaluate the performance of hardened pervious concrete using cylinder specimens with diameter of 15 cm and 30 cm height according to ASTM C39 and ASTM C496 standards for cylindrical concrete specimens.

RESULTS AND DISCUSSION

Compressive Strength

The effect fly ash as partial replacement of cement on compressive strength of pervious concrete using recycled aggregate was illustrated in Fig. 3. It indicated that the utilization of fly ash in pervious concrete using natural coarse aggregate significantly improved the compressive strength. 15 % of fly ash increased compressive strength of pervious concrete using natural aggregate up to 83.65%, while 25% of fly ash increased 149.49% of compressive strength compared to natural aggregate pervious concrete with 0% of fly ash.

Figure 3 also illustrated the effect of utilization of recycled coarse aggregate to replace specific natural coarse aggregate. It shown that 50% and 100% recycled coarse aggregate to replace specific natural aggregate with 0% of fly ash indicated to improve compressive strength up to 76.18% and 71.88%, respectively. However, in 15% of fly ash to replace cement, 50% of recycled coarse aggregate to replace specific natural coarse aggregate the compressive strength increased 16.62% the compressive strength of pervious concrete, while 100% recycled coarse aggregate lower the compressive strength of pervious concrete instead. In contrary with the 0% of fly ash that recycled coarse aggregate to replace specific natural coarse aggregate tends to improve its

compressive strength, 25% of fly ash significantly decreased pervious concrete compressive strength when percentage of recycled coarse aggregate was increased.

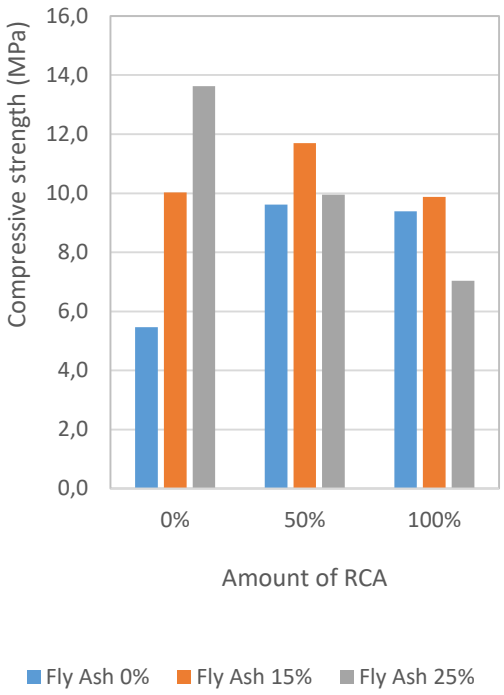

Fig 3. Compressive strength of pervious concrete

Splitting Tensile Strength

The result of splitting tensile strength test of pervious concrete with the effect of utilization of fly ash and recycled coarse aggregate to the strength of previous concrete are presented in Fig. 4. It indicated that the utilization of fly ash in pervious concrete using natural coarse aggregate significantly improved the splitting tensile strength. 15 % of fly ash increased splitting tensile strength of pervious concrete using natural aggregate up to 57.035%, while 25% of fly ash increased 94.93% of splitting tensile strength compared to natural aggregate pervious concrete with 0% of fly ash.

Figure 4 also illustrated the effect of utilization of recycled coarse aggregate to replace specific natural coarse aggregate to its splitting tensile strength. It shown that 50% and 100% recycled coarse aggregate to replace specific natural aggregate with 0% of fly ash indicated to improve splitting tensile strength up to 101.21% and 61.78%, respectively. However, in 15% of fly ash to replace cement, 50% of recycled coarse aggregate to replace specific natural coarse aggregate the splitting tensile strength increased 32.7% the splitting tensile strength of pervious concrete, while 100% recycled coarse aggregate increased the splitting tensile strength of pervious concrete 13.01%. Instead, 25% of fly ash significantly decreased pervious concrete splitting tensile strength when percentage of recycled coarse aggregate was increased compared to 0% of fly ash.

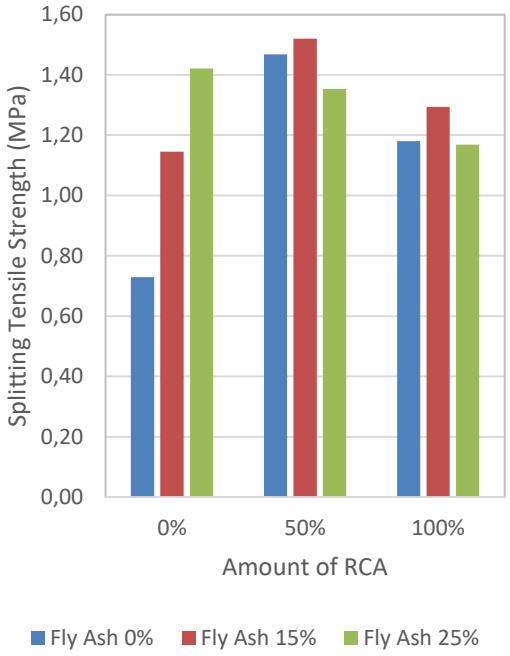

Fig 4. Splitting tensile strength of pervious concrete

CONCLUSION

Compressive strength test and splitting tensile strength test of pervious concrete were examined to investigate the utilization of fly ash and recycled coarse aggregate. The following conclusions are drawn from the test result :

1. The utilization of recycled coarse aggregate to replace selected natural coarse aggregate increases compressive strength and splitting tensile strength of pervious concrete
2. Utilization of fly ash up to 25 % to replace cement improves compressive strength, splitting tensile strengh and flexural strength of pervious concrete using natural coarse aggregate. However, replacing natural coarse aggregate with recycled coarse aggregate up to 50% improves the strength of pervious concrete, particularly in 15% of fly ash to replace cement.

[5]Faculty of Economics and Business, University of Lampung, Indonesia

ABSTRACT

The purpose of this study is to create added value in coconut fiber waste that is commonly found in tropical countries, especially in Indonesia. This study analyzes the change in foundation resistance value by using concrete mixed with bentonite and coconut fiber and finding out the best mixture to reduce the earth resistance value. The highest percentage change in resistance value is 72% with an average resistance value of 45,896 Ω that is using concrete mixed with bentonite 30% from the amount of cement and coconut fiber 1.5% from the concrete volume which is 25 x 25 x 30 cm. The use of coconut fibers is very effective as one of the additives mixed into concrete as a grounding uffer grounding system. Aside from being effective, the use of coconut fiber is also economical because of its high availability at low prices. This study contributes to the use of coconut fiber to reduce the value of grounding resistance. This study also shows that the value of grounding resistance is influenced by the amount of resistance of soil types that can be reduced by adding bentonite. There are 4 variations of concrete used, namely concrete mixed with 30% bentonite, concrete mixed with 30% bentonite and coconut fiber 300 gr, concrete mixed with 30% bentonite and coconut fiber 150 gr, and concrete mixed with coconut fiber 300 gr. The best concrete variation to reduce the value of grounding resistance is 30% bentonite mixture and 300 gr coconut fiber. This research has succeeded in finding that coconut fiber waste can provide more benefits in the form of a decrease in soil resistance to ensure the safety of the electrical system.

Keywords: Grounding resistance, Concrete, Bentonite, Coconut fiber

INTRODUCTION

A good and effective grounding system has a role in security and protection in electric power systems, especially when there are land-related disturbances so that losses can be reduced and even avoided. When there is a disruption in the electric power system, with the grounding system, the disturbance currents that arise can be quickly flowed into the ground and spread in all directions [1].

The grounding system serves as a safeguard against devices that use electricity as a source of energy. Several factors can influence the value of grounding resistance including soil type, soil salinity, soil temperature, soil moisture and chemical content in the soil. The existence of several of these factors causes the value of grounding resistance not in accordance with existing standards. In areas that have high soil type resistance, it is often difficult to achieve small earth resistance values according to the standard [2].

There are several ways to condition the soil so that the location of the electrodes that will be planted has low and standard soil type resistance, one of which is the addition of additives to the soil. These additives can be in the form of gypsum, salt, zeolite, charcoal powder, and bentonite. Addition of bentonite additives and coconut fiber waste into the concrete to influence the increase in water absorption in the concrete so that the value of the resulting earth resistance will be more stable. From the results of this research, it is expected that the bentonite and coconut fibers mixed into the concrete can improve the value of ground resistance and later can be used as a reference in planning or installing ground systems [3].

BASIC THEORY

Grounding system is one of the factors that has an important role in efforts to protect the electric power system when there is interference caused by excess current and voltage. When there is interference with the electrical equipment, the grounding system will flow the fault current quickly to the ground and spread in all directions. In other words, the grounding system will provide the equipment to be protected from the negative impact of excess voltage.

Concrete

Concrete is a homogeneous mixture between

cement, water and aggregate. The characteristics of concrete are high crushed stress and low tensile stress. Concrete is a function of its constituent material consisting of hydraulic cement (Portland cement), coarse aggregate, fine aggregate, water, and added material (admixture or additive) [5]. The advantage of using concrete is that it has a wider surface so that it can absorb more water and be able to keep soil moisture longer.

Bentonite

Bentonite is a type of clay which mostly contains more than 85% montmorillonite with minerals such as quartz, calcite, dolomite, feldspars, and other minerals [see 6]. Based on the type, bentonite is divided into two, namely Na-Bentonite and Ca Bentonite. Comparison between Na + cations and Ca + cations contained therein is quite high, and the colloidal suspension has a pH of 8.5 to 9.8. Fig 1 shows the bentonite powder and Figure 2 shows the chemical structure of the bentonite powder

Fig.1 Bentonite

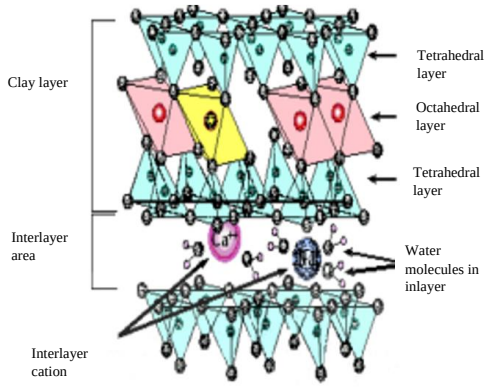

Fig.2 Structure of Bentonite

Coconut fibers

Coconut fiber is one of the bio-mass that is easily obtained and utilized because it can withstand the water content and chemical elements of fertilizers and can neutralize the acidity of the soil. Coconut fibers consist of fiber (fiber) and cork (pitch) which connects one fiber to another fiber. Coconut fibers consist of 75% fiber and 25% cork. Nutrient content that is owned by coconut fibers either macro or micro turns out to be needed by plants.

Macro and micro nutrients contained in coconut fiber include (K) Potassium, (P) Phosphorus, (Ca) Calcium, (Mg) Magnesium, (Na) Sodium and several other minerals. But of the many nutrients that cocopeat has, it turns out that the most abundant amount is the element K (potassium). Fig. 3 shows the coconut powder used for mixing bentonite.

Coconut fiber is very preferred as an absorber because it contains cellullose which in its molecular structure contains carboxyl groups and leginins containing phenoelat acids which take part in metal binding. Cellullose and liginin are biopollymers associated with heavy metal processes

Fig.3 Coconut fiber

Uffer grounding system

Uffer grounding is an electrode wrapped in concrete like a building foundation that is in direct contact with the earth to be used as grounding. This concept is based on concrete conductivity and its large surface area so that it can handle very high current loads [7][8]. Fig.4 Shows grounding system using the uffer grounding method

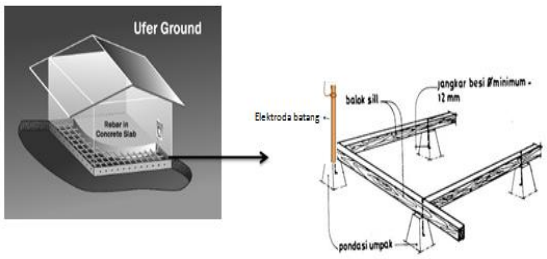

Fig.4 Uffer grounding[8]

EXPERIMENT

Based on literature study research, this research design uses concrete that is volume (25 x 25 x 30) cm and planted at a depth of 50 cm and uses copper-coated electrodes that are 16 mm in diameter and 50 cm in length. Before the research design used

additives added to the grounding system using the grounding fermentation system, the preliminary data was collected using pure concrete without additives. Measuring the value of grounding resistance using pure concrete was carried out five months before measuring the value of grounding resistance using concrete mixed with bentonite additives and coconut fiber waste so that the value of pure concrete resistance with the value of concrete resistance mixed with the additives could not be compared because the treatment between the two was different.

Comparison of material for pure concrete is (cement: sand: gravel = 1: 2: 4) the measurement of the value of grounding resistance in this study is using the three points method [9][10]. Fig.5 shows how earth measurements use the 5 points method

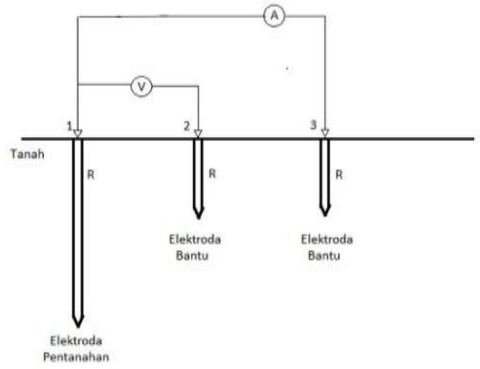

Fig.5 Three points measurement method

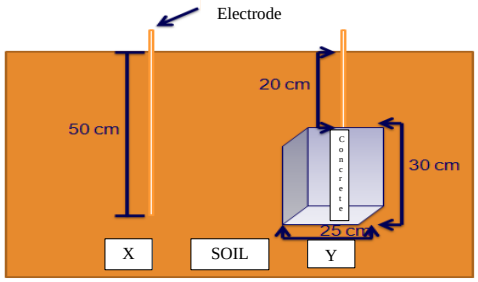

Fig.6 Visualization of testing grounding holes with pure concrete

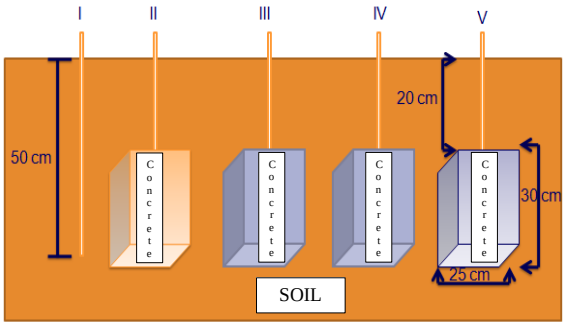

Fig. 7 Visualization of testing of grounding holes with concrete mixed with additives

There are 4 types of concrete mixed with bentonite additives which will be used. First, with the composition of the concrete mixture is mixing bentonite 30% from the amount of cement. Both donit and coconut fiber waste with the composition of the concrete mixture is mixing bentonite 30% of the amount of cement and adding coconut fiber waste 1.5% which is 300 gr.

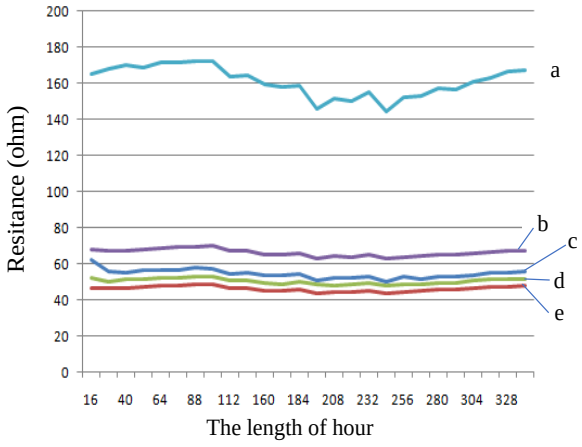
The third with the composition of the concrete mixture is mixing 30% bentonite from the amount of cement and the addition of coconut fiber waste 0.75% (ie 150 gr). The fourth with the composition of the concrete mixture is the addition of 1.5% coconut fiber waste, namely 300 gr. The following is the research design of the grounding system using concrete mixed with bentonite and coconut fiber [11]

Note:
I= Grounding hole without concrete or without substance additives.
II= Grounding hole using concrete (bentonite: cement: sand: gravel = 0.3: 0.7: 2: 4) and the addition of coconut fiber waste 1.5%, 300 gr.
III= Grounding hole using concrete (bentonite: cement: sand: gravel = 0.3: 0.7: 2: 4) and the addition of coconut fiber waste 0.75% which is 150 gr.
IV= Grounding hole using concrete (cement: sand: gravel = 1: 2: 4) and the addition of coconut fiber waste 1.5% which is 300 gr.

RESULT AND DISCUSSION

The value of grounding resistance in accordance with the PUIL standard, namely ≤ 5Ω is used as a security system for devices with a power source for interference caused by short circuit or lightning. To reduce the value of grounding resistance by several methods, one of them is by adding additives to ground earthing.

Testing of Ground Resistance



Note:
a = 30% bentonite composition
b = concrete composed of 30% bentonite and 300gr fibers
c = bentonite 30% concrete composition and 150gr fibers
d = 300gr concrete fiber composition
e = Soil

Fig. 8 Graph comparison of measurement results of grounding resistance by composition of bentonite and coconut fiber waste

Figure 8 shows a graph of the comparison of the results of measuring the value of earth resistance from concrete variations which are composed of bentonite and coconut fiber waste. From the figure, it can be seen that the value of the resistance on the ground looks fluctuating, while the variation of the concrete mixture of bentonite and coconut fiber waste looks more stable.

The average value of grounding resistance from the composition of concrete that is composed produces different grounding resistances, namely 54.546 Ω for bentonite composition 30%, 45.889 Ω for bentonite compositions 30% and coconut fibers 300 gr, 50.192 Ω for bentonite compositions 30% and 150 gr of coconut fiber, 66,157 Ω for coconut fiber compositions 300 gr, and 162,2 Ω for grounding prisoners.

Results of Percentage Changes in Land Detention Value

Calculation of the percentage change in value of grounding resistance to obtain how much the change in the percentage value of grounding prisoners between land using bentonite and coconut fiber waste which is composed of concrete with the value of grounding resistance without using concrete or additives is as follows:

$$\% \text{ Change } R = (R\_X - R\_Y) / R\_X \times 100\%$$

Note:
Rx = value of grounding resistance without additives
Ry = value of grounding resistance with additives

Table 1 Percentage change in value of grounding resistance

Item	R (Ω)	Change R (%)
I	54,546	66%
II	45,896	72%
III	50,192	69%
IV	66,158	59%
V	161,2	-

Note:
I = Grounding of concrete is composed of 30% bentonite mixture.

II = Grounding of concrete is composed of 30% bentonite mixture and addition of coconut fiber waste 300 gr.

III = Grounding hole of concrete composed of 30% bentonite mixture and addition of coconut fiber waste 150 gr.

IV = Grounding of a mixture of compressed concrete added coconut fiber waste 300 gr.

V = Grounding hole without concrete or without additives.

Table 1 show the percentage change in the value of the largest grounding resistance, namely with concrete which is composed of 30% bentonite and the addition of coconut fiber waste 300 gr is 72%. The difference in the percentage change value of grounding resistance from concrete which is composed of 30% bentonite from the addition of coconut fiber waste 150 gr and 300 gr is not too significant, namely with each change in the percentage value of 69% and 72%.

Comparison of the percentage change in the value of grounding resistance between concrete which is composed of 30% bentonite and concrete that is composed of coconut fiber waste 300 gr is the value of each change in percentage of 66% and 59%. From these data it can be concluded that using concrete that is composed of bentonite and coconut fiber waste is better with the percentage change in the value of grounding resistance higher than that of only bentonite and coconut fiber waste. To be clearer in comparing the percentage change in value of grounding resistance can be seen in the Fig 9.

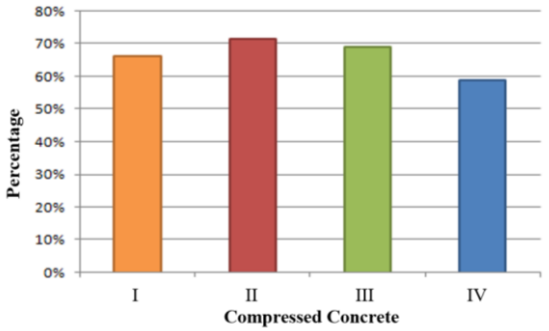


Fig.9 Percentage change in value of grounding resistance

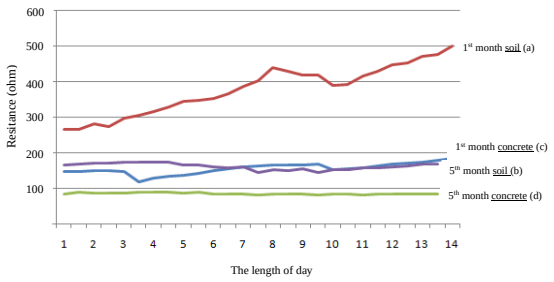
Pure Concrete Test Results

Fig.10 Graph of the measurement results of grounding pure concrete resistance



Pure concrete testing is the preliminary data from this study which has been carried out for five months from October 2017 to March 2018 and is measured 14 days in the first month and the fifth month in the morning and evening. This pure concrete testing is

planted at the same depth of 50 cm and the same volume of concrete is 25 x 25 x 30 (cm). This is to find out the testing of grounding prisoners using concrete for a longer period of time.

Figure 10 shows the results of pure electrode testing in the first 14 days. In the figure there is a decrease in the value of soil resistance in the first month (a) where on the first day measured 266 and on the 14th day measured by 499 Ω on the first month, and decreased resistance on the fifth month (b) on the first day measured by 165 and on the 14th day measured by 167. These results indicate that even in wet environmental conditions in tropical countries (such as in Indonesia) the resistance of pure concrete has decreased. Condition (a) and (b) occurs when the electrodes are directly implanted into the ground without concrete (see picture 6 [X]).

Meanwhile, electrodes implanted into concrete showed lower resistance, i.e. in the first month (c) the measured value on the first day was 147 Ω to the 14th day measured at 185 Ω. Testing the value of pure earth ground resistance in the fifth month (d) looks more stable than the first month which is around the earth resistance value of ± 85 Ω. These conditions (c) and (d) occur when electrodes are implanted into pure concrete before they are implanted into the ground (see figure 6 [Y]).

Discussion of Uffer Grounding

Uffer grounding is an electrode wrapped in concrete like a building foundation that is in direct contact with the earth to be used as a grounding resistance system. Concrete is composed of materials in the form of cement, sand, and gravel with a ratio of 1: 2: 4. Where cement itself is composed of several ingredients, namely as showes at table 4

Table 2 Chemical composition of Portland cement

Oksida	Persen (%)
Kapur (CaO)	60 – 65
Silica (SiO_2)	17 – 25
Alumunia (Al_2O_3)	3 – 8
Besi (Fe_2O_3)	0,5 – 6
Magnesia (MgO)	0,5 – 4
Sulfur (SO_3)	1 – 2
($Na_2O + K_2O$)	0,5 – 1

Source: Tjokrodimuljo, 1996 [12].

Table 2 the main ingredients of cement are lime and silica (clay). Limestone is the main source of compounds of calcium carbonate (CaCO3). Therefore, when cement is made as one of the concrete forming materials it will increase Ca + 2 levels while CO3-2 and if it reacts with H2O to H2CO3, it can eventually break down into CO2 and water vapor [13] [14].

CaCO3 + 2H + Ca + 2 + CO2 + H2O

The concrete structure that contains cement, creates concrete pore spaces, especially water binding pores which can reduce resistance through the role of water as an electrolyte. Whereas clay is the main source of silica compounds. Silica compounds have the ability to absorb large amounts of water because they have a large surface and large pore volume. In addition, when concrete becomes a solid object it will have absorption characteristics that can absorb water for a long time and maintain substances around it so that it can retain moisture in the soil [5].

This research uses 50 cm long and 16 mm diameter rod electrodes which are bound to an iron frame 8 mm in diameter and then wrapped with concrete mixed with bentonite and coconut fiber waste. The electrodes were planted at a depth of 50 cm and the volume of concrete was 25 x 25 x 30 cm with four different methods of mixing additives namely concrete plus bentonite 30% from the amount of cement, concrete plus bentonite 30% from the amount of cement and adding coconut fiber waste 1.5 % is 300 gr, concrete plus bentonite 30% of the amount and the addition of coconut fiber waste is 0.75% which is 150 gr, and concrete plus coconut fiber 1.5% is 300 gr. From the variations in the addition of zat additives so that the best final results are known.

The use of coconut fiber waste is used to increase water absorption and compressive strength of the concrete so that the value of grounding resistance will be better than without the addition of coconut fibers. Addition of coconut fiber waste must be limited because it will affect the compressive strength of the concrete itself. The best addition of coconut fiber waste is 0% - 3% of the concrete volume. In this study with the volume of concrete 25 x 25 x 30 cm, the amount of addition of coconut fiber waste which must be limited to 1.5% is ± 316 gr.

The addition of coconut fiber waste was varied to 0.75% and 1.5% in mixing electrodes with bentonite 30% of the amount of cement. From the addition of the two variations of coconut fiber addition, we should know the best mixture of coconut fiber waste. From the results of measurements obtained by the addition of 30% bentonite from the amount of cement and coconut fiber waste of 1.5%, 300 gr mixed into the concrete has the best value of detention, namely the value of the average resistance 45,896 Ω.

CONCLUSION

The purpose of this study is to create added value in coconut fiber waste that is commonly found in tropical countries, especially in Indonesia. This study analyzes the change in foundation resistance value by using concrete mixed with bentonite and coconut fiber and finding out the best mixture to reduce the soil resistance value. The best concrete variation to reduce the value of grounding resistance is 30%

bentonite mixture and 300 gr coconut fiber. This research has succeeded in finding that coconut fiber waste can provide more benefits in the form of a decrease in soil resistance to ensure the safety of the electrical system. In other words, this grounding system can secure electrical equipment.

Based on the some conclusions are obtained as follows:

(1) Concrete has the ability to maintain the water content in it and is able to maintain the surrounding soil moisture and the effect of adding bentonite and coconut fibers to the concrete can increase water absorption in concrete resulting in better grounding resistance than without addition of bentonite or coconut fibers only.
(2) In this study, the best composition of the mixture was 30% mixed bentonite concrete from the amount of cement and the addition of 1.5% coconut fiber at a volume of 25 x 25 x 30 cm which had a better average value of grounding resistance, 45,896 Ω.
(3) Concrete which is composed of bentonite and coconut fiber waste has a lower grounding resistance value of 45,896 Ω compared to concrete which is only bentonite composition which is 54,546 Ω or coconut fiber waste is 66,158 Ω.

ABSTRACT

A superassembalage of corner beam-column joint specimen equipped with fuse-bars were designed, constructed, tested, analyzed, modelled using Ruaumoko 2D program and validated is presented. The full-scale of corner beam-column joint was designed using Eurocode 8 (seismic code of practice) under Ductility Class Medium (DCM). Experimental results such as hysteresis loops, stiffness, ductility and equivalent viscous damping have higher values than the corner beam-column joint which designed using BS8110 (non-seismic code of practice). The ductility with 2.69 was achieved at 2.5% drift (lateral displacement) when applied in-plane lateral load to the specimen. The fuse-bars were placed inside the corner beam-column joint acted as energy dissipator which can reduce the structural damages and at the same time to increase the rigidity and stiffness of structures by producing bigger hysteresis loops. This loops can contribute to higher value of equivalent viscous damping of the structures. Subsequently, the experimental hysteresis loops was modelled using HYSTERES program in Ruaumoko folders and validated with experimental hysteresis loops. There is good correlation and agreement between them. Therefore, this hysteresis loops can be used to model the real RC frame and tested under different level of earthquake excitation.

Keywords: corner beam-column joint, fuse-bars, Ductility Class Medium, ductility, stiffness

INTRODUCTION

Currently, there are a lot of research which had been conducted on super-assemblage and sub-assemblage of beam-column joint under in-plane lateral cyclic loading using different seismic code of practices and philosophies. There are three types of beam-column joints mainly corner, exterior and interior joints [1]. Initially, the beam-column joints were designed using non-seismic code of practice subjected to gravity loads only and tested under reversible vertical cyclic loading [2,3]. Later on, more experimental studies were conducted to investigate the exterior non-seismic precast RC beam-column joint and corner beam-column joints with floor slabs [4,5,6]. In seismic design, ductility is the main parameter to determine the survivality of the structures under earthquake attack. In order to obtain higher ductility, rectangular spiral transverse reinforcements and FRP bars were used [7,8], mechanical anchorage [9], different arrangement of detailing [10] and fuse-bars [11]. The validation between experimental results and modeling results of seismic behavior of beam-column joints need to be carried out [12,13,14].

Following the past earthquake events, there were a lot of structural damages especially at beam-column joints. Several methods had been used to repair and retrofit the beam-column joints such as ferrocement layers [15], CFRP composite [16,17], combination of GFRP sheets and steel cage [18], prestressed steel angles [19] and CFRP and steel plate [20]. However, it is important to design the RC beam-column joint using current seismic code of practice such as Eurocode 8, NZ3101, UBC 2004, FEMA 276 and others international seismic code of practice. Previous had been conducted on RC interior beam-column joint with fuse-bars designed using Eurocode 8 [11] and this paper will present the seismic behavior of RC corner beam-column joint with fuse-bars. The detail designed of beam-column joints, construction of specimen, experimental set-up and analysis of results in terms of hysteresis loops, lateral strength capacity, stiffness, ductility and equivalent viscous damping will be presented in the following section.

DESIGN BEAM-COLUMN JOINT USING EC8

Figure 1 shows the plan view of the two-storey school building with the locations of exterior, interior and corner beam-column joints. The exterior beam-column joint connected with two parallel beams and one column, meanwhile the interior joint has one perpendicular beam, two parallel beams and one column. The corner beam-column joints has two beams with perpendicular with each other and one

column. The RC corner beam-column joint is equipped with fuse-bars and designed using EC8. Figure 2 shows the 3D corner beam-column joint seats on the foundation beam which bolted to the strong floor. Figure 3 shows the 25mm diameter of fuse-bars with reduce section of 20mm at the middle. This fuse-bar is acting as passive energy dissipater where during earthquake it will behave in elastic behavior and yielded the earliest as compared to other reinforcement bars.

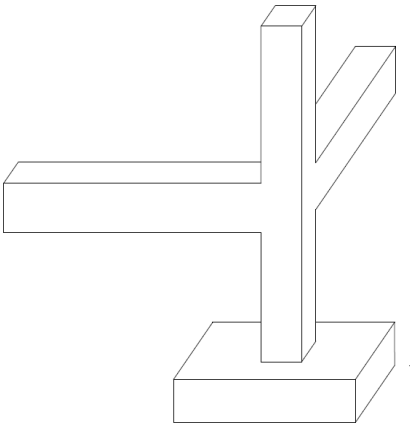

Fig. 2: 3D corner beam-column joint

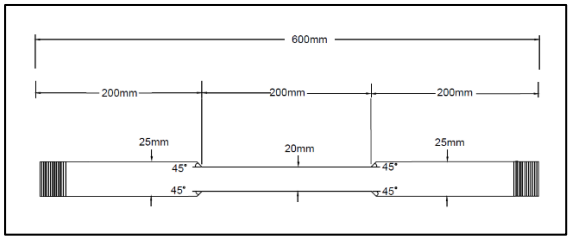

Fig. 3: Fuse-bars inserts inside corner joint.

CONSTRUCTION OF SPECIMEN

Figure 4 shows the construction of RC corner beam-column joint which seated on the foundation beam. Foundation beam was constructed before preparing the reinforcement bars cages for the column. After that formwork was prepared and nailed to the reinforcement cages prior to pouring the wet concrete into the column. Then, let the wet concrete curing for 3 days before dismantle the formwork and the hardened concrete achieved 40% of its compressive strength.

Fig. 4: Pouring of wet concrete into formwork on corner beam-column joints at construction site.

Figure 5 shows the installation of fuse-bars inside the RC corner beam-column joints before pouring the wet concrete into two perpendicular beams. Figure 6 shows column with foundation was lifted to the strong floor before construction of RC corner beam-column joint. After the installation of fuse-bars, formworks were built along the two beams and columns. Subsequently, wet concrete was poured into the formwork and dismantle formwork after its achieved 40% compressive strength. The specimen was ready for experimental set-up and calibration.

Fig. 6: Construction of corner beam-column joints inside the Heavy Structural Laboratory.

EXPERIMENTAL SET-UP AND PROCEDURE

Figure 7 shows the RC corner beam-column joint specimen is ready for instrumentation, calibration and testing. Figure 8 shows the systematic arrangement of linear potentiometers which labelled LVDTs to measure the vertical deformation on the column and lateral displacement on two beams. Double load actuator was applied at top of the column using displacement control method. Data logger was used to record the displacement, load and strain in the reinforcement bars. This specimen will be tested under quasi-static in-plane lateral cyclic loading using the loading regime as shown in Figure 9.

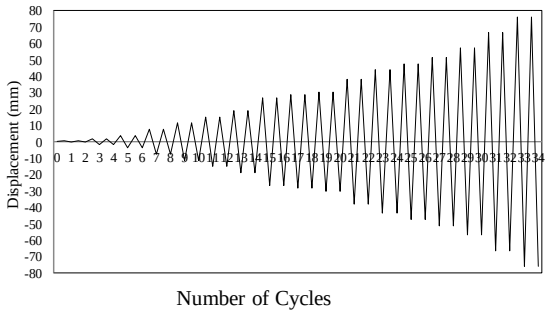

Fig. 9: Loading regime for testing the specimen

EXPERIMENTAL RESULT AND ANALYSIS

The experimental work was conducted in the Heavy Structural Laboratory, Faculty of Civil Engineering, Universiti Teknologi MARA, Malaysia. The specimen was applied quasi-static in-plane lateral cyclic loading using double actuator under displacement control. The lateral displacement is converted into drift by dividing the displacement with effective height of the actuator from strong floor and multiplying by one hundred percent. The specimen was tested from ±0.01% drift until ±2% drift using the loading regime as shown in Figure 9. The RC corner beam-column was failed at 2% drift and lost its lateral strength The photo graphic visual observation of damages was taken, the seismic parameter such as hysteresis loops were recorded, lateral strength capacity, stiffness, ductility and equivalent viscous damping were calculated and analyzed.

Hysteresis loops

Hysteresis loops is one of the important graph that measured and recorded using experimental work. The graph load versus displacement was plotted during testing starting from ±0.01%, ±0.05, ±0.10%, ±0.20%, ±0.50%, ±0.75%, ±1.00%, ±1.15%, ±1.25%, ±1.35%, ±1.50%, ±1.75% and ±2.00% drift. Two cycles of loading and unloading were imposed for each drift. Figure 10 shows the shape of the hysteresis loops where it started with linear behavior, non-linear and experienced the strength degradation starting from ±1.50% until ±2.00% drift.

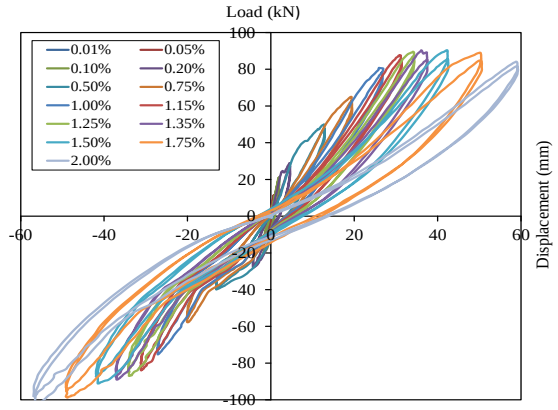

Fig. 10: Hysteresis loops under cyclic loading

Visual Observation of Damages

Figure 11 shows the overall cracks at beam-column joint interfaces starting from -0.2% drift until -1.5% drift. Vertical cracks were observed at beam-column interfaces and horizontal cracks were occurred at column. The measured cracks width were 12mm and the joint started to loss its lateral strength. Figure 12 exhibits the vertical and horizontal cracks were occurred on the vertical and horizontal surfaces

of the beam starting from -0.2% until +1.0% drift. It was also observed that the cracks were around the horizontal beam. Figure 13 displays the spalling of concrete underneath the beam-column joint at +1.75% drift. The opening and closing the gaps of the cracks made the concrete cover spalling and felt down to the strong floor.

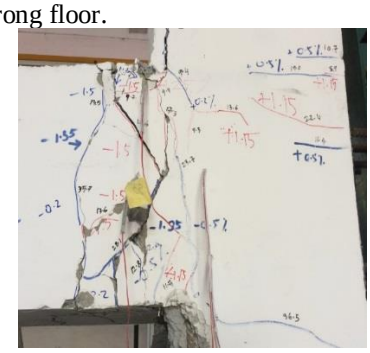

Fig.11: Vertical cracks on the beam-column interfaces at -1.5% drift

Fig. 12: Vertical and horizontal cracks were occurred on the beam starting from+0.5% drift

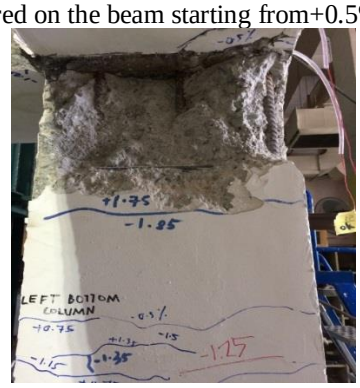

Fig. 13: Spalling of concrete occurred at +1.75%

Lateral Strength Capacity

Figure14 shows the "backbone curve" or graph of load vs displacement for 1st cycle. Based on the graph, the H_u and Δ_u were estimated at 90.79kN and 42.22mm, respectively. Therefore, the value of Hy, taken as 75% of Hu is 67.79kN with the projection of displacement being 27mm making it the yield displacement (Δ_y). Meanwhile, in the pulling direction, Hu and Δu is about -102.66kN and -56.37mm, respectively. The H_y was estimated at -76.7kN while Δ_y at -38mm. Figure 15 shows the lateral strength capacity for second cycle. In pushing direction, H_u was estimated as 87.20kN and Δ_u at 34.26mm. Therefore, Δy was estimated at 27mm. In the pulling direction, Δy was estimated at -36.50 mm. This was taken based on the value for Hu at -98.08kN and Δ_u at -56.95mm.

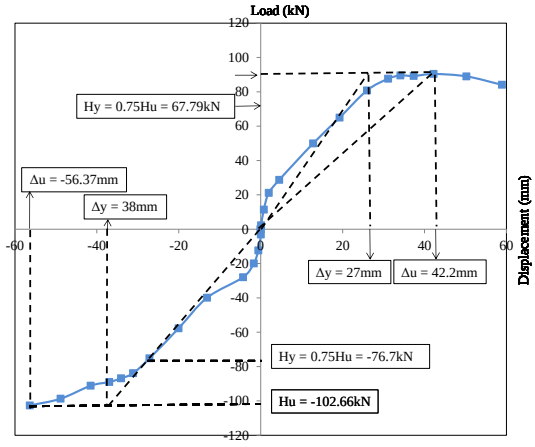

Fig. 14: Lateral strength capacity for the first cycle

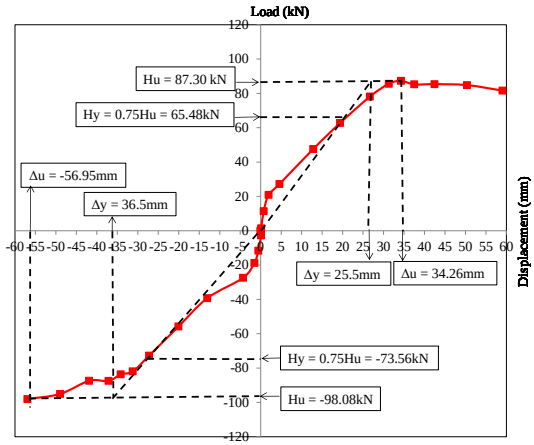

Fig 15: Lateral strength capacity for second cycle.

Stiffness

Stiffness of the structures can be classified into elastic stiffness (K_e), secant stiffness (K_{sec}) and effective stiffness (K_{eff}). Figure 16 shows the equation of stiffness using lateral strength capacity of RC corner beam-column joint. The elastic stiffness has the highest value, followed by effective stiffness and secant stiffness has the lowest value. Figure 17 shows the values of these stiffness versus drift starting from 0.01% drift until 2.0% drift for first and second cycle. The highest value of stiffness occurred in first cycle in pushing direction.

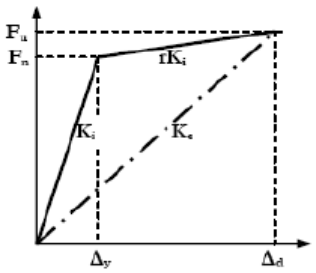

Fig 16: Definition of stiffness

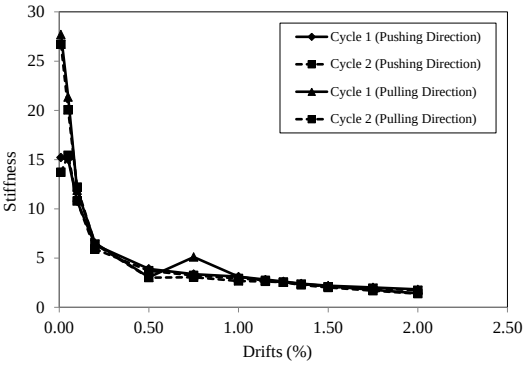

Fig. 17: Stiffness of corner beam-column joint for the 1st and 2nd cycle of each drift.

Ductility

Ductility can be defined as the capacity of a structure or its members to undergo large inelastic deformations beyond the initial yield deformation without losing much of its load carrying capacity or without rupture before failure [21]. Table 1 tabulates the values of ductility for the first and second cycles in pushing and pulling directions. The highest value of ductility for corner joint is 2.69 at 2.00% drift for the 1st cycle in pushing direction. It means that when ductility higher than 2, the building will be able to withstand moderate or severe earthquake excitations.

Table 1: Ductility for the First and Second Cycles in Pushing and Pulling Directions

Target Drift (%)	Pushing Direction		Pulling Direction	
	Cycle 1	Cycle 2	Cycle 1	Cycle 2
0.01	0.00	0.01	0.00	0.00
0.05	0.03	0.04	0.02	0.02
0.10	0.09	0.09	0.06	0.06
0.20	0.21	0.22	0.15	0.15
0.50	0.58	0.61	0.47	0.47
0.75	0.88	0.92	0.72	0.72
1.00	1.18	1.00	0.98	0.97
1.15	1.42	1.27	1.12	1.12
1.25	1.56	1.49	1.23	1.22
1.35	1.71	1.63	1.33	1.33
1.50	1.93	1.79	1.50	1.50
1.75	2.29	2.02	1.76	1.75
2.00	2.69	2.40	2.04	2.03

Equivalent Viscous Damping

The equivalent viscous damping corresponding to the hysteretic response, the concept of dissipated and stored energy has been used [22]. Equivalent viscous damping ratio can be calculated by dividing the total area under hysteresis loops with strain energy under triangle area and multiplying by 100. The fatter the hysteresis loops, more work done by the structures before it started to collapse. The best shape of the hysteresis loops is the flag shape which contribute from post-tensioned tendons. Table 2 shows the values of equivalent viscous damping for the 1st and 2nd cycle starting from 0.01% drift until 2.00% drift. The highest value of the equivalent viscous damping is 2.05% which occurred at 2.00% drift under the 1st cycle.

Table 2 Equivalent viscous damping corner joint

Drift (%)	Cycle 1	Cycle 2
	ζeq	
0.01	0.06	0.11
0.05	0.10	0.15
0.10	0.15	0.20
0.20	0.25	0.30
0.50	0.55	0.60
0.75	0.80	0.85
1.00	1.05	1.10
1.15	1.20	1.25
1.25	1.30	1.35
1.35	1.40	1.45
1.50	1.55	1.60
1.75	1.80	1.85
2.00	2.05	2.10

CONCLUSIONS

Based on the visual observation of damages, experimental data and analysis of result, the following conclusions can be drawn;

1) The corner beam-column with fuse-bars can shift the diagonal cracks from the intersection beam-column joint to the interface and spalling of concrete at the bottom beam.
2) The maximum lateral strength capacity of the joint is 102.66 kN in pulling direction for the first cycle at 2.00% drift.
3) The stiffness of the corner beam-column joint become the highest at elastic region before 0.20% drift and reduce starting from 0.50% until 2.00% drift.
4) The highest value of ductility for corner joint is 2.69 at 2.00% drift for the 1st cycle in pushing direction which meaning to say that the structures survive under moderate and strong earthquake excitation.
5) The highest values of equivalent viscous damping is 2.05% at 2.00% drift.

COMPRESSIVE STRENGTH AND WORKABILITY OF CEMENT MORTAR CONTAINING RECYCLED ASPHALT PAVEMENT

Jirayut Suebsuk[1] and Panupong Panpipat[2]
[1,2]Department of Civil Engineering, Faculty of Engineering and Architecture,
Rajamangala University of Technology Isan, Thailand

ABSTRACT

This article presents the compressive strength and workability of cement mortar (CM) containing recycled asphalt pavement (RAP) as fine aggregate replacement. The effect of RAP replacement, water to cement ratio, curing time, and aggregate water absorption on compressive strength and flow workability are reported. The results showed that the mixing water and mixing time play a significant role in the compressive strength and unit weight of CM containing RAP. The RAP has higher the water absorption and slower rate of water absorption than those of sand. The flow workability of CM increases with RAP replacement due to the unabsorbed water at the initial mixing stage. The main negative factors affected the compressive strength of CM containing RAP as a fine aggregate replacement was revealed. The unabsorbed water at the initial state of mixing before hardening causes increased flow workability and decreased compressive strength. The modified water to cement ratio was recommended for the mix design of CM containing RAP. The findings from this research will promote the mix design approach of CM containing RAP as a fine aggregate replacement for moving toward increased applications of recycled materials in a sustainable manner in civil engineering construction.

Keywords: Compressive strength, Flow workability, Cement mortar, Recycled asphalt pavement

INTRODUCTION

The recycled or reclaimed asphalt pavement (RAP) is pavement materials containing asphalt binder and selected aggregate. The RAP is from constructions and rehabilitation of damaged asphalt pavement road. The recycled asphalt pavement mixture and in-situ pavement recycling base course are increasingly used during recent years [1-3]. It is due to the substantial saving in cost and conservation of natural aggregate source. The RAP has been successfully repurposed in the mix asphalt for new paving applications [1, 4]. Although RAP can be used to replace virgin aggregates for new hot mix asphalt concrete with high percentage replacement [1, 5-6], the remaining RAP poses an environmental problem in many developing and developed countries including Thailand. The good use of RAP in civil engineering application is to reuse it in the concrete pavement for disposing the excess RAP. The RAP can improve the performance and cost effectiveness of the new concrete pavement.

The properties of RAP depend on the source of aggregates used in asphalt pavement mixtures. In Thailand, three main types of aggregates are used for preparing the asphalt concrete by Department of Highway and Department of Rural Roads; those are limestone, granite, and basalt. Moreover, the variation in characteristics of RAP is due to the type of mix, asphalt mix consistency, bitumen content, and milling procedure. Typical size of RAP produced from cold milling process is between 0.1-25 mm in size [7-9].

Previous research studied the engineering properties and feasibility of using RAP as fine and coarse aggregates replacement in the concrete application, including concrete slab for pavement [9]. Huang et al. [7] presented the schematic behavior of concrete containing RAP that the asphalt forms a thin film at the interface of cement binder and aggregate. The asphalt interface is useful in resisting the crack propagation through the aggregate. The crack development occurs along with the asphalt film, which more energy dissipation is higher than those of normal concrete. The reduction in compressive strength and increase in toughness have been observed for the laboratory test on concrete containing RAP. Generally, strength and stiffness of concrete depend on the asphalt binder in RAP [10-14]. The performance of concrete containing RAP can be improved with the use of fly ash as indicated by the measurements of porosity and permeability. Concrete containing RAP enhances the ductility and strain capacity of concrete. This improvement in property can be useful for application such as rigid pavement, road, or railway base [15-16].

The present study aimed to investigate the strength formation mechanisms of CM containing RAP under various RAP replacements, water to cement ratio, curing time. The flow workability and compressive strength were carried out for fresh and harden mortar, respectively. The different water

absorption between natural sand and RAP, which is a key point of workability of CM containing RAP has been studied and discussed. The mixing and effective waters have been defined separately. The strength-effective water to cement ratio law of CM containing RAP is satisfied with the traditional Abrams' law. This study has significant impacts on vibrating support applications (such as concrete pavement, road or railway base) by using CM containing RAP as fine aggregate replacement.

MATERIALS AND METHODS

Materials

The Portland cement type I used in this study is, according to ASTM C150/C150M. The clean sand and the RAP were collected from a stockpile of the Department of Highway (DOH), Thailand. The RAP consisted of crushed Basalt rock, which is a very common dark-colored volcanic rock composed of calcic plagioclase, clinopyroxene and iron ore, with asphalt binder. Only 45% of raw RAP from stockpile passes through 4.75 mm sieve. This portion is defined as a fine RAP. The particle size distribution curves of sand and fine RAP are shown in Fig. 1. The particle size of fine RAP is larger than that of the ASTM C33 upper bound, while the particle size of natural sand is on the lower bound of ASTM C33. However, the RAP passed 4.75 mm-sieve was used to replace the natural sand as fine aggregate in this study. The fine RAP, composed of approximately 4.8% bitumen content, was determined by the extraction method recommended by McDaniel and Anderson [17]. The physical properties of the aggregate are listed in Table 1.

Methods of study

The CM samples were prepared using natural sand and fine RAP as aggregate. Twenty-five mix proportions were used in this study, as shown in Table 2. The CM with the percentage of RAP is denoted by M†R**, which † is water to cement ratio and ** is the percentage of RAP replacement. The cement paste is prepared at any water to cement ratio (*w/C*) as reference.

The natural sand and RAP were prepared and mixed at dry state in practice. The mixing water (w_{mix}) included the water counting for reacting with the cement (w) and compensated water for aggregate as SSD state (w_{SSD}). The water absorption (A) from Table 1, according to ASTM C128 was used to determine the compensated water for mix design. The flow test of fresh mortar was investigated according to ASTM C109. Moreover, the flow loss test with time was performed on fresh mortar to investigate the setting time and variation of workability with elapsed time.

Table 1 Properties of aggregates

Properties	Sand	RAP	RAP*
Fineness modulus	2.38	3.91	3.80
Specific gravity (G_s)	2.62	2.66	2.82
Unit weight (kg/m^3)	1,647	1,442	1,632
Water absorption (%)	1.15	2.56	2.31

* RAP without Asphalt determine by the extraction method recommended by McDaniel and Anderson [29]

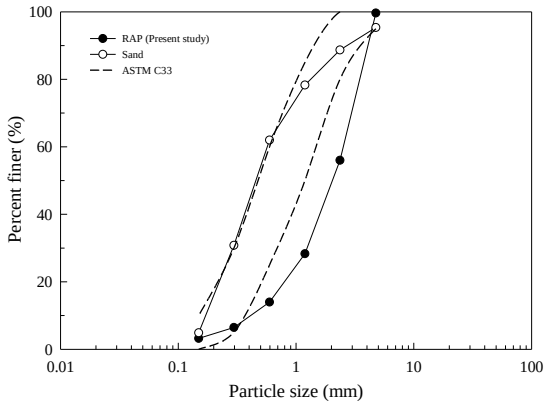

Fig. 1 Particle size distribution curves of aggregate

The mortar samples of 15x15x15 mm were demolded after 24 hours and immediately wrapped with the vinyl sheet then cured under room temperature. The unit weight of harden mortar was measured before the compression test. The compressive strength was measured at a specific curing time using the 600 kN universal testing machine (UTM) according to ASTM C109. The strength was the average value of five samples.

RESULTS AND DISCUSSION

Flow workability of fresh mortar

The twenty-five test results of flow of mortar are represented in Fig. 2. The water in mix proportions with *w/C* between 0.40 and 0.50 is inadequate for workability. The zero percentage of flow was observed for *w/C* of 0.40. The appropriate *w/C* is between 0.50 and 0.70. The percentage of the flow of mortar with 25% to 100% RAP replacement passes the requirements by ASTM C109.

The flow of mortar for all aggregate types depends on the *w/C* [18]. The higher the *w/C*, the higher the mortar flow. Quiroga [19] found that the concrete mixtures optimized for maximum packing density produced poor workability and high susceptibility to segregation, which was possibly due to the reduced spacing and increased friction between aggregates. For the same reason, the increase in the volume fraction of aggregate in mortar generally results in a reduced flow. Hu and Wang [20] presented in the same way that the flow workability depends mainly on the fineness modulus (FM) which was possibly

* is control sample

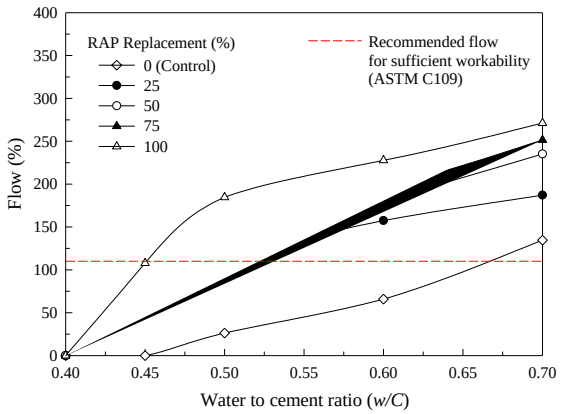

Fig. 2 Flow workability of CM containing RAP

due to the size of the aggregate. Although the RAP is rougher than that of sand and the RAP replacement tends to induce the increased volume fraction of aggregate due to the lower unit weight of RAP when compared with that of sand, the percentage of mortar flow increases directly with RAP replacement due to the effect of aggregate type. This unique behavior is different from past work by Hu and Wang [20]. RAP replacement affects the increasing flow of fresh mortars. At a particular mixture, RAP in the proportion increases both friction and the average size of aggregate which are represented by the higher FM when compared with sand but flow workability increases with the RAP replacement. This unique behavior can be revealed by the effect of water absorption, which is presented in the next section.

Compressive strength

The compressive strengths of CM at 7, 28, and 60 days of curing are presented in Fig. 3. For inadequate zone (*w/C* = 0.4 – 0.5), the compressive strength increased with 25% of RAP replacement then the strength dropped with the increase in RAP replacement. This pattern was observed for all the curing ages. The compressive strength development with curing time was observed for both RAP replacement and control samples.

The water to cement ratio of 0.45, which is an optimum point provided the maximum compressive strength for CM containing RAP. While the optimum point of control CM was observed at *w/C* of 0.5, these investigated results are in line with other past research [21-22]. The 7 and 28 days compressive strength of M†R25 and M†R50 passed the minimum requirement of Portland CM specified for high-speed railway application [22] for *w/C* of 0.40, 0.45, 0.50 and 0.60. The compressive strength varied according to the flow workability. However, the compressive strength of mortar decreased slightly, related to the RAP replacement.

The results of the unit weight of harden mortar are shown in Fig. 4. The unit weight decreased with increasing RAP replacement compared with those of M†R0 series (control mortar). It was due to the bulk unit weight of fine RAP lower than that of sand (*vide* Table 1). The maximum unit weight for RAP replacement was observed for the sample with *w/C* of 0.45. The bulk unit weight of mortar decreased with increasing w/C due to the pores of cement paste [23]. The mixing water in Table 2 includes the water reacted with cement and water that fills the pore of sand and RAP for SSD state. The experiment result conforms with the flow workability. However, the mixing water and mixing time played a significant role in the compressive strength and unit weight. The modified water absorption test was performed under various soaking time at 3, 6, 12, and 24 hours to investigate the variation of workability with mixing time.

Although the SSD-water absorption of RAP was higher than that of sand (*vide* Table 1), the percentage of flow increased with increase in the amount of RAP in mix proportion for *w/C* of 0.45 to 0.70. The rate of water absorption with the time of sand and RAP were different. The water absorption of sand and RAP under various elapsed times is shown in Fig. 5. The initial rate of water absorption of RAP for 1.5 hours (90 minutes) to 12 hours was slower than that of sand but gradually increased for 12 to 24 h. The compensated water, which was not fully absorbed at the initial mixing stage, is defined as free water. The additional percentage of flow composes of the percentage of flow due to reacted water and free

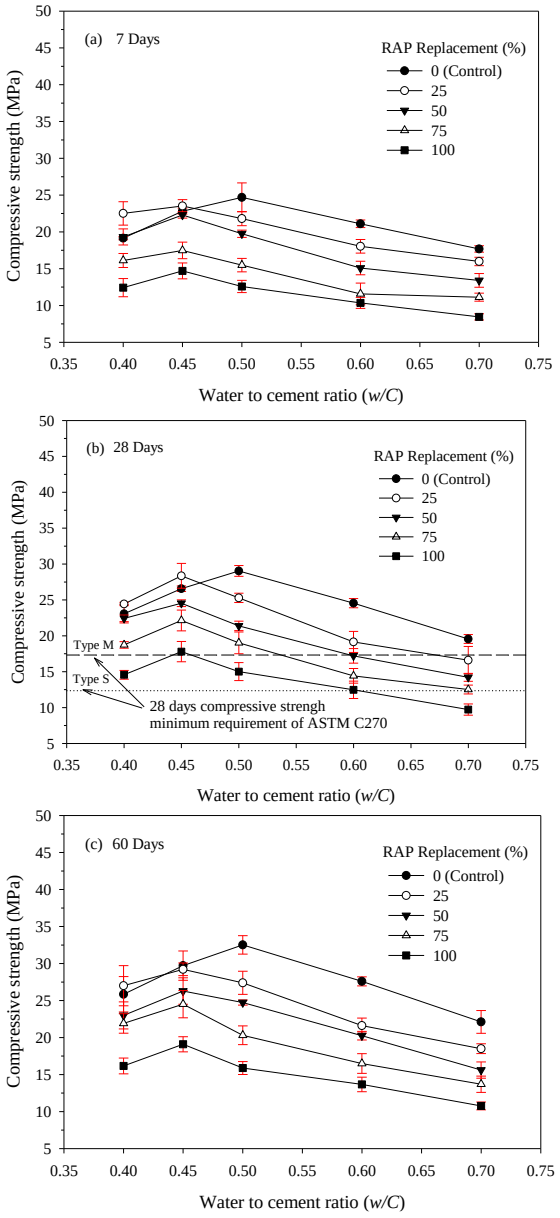

Fig. 3 Compressive strength of mortar for w/C of 0.40-0.70 at various RAP replacements and curing time

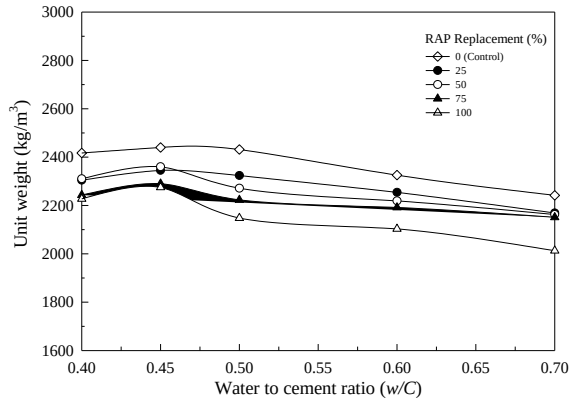

Fig. 4 Unit weight of harden CM containing RAP

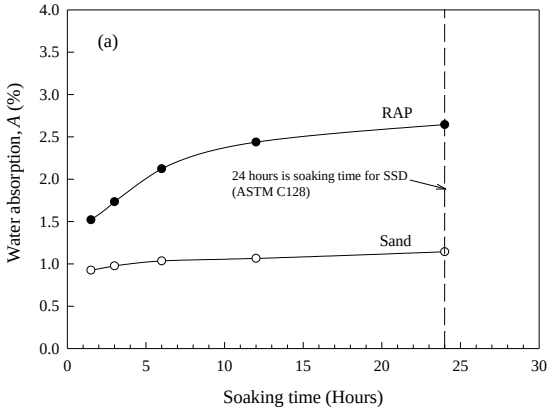

Fig. 5 Water absorption characteristic of sand and RAP

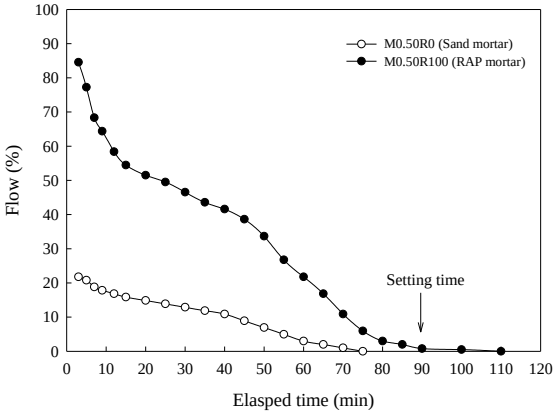

Fig. 6 Flow workability of mortar loss with elapsed time

water. The flow workability of mortar loss proved this assumption with elapsed time, as shown in Fig. 6 for sand and RAP mortars. The setting time of sand and RAP mortar were observed for 90 minutes of elapsed time. While the flow workability of RAP mortar was higher than that of sand mortar, it decreased rapidly with elapsed time. This result revealed that the increasing flow workability of mortar with RAP replacement was mainly affected by the free water at mixing time. The growing free water induces the decreasing compressive strength due to the increasing *w/C*. The effective water (*w**), which is a summation of reacted water and free water at 90 minutes of mixing time, is recommended for the analysis of strength development in CM contacting RAP.

Strength development with curing time

The compressive strengths increased with curing time for all of the RAP replacements. Fig. 7 presents the strength development of mortars in terms of curing time. The curves of strength development with curing time were the same for all mixtures. The compressive strength from the hydration reaction of cement increased up to the 28 days of curing; then the strength development curves went flat. At the early

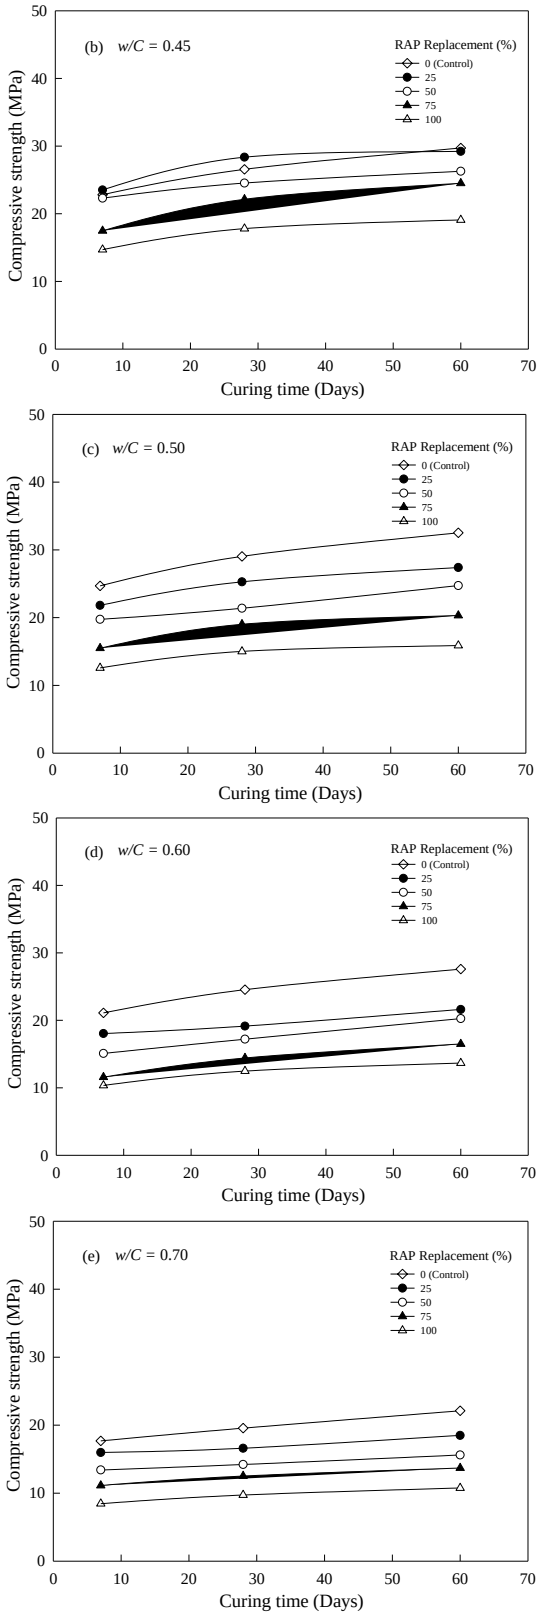

Fig. 7 Strength developments with curing time of sand and RAP mortar

ages of curing (7 days), the compressive strength of M†R25 and M†R50 were higher than those of control mortar (M†R0) for *w/C* of 0.40 and 0.45 while the compressive strength of other series was lower than the control mortar. At the long terms strength (60 days), the strength was mainly dependent on the RAP replacement as fine aggregate. The higher RAP lowered the strength.

CONCLUSIONS

A series of laboratory test was conducted to assess the strength mechanism of concrete mortar containing RAP instead of natural sand. The influence factors studied were mix proportions (RAP replacement, water to cement ratio), and curing time. The flow workability of CM increases with RAP replacement due to the free water, which is the compensated water, not fully absorbed at the initial mixing stage. The effective water to cement ratio (*w*/C*) is recommended for strength analysis. The compressive strength varies according to the flow workability. The compressive strength of mortar decreases slightly, related to the RAP replacement. However, the 7 and 28 days compressive strength of M†R25 and M†R50 passed the minimum requirement of Portland CM specified for railway application [22] for *w/C* of 0.40, 0.45, 0.50 and 0.60.

ABSTRACT

This study aims to investigate the effect of cations associated in three different chloride solutions, NaCl, CaCl2, and MgCl2, on the rate of chloride penetration into concrete. Chloride ponding test was conducted at 15 and 30 days of exposure. The concentration profiles of various ions were undertaken including Cl-, Na+, K+, Mg2+ and the effect of different cations on the diffusion rate of chloride ion into concrete was systematically studied. The test results showed that cations in different chloride solutions have strong influence on the diffusion rate of chloride ions. The rate of chloride penetration in order of fastest to slowest was CaCl2, NaCl, and MgCl2, respectively. The experimental data were compared to numerical results obtained from a numerical model developed based on the Nernst-Planck equation which took into account the ionic coupling effects among ions in chloride solutions and ions in concrete pore solution, Na+, K+, and OH-, and a satisfactory agreement was observed.

Keywords: Chloride, Concrete, Deicing salts, Associated cations.

INTRODUCTION

It has been established for several years in the research studies that chloride is one of the most significant causes of corrosion of steel in reinforced concrete structures. This deleterious effect can reduce the load-bearing capacity, service life, and aesthetics of structures subjected to chloride environments such as bridge decks, parking garages, and marine/offshore structures. Also, the degradation due to corrosion is one of the long-term durability problems for reinforced concrete structures. This study focuses on penetration of deicing salts which are considered as one of the chloride sources. Chloride based deicers are widely used for ice and snow control on roads and bridges in snow-belt regions. In some areas, one mile of four-lane roadways requires the application of more than 100 metric tons of deicing salts each year. About 15.4 million tons of road salts used annually in the U.S. for deicing of highways and roadways [1]. In general, different deicers are frequently used on the same areas for ice and snow control, for example, magnesium chloride solution is used before a snow storm for ice control, and calcium chloride solid salt is used during the snow storm for snow control. As a result, multiple species of deicing salts coexist on the surface and penetrate into concrete simultaneously. The studies of the effect of deicing salts and chloride solutions on concrete have been done by some researchers. Al-Hussaini et al. [2] conducted the experimental study on the effect of free chloride ion source mixed in cement mortar. Two different types of chlorides, NaCl and $CaCl_2$, were selected in the study. They found that NaCl presented more free chloride ion than $CaCl_2$ at all concentration, from 0.5% to 2% by mass of cement, and pH of cement mortars were lower in the case of NaCl. As a result, cement mortars mixed with NaCl can accelerate the corrosion mechanism when compared with $CaCl_2$. In contrast to Arya et al. [3] study, $CaCl_2$ had greater effect than NaCl in terms of producing more free and bound chloride ions when mixed and immersed in specimens. Also, they found from the thin cement pate specimens immersed in 20 g/l of different types of chloride solutions that associated cation in solutions was one of the most important factors affecting on chloride binding capacity. The highest free chloride content was found from the specimens immersed in $MgCl_2$ solution and it decreased in the order of $MgCl_2$ > NaCl > Sea-water > $CaCl_2$. Similar to bound chloride content, $MgCl_2$ had the highest binding capacity and it ranked as $MgCl_2$ > $CaCl_2$ > NaCl > Sea-water. In terms of total chloride content, it can be ordered as $MgCl_2$ > $CaCl_2$ > NaCl > Sea-water.

In this study, three different types of deicers with different associated cations were selected to investigate how these ions affect the chloride ingress rate in concrete. The laboratory tests were conducted to evaluate the penetration of three types of chloride-based deicers, i.e. 3% NaCl, 3% $CaCl_2$, and 3% $MgCl_2$. The study was performed in terms of ponding test. This method was chosen because, in reality, deicing salts are applied on the top surface of concrete structures and then ingress into the bottom where reinforcing steels were located.

EXPERIMENTAL PROCEDURE

The mix proportions with two different water-cement ratios, 0.55 and 0.65, used in this study. After 28 days of curing time, all specimens were immersed in water for 30 days to achieve saturation. The chloride ponding test in this study was conducted in saturated condition so that the effect of moisture was not considered. In order to perform chloride ponding test, the ponding reservoirs were designed by using 5" tall plastic sleeves cut from PVC concrete cylinder molds with 4" diameter. Then, PVC sleeves were put on the top of concrete specimens for 2" in depth so that this created the 3" reservoir. Steel band clamps were used to tighten the PVC sleeves and concrete specimens in order to prevent leakage. A bead of silicone was added around the interface between sleeve and specimen to further prevent water leakage and create watertight compartment for chloride solution at the top of specimen as seen in Fig. 1.

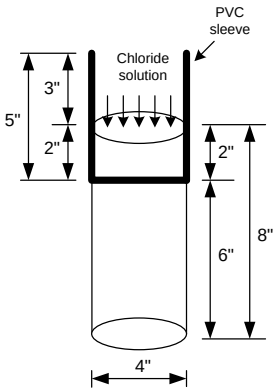

Fig. 1 A concrete sample prepared for the chloride ponding test.

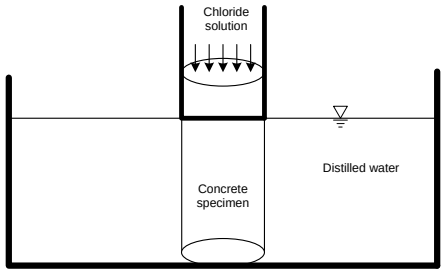

Fig. 2 Chloride ponding test set up.

Once the silicone had dried, all specimens were exposed to chloride solutions. The three different types of chloride solutions, as mentioned above, were ponded on top of samples. The bottom face of specimen was exposed to distilled water so that there would be no moisture effect due to moisture gradient as shown in Fig. 2. The samples were removed from the solutions after 15 and 30 days. The chloride concentration was measured by samples of concrete powder collected at various depth from the surface exposed to chloride solutions. The total chloride contents were obtained from concrete powder samples by using the rapid chloride test instrument.

RESULTS AND DISCUSSION

As mentioned previously, total chloride concentration is analyzed by using the Rapid Chloride Test Water-soluble (RCTW) method [4]. The results of this electrochemical analysis were represented in mille Volt (mV) which is responded to chloride concentration at each depth of concrete specimen. Total chloride profiles are illustrated in Figs. 3 through 6. Figs. 3 and 4 are plotted for specimens with 0.55 w/c exposed to chloride solutions, and Figs. 5 and 6 are represented for samples with 0.65 w/c.

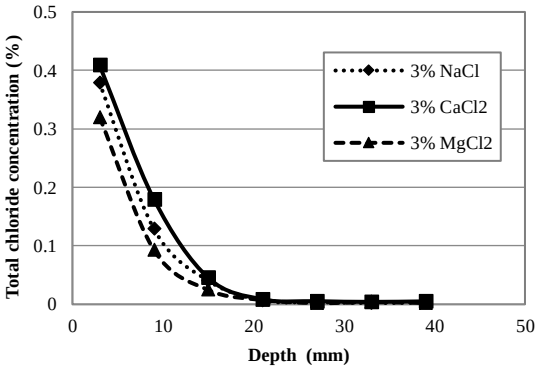

Fig. 3 Chloride profiles of concrete specimen at 15 days of exposure with 0.55 water-cement ratio.

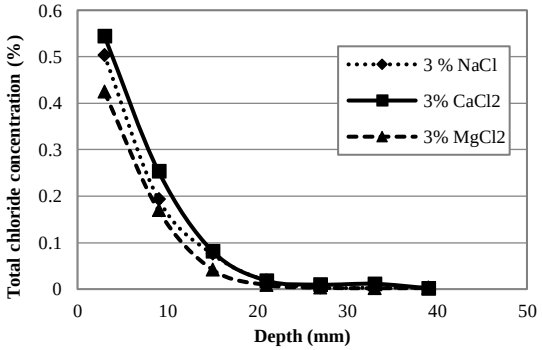

Fig. 4 Chloride profiles of concrete specimen at 30 days of exposure with 0.55 water-cement ratio.

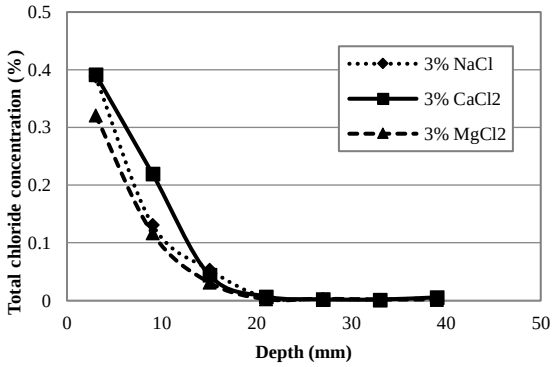

Fig. 5 Chloride profiles of concrete specimen at 15 days of exposure with 0.65 water-cement ratio.

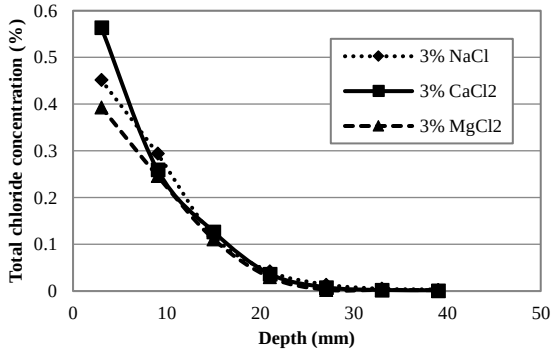

Fig. 6 Chloride profiles of concrete specimen at 30 days of exposure with 0.65 water-cement ratio.

It can be observed from the profiles in Figs. 3, 4, 5, and 6 that the chloride concentrations contribute from 3% $CaCl_2$ solution tend to be the highest when compared with 3% NaCl and 3% $MgCl_2$, at the same depth. This is because 3% solid $CaCl_2$ salt diluted in water produces higher chloride ions than 3% NaCl and 3% $MgCl_2$. The extraction of these three chloride-based salts in solution can be described as Eqs. (1), (2), and (3). In order to compare the test results with numerical results, 3% NaCl, 3% $CaCl_2$, and 3% $MgCl_2$ by weight diluted in 1 liter of distilled water can be converted into mol/l as 0.513, 0.270, and 0.148, respectively. One can see from the Eqs. (1), (2), and (3) that 3% $CaCl_2$ can extract chloride ions higher than 3% NaCl and 3% $MgCl_2$ and 3% $MgCl_2$ produces the smallest amount of chloride ions in solution. This means, at the fixed depth, the highest total chloride concentration is found in the case of 3% $CaCl_2$ and the lowest one occurs in the case of $MgCl_2$.

$$\underset{(0.513\ mol/l)}{3\%\,NaCl} \rightarrow \underset{(0.513\ mol/l)}{Na^+} + \underset{(0.513\ mol/l)}{Cl^-} \quad (1)$$

$$\underset{(0.270\ mol/l)}{3\%\,CaCl_2} \rightarrow \underset{(0.270\ mol/l)}{Ca^{2+}} + \underset{2(0.270\ mol/l)}{2Cl^-} \quad (2)$$

$$\underset{(0.148\ mol/l)}{3\%\,MgCl_2} \rightarrow \underset{(0.148\ mol/l)}{Mg^{2+}} + \underset{2(0.148\ mol/l)}{2Cl^-} \quad (3)$$

To compare experimental data with numerical results, chloride diffusion in concrete is simulated using the Nernst-Planck equation which is dependent on diffusion mechanism due to concentration gradient and migration due to ionic interaction. The flux equation of each ionic species is expressed as,

$$J_i = -D_i\left(\frac{\partial C_i}{\partial x} + \frac{z_i F}{RT}\frac{\partial \phi}{\partial x}C_i\right) \quad (4)$$

where C_i is the concentration, D_i is the diffusion coefficient, z_i is the charge number, F is the Faraday's constant, R is the gas constant, T is the temperature, Φ is the electrostatic potential, and index i represents for the *i-th* species. Theoretically, the Nernst-Planck equation can be used to explain the penetration of multi-types of chloride solutions into concrete. This is because each type of salt has different associated cations that affect in the second term, migration process, of the Nernst-Planck equation. In order to verify the experiments, the test results of concrete specimens exposed to chloride solutions with 0.55 water-cement ratio at 15 and 30 days of exposure are plotted compares with the numerical results obtained by the Nernst-Planck equation. Figs. 7 and 8 show the total chloride profiles obtained from the experiment compared with the numerical results. It is noticed from these figures that the total chloride concentrations obtained from the experiment agree very well with numerical results. The present model can be used to simulate not only chloride diffusion but also other chemical species. Due to test data available for cation species, Na+ and K+, the concentration profiles of sodium and potassium predicted by this present model are compared with the test data obtained from concrete specimens with 0.55 water-cement ratio exposed to three different chloride solutions at 15 days of exposure as illustrated in Figs 9 through 11. As seen, the trends of sodium and potassium profiles resulting from ponding test match the prediction model. However, the concentration values of these ions deviate from the model in cases of specimens exposed to 3% $CaCl_2$ and 3% $MgCl_2$. A good agreement can be observed in case of concrete sample exposed to 3% NaCl. From the comparison point of view, it can be concluded that the cations associated in chloride solution have influence on the penetration of chloride ions into concrete structures.

CONCLUSIONS

1. An experimental study was conducted on the penetration of various types of deicing salts into concrete. Three different types of deicers, chloride-based salts, were selected to investigate the influence of associated cations on diffusion rate of chloride solutions.

2. Concrete specimens were divided into three groups exposed to six different chloride solutions that is 3% NaCl, 3% $CaCl_2$, and 3% $MgCl_2$.

3. In order to investigate only the diffusion mechanism of the effect of cations associated in chloride solutions, the moisture effect is neglected so that the experiment was performed in saturated condition.

4. The experimental results show that cations associated in chloride solutions have significant effect on the penetration rate of chloride ions. This can be summarized in the order of $CaCl_2$ > NaCl > $MgCl_2$ from the fastest to slowest chloride penetration.

5. The experimental results are compared to the numerical results obtained from the Nernst-Planck model which accounts for the interaction between

ions and a good match is obtained in a case of total chloride concentration. The good trends of sodium and potassium profiles obtained from the experiment can be observed when compared to the mathematical model.

UNCONFINED COMPRESSIVE STRENGTH OF CLAY REINFORCED WITH KEROSENE-TREATED COIR FIBER

Lestelle Torio-Kaimo[1], Annamarie M. San Diego[1], Matthew Travis Alcantara[1]
[1]Geotechnical Engineering Group, Institute of Civil Engineering, University of the Philippines Diliman, Quezon City 1101

ABSTRACT

The need for ground modification is more prevalent as the availability of good site conditions decrease. Among the available methods of ground modification, soil reinforcement is emerging as a promising alternative. Fiber reinforcement involves mixing fibers with soil to improve its strength characteristics. Natural fibers have the following advantages over synthetic: affordability, bulk availability, and eco-friendliness. Coir fiber has the greatest tensile strength and slowest rate of biodegradation among natural fibers. This study presents the effect of kerosene-coated coir on strength and stress-strain response of a cohesive soil. Preliminary soil tests were performed and the soil was classified as CH or high-plasticity clay. Water absorption capacity tests revealed that kerosene reduces moisture intake of coir by up to 170%. Reconstituted samples, with fiber concentrations ranging from 0% to 2% by dry weight of soil, were tested for unconfined compressive strength in optimum moisture and dry states. Results showed that incorporation of coir improved the strength and stress-strain response of high-plasticity clay by as much as 52% compared to unreinforced samples. Aside from increasing peak strength, addition of coir also improved the post-peak behavior of the samples. Results show improved ductility in the coir-reinforced samples tested at optimum moisture condition. An increase in the elastic modulus, by as much as 78%, was also observed. These improved performance was exhibited at 1.5% fiber content. Dry samples tested show that addition of coir caused a 43% strength gain. However, dry samples exhibited brittle failure and minimal post-peak shear resistance, regardless of fiber content

Keywords: Soil reinforcement, Coir fiber, Clay reinforcement, Ground modification

INTRODUCTION

Ground modification refers to a variety of techniques used to improve the engineering characteristics of the ground. It can be used in various soil conditions such as collapsible soils, expansive soils, soft soils, or soils with inadequate mechanical properties. One method of modifying the ground is the use of reinforcing elements in the form of strips, bars, sheets, membranes, and fibers.

Fiber reinforcement involves mixing natural or synthetic fibers with soil, where the fibers act as tensile resisting elements that improve soil strength. The primary advantages of natural fibers are that they are cheap, abundantly available, and biodegradable. In the Philippines, the locally available natural fibers include abaca, coir, banana, pineapple, and bamboo. Among these natural fibers, coir has the greatest tensile strength and has the slowest rate of biodegradation [1]. Coir is useful in practical applications as a geotextile material. The fibers are twined and woven into "coco nets" which are primarily used for erosion control. Other coir products include coir mattresses, coir tufted mats, coir ropes, and coir logs.

The Philippines, being a tropical country, is abundant in coconut trees. In 2015, the Philippine Coconut Authority reported a total of 3.517 million hectares planted with coconuts in the country. This area is also 26% of the country's total agricultural land. The average nut production is 14.902 billion nuts/year.

In the context of sustainable development, coir fiber is a promising soil reinforcement material because it is indigenous, abundantly available, cheap, and environment-friendly. It can be a cost-effective alternative to commercially available additives such as cement and lime. Coir fiber reinforcement can be used in cases where mixing with fibers can be done onsite, such as in pavement subgrade, small embankments, and engineered fill.

Processing of coir contributes to rural employment and income generation. Large-scale utilization of coir can expand the market for the country's coir industry.

Lastly, there is a need to find a suitable treatment method that will increase the life span of coir fibers. To serve its intended purpose as soil reinforcement for a longer duration, a protective coating may be required.

Coir, just like any natural fiber, gradually loses strength over time. Depending on the duration of use,

it may require a physical coating to protect it from moisture-induced degradation. In this context, this paper presents the results of an experimental investigation on the effect of coated coir fiber reinforcement on the strength and stress-strain response of local clayey soil.

The primary objective of the research is to study the effect of kerosene-coated coir fiber reinforcement on the strength of clayey soil. To attain this, it is necessary to investigate effect of kerosene coating on water absorption capacity of coir, examine effect of coir on the unconfined compressive strength of soil and the soil stress-strain response, and, evaluate effect of coir on soil samples tested at optimum moisture content and dry state.

FIBER REINFORCEMENT IN SOIL

Hausmann [2] classified ground modification techniques into four: mechanical modification, hydraulic modification, physical and chemical modification, and modification by inclusions and confinement.

Mechanical modification involves increasing the density of soil by compaction, which requires mechanical energy. This is achieved through plate vibrators, impact rollers, and special techniques like vibro-flotation and blasting. Hydraulic modification involves removal of pore water from the ground using vertical drains or wells. Physical and chemical modification is the use of additives mixed or blended with soil. Natural soils, cement, fly-ash, and limestone are some examples of soil additives. Modification by inclusions and confinement is the use of strips, meshes, bars, fabrics, and fibers to reinforce the soil.

Soil reinforcement by inclusions has the ability to improve strength and stability, reduce settlements, improve bearing capacity, and reduce lateral deformation [3]. One method of reinforcing soil is with the use of fibers. Nature provides an example of this in the roots of trees stabilizing near-surface soil with low shear strength. The roots are distributed randomly within the soil mass and act as tension members to improve the strength characteristics of the soil [4].

The stabilizing effects of plant roots may be replicated artificially with the use of natural or synthetic fibers. Randomly distributed fibers (RDFs) are mixed with soil in the same manner as an additive. Unlike traditional geosynthetics, they are not oriented in a specific direction. The main advantages of RDFs are the relative isotropy of the soil mass and the absence of predefined planes of weakness [5].

Fiber

Shukla [4] defines fiber as a unit of matter characterized by fineness, flexibility, and high ratio of length to diameter. Fibers fall under two categories: synthetic and natural. Examples of synthetic fibers are glass fibers, polypropylene (PP) fibers, polyester (PET) fibers, polyethylene (PE) fibers, metal fibers, carbon fibers [4]. Natural fibers include coir, jute, palm fibers, sisal fibers, bamboo fibers, banana fibers, manila fibers, and cotton fibers.

The advantages of natural fibers are strength, bulk availability, affordable cost, and environmental-friendly characteristics. Unlike synthetic fibers, natural fibers do not contribute to greenhouse gas emissions in construction.

Some practical disadvantages of natural fibers are variability of the fiber geometry and biodegradability. Most natural fibers except coir are not durable in alkaline environments. Natural fibers exhibit gradual loss of strength over time, with rate of strength loss varying across fiber types [4].

Fiber Treatment

The issue of biodegradability can be overcome by suitable fiber treatment methods. These modification techniques can make natural fibers on par with or even superior to synthetic fibers. Unnikrishnan [6] provides some possible treatment methods for natural fibers. These are alkali treatment, enzyme treatment, UV grafting with monomers, treatment using chemicals, natural anti-microbial finishing, vegetable oils, and physical coatings.

Physical coatings modify the surface of fibers using synthetic polymers or resins. By physically preventing the entry of moisture into the fiber, this technique improves the durability of natural fibers [6].

A study by T. Sanyal and K. Chakraborty [7] found that bitumen coating applied on jute geotextiles could defer degradation by 3 to 4 years. However, bitumen affects the flexibility and drapability of the geotextile. H.N. Ramesh and K.V. Manoj Krishna [1] conducted water absorption studies on coir coated with kerosene, bitumen, and varnish. After 365 days of submergence, kerosene and bitumen coated coir fibers showed decreased water absorption, with kerosene providing the highest reduction in moisture intake compared to uncoated coir. Varnish, on the other hand, did not exhibit significant difference.

Coconut Coir as Soil Reinforcement

Coir is a fiber extracted from the outer husk of coconuts. There are two types of coir: brown fibers

from mature coconuts and white fibers from young coconuts. Brown fibers are thick and have strong resistance to abrasion. White fibers have a smooth and fine surface, but are also weaker than brown fibers [8].

Coir has the greatest tensile strength of most natural fibers [4]. It contains 40% lignin and 54% cellulose [9]. Its high amount of lignin, a complex hydrocarbon polymer, is what makes coir degrade slower than other natural fibers. Lignin makes the stem rigid and protects the fiber against biological attack [6]. Coir fibers may be used in engineering applications for a period of 1 to 2 years [4].

Several researches have investigated coir as randomly distributed fiber on different types of soil. Laboratory tests including triaxial tests, unconfined compression tests, and California bearing ratio tests showed significant results on the effect of coir inclusion.

Sujatha et al. [10] studied the influence of randomly distributed coir fiber on the compaction characteristics, stress-strain behavior, and unconfined compressive strength of highly compressible clay. The soil sample has a liquid limit of 53 and plasticity index of 38. Compaction tests were performed to determine the optimum moisture content (OMC) and maximum dry density (MDD) of unreinforced and reinforced samples. Study showed that OMC increased and MDD decreased with the inclusion of coir. The increase in OMC was attributed to the tendency of coir fibers to absorb moisture. Replacement of fibers in the soil matrix caused a decrease in mass occupied in the standard volume, explaining the decrease in MDD.

Unconfined compression tests were carried out to determine the effect of coir fiber on stress- strain behavior and unconfined compressive strength of the soil sample. Four fiber concentrations were studied: 0%, 0.25%, 0.5%, 0.75%, and 1%. Addition of coir fiber resulted to an increase in unconfined compressive strength, with the optimum fiber content being 0.75%. Beyond 0.75%, clumping of fibers was observed and resulted to a decrease in strength. Figure 1 shows that stress-strain of soil shifted to a more plastic behavior.

Devdatt et al. [11] made an experimental study on expansive soil mixed with varying concentrations of coir (0% to 1%). Results of compaction tests revealed a decreasing trend in OMC and increasing trend in MDD with addition of coir. Soaked and unsoaked California bearing ratio (CBR) tests were also conducted. Results exhibited a linearly increasing trend in both soaked and unsoaked CBR value. A similar study by Peter et al. [12] investigated the behavior of soft soil stabilized with varying concentrations of coir pith (0% to 3%) and coir fiber (0% to 1%) by conducting California bearing ratio (CBR) tests and static triaxial tests. The optimum stabilization scheme found in the study was 2% coir pith and 6% short coir fiber, which exhibited the greatest improvements in CBR value. Stress-strain curves from triaxial testing revealed a more ductile behavior in the coir-stabilized sample. The combined treatment of coir pith and fiber also increased the elastic modulus by 1.74 MPa.

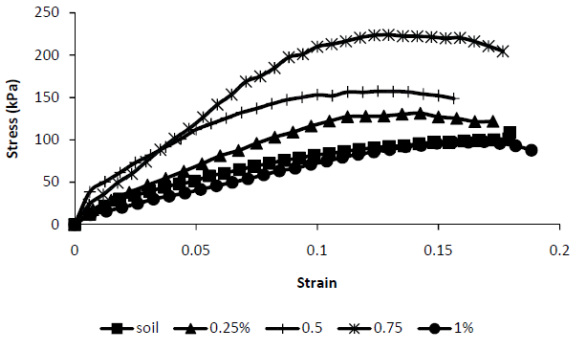

Fig.1 Stress-strain Plots of Unreinforced and Coir-Reinforced Samples [11]

In a study by Sivakumar Babu, et.al. [13], the effect of coir fiber parameters on strength and stiffness of sandy soil was studied. Triaxial tests were performed for varying confining pressures, fiber lengths, fiber contents, and fiber diameters. Fiber contents varied from 0% to 2.5% by weight of soil. Test results showed that deviator stress at failure increased as the fiber content increased. This was observed in all variations of confining pressures. The optimum coir content corresponding to the maximum strength improvement was at 2% to 2.5%. The researchers also noted that preparing specimens beyond 2.5% fiber content was quite difficult. Coir fibers grouped according to diameter (0.15, 0.25, and 0.35 mm) were also tested to observe the effect of fiber diameter on strength of soil. For both confining pressures of 50 and 100 kPa, the deviator stress at failure increased with increasing fiber diameter. This was attributed by the researchers to the increase in pullout resistance for fibers with larger diameter.

Fiber diameter and content was also kept constant while lengths were varied (10, 15, 25, and 30 mm). The maximum strength improvement was exhibited by samples with 15 mm fibers. Short fibers (10 mm) have less area in contact with soil, resulting to less pullout resistance and less strength gain. Preparing samples with longer (30 mm) fibers was reported to be difficult, making them ineffective as reinforcements.

Sivakumar Babu, et.al, [14] conducted an experimental investigation on the use of coir for

improving expansive black cotton soil. The degree of improvement in strength, shrinkage, swelling, and compressibility due to addition of fibers was measured. Length of coir fibers were kept at 15 mm, since this was the optimum length found in Sivakumar Babu and Vaseduvan's related study on coir-fiber reinforced sand.

Test results revealed the following: (1) deviator stress at failure increased with increasing fiber content; (2) deviator stress increased with increasing fiber diameter; (3) cohesion and friction angle increased as fiber content increased; (4) coir fibers reduced soil swell potential and compression index. The study concluded that coir as randomly distributed fiber contributes significant improvement in expansive black cotton soils.

Another study by Dasaka and Sumesh [15] evaluated the effect of coir on the stress-strain response of a reconstituted fine-grained soil. Unconfined compression tests and unconsolidated-undrained (UU) triaxial tests were performed using fiber contents in the range of 0% to 2% by dry weight of soil. Results of the study show that unconfined compressive strength (UCS) increased with increase in fiber dosage. At 1.5% fiber content (optimum), the UCS of reinforced soil is more than twice that of unreinforced soil. However, the study also found that UCS of soil reinforced with 30-mm length fibers is less than that of unreinforced soil. The researchers recommend using 15 mm fiber lengths when forming 38 mm-diameter soil specimens.

From triaxial test results, it was found that peak deviator stress and major principal stress at failure increased with increase in fiber dosage for all confining pressures. Cohesion and friction angle both increased significantly. Cohesion achieves maximum value at 1.5% fiber content. Friction angle, on the other hand, steadily increased with increase in fiber content. Researchers also noted an overall shift to ductile behavior in the stress-strain response of coir-reinforced samples.

In both UCT and UU triaxial tests, addition of coir fiber in the range of 1.5% to 2% was reported to produce significant improvement in the soil. Fiber dosages less than 1.5% exhibit minimal strength improvement. For dosages greater than 2%, specimen preparation becomes too difficult because of fiber agglomeration.

Ramasubbarao [16] investigated the effect of kerosene-coated randomly distributed coir fibers on highly compressible clay. Using fiber length of 5 mm and varied fiber contents (0.5%, 1%, and 1.5%), the optimum coir content was found to be 1% based on peak compressive strength. Stress-strain response shifted from brittle to a more ductile one with addition of coir. The researcher also performed water absorption capacity tests on uncoated and coated fibers, where it was found that kerosene coating significantly reduced the moisture absorption of coir.

METHODOLOGY

The research focused on soil improvement with respect to unconfined compressive strength. Initial steps were acquisition and preparation of the soil samples, kerosene, and coir. Local clayey soil used in the study was obtained from Sikatuna Village, Quezon City. Coir fibers were obtained from a small-scale farm in Dolores, Quezon. Preliminary soil tests were conducted on oven-dried soil for classification purposes. All tests are performed according to ASTM standards. Coir fibers were cut to a fixed length and coated with kerosene. Coated and uncoated fibers were subjected to water absorption capacity tests. Standard proctor test provided the maximum dry density and optimum water content of the soil sample. Coated fibers were added to soil in varying concentrations. Reconstituted samples were prepared using the soil-fiber mixes. The orientation of the fibers due to the soil mixing process cannot be controlled.

Unconfined compression tests were conducted on soil samples at optimum moisture condition. Stress-strain plots were generated and compressive stresses at maximum load were obtained. Statistical analysis was performed on the data to determine the optimum fiber concentration. The long-term performance of coir fibers as reinforcement was not investigated.

RESULTS AND DISCUSSION

Soil Analysis

Laboratory tests were performed for characterization of the soil sample. The tests include sieve analysis, Atterberg limits tests and standard proctor test. Results of the said tests were used to classify the soil sample according to the Unified Soil Classification System. Table 1 shows the results of the tests performed.

Fiber Testing

Water absorption capacity tests were carried out to determine if a physical coating can help defer the degradation of coir by reducing moisture intake. Figure 2 illustrates the effect of kerosene coating on the water absorption behavior of coir. It is evident that kerosene-coated fibers have significantly lower water absorption level than uncoated fibers. There is also a steep increase in water absorption at the beginning of the test. As immersion time increased, water

absorption capacities leveled off, approaching equilibrium.

Table 1 Index properties of soil sample used

Soil Property	Soil Sample
Passing #4 sieve	99.97%
Passing #10 sieve	94.45%
Passing #20 sieve	85.23%
Passing #200 sieve	53.68%
Liquid Limit	80
Plastic Limit	35
Plasticity Index	45
USCS	CH
Max. Dry Unit Weight	12.05 kN/m^3
Optimum Moisture Content	31.15%

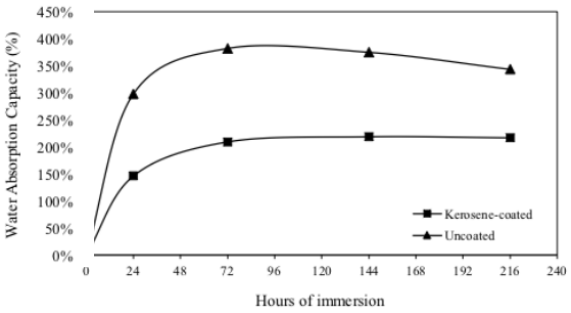

Fig.2 Effect of Kerosene Coating on Water Absorption Capacity of Coir

Unconfined Compression Strength

A total of 25 reconstituted samples of unreinforced and reinforced clay were tested for unconfined compressive strength immediately after preparation. The samples after failure were oven-dried to determine water content. Table 2 presents the average values of maximum load and its corresponding compressive strength at maximum load and water content for each fiber concentration.

Table 2 Mean values of maximum load for each fiber concentration

Fiber Concentration (%)	Average Max Load (N)	Stress at Max Load (MPa)	Water Content (%)
0	264.65	0.132	34.50
0.5	303.75	0.150	33.08
1.0	371.74	0.183	34.09
1.5	406.06	0.200	32.98
2.0	320.69	0.158	33.75

From figure 3, it can be observed that strength of reinforced samples has significant difference from that of unreinforced samples. This can be said for all fiber concentrations. Furthermore, the maximum strength improvement was seen in the 1.5% coir-reinforced group. It also shows that compressive strength values increased as fiber content increased. At the optimum fiber content of 1.5%, average unconfined compressive strength was increased by 52% compared to plain samples. The strength increase can be attributed to the pull-out resistance of the coir fibers during compression.

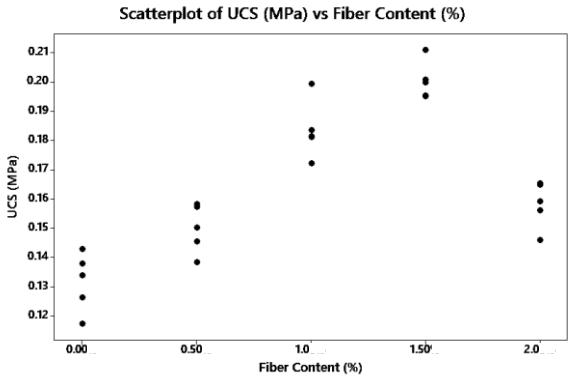

Fig.3 Plot of the compressive strength obtained for each samples

Sample preparation at 2% fiber content was made difficult by the clumping of coir fibers. Failure mostly occurred in the weak regions of the samples where fiber agglomeration was observed. This explains the decrease in strength from 1.5% to 2% fiber concentration. Still, samples with 2% coir exhibited higher compressive strength than unreinforced samples.

Typical results of the stress versus strain response for various fiber concentrations are presented in figure 4. Resulting stress-strain curves for the 25 samples are shown in figure 5.

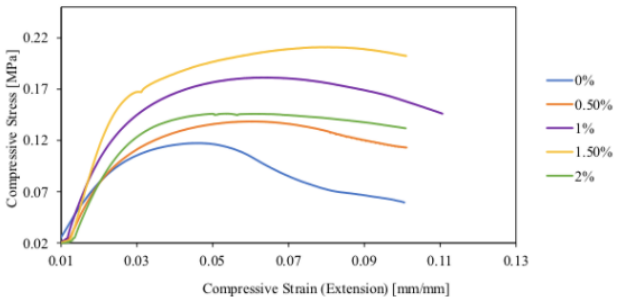

Fig.4 Typical Stress-strain Curve of Soil for Different Fiber Concentrations

Peak strengths for all the samples occurred at about 4% to 7% strain. Aside from increasing peak strength, coir fiber reinforcement was also found to improve the post-peak behavior of the soil. Compared to plain samples, coir-reinforced samples exhibited less reductions in strength after peak. Soil with coir

behaved more like a ductile material.

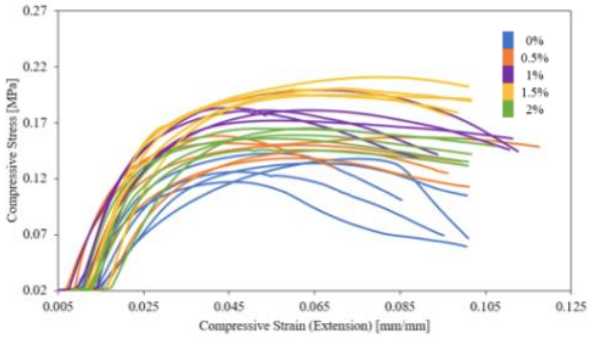

Fig.5 Stress-strain Curves of Soil for Different Fiber Concentrations

The elastic modulus of all the samples were obtained by from the stress-strain curves. The mean values are presented in Table 3.

Table 3 Mean elastic moduli for different fiber concentrations

Fiber Concentration (%)	Elastic Modulus (MPa)
0	5.73
0.5	8.34
1	9.94
1.5	10.21
2	8.09

The same trend in the case of peak compressive strength was observed in the elastic modulus of the groups. Values steadily increased from 0% to 1.5%, where the maximum improvement was observed. Addition of 1.5% coir resulted to a 78% increase in elastic modulus compared to plain soil. At 2% coir, there was also a decrease from the maximum value seen at 1.5% coir.

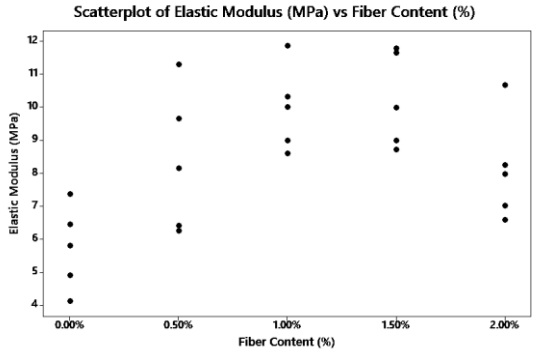

Fig.6 Elastic modulus of samples with different fiber content

Failure Patterns

Figure 7 presents the failure patterns of samples under unconfined compression test. A well- defined shear plane was observed in the 0% and 0.5% reinforced samples. In contrast, samples with 1% and 1.5% coir exhibited bulging failure and formation of small cracks. The samples at the optimum fiber content showed minimal signs of failure compared to plain samples. As the fiber content increases, failure would happen slowly and the sample behaves like a ductile material. The increased ductility due to fiber reinforcement allows the samples to bear stress even after peak. At 2% fiber content, it was observed that failure mostly occurs in the regions where fiber has agglomerated, contributing to the lower compressive strength.

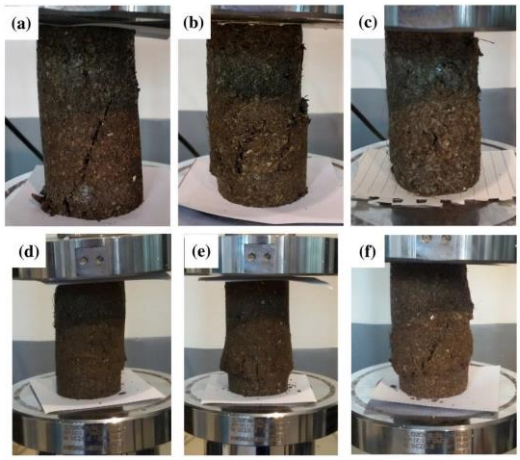

Fig.7 Typical Failure Patterns: (a) 0%, (b) 0.5%, (c) 1%, (d) 1.5%, (e) 1.5%, (f) 2%.

CONCLUSION

The present study investigated the effect of kerosene-coated coir fiber on strength and stress-strain characteristics of a reconstituted cohesive soil sample. The soil sample was classified as high-plasticity clay and found to have a maximum dry density of 12.05 kN/m^3 and optimum moisture content of 31.15%.

The use of kerosene as protective coating significantly lowers the water absorption capacity of coir by up to 170%. It was proven to be an effective protective coating to reduce moisture-induced coir degradation.

Coir fiber reinforcement was found to be beneficial to clayey soil. The maximum strength improvement was at 1.5% fiber content, with a 52% increase in strength compared to unreinforced soil. However, fibers tend to clump together at fiber concentration of 2%, resulting to a decrease in strength from the average strength at 1.5%. Still, 2% reinforced samples have higher compressive strengths than samples with 0% coir. Addition of coir fiber limited post-peak strength reduction in the soil.

From the stress- strain graphs, it was observed that samples with coir exhibited improved ductility. A 78% increase in soil elastic modulus was also observed at the optimum fiber content. Well-defined shear failure planes were seen in the 0% and 0.5% samples. At higher fiber concentrations, failure occurs slowly and minimal signs of failure were observed.

RECOMMENDATIONS

The researcher recommends that experiments can be conducted to determine the effectiveness of kerosene coating on preserving coir fibers under buried conditions over a long period of time. Furthermore, tensile strength tests can be performed to determine if kerosene has any effect on coir tensile strength. It is also suggested to know the applicability of coir on other soil types such as silts and sands may also be studied. For a more in-depth experimental study, shear strength tests such as triaxial compression tests and direct shear tests may be used to evaluate coir as soil reinforcement. California bearing ratio tests may be used to determine the effect of coir on weak subgrade. Swell index tests may also be done for expansive soils mixed with coir. The effect of varying coir fiber parameters (e.g. length, diameter) on the strength improvement may also be further studied. Additionally, regression models may be proposed to quantify the effect of fiber parameters on the shear strength of soil.

STUDY ON ENGINEERING APPLICATION OF CRUSHED SHELL PARTICLES FOR THE CONSTRUCTION MATERIALS

Ryota Morizaki[1], Kaoru Kobayashi[2], Kenjiro Honda[3] and Wataru Miyazaki[4]
[1,2]Ibaraki University, Japan; [3,4] A×C corp., Japan

ABSTRACT

Scallop shells are by-products of fishery and are stock piled around the fishing ports such as Hokkaido. Effective method(s) of their disposal and utilization have not been established as yet. These pileups cause a disagreeable odor and destruction of landscapes. There have been few attempts to effectively use scallop shells as a construction material. Crushed scallop shell particles (hereinafter referred to as crushed shell particles) in actual construction have only been effectively used as a mixture material in caisson fillings, and quay-wall back fillings in fishing ports. It is necessary to utilize a significant amount of scallop shells for construction, because problems that arise due to the pileup of scallop shells has not been solved yet. This study confirmed the specific characteristics of the crushed shell particles considering particle size via laboratory experiments, and analytically evaluated the applicability of crushed shell particles as an improvement material considering shear strength and permeability for soft ground, based on their circular slip calculation and one-dimensional effective stress analysis. This study elucidated the potential of the crushed shell particles as highly effective construction material. The utilization of crushed shell particles may significantly contribute to the promotion of a recycling society promotion.

Keywords: Crushed shell particles, Construction materials, Particle size, Shear strength, Permeability

INTRODUCTION

In recent years, research on effectively utilizing waste resources [1] is being increasingly carried out in the field of civil engineering for constructing a recycling society [2]. Scallop shells are the by-products of the fishery industry, and one such utilizable waste resource. Shells account for a large percentage of landing. Fig. 1 shows year-wise landing amount of scallops in Japan [3]. Landing amount of scallops in 2014 was 560,000. Because scallop shells account for approximately half of mass of scallops [4], their shells amounted to 280,000 in number. A large amount of these scallop shells is piled up (Fig. 2) [5] in the open areas surrounding the fishing ports, because disposal method for scallop shells have not been established yet. These pileups cause a disagreeable odor and destruction of landscapes. The use of scallop shells which pile up around fishing ports effectively use considered environment has been required to convert into a recycling society in Japan by using as construction materials.

Attempts have been made to effectively use scallop shells because their primary chemical component is calcium carbonate [6] providing them strength. Crushed scallop shells particles (hereinafter referred to as crushed shell particles) can be effectively used in mixtures for caisson fillings [7] and quay wall back fillings in the fishing ports [8]. However, till date, the effective use of scallop shells is restricted as a mixing material with sand and concrete aggregates. A larger number of effective utilization methods is required to solve the problem.

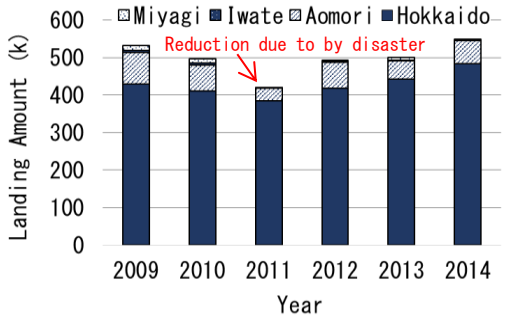

Fig. 1 Landing amount of scallops in Japan [3].

Fig. 2 Pileup of scallop shells [5].

Therefore, the purpose of this study is to effectively utilize scallop shells for construction materials. This study confirmed the specific shear strength characteristics of the crushed shell particles considering particle size on triaxial compression.

Circular slip calculation and one-dimension effective stress analysis in this study analytically evaluated the countermeasure effect considering shear strength and permeability for soft ground countermeasure. This study elucidated that the crushed shell particles have high potential for use as effective construction materials. The utilization of crushed shell particles is expected to contribute greatly to the promotion of recycling society.

BASIC CHARACTERISTICS OF CRUSHED SHELL PARTICLES

The proposed methods of crushing the scallop shells in construction include the use of heavy machinery such as bulldozers and crushing stone factories [9]. In recent years, adjustable rotary crushers are used for the purpose that aid in monitoring the particle size of crushed material [10], [11]. Rotary crusher is an on-board type equipment (it can be easily moved on a truck and belt conveyor) and can be effectively used on-site. Its use also makes it possible to reduce the cost of transporting a large amount of piled shells to the crushing plant.

Fig. 3 shows particle size accumulation curve. The scallop shells from the Aomori prefecture were used in this study. The shells were washed with water to remove impurities such as salt, and then dried in a drying oven at 80°*C* for 24 *h*. They were cooled to approximate room temperature, and crushed using a small crusher. Particle size analysis [12] was conducted to understand particle size character of crushed shell particles. Crushed shell particles sieved, and divided into three categories based on the particle size: less than 2 mm, less than 4.75 mm, and less than 9.5 mm to understand particle size characteristics. In addition, the same tests were carried out using silica sand No. 6 to compare the strength characteristics of crushed shell particles with general sandy soil. 50% particles size (D_{50}) of less than 2 mm, less than 4.75 mm, and less than 9.5mm are 0.8 mm, 1.6 mm and 2.0 mm, respectively. D_{50} of crushed shell particles are larger than silica sand No.6.

Table.1 shows the soil test results of the samples. Crushed shell particles have many voids when they are crushed, because the void ratio e and saturation permeability k_s (only less than 9.5 mm) of crushed shell particles having a flat shape are larger than that of sand. The particle density ρ_s is also found to be about the same as or slightly larger than that of sand.

SPECIFICITY CHARACTERISTICS OF CRUSHED SHELL PARTICLES IN TRIAXIAL COMPRESSION TEST

Materials

Fig. 4 shows three types of crushed shell particles in triaxial compression test [12]. The materials used

Table 1 The soil test results of sample

Sample	Crushed shell particles			Silica sand No. 6
	Less than 2 mm	Less than 4.75 mm	Less than 9.5 mm	
Particle density ρ_s (g/cm^3)	2.698	2.718	2.739	2.689
Water content ratio W_n (%)	0.2	0.2	0.2	0.5
Maximum void ratio e_{dmax} (–)	1.671	1.381	1.218	1.050
Minimum void ratio e_{dmin} (–)	1.227	0.788	0.705	0.629
Dry density ρ_{d60} (g/cm^3)	1.198	1.342	1.433	1.868
Permeability K_s (m/s)	–	–	3.34×10^{-1}	1.62×10^{-4}

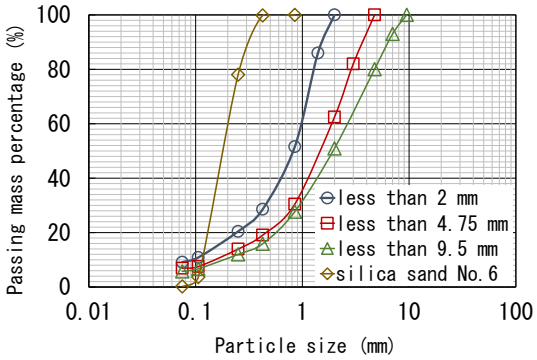

Fig. 3 Particle size accumulation curve.

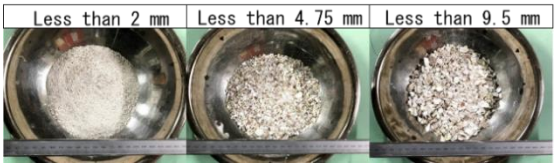

Fig. 4 Three types of crushed shell particles in triaxial compression test.

had three types of crushed shells with different particle sizes as compared to silica sand No. 6. The particle sizes of crushed shell particles are less 2 mm, less 4.75 mm, and less 9.5 mm in the sample (diameter 5 cm, height 10 cm) used in the triaxial compression test. Fig. 3 and Table 1 show Particle size accumulation curve and physical properties obtained by particle size analysis of the crushed shells and silica sand No. 6. The maximum and minimum void ratio materials were calculated from the maximum and minimum density tests of sand respectively [12].

Method

Table 2 shows the soil test results of the sample. To prepare the specimens, a rubber sleeve of thickness 0.3 mm was placed in two molds of diameters 50 and height 100 mm, and negative pressure was applied. Samples in the dry condition were filled and compacted in five layers using the air drop method to obtain a relative density of D_r = 60 %. Then, the saturation of the specimens was attempted using the CO_2 method (back pressure of 100 kPa, pore pressure coefficient of $B \geqq 0.95$). Then, isotropic

consolidation was performed at effective confining pressures of σ_c' = 50, 100, and 200 kPa. Axial compression was performed at an axial strain of ε_a = 15 % under undrained conditions while measuring the pore water pressure u with the shaft strain rate set to 0.1 %/mm.

Result

The specificity characteristics of the crushed shell particles were grasped for each shell particle size in this test. Fig. 5 shows the relationship between the deviator stress q vs axial strain ε_a. Fig. 6 shows the relationship between the excess pore pressure Δu vs axial strain ε_a. The deviator stress q at the axial strain ε_a = 15 % is followed by Case G, Case D, Case A, and Case J in a descending order, based on the effective confining pressure σ_c' = 50 kPa. All crushed shell particles had a larger deviator stress q than silica sand No. 6. The larger the size of crushed shell particles, the more remarkable the difference is. This behavior of the deviator stress q showed the same tendency at effective confining pressures σ_c' = 100 kPa and 200 kPa. The influence of the particle size on the excess pore water pressure Δu was basically not observed. The excess pore water pressure Δu depends on the effective confining pressure σ_c'.

Fig. 7 shows the strength parameters total stress and effective stress. Crushed shell particles have both internal frictional angle φ' and soil cohesion c'. It means crushed shell particles have different strength characteristics in contrast to a sand material with only internal friction angle φ'. Compared with the strength parameters (c', φ') of silica sand No. 6, the crushed shell particles show large values. This tendency is more remarkable with an increasing particle size.

Discussion

The specificity characteristic of crushed shell particles may affect the behavior and strength parameters in the triaxial test. The maximum and minimum density tests of sand suggested a dry density ρ_{d60} of the crushed shell particles. The samples with a relative density D_r = 60 % as a standard were prepared in a mold of 5 cm diameter and 10 cm height. Dry densities ρ_{d60} of less than 2 mm, less than 4.75 mm, less than 9.5 mm, and silica sand No. 6 were 1.227 g/cm^3, 1.342 g/cm^3, 1.433 g/cm^3, and 1.868 g/cm^3, respectively. The larger the dry density ρ_{d60}, larger is the particle size. Therefore, it is considered that the deviator stress q becomes larger at the same relative density. In addition, the crushed shell particles have both internal frictional angle φ' and soil cohesion c' owing to the surface roughness and cementation due to calcium carbonate of main component. The component of soil cohesion c' exerts resistance in the shallow layer slip. The component of internal frictional angle φ' in the deep layer slip.

POTENTIAL INVESTIGATION OF CRUSHED SHELL PARTICLES AS CONSTRUCTION MATERIALS

Estimation of Circular Slip

Analysis conditions

Fig. 8 shows the embankment model; the ground configuration used in the trial is where the embankment is built on soft ground with a supporting ground. This analysis assumed that ground improvement construction on the sea was performed using the soft ground improvement method and the sand compaction pile (SCP) method because the crushed shell particles can effectively exert strength and permeability as a pile in case they have a flat shape. As the triaxial test results, the soft ground between the crushed shell pile or sand pile was considered as composite ground considering the obtained strength parameters. The improvement rate for a satisfying safety factor $F_s \geqq 1.2$ was calculated using the modified Fellenius method [13].

$$F_s = \frac{\text{Resistance force}}{\text{Sliding force}} = \frac{\sum\{cl + (W\cos\alpha - ul)\tan\varphi\}}{\sum W\sin\alpha} \quad (1)$$

where u is the average pore water pressure of the split plane, l is slip surface length of the split plane, W is the soil unit weight of the split plane, and α is the slip surface inclination angle of the split plane. The required shear strength τ [14] of the composite ground considering the improvement rate to show the resistance value was calculated by

$$\tau = (1 - a_s)\left(c_0 + kz + \frac{\mu_c \Delta\sigma_z \Delta c}{\Delta p} U\right) + \left(\gamma_s z + \mu_s \Delta\sigma_z\right) a_s \tan\varphi_s \cos^2\theta \quad (2)$$

where τ is the average shear strength on the slip surface, a_s is the improvement rate, c_0 is the undrained shear strength of the soft ground at $z = 0$, k is the strength increase rate in the depth direction, and z is the vertical coordinate; μ_c is the stress concentration factor for the soft ground part, $\Delta\sigma_z$ is the vertical stress increment caused by the external force on the slip surface, $\Delta c/\Delta p$ is the strength increase rate of the soft ground, and U is the average compressive density; and γ_s is the unit weight of the sand pile, μ_s is the sand stress reduction coefficient for the pile, φ'_s is the internal friction angle of sand pile, and θ is the angle of the sliding surface with the horizontal plane.

There is no strength increase at the time of embankment loading because the average compaction density $U = 0$. The stress sharing ratio n was calculated as $n = 3$ using the calculation formula [15] provided in the SCP method. The internal friction angle $\varphi'_s = 30°$ of sand piles was selected from the previous construction cases [14]. The internal friction angle φ'_s of sand piles was set to a low value considering construction uncertainty. The resistance and sliding forces of the slip surface were obtained from the same arc center and arc radius for easy comparison. Based on the above conditions, circular slip estimation was performed to identify the resistance force provided by the crushed shell pile in comparison to that provided by the sand pile (SCP).

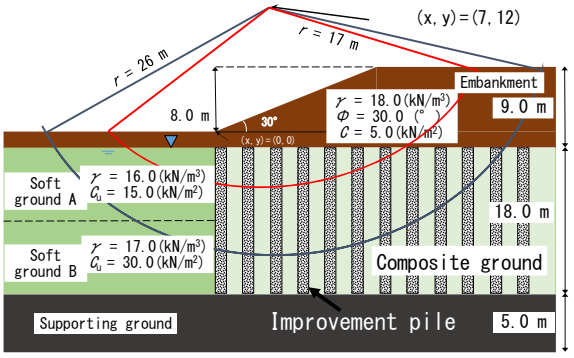

Fig. 8 Embankment model.

Table 3 Results of circular slip analysis

Resistance force (kN/m) / Sliding force (kN/m)	Shallow circle radius	Deep circle radius
No improvement	956 / 1884	1129 / 1962
Sand pile a_s = 30 %	1528 / 1884	2596 / 1962
Sand pile a_s = 90 %	2291 / 1884	3526 / 1962
Less than 2 mm Shell pile a_s = 30 %	2376 / 1884	4014 / 1962
Less than 4.75 mm Shell pile a_s = 30 %	2437 / 1884	4086 / 1962
Less than 9.5 mm Shell pile a_s = 30 %	2630 / 1884	4458 / 1962

Analysis result

Table 3 summarizes the results of the circular slip estimation. The resistance force showed a tendency of increasing in both the shallow and deep layers for the same improvement rate a_s when the crushed shell particles were used for the composite ground as the pile. In particular, the larger the particle sizes of crushed shell particles, the higher was the resistance force. Further, the resistance force of the crushed shell particles had a larger value than the resistance of sand, which implies the strength parameters (c', φ') obtained from the triaxial compression test is effective as a soft ground improvement method because strength parameters (c', φ') considered in equation (1) increases the resistance force by adding to the shear strength τ of the composite ground calculated from equation (2). For comparison of the improvement rate a_s, it was necessary to use the crushed shell particle piles for both shallow and deep arcs with an improvement rate a_s = 30 % to satisfy the safety factor F_s = 1.2.

On the other hand, sand piles were necessary for a deep arc with an improvement rate a_s = 30 % and with a shallow arc with an improvement rate a_s = 90 % (construction with improvement rate a_s = 90% is impossible). The improvement rate a_s is decreased to ensure that the resistance force of crushed shell piles is large enough to secure the crushed shell

particles with an internal friction angle φ' and soil cohesion c' according to the triaxial compression test. The internal friction angle φ' works more effectively on soft ground and gets deeper due to the relationship with the effective confining pressure σ_c'. The soil cohesion c' works effectively on the soft ground in the shallow layer.

From the above, it is possible to use crushed shell particles as effective construction materials as a countermeasure for soft ground because the crushed shell particles showed exert both depth and shallow of the layer slip by resistance having strength parameters (c', φ').

One-Dimensional Effective Stress Analysis

Analysis condition

Table 4 summarizes the parameters for effective stress analysis. One-dimensional effective stress analysis was performed using analysis code LIQCA2D16 [16]. An effective stress analysis confirms whether crushed shell particles considering high permeability and strength parameters (c', φ') larger than sand have the effect as SCP for liquefaction; it was assumed that the soft ground was totally replaced with crushed shell particles (less than 9.5 mm). The liquefaction layer was the cyclic elastic-plastic constitutive model modeled 24 m and the non-liquefaction layer was an elastic model modeled in 5 m. The analysis parameters are taken from Oka et al.'s study [17]. The saturated permeability coefficient k_s and the fracture stress ratio M_f changed, as shown in Table 5, because the various dynamic tests for grasping the dynamic strength and deformation characteristics were not conducted. The saturated permeability coefficient k_s was determined by the soil permeability test; the fracture stress ratio M_f was calculated from the internal friction angle φ' obtained by the triaxial compression test using

$$M_f = \frac{2\sqrt{6}\sin\varphi'}{3 - \sin\varphi'} \quad (3)$$

The input seismic wave was a Level 2 earthquake movement inland type 1 of the concrete standard specification [18]. The effective stress reduction ratio effective stress decreasing ratio (ESDR) is calculated using equation (4) to judge the liquefaction suppression effect of crushed shell particles.

$$ESDR = 1 - \frac{\sigma_m'}{\sigma_{m0}'} \quad (4)$$

where σ_{m0}' is the initial average effective stress and σ_m' is the average effective stress at a certain time. Complete liquefaction shows $ESDR$ = 1.0.

From the above condition, effectiveness as a countermeasure for the liquefaction of crushed shells particles as construction materials for liquefaction were examined from *ESDR* by comparing it with no improvement measures.

Table 4 Parameter for effective stress analysis

	No improvement	Crushed shell particles (less than 9.5 mm)
Compression index λ (–)	0.025	
Swelling coefficent κ (–)	0.0025	
Normalized initial shear modulus G_0/σ'_{m0} (–)	563.3	
Saturated permeabillty coefficent k (m/s)	1.00×10^{-5}	3.34×10^{-1}
Initial void ratio e_0 (–)	0.8

Elastic shear strain γ_r^E (–)	0.1	

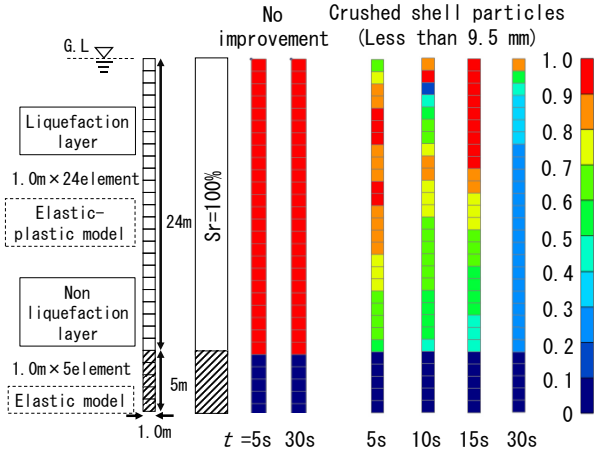

Fig. 9 Analysis result of *ESDR*.

Analysis result

Fig. 9 shows the analysis result of *ESDR*. The *ESDR* with no improvement showed a high value for the shallow and deep elements at any times from the occurrence of the earthquake, which implies sand liquefaction occurred in this analysis. On the other hands, the *ESDR* of crushed shell particles (less than 9.5mm) showed a low value under the same conditions; this means crushed shell particles suppressed liquefaction. In detail, the *ESDR* of the crushed shell particles increased in the shallow element at t = 5 s , 10 s, and 15 s before the earthquake happens, and it finally decreased both the shallow and deep elements at t = 30 s. The reason why crushed shell particles can have suppression for liquefaction more than no improvement is that crushed shell particles are related to the particle size, surface roughness and cementation due to calcium carbonate of main component. The saturated permeability

coefficient k_s of the crushed shell particles was obtained from the soil permeability test is larger than no improvement because larger particle size makes permeability larger. The fracture stress ratio M_f of the crushed shell particles was obtained from triaxial compression test showed large internal friction angle. The influence of the two factors on the crushed shell particles helped suppress liquefaction. Therefore, crushed shell particles can be employed as a construction material because they showed a liquefaction suppression effect to make the *ESDR* value of no improvement ground low.

The results of the one-dimensional effective stress analysis indicate that crushed shell particles can be possibly employed as construction materials owing to its liquefaction suppression effect.

CONCLUSIONS

This study obtained the following results to validate the use of crushed shell particles as construction materials.

(1) Crushed shell particles can have a large value of deviator stress q and strength parameters (c', φ') because of the surface roughness and cementation due to calcium carbonate of main component.

(2) Crushed shell particles can exert a resistance force effectively at depth and shallow layer due to strength parameters (c', φ') in the improvement pile in estimate of the circular slip.

(3) Crushed shell particles can exert the liquefaction suppression effect due to the saturated permeability coefficient k_s and fracture stress ratio M_f in a one-dimensional effective stress analysis.

For wider implementation, the influence of the chemical component in the crushed shell particles—made of calcium carbonate owing to its strength—and the detailed strength characteristics of the crushed shells particles need to be obtained via investigation and examination at the particle level.

ULTRASONIC PROTECTIVE IMPREGNATION OF POROUS CONSTRUCTIONS AND NATURAL MATERIALS

Valery Tsaplev[1], Sergey Konovalov[1], Roman Konovalov[1,2] and Sergey Nikolaev[2]
[1]Electroacoustics and Ultrasonic Engineering, Saint Petersburg Electrotechnical University "LETI", Russia;
[2]Devices and Methods of NDT, Emperor Alexander I St. Petersburg State Transport University, Russia

ABSTRACT

The results of the experimental and theoretical studies of the acoustical flows in the porous or microcrumbling building and natural materials are presented. Building constructions, walls or foundations of concrete, brick or natural facing stone material being porous media absorb water due to the natural capillary effect. This happens mostly in countries with humid climates and if the faces of building structures are not protected by a waterproof layer. The damp penetrates into the foundation if the waterproofing layer between the foundation and the wall is damaged, the damp comes up the wall due to the natural capillary effect. Just the same, if the protective covering of the concrete or brick wall is damaged, they begin to absorb the damp from the air, growing damp by and by and worsening their protective properties. There exist different ways to restore damaged waterproofing layers. One possible way is to impregnate walls or/and foundations by some special hydrophobic liquid using the ultrasound. Being then dried out, the elements of constructions become water-repellent, do not absorb damp more and remain dry. The usage of the ultrasound makes the impregnation much more effective and fast, being at the same time the nondestructive method. The speed of the penetration depends on the porosity or microcrack or porosity factor. The paper presents the results of the study of the dependence of the velocity of the hydrophobic liquid movement from the average diameter of the capillaries and from the acoustical intensity.

Keywords: Ultrasonic impregnation, Porosity, Building materials, Capillary effect, Nondestructive protection

INTRODUCTION

It is possible to accelerate the impregnation and to increase its efficiency using ultrasound. The effect of saturation of porous media by the liquid in the ultrasonic field is based on the fact, That the acoustic pressure causes acoustic flow in the liquid. That is why the ultrasonic oscillations essentially help the liquid to move into the pores or capillaries of the material. The effect is strong within the wide range of frequencies and intensities of sound. The effect is well known. It is so called "ultrasonic capillary effect". This effect was first opened in the USSR, described by Konovalov and Germanovitch [1] and was also studied by Prokhorenko and Dezhkunov [2,3], ets.

The effect essentially increases after the arrival of cavitation. The essence of this effect is that the depth and the velocity of movement of the liquid into the capillaries increase significantly under the influence of cavitation in comparison with the influence of the acoustic radiation field.

FLOWS IN WALLS AND BRICS

The impregnation in the presence of ultrasonic oscillations is widely used in electronic and chemical-engineering industry. As a rule, it is used in plants, where it is possible to submerge the detail fully into the impregnating bath filled with the liquid and having the high power ultrasonic transducer inside the bath.

The main goal of our investigation was to study the process of liquid penetration in real, not in laboratory conditions. It is quite clear, that the concrete foundation or the brick wall cannot be submerged into the bath. Obviously, we had to look for some other engineering solution.

The main goal of our investigation was to study the process of liquid penetration in real, not in laboratory conditions. It is quite clear, that the concrete foundation or the brick wall cannot be submerged into the bath. Obviously, we had to look for some other engineering solution.

Figure 1 shows our design [4]. The ultrasonic vibrator 1 is mounted upright near the wall 2, subject to impregnation. The liquid 3 (special silicone hydrophobic liquid) forms an intermediate layer between the emitting surface of the vibrator and the wall. A special elastic rubber U-tank 4 prevents liquid leakage from the layer. This U-tank forms a kind of a small caisson. The tank is feeded by the liquid from a special feeding service tank (not shown in the figure). The vibrator is firmly attached to the wall (the attaching construction is not shown in the figure), but it is necessary to control the layer thickness. This thickness must be quite definite – it is very important. The

vibrator is excited by means of the power ultrasonic generator 5, that has the self-tuning circuit. The depth *L* of liquid penetration into the porous material (brick) was measured by pulse ultrasonic method.

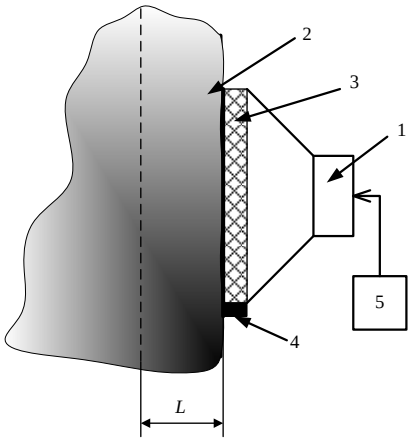

Fig. 1. Experimental setup

The main goal of this work is to compare this depth of the liquid penetration into different types of bricks under the influence of ultrasound of different power and different frequency.

EXPERIMENTAL RESULTS

Three types of porous material were used for the experiment. These were bricks, and their properties one can see in the following table.

Table 1 Specimen properties

№	Density ($\times 10^3$ kg/м^3)	Aver. grain diam. (мм)	Mean capillary diameter (mm)	Density (%)
1	3.4	0.35	0.02	8
2	2.9	0.5	0.05	17
3	1.8	1.0	0.17	38

The filling liquid was a special organic-silicon hydrophobic solution "Gifob" (density $\rho=1.07\cdot10^3$ kg/m^3, viscosity $\eta=0.19\cdot10^{-3}$ Ps), the temperature t=+20±2 C°).

First it was necessary to compare the theoretical velocity of ultrasound in the porous partially filled material with experimental. Different authors proposed various theoretical models for the velocity of elastic wave. The best approaches were obtained by Sato [5] and Gilberstein [6].

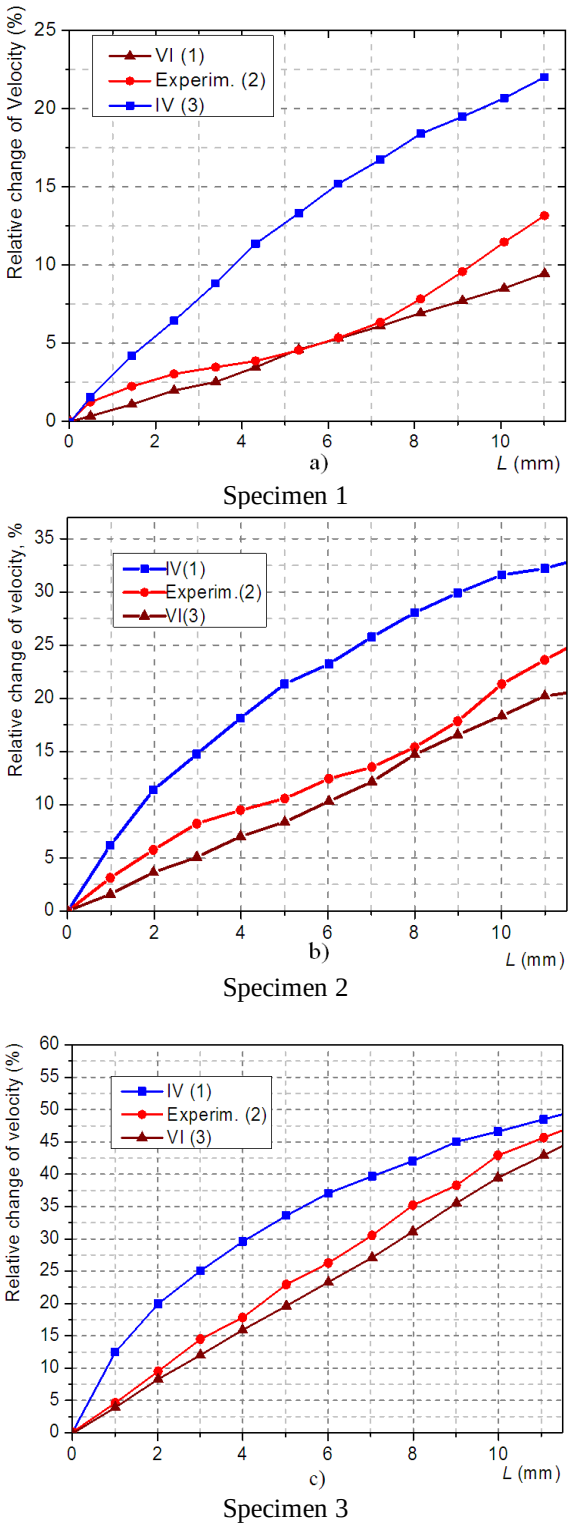

Fig. 2. Calculated and experimental changes of ultrasound velocity from the depth of filling (L). IV and VI correspond to [5] and [6] respectively

Approximation by Sato [5] is the following:

$$C_x = C_0\{1 - z\cdot\frac{\varphi}{2}[\frac{(1-k)(1+\sigma_1)}{2(1-2\sigma_1)+k(1+\sigma_1)} + \quad (1)$$

$$+10\frac{1-2\sigma_1}{7-5\sigma_1} - (1-D)]\}$$

where: $k = \frac{\rho_2 C_{2l}^2}{\rho_1 C_0^2}$;

C_0 – longitudinal velocity of elastic wave in porous media;

σ_1 – Poisson's ratio for 3*D* infinity media;

φ – porosity;

k – bulk elastic modulus of the liquid, filling capillaries, to that of continuous media;

D – density of the liquid to that of continuous media ratio;

z - depth of penetration factor.

Gilberstein [6] proposed the following approximation:

$$C_x = \frac{C_0}{\sqrt{\frac{1-zQ}{1-1{,}08zQ}(1+1{,}08zQS)}}, \quad (2)$$

$$S = \frac{1+2\sigma_1(1-\sigma_1)}{1-\sigma_1},$$

where C_0 – longitudinal velocity of elastic wave in porous media;

σ_1 – Poisson's ratio for 3*D* infinity media;

Q – total volumes of holes to that of material;

z – depth of penetration factor.

One can see from figure 2, that the model, proposed by Gilberstein fits very good with experiment.

The experiment showed, that the intensity of filling the specimen by liquid increases with increasing of the ultrasonic field power. This effect can be seen from figures 3, 4 and 5. Figure 3 shows the dependences of time of filling from the depth of penetration for different frequencies – 20 kHz, 60 kHz and 100 kHz and different values of power for the specimen № 1. Different values of electric amplitude on transducer – 100 V, 370 V and 780 V correspond to different values of sound-energy-flux density. These values are $2\cdot10^4$ Wt/m^2, $4\cdot10^4$ Wt/m^2 and $8\cdot10^4$ Wt/m^2, correspondingly. All The measurements were carried out below the threshold of cavitation. This level for this type of the hydrophobic liquid was about $8.4\cdot10^4$ Wt/m^2. The increase of the sound intensity causes the increase of the impregnation velocity, but it is quite necessary to avoid cavitation, because cavitation demolishes the water-repellent properties of liquid.

The increase of the impregnation time is caused by the growth of the ultrasound frequency, which leads to the wave decrement. This causes the reduction of the ultrasonic power as the depth of filling increases. As a result, the time of impregnation increases.

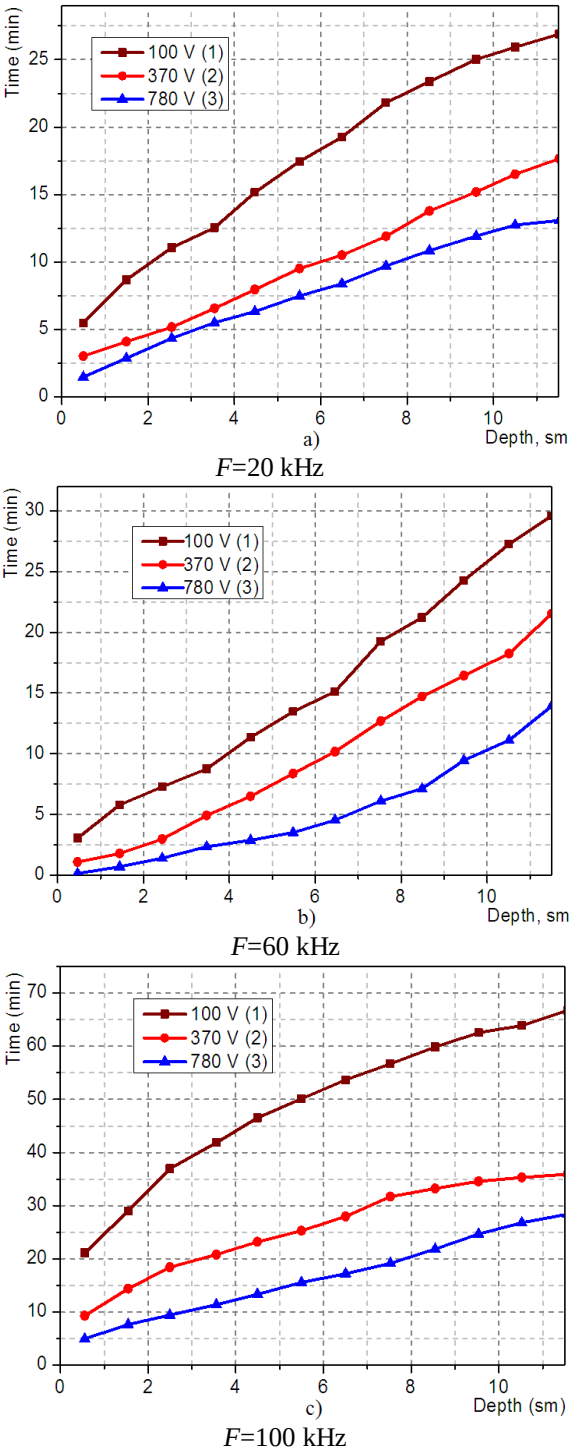

Fig. 3. Times (*t*) of filling specimen № 1, *L*=12 sm

The interpretation of the fill-up time of the porous material from the frequency shows, that the time grows as the frequency increases. That is illustrated by figures 5,6 and 7. At the beginning of the process the velocity of flow is proportional to the ultrasonic

frequency, but then the time of filling up slows down due to reduction of power.

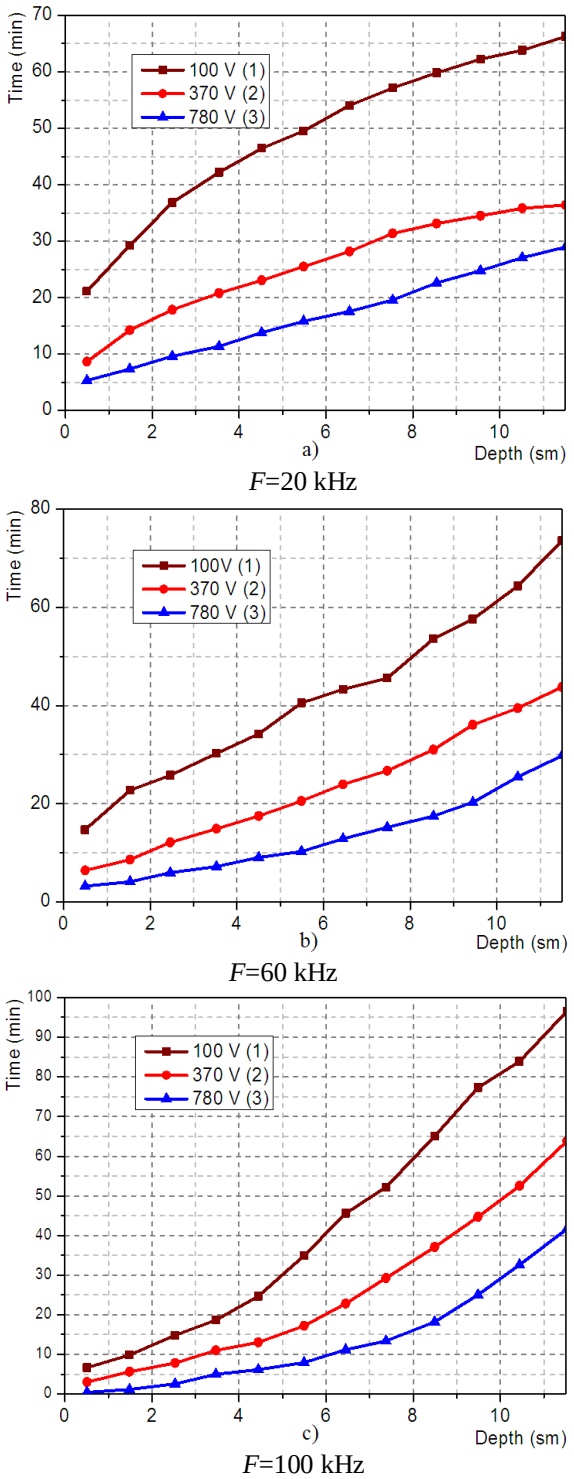

Fig. 4. Mean times (*t*) of filling specimen № 3, *L*=12 sm for different frequencies and different signal amplitudes

Figure 5 shows the dependence of the average filling-up time from the depth of penetration at different frequencies (20 kHz, 60 kHz and 100 kHz) and different signal amplitudes (100 V, 370 V and 780 V, that correspond to values of sound-energy-flux density of $2 \cdot 10^4$ Wt/m^2, $4 \cdot 10^4$ Wt/m^2 and $8 \cdot 10^4$ Wt/m^2.

Figure 5 is for specimen №1, *L*=12 sm, figure 6 is for specimen №2, *L*=12 sm and figure 7 shows these dependences obtained for specimen №3, also for *L*=12 sm.

All dependences are in good accordance with those of figures 2, 3 and 4.

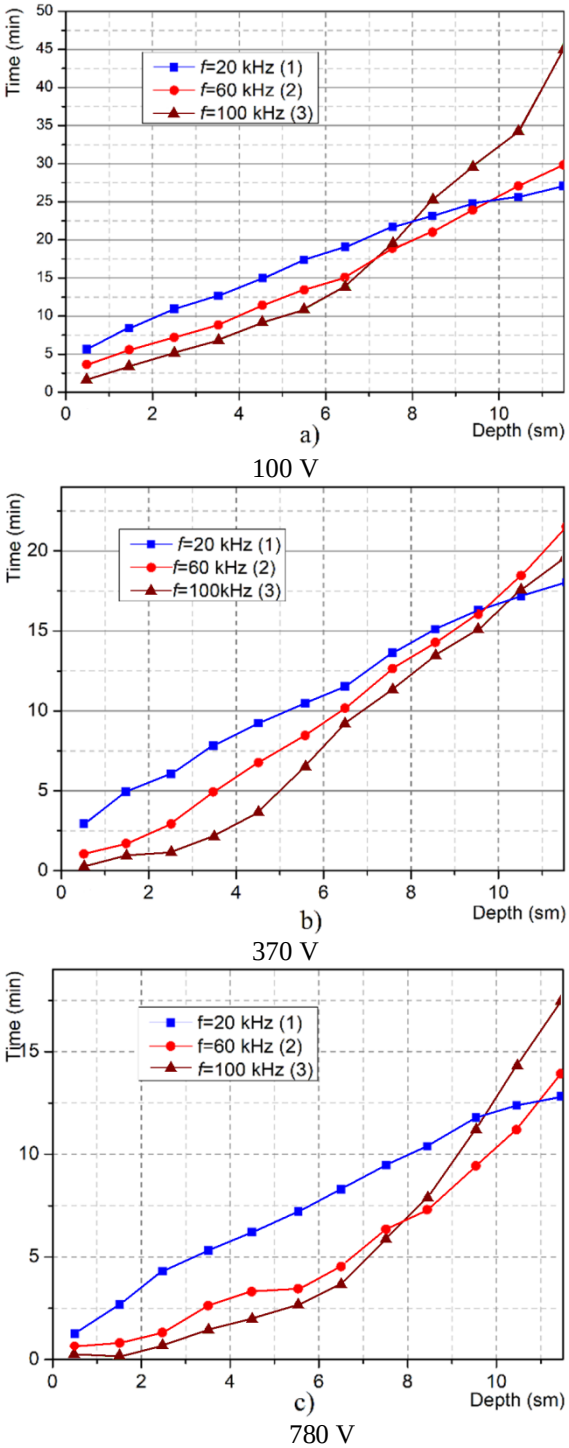

Fig. 5.Times (t) of filling specimen №2, *L*=12 sm for different frequencies and different signal amplitudes

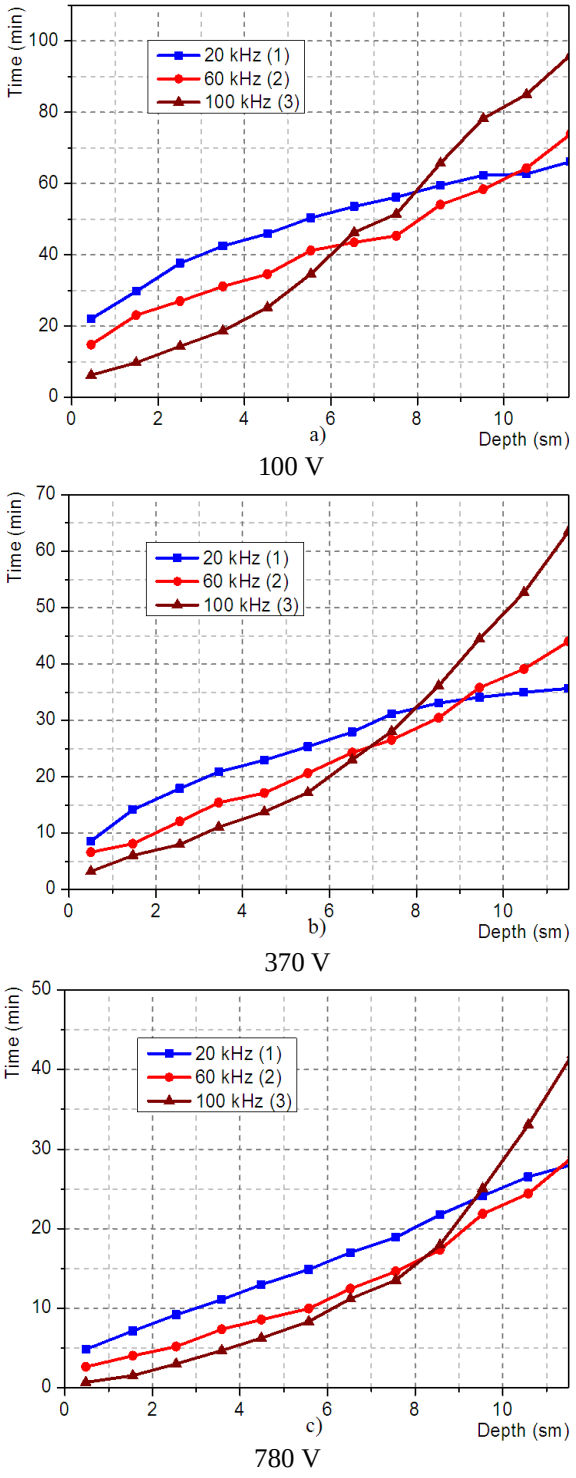

Figure 6. Mean times (t) of filling specimen № 3, L=12 sm for different frequencies and different signal amplitudes

DISCUSSION OF RESULTS

Our theoretical and experimental studies have found that in most solution-saturated samples the velocity of elastic longitudinal waves is higher than in dry ones. The total increase of the sound velocity in filled bricks reaches 13-50%. relatively dry bricks, depending on the brand of material.

From the theoretical and experimental results obtained, one can see that the best match of the measured values of the longitudinal wave velocities with the theoretical ones for various brick samples is obtained by the Hilberstein formula.

In bricks there is usually a more or less natural increase in speed with saturation.

One can also notice that with a small filling of capillaries (up to 10-20 mm), the change in speed is more abrupt than with further saturation.

With an average pore filling (up to 30-70 mm), the velocity usually increases smoothly, but when saturation reaches the values over 80 mm, the sound velocity increases sharply. It should be noted that in samples with higher porosity the velocity changes more smoothly, while in samples with lower porosity more sharp and significant changes are observed.

With the gradual saturation of the bricks with liquid, an uneven increase of the velocity is usually observed. At the stage of ultimate saturation, associated with a sharp transition of the system to a new physical state, usually there comes an abrupt change in speed.

In General, the nature of the change in the saturation velocity can be explained from the point of view of the contact model, i.e. is associated with a change in the contact area.

However, a significant role is also played by the nature of the links, their rigidity, so the reasons for the change in speed are often more complex than in the simplified model.

The velocities of longitudinal elastic waves in water-saturated materials are determined by the following:

a) the elasticity of the skeleton and fluid, as well as porosity;

b) lithological features of rocks affecting the state of elastic bonds (mainly composition and type of cement).

While the first factor is quantifiable, the second is much more difficult to account for. Note that in natural conditions the velocity of longitudinal elastic waves is affected by a number of other factors (pressure, temperature, etc.).

Measurements of the velocity of ultrasonic oscillations in various depths of fill brick mortar showed the impermanence of the velocity of propagation of the oscillations. This is due to the heterogeneity of the brick material.

The statistical analysis of the results showed that the confidence interval of the measured values varies depending on the frequency of ultrasonic vibrations. As the frequency increases, the confidence interval of the measured velocity values decreases.

For combining on the same physical principle of impregnating the material hydrophobic solution and simultaneously to control the depth of penetration of

this impregnation was carried out by additional experimental research of ultrasonic impregnation of porous material by hydrophobic solution. During the experiments it was found that the filling of the brick increases with increasing power of the ultrasonic field. However, the increase in power at certain values can cause cavitation of the hydrophobic solution.

The obtained results show that the time of filling the brick increases with increasing frequency: the increase in impregnation time is associated with an increase in the frequency of the acoustic signal, which leads to weakening of the signal. This in turn leads to decrease of the acoustic power along with increase in the depth of the brick filling respectively, a decrease in the rate of impregnation.

The time of filling the porous material is also related to the adsorption forces in the capillaries of the brick. This is due to the change in the capillary volume, which affects the mechanism of rigid friction of the wall surface. When the diameter of the capillary decreases, the number of rubbing areas of the surface of the capillaries increases, which leads to an increase in the slowing down of the velocity of the liquid along the capillary of the porous material.

CONCLUSION

In conclusion we can say, that the results of this investigation provide new possibilities to water-repellent treatment of brick walls and concrete foundations. The time of hydrophobic liquid fill-up under the influence of ultrasound is about 8-10 times less than without the ultrasound, in the course of natural capillary seepage. Generally speaking, the ultrasonic effect on the fluid flow is complex. The acceleration of the rate of the impregnation can be explained by different effects. Among these effects the most important ones seem to be the capillary wall vibrations, the influence of ultrasound on the meniscus in the capillary channel, changes in physic-chemical properties of the fluid, acoustical pressure and cavitation.

Similar results were obtained for different other porous materials, including concrete, ceramics, and some natural porous materials, such as marble and polycrystalline rocks, some natural facing materials.

It should be noted that the majority of theoretical works in both seismic and acoustic literature are devoted to the study of the propagation velocities of longitudinal and only in some cases transverse waves, and usually idealized media were considered.

Therefore, it became necessary to analyze the basic theoretical expressions derived for different types of aggregates, in terms of their applicability to the characteristics of porous materials, and to find out to what extent the available theoretical provisions are linked to the experimental data.

Our future work deals only with studies related to the study of elastic properties of porous media containing different types of hydrophobic liquids.

The use of ultrasonic technologies is not limited to hydrophobic water-repellent impregnation of building structures. For the operation of stationary mining, fixed with concrete, it is often necessary forced repair of concrete support, caused by the destruction of its individual sections. That is why it seems possible to prevent impregnation of the concrete lining workings by hydrophobic liquid using the ultrasonic technologies. High efficiency and manufacturability, small consumption, low cost and environmental solutions and liquids allow us to hope for their use in the extraction of minerals both open and underground methods [7]. Solutions of the corresponding consistencies and liquids in combination with acoustic technologies can be used for fixing the walls of mine workings, and also for strengthening of the massif of rocks, including water-saturated (siltstone, mudstone, sand and others).

ABSTRACT

Conventionally, high-quality quarry materials are used in pavements and railway substructure. Traditional building materials is becoming scarce in some regions. Moreover, rate of consumption of high strength aggregates is increasing rapidly in different industries. The use of traditional quarry materials at current rate of consumption is unsustainable from both environmental and cost perspective. Chemical stabilization has been extensively applied for improving the mechanical properties of the recycled construction and demolition (C&D) aggregates. However, the high carbon footprint burden imposed by use of conventional binders for stabilization increases the overall cost and decreases the sustainability of the construction activities. Alternatively, industrial by-products which are rich in alumina, silica and calcium are a strong potential replacement for Portland cement and lime stabilization with no carbon footprints. In addition, the stiffness of the mixtures can be optimized to increase the serviceability of the stabilized materials under repeated loadings.

Keywords: recycled waste materials, alkali activation, stabilization, resilient modulus

INTRODUCTION

It has been well established that light stabilization of construction and demolition (C&D) aggregates can potentially be utilized as a low-carbon alternative to quarry aggregate materials [1, 2]. However, the stabilized layer are often show low tolerance of flexibility and can cause progressive failure after crack propagation in the stabilized layer [3]. Unbound granular mixtures have the potential to absorb minor differential displacement by rearrangement in the soil matrix known as "self-healing" capability [4]. However, the developed crack in stabilized material can cause progressive settlement leading to failure.

The stabilization is often targets to increase the modulus of a structural layer in order to reduce the overall thickness and consequently the cost of construction [5]. However, brittle failure of heavily stabilized layers have limited their use in design procedures of road authority design approaches [6]. Hence, a definition for lightly stabilized layer (i.e. modified layer) have been recommended to reduce the binder content to moderate the impact of the local failures in the structural layer that will lead to excessive settlement [6].

Reducing the cement percentage results in reduction in number and area of contact points throughout the stabilized soil matrix and consequently increases the localized pressure which in turn accelerate the local failure in the soil structure. It is noteworthy that general Portland cement is often used in these studies for creating the stabilized layer [6-8]. Considering higher aggregate crushing value of C&D aggregates, researchers have attempted to reduce the amount and stiffness of binders to moderate the homogeneity of the stabilized C&D materials [9, 10].

The size variation of solid binder gels in low-calcium and high calcium systems and stiffness variation of these bounds can significantly impact the load-bearing and deterioration of the stabilized layer under repeated loadings [3]. The impact of binder chemistry on flexural compressional behavior of lightly stabilized C&D aggregates have been studied in this research.

MATERIALS AND METHODS

Despite the increase in the rate of recycling solid waste, the C&D waste production stream has also increased leaving the rate of disposal to landfills unchanged [11]. Approximately, 50% of the C&D waste generation is disposed to landfills in Australia [12]. Crushed brick (CB) and Recycled Concrete Aggregate (RCA) comprise the majority of the C&D waste stream and was used for this research.

Industrial by-products was used for stabilization of the recycled aggregates as low-cost and sustainable alternative to general Portland cement. Fly ash (FA) is a rich source of Alumina for producing aluminosilicate gel in a low calcium system [13]. However, the combination of high calcium precursors such as ground granulated slag (S) can be beneficial to implement the stable C-S-H gel as well as

aluminium-substituted C-A-S-H gels [14].

Recycled materials

Granular aggregates

Crushed brick (CB) and Recycled Concrete Aggregate (RCA) have been collected from a recycling facility in Melbourne, Australia. The aggregates have a nominal size of 20 mm with less than 5% of fine content (Fig.1). The materials are classified as well-graded gravel and fit within the envelope suggested by local road authority [15]. Both CB and RCA have acceptable durability with a Los Angeles abrasion value of 35 and 31 respectively.

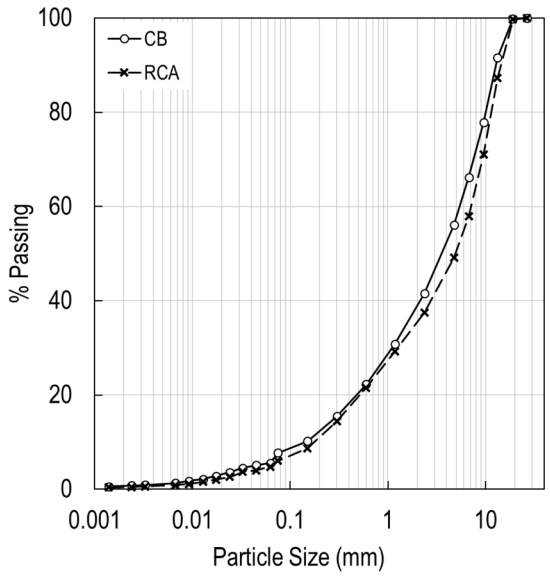

Fig. 1 Particle size distribution of C&D aggregates

Industrial by-products

Low calcium class F FA with mean diameter of 36 µm and slag with mean diameter of 20 µm was procured locally as low carbon alternatives for Portland cement. The chemical composition and physical properties of FA and S are presented in Table 1 and Table 2 respectively.

Table 1 Chemical composition of FA and S

Chemical	FA (wt.%)	Slag (wt.%)
AL_2O_3	25.56	13.8
SiO_2	51.11	34.2
CaO	4.3	43.1
Fe_2O_3	12.48	0.4
K_2O	0.7	0.4
MgO	1.45	5.4
Na_2O	0.77	0.1
SO_3	0.24	0.8
LOI[a]	0.57	1.8

Table 2 Physical specification of FA and S

Specification	FA	Slag
Diameter at 10% - D_{10} (µm)	7.2	6.4
Diameter at 50% - D_{50} (µm)	35.8	20.5
Diameter at 90% - D_{90} (µm)	69.1	54.6
Mean Diameter (µm)	35.0	20.7
Specific Gravity, G_s	2.3	3.15
Bulk density (Mg/m^3)	0.90	0.88
Solubility in water (g/L)	< 10	< 1
pH (25°C)	10	12

The scanning electron microscope (SEM) image of the precursors are presented in Fig.2. The FA particles are spherical and need a high pH to dissolve and start the activation. Aluminosilicate gels are often spiky and create a bridge between the particles while the calcium silicate hydrate (C-S-H) gel are bulky. Combination of the two gels are often create a dense and well-connected matrix.

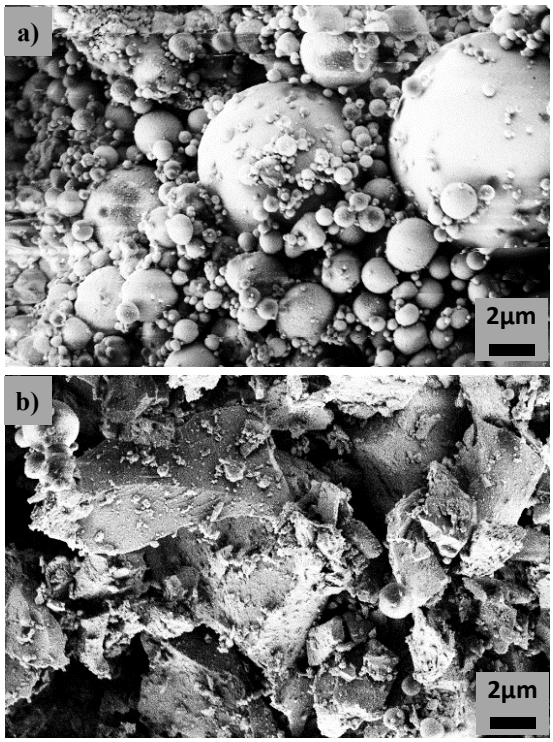

Fig. 2 SEM image of the precursors a) FA and b) S

Alkaline activators

To activate the precursors in room temperature, a 8 molar solution sodium hydroxide (NaOH) in combination with grade D solution of sodium silicate (Na_2SiO_3) was used. The ratio of silicate to hydroxide solution was kept under 2.5 : 1.0 as a result of study performed by Mohammadinia, et al. [3].

Experimental program

Advanced geotechnical tests

The basic characteristics of the C&D aggregates have been detailed in the research performed by the authors [3]. Complementary advanced testing such as repeated load triaxial (RLT) test have been performed to evaluate the compressional resilient modulus of the stabilized materials under repeated loading according to AASHTO T 307 [16]. In addition, four-point beam testing was performed on the stabilized materials to compare the static flexural strength (Modulus of rupture) as well as flexural resilient modulus.

The repeated loading nature in the moving load in transportation geotechnics comprise a complex combination of shear and moment and the impact of these loadings can have different impact on the stabilized layer [17]. Hence, the four-point beam was designed (Fig.3) to create a zone of pure moment where the specimen experience pure moment under repeated loads [18]. The modulus of rupture is determined under monotonic loading [19]:

$$f_{cf} = \frac{PL\,(100)}{BD^2} \quad (1)$$

Where f_{cf} is modulus of rupture (MPa), P is maximum applied load (kN) and *L, B and D* are average span length, width and height of the beam in mm. The resilient modulus will then be performed at a fraction of maximum load (70% of peak load in this case) to evaluate the deterioration of modulus over time. Once the beam reaches half of the initial modulus, the beam is considered to reach end of its serviceability. However, a brittle failure is often observed close to the halfway point of initial resilient in the beam [18].

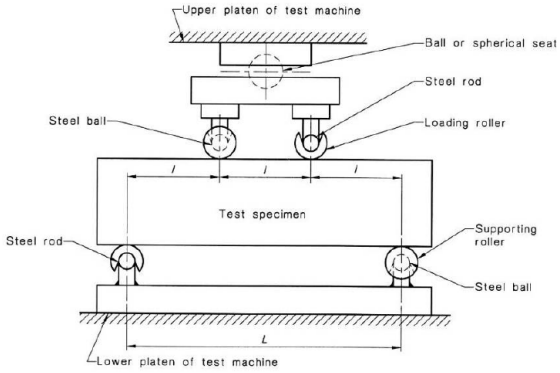

Fig. 3 Schematic of four-point beam test setup [19]

Preparation of specimens

In this research, 10% additive precursor based on dry mass of CB and RCA was mixed with blend for consistency among the blends. The dry precursors have been mixed thoroughly and was mixed with the diluted activator in a mixer to create a lean mortar. The remaining water content was mixed with the aggregates and cured for 3-4 hours to allow for aggregates water absorption before mixing. The mortal and wet aggregates have been mixed thoroughly and was placed in layers into the moulds.

The triaxial specimens with a diameter of 100±0.5mm were compacted in 8 layers of 25 mm (specimen height = 200±1mm) in a split mould at modified energy of compaction and optimum moisture content. The moisture content was limited to the value obtained from the compaction curves in order to demould the sample instantly after compaction. The samples were wrapped in plastic sealing and were cured in a moisture chamber for 7 days before testing. The height of each sample was monitored for swelling which was limited to 0.2 to 0.6 mm (less than 0.3% strain).

Two beam samples were compacted in a rectangular prism mould (400±1mm × 100±0.5mm × 100±0.5mm) in three layers using under compaction technic suggested by Vallejo [20]. A haversine dynamic load with a frequency of 2 Hz including a 250 ms worth of loading and 250 ms of rest at a minimum sitting pressure (Fig.4).

The recoverable mid-span deformation of the beam is used to calculate the resilient modulus under repeated loading. Hence, a small sitting area for the tip of LVDT should be prepared to avoid unnecessary drop in resilient modulus. The average modulus calculated at first 50 cycles are determined as the initial modulus of the beam and will be used to determine the fatigue life of the specimen.

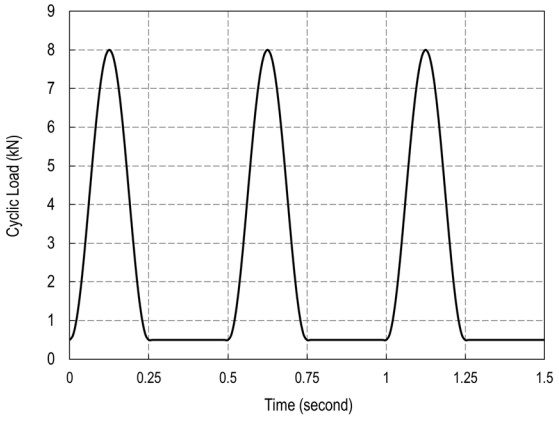

Fig. 4 Typical haversine loading of Fatigue beam test

RESULTS AD DISCUSSIONS

Repeated load triaxial test

The compressional average resilient modulus (R_m) of stabilized CB and RCA over 65 stress combination have been reported in Fig.5. The addition of FA showed negative impact on the compressional

resilient modulus. Addition of 10% FA had limited impact on uniaxial strength improvement as well as resilient modulus of the C&D aggregates as discussed by Mohammadinia, et al. [3]. The beam samples prepared with this blend have failed prior to loading due to low shear strength.

The low strength development at low-calcium systems that rely on alominosilicate gel activation have been reported previously [21]. On the other hand, using a high calcium-based precursors like slag have resulted in rapid strength and stiffness gain. It worth noting that at 10% of stabilization, the compressional resilient modulus between CB and RCA are very close which suggest it is mainly controlled by binder rather than the aggregates in the blend.

Considering the high stiffness of these blends and relatively low-stress level of the RLT testing regime, it is evident that the samples have remained in the elastic zone and the bound between the aggregates have not been broken. On the other hand, the mixed system of FA and S mixtures show similar resilient modulus levels and also lower stiffness compared to that of the higher calcium systems.

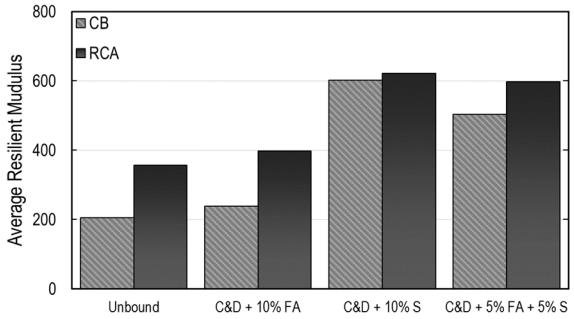

Fig. 5 *Rm* of 7-day cured stabilized C&D aggregates

Four-point beam test

The modulus of rupture of the stabilized samples have been reported in Table 3. The Monotonic loading of the first of two beams reveals the peak load that the beam can carry before failure under pure moment. The relation between compressive strength and modulus of rupture of the stabilized materials is depicted in Fig.6. The samples show a similar behavior at failure under uniaxial compressive strength and flexural peak load. However, the stress levels as high as the peak load is hardly reached in railway and road layers. Yeo [18] suggest a reduced fraction of peak load to be utilized to assess the behavior of the stabilized layer. This fraction should be selected to push the stabilized materials out of the elastic zone and still low enough to avoid premature failures in the stabilized layer. For this research, 70% of the peak load have been used to evaluate the fatigue behavior of the stabilized materials.

Table 3 Four-point beam test results

Sample Designation	Modulus of rupture (MPa)	Flexural Modulus‡ (MPa)
CB + 10% S	1.68	11,113
CB + 5% FA + 5% S	1.90	8,784
RCA + 10% S	1.90	14,274
RCA + 5% FA + 5% S	2.10	12,088

‡ The initial flexural modulus was calculated as the average of second 50 cycles performed at 70% of peak load from rupture test.

On top of quick setting time of specimens stabilized with S, Fig 6 shows that although the rapid strength gain and stiffness improvement in high calcium system stabilized aggregates is desirable, these blends are susceptible to brittle failure under flexural loadings. Although the peak of compressive strength for both C&D aggregates stabilized with S is higher compared to the respective blends stabilized with combination of FA and S, the modulus of rupture at the peak of flexural strength for specimens stabilized with S are lower.

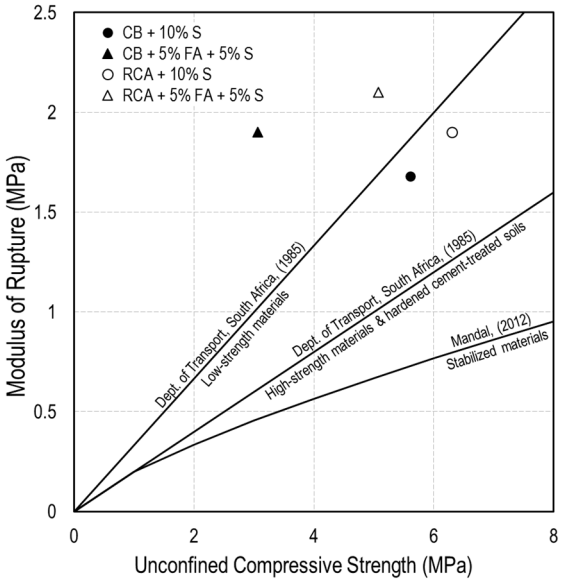

Fig. 6 comparison between modulus of rupture and uniaxial strength of stabilized C&D aggregates

This theory is confirmed by the deterioration rate observed in the four-point beam flexural fatigue test (Fig.7). The higher initial resilient modulus (Table 2) is mainly due to higher stiffness and higher Young modulus of the high-calcium systems. However, the brittle behavior of these samples results in quick deterioration of the gel which in turn amplify the reduction in resilient modulus which resulted in failure of CB + 10%S and RCA + 10%S at cycle number 253 and 403, respectively.

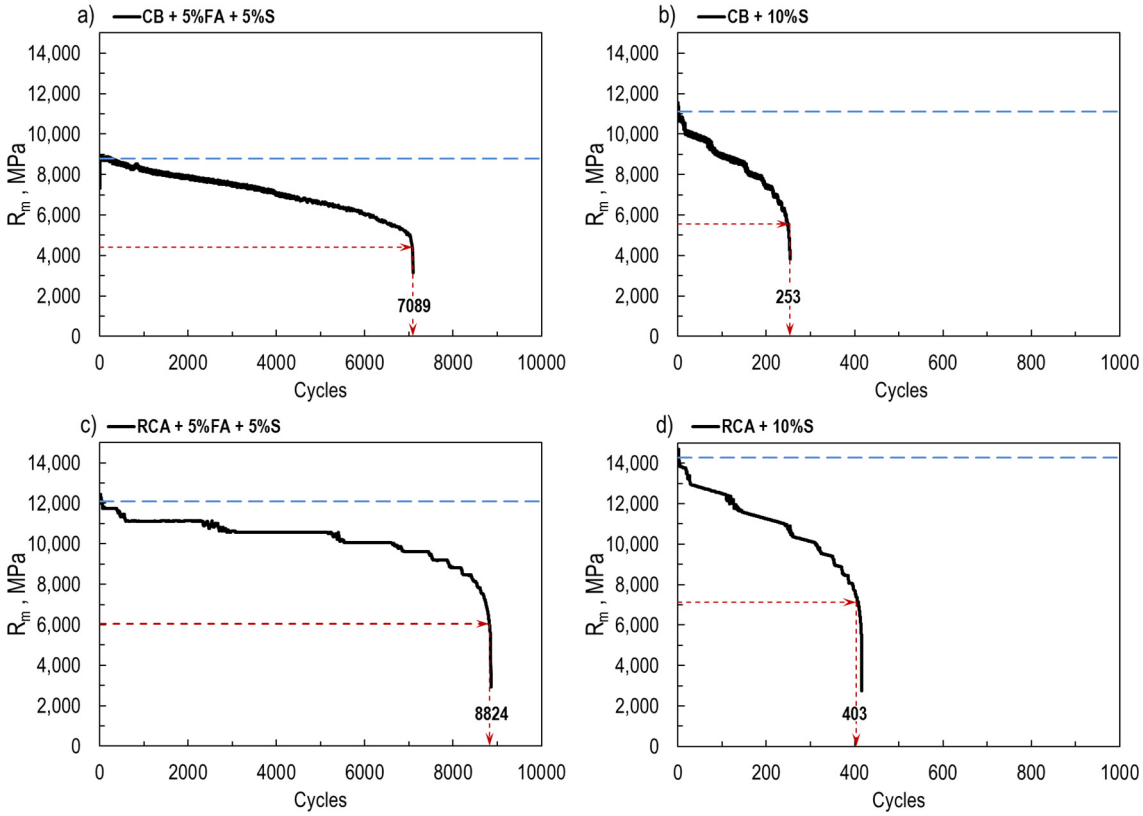

Fig. 7 Four-point beam flexural fatigue test on lightly stabilized C&D materials

In contrast, samples stabilized with FA and S with lower initial stiffness and lower resilient modulus can sustain longer at elastoplastic repeated loading region with minimum deterioration. CB + 5%FA + 5%S and RCA + 5%FA + 5%S have persisted under the repeated loading up to cycles 7089 and 8824 respectively.

It should be noted that at 10% additive content, the stabilized materials behavior, particularly in flexural loading, is governed by the binder behavior. This is particularly important to note that despite the lower compressive strength of stabilized CB blends compared to that of RCA, lower durability of the CB aggregates is less significant under flexural loading conditions.

CONCLUSIONS

The sustainable use of C&D aggregates have often limited to low bearing capacity layers in railways and pavement construction. Utilization of industrial by-products have been researched as an environmental friendly approach for stabilizing solid waste aggregates. Understanding the stiffness and resilient modulus of the binders as well as the geo-materials generated for construction of stabilized layers can potentially promote utilization of C&D aggregates in railway capping layer and pavement construction activities.

Furthermore, the loading condition and the stress levels induced to the intended stabilized layer can significantly affect the behavior of the materials. Resilient modulus of the stabilized layers in pavement and railway structures is not only relying on the stiffness of the geo-materials but also relies on the thickness of the layer.

Additionally, the lack of flexibility in the stabilized layer can lead to progressive and potentially sudden failure of the layer while gradual deterioration can often be rectified. In this research, the fatigue life behavior of the two stabilizing precursors were compared to demonstrate the advantages and disadvantages of the stabilization process.

ACKNOWLEDGMENTS

This research was conducted by the Australian Research Council Industrial Transformation Training Centre for Advanced Technologies in Rail Track Infrastructure (IC170100006) and funded by the Australian Government. The authors would like to thank Alex Fraser Group for providing the demolition aggregates used in this research.

ABSTRACT

This research studied the use of natural rubber latex as an additive in high calcium fly ash geopolymer. The high calcium fly ash geopolymer with natural rubber latex (medium ammonia concentrated latex type) content of 0, 1, 2, 3, 5 and 10 % by weight of fly ash was incorporated in the mixtures. Setting time, workability, absorption, apparent porosity, compressive strength, flexural strength, and surface abrasion resistance were tested. The test resulted shows that the optimum latex content was 1.0 % of fly ash to obtain mortar with improved mechanical properties and a slight reduction in workability, and an increase in setting time.

Keywords: Geopolymer, Fly ash, Rubber, Setting time, Medium ammonia concentrated latex

INTRODUCTION

Geopolymer is an aluminosilicate material consisting of a structure of amorphous and semi-crystalline phases. The substrate used in geopolymer production can be liberated from the particle surface with the use of base solution at both room temperature and moderate temperatures of 40-80 °C. Consequently, the geopolymerization leads to the reaction, which forms aluminosilicate chain. The material sets and endures compressive strength well [1].

The high calcium fly ash consists of a high CaO content and is categorized as type C fly ash. The high CaO content gives a higher self-cementitious property for high calcium fly ash. [2]. The high calcium content also leads to the shortening of the setting time[3] and comparable strength development to the class F fly ash. The main advantages of using high calcium fly ash are increase in the degree of hydration at the early age and the hardening and gain in strength at ambient curing temperature without the use temperature heat curing [4, 5].

The mechanical property of geopolymer mortar and concrete is similar to the mechanical property of those from Ordinary Portland cement [6]. One of the outstanding properties of geopolymer is the high strength gain in a short period when the heat is used to accelerate the reaction [7, 8]. This is suitable for precast concrete, which is in high demand in the market. The fly ash geopolymer can resist acidic and alkaline environments better than Portland cement products because it has a strong structure of aluminosilicate [9, 10] with excellent fire resistance [7, 11]. However, there are reports that geopolymer concrete exhibits higher brittleness than OPC concrete [12, 13] and to improve brittleness, elastomeric latexes can be applied to the geopolymer system [14]

Elastomeric latex is a natural or synthetic polymer having elastic properties. The use of elastomeric latex improves the durability in concrete [15, 16], and increases the flexural strength [17]. It also decreases absorption, improves workability, resists chemical aggressions, and reduces brittleness [14]. In general, there are two basic elastomers for cement mixes viz.., natural rubber latex (NRL) and synthetic rubber latexes (SRL). These elastomers affected the property of concrete in a similar way. The advantage of NRL is that it is readily usable and consumes less processing and energy in the production than that of synthetic rubber latex.

Moreover, the synthetic rubber latex cost is high as it required additional processing and other natural resources[18]. Very few researchers have studied the use of NRL with geopolymer. Lee (2016) used Styrene-butadiene with geopolymer [19] and found that it significantly increased the flexural strength in the order of 50%.

Generally, the use of NRL with OPC needs to be mixed with non-ionic surfactant to avoid agglutination when it is mixed with water and cement [20, 21]. However, geopolymer has high alkalinity, and the anion is similar to that of NRL. Therefore, it should distribute itself well in the geopolymer system. The basically sound properties of geopolymer could thus be improved with the incorporation of rubber latex. This research is thus aimed to study the properties of geopolymer mortar incorporating NRL.

The setting time, water absorption, abrasion resistance, compressive strength, direct tensile strength and bending strength were tested.

EXPERIMENTAL DETAILS

Materials

The high calcium fly ash was from Mae Moh power station in the north of Thailand. The oxide composition of fly ash is summarized in Table 1 and its X-ray diffraction (XRD) is shown in Fig.1. Scanning Electron Microscopy (SEM) results as shown in Fig. 2 showed that the fly ash particles were spherical. The fly ash was relatively fine with 24% retained on sieve No. 325 (45 µm), the median particle size of 15.6 µm, and a specific gravity of 2.64. The particle size distribution also revealed that 76% of fly ash particles were smaller than 50 µm as shown in Fig. 3.

The NRL (medium ammonia concentrated latex type) was used as an additive to improve the properties of geopolymer mortar. The properties of concentrated latex are presented in Table 2. Sodium silicate solution (Na_2SiO_3) and sodium hydroxide solution (NaOH) with Na_2SiO_3 to NaOH ratio of 0.33 were used as alkali activators. The low Na_2SiO_3 to NaOH ratio was selected for reason of environmental concern. Sodium hydroxide solutions with 6, 8, 10, and 12 molars (M) concentrations were prepared using sodium hydroxide flakes of 97% purity and distilled water. Sodium silicate with 15.32% Na2O, 32.87% SiO_2 and 51.80% H_2O by weight was used. The fine aggregate was local river sand in saturated surface dry condition with a specific gravity of 2.62 and a finesse modulus of 2.95.

Mix proportion and specimen preparation

In this study, geopolymer mortars were prepared. The ratios of sand to fly ash of 2.75, liquid to fly ash ratio of 0.6 and Na_2SiO_3 to NaOH ratio of 0.33 were used for all mixtures with the NRL addition of 0, 1, 2, 3, 5 and 10 % by weight of fly ash.

For mixing, fly ash and sodium hydroxide were mixed for 5 minutes. Sand was added at this stage and the mixing was done for another 2 minutes. The premixed rubber latex and sodium silicate were then added, and the mixing was continued for three more minutes. For mortar, the fresh geopolymer mortar was tested for flow in accordance with ASTM C1437-15 (2015) and setting time in accordance with ASTM C807-13 (2013). The fresh mortar was then cast in 50x50x50 mm cubic moulds as described in ASTM C109/C109M-16a (2016). The mortar was also cast in 100x100x100 mm cube mold for abrasion test and 40x40x160 mm prism for the flexural strength test. All specimens were covered with plastic sheets and left in a controlled 25 °C and 50 % R.H. room for 24 hours. They were then demolded and wrapped with plastic sheets to prevent moisture loss and stored in a 25 °C and 50 % R.H controlled room until the testing age.

Testing procedure

The workability of the mortar mix was tested using the flow of mortar following the ASTM C109 / C109M - 16a (2016) The setting time of the mortar was tested in accordance with the ASTM C807-99 (1999) The compressive strength and tensile strength of mortar were tested at the ages of 7 and 28 days in accordance with ASTM C109 / C109M - 16a (2016) and ASTM C307 – 03 (2012). The reported strengths were the average of three tests.

The abrasion resistance of mortars was determined according to ASTM C944 / C944M – 12 (2012) with a normal load on the specimen surface of 98 N for 2 minutes. The absorption of mortar was also tested using 50 mm cube specimen oven dried at 85 °C for 24 hours with immersion time of 48 hours. The reason for applying 85 °C was to avoid the effect of high temperature on geopolymer structure [19].

RESULT AND DISCUSSION

Setting time and flow

The results of setting time and flow of mortar are shown in Table 3. The increase in NRL content resulted in longer initial and final setting times due primarily to the reduced increased water content of system as rubber latex contained some water. Without rubber latex additive, the initial and final setting times of geopolymer mortar were 60 and 105 mins and conformed with the previously reported results [22]. The addition of 10% rubber latex slightly increased these values to 87 and 135 mins.

With regards to the flow of mortar, the increase in the rubber latex content decreased the flow of fresh mortar. The flow of mortar without rubber latex additive was 20.6 cm and reduced to 11.4 cm with 10% NRL. The NRL was a high viscosity liquid, and thus its presence reduced the workability of mixture.

Table 3 Setting time and flow of geopolymer mortars

Rubber Latex (%)	Setting time (min)		Flow (cm)
	Initial	Final	
0	60	105	20.6
1	62	120	18.1
2	65	122	17.2
3	67	125	17.0
5	80	130	14.5
10	87	135	11.4

Absorption and apparent porosity

The results of absorption and apparent porosity of mortar are shown in Fig. 4. The incorporation of 1.0 % rubber latex resulted in the reduced apparent porosity and absorption of mortar. The reduced porosity indicated the filling of pore with rubber latex. As the particles of rubber latex were between 50-100 nanometers. The cavity of paste is slightly larger at between 100 picometers to several hundred nanometers [23].

However, when the rubber latex additive was increased, the absorption and apparent porosity of mortar started to decrease. The optimum amount of rubber latex was 1.0% and the increase in the additive beyond this level resulted in the surplus rubber latex in the matrix. The increased latex particles resulted in the increases in non-homogeneity, interface, and the gap between rubber latex and paste as shown in Fig. 5 The reduced absorption was one of the important factors that improved chemical absorption resistance ability of specimen[24]. The addition of 1% rubber latex decreased the absorption and porosity of specimen at the age of 28 days by 0.7% and 3%, respectively. The geopolymer mortar containing appropriate amount of rubber latex could enhance the absorption characteristics of mortar. In addition, the experiment also showed that the absorption improved with age due to the continued reaction of geopolymer and the forming of additional calcium silicate hydrate (C-S-H) and calcium aluminosilicate hydrate (C-A-S-H) and sodium aluminosilicate hydrate (N-A-S-H) in the geopolymer matrix [25]. When the age of specimen increased, the matrix of the sample became denser and the apparent porosity decreased by 9-16

%.

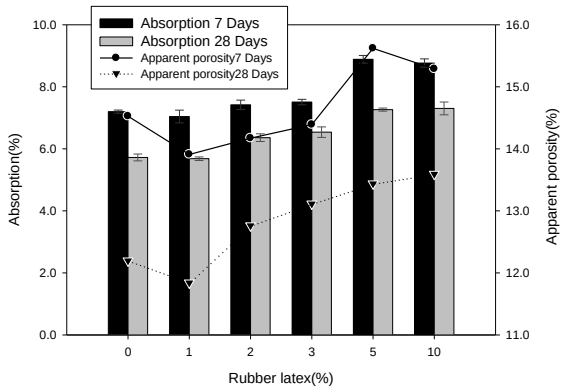

Fig. 4 Absorption and apparent porosity of geopolymer mortar at 7 and 28 days

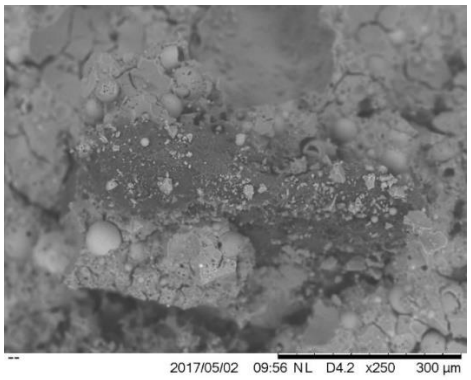

Fig. 5 SEM of rubber latex particle and geopolymer matrix

Compressive strength

The results of the compressive strength of geopolymer mortars are shown in Fig. 6. The optimum amount of latex was 1% and this produced mortar with increased compressive strength. The addition of latex beyond this level resulted in a decrease in compressive strength. A small amount of latex could fill the pore of matrix and make the mortar denser. The filling of pore at this level reduced the void in the matrix and slightly increased the compressive strength. The addition of more latex started to reduce the compressive strength due to increases in rubber particle, interface, and gap between rubber particle and paste. The compressive strength results agreed with the porosity which showed that the lowest porosity (optimum) was with the incorporation of 1% NRL. The reduction in the mechanical properties with increased NRL content complies with other reported results on the use of elastomer[16, 19] .Under the compression loading, the additional rubber latex and interface resulted in additional internal tensile strain resulting in a decrease in the compressive strength of mortar. The 7-day compressive strength of 1% latex sample was optimum at 30.0 MPa and this reduced to 7.0 MPa with the incorporation of 10 % latex.

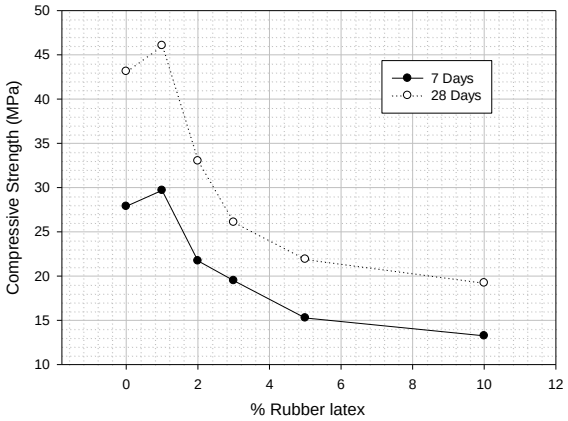

Fig. 6 Compressive strength of NRL modified geopolymer mortar at 7 and 28 days

Flexural Strength

The results of flexural strength of geopolymer mortars are shown in Fig. 7. At the age of 7 days, the flexural strengths of specimens containing 1-3 % NRL were approximately the same with that without NRL. The good performance of samples with a small amount of NRL followed similar trend to that of the compressive strength. However, at the age of 28 days, the increase in the amount of NRL reduced the flexural strength of sample. The incorporation of rubber latex seemed to have an adverse effect on the flexural strength of the mortar particularly for the samples with high strength normally obtained with advanced age. In this test, there is an indication here that the benefit of incorporation of a small amount of NRL on the flexural strength was more pronounce at the low strength level, i.e. at the early age of sample of 7 days.

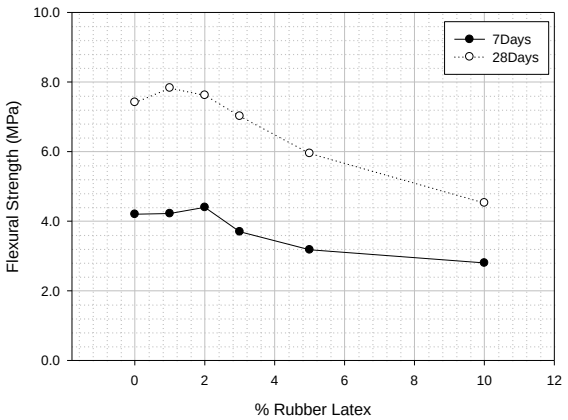

Fig. 7 Flexural strength of NRL modified geopolymer mortar at 7 and 28 days

Surface abrasion resistance

The result of abrasion resistance as shown in Fig. 8 follows the same trend as that of compressive strength. The surface abrasion resistance has been shown to relate to the compressive strength of samples [26]. In this research, the optimum NRL content of 1 % resulted in the lowest surface abrasion weight loss which corresponded to the highest compressive strength. The optimum amount of NRL addition resulted in the filling of pore of geopolymer paste and thus enhanced the properties of the mixture. The presence of NRL has also been shown to increase the absorption of impact and the impact resistance of samples [27]. The better characteristics of absorbing energy rendered the sample with increased resistance to the abrasion action of the rotation and impact of rotating cutters and decreased the surface abrasion weight loss as shown in Fig.8. As already pointed out that the increase in the NRL resulted in the non-homogeneity, interface, and gap between rubber latex and paste. In addition, the incorporation of more than 1 % NRL resulted in surplus NRL and reduced amount of paste for the basic strength unit as it reduced the amount of fly ash in the system. In some cases, the surplus NRL was prone to adhere to each other and this larger particle caused the weakness in the matrix. The results thus confirm that resistance to the surface abrasion is related to the strength of materials as indicated by the direct relation to the compressive and tensile strength of the samples.

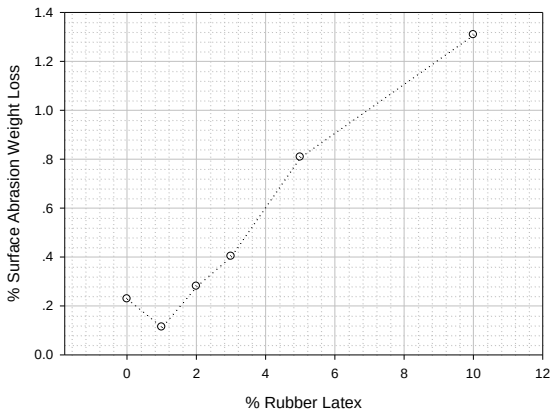

Fig. 8 Surface abrasion weight loss of rubber modified geopolymer mortar at 28days

CONCLUSIONS

Based on experiment result, the following conclusion can be made:

(1) The incorporation of natural rubber latex (NRL) increased the setting time of geopolymer mortar due to the increase in the water content of the system. The flow of mortar decreased with increasing NRL content as the NRL was a high viscosity fluid and thus increased the viscosity of system.

(2) The incorporation of 1% of NRL was optimum for the geopolymer mortar system to obtained reductions in apparent porosity and absorption of specimens. This would have a positive effect on the durability of the samples as the decreased apparent porosity and low absorption would lower the chemical absorption of sample.

(3) The compressive, and flexural strength tests confirmed that the optimum amount of NRL addition was 1%. This produced mortar with increased strengths due to the filling of pore and associated improved mechanical properties. The incorporation of NRL beyond this level resulted in the surplus NRL and reduction the strengths of mortar was observed. The surplus NRL resulted in increases in non-homogeneity, interface, and gap between rubber latex and paste. In addition, the amount of geopolymer gel was also reduced as the amount of rubber was increased.

(4) The results also confirmed that the resistance to surface abrasion was highest with the incorporation of optimum amount of NRL of 1%, which resulted in the lowest surface abrasion loss.

Overall, the results showed that NRL could be used as additive in the high-calcium geopolymer with optimum content of 1% by weight of fly ash. The geopolymer mortar with 1%NRL showed improved properties with increased in strengths (compressive, and flexural strengths), increased resistance to surface abrasion, and reduced porosity and absorption.

ABSTRACT

Moisture susceptibility or known as stripping are very common road distress in tropical country and it is a safety treat to road users. Polymer modified asphalt binder has been conducted previously to find an alternative material in pavement construction that can be used as new improvement for asphalt mix design. This research was carried out to determine the potential benefits of rubber polymer as modifier to enhance the properties and strength of the bituminous road. In this study, three different types of dense graded Superpave HMA mix were developed consists of unmodified asphalt binder (Control) mix, Rubber Polymer Modified Asphalt binder (RMB) mix and Rubber Polymer Modified Asphalt binder with Hydrated Lime (RMBL) mix. This research evaluates the physical properties and moisture susceptibility performance of dense graded Superpave-designed HMA mix. Laboratory tests, i.e. aggregate testing and Superpave volumetric properties were performed to evaluate the physical properties of these mixtures. The Moisture Susceptibility Test (AASHTO T283) was used to characterize stripping performance of dense graded Superpave HMA mixes. The addition of 4 percent 40-mesh tyre crumbs by weight of asphalt binder into asphalt binder were used to prepare rubber polymer modified asphalt binder. 1 percent Hydrated lime by total weight of aggregate was added into the aggregate to improve the bond between aggregate particles and, thereby mitigating moisture damage. Results from the study revealed that, all the mixes passed the Superpave volumetric properties criteria which indicate that these mixtures were good with respect to durability and flexibility. The addition of rubber polymer significantly enhances the properties of asphalt mixtures. The moisture susceptibility result showed that RMB mix demonstrates better resistance to stripping than those prepared using Control mix. While the addition of hydrated lime as antistripping additive with rubber polymer into bituminous asphalt binder would improve the stripping performance of HMA mixes which indicated that RMBL has the most potential to improve stripping resistance eventually increasing the life span of the pavement and reduce premature pavement failure. Therefore, rubber polymer has high potential recycling market value which can be used as additive to, reduce temperature susceptibility, improve adhesion and cohesion properties and further enhance performance of Superpave designed pavement in tropical climate.

INTRODUCTION

Malaysia being in tropical climate receives a significant amount of rainfall throughout the year. Climatic factor such as temperature and moisture and high traffic impact stress have profound effect on the durability of hot mix asphalt (HMA) pavements against pavement failures. The selection of poor-quality material may also affect the overall performance of the pavement including stiffness, stability, durability, workability, fatigue resistance, frictional resistance and resistance to stripping [1,2]. Stripping happens when water infiltrates between an asphalt film and the aggregate surface, and replaces the asphalt aggregate's coating. This situation causes a loss of bond between the aggregate and the asphalt cement [3,4]. The most serious consequence of stripping is the loss of strength and integrity of the pavement. Stripping failures within the asphalt pavement structure can translate into various types of pavement failure such as fatigue cracking, rutting, raveling and potholes. This condition makes the driving comfort and safety of the drivers in dangerous. The damage of asphalt pavements due to moisture also can significantly increase the maintenance costs of a pavement and ultimately, reduce the life of the pavement. Due to these problems, it has been seen increased interest to improve HMA mixture properties for better performance and safe riding comfort.

Currently, there are a number of additives that are available that can be added to the Hot Mix Asphalt (HMA) mixture as a solution to the stripping problem and hence, create a high performance pavements characteristics. For many years' polymers are used as additives to modify asphalt cement to increase the high temperature stiffness of the HMA mixture which can reduce the probability of pavement failures. Many studies explored the effects of polymer/additives on the properties of conventional. Results showed that the incorporation of polymers to also has beneficial effects

on asphalt binders on road pavement. It would decrease the thermal susceptibility and permanent deformation under load (rutting) and increased the resistance to low-temperature cracking. It also brings greater adhesion to aggregate [5,6]. Hydrated lime and Portland cement are the most effective antistripping fillers. It can considerably improve the stripping resistance characteristics of asphalt mixtures [7]. Study conducted by Huang (2010) studied the moisture susceptibility of hot-mix asphalt (HMA) containing hydrated lime [8]. They concluded that the strong interaction between hydrated lime and can improve the bond between aggregate particles and, thereby mitigating moisture damage. Researchers found that the mixes containing hydrated lime and liquid anti-stripping agent are stiffer, less susceptible to rutting, moisture damage and cracking. Studies have shown that lime reduces the potential for moisture to disrupt the adhesive bond that exist between the and aggregate [9]. In this study, the usability of rubber polymer in asphalt mixture and the effectiveness of hydrated lime additives on the HMA mixes was also investigated in term of moisture susceptibility or stripping performance. Finally, this research will investigate and show that the use of hydrated lime as antistripping additives and the modification of the asphalt binder by using rubber polymer will reduce the stripping problem.

METHODOLOGY

Materials

Granite aggregate and two types of asphalt binder; unmodified asphalt binder of penetration grade 80/100 and rubber polymer modified were used in this study. The aggregates were obtained from Hanson Quarry, Semenyih. The aggregate undergone and satisfy the Jabatan Kerja Raya (JKR) material specification test and also Superpave recommended evaluation tests. Consensus aggregate test; Flat and Elongated Particles (ASTM D4791), Fine Aggregate Angularity (AASHTO TP33), Clay Content (ASTM D2419) are performed to assure that the selected aggregate is acceptable for the mix design. Source properties tests; Toughness (ASTM C131), Soundness (ASTM C88), Deleterious Material (ASTM C142) are used to qualify local source of aggregate.

Rubber Polymer Modified binder used in this study was produced by modifying of PEN 80/100 with 4 percent 40-mesh tyre crumbs by weight of asphalt binder. A high shear mixer was used for blending tyre crumb particles into the asphalt binder. An acceptable tyre crumb particle dispersion was achieved by operating the high shear mixer at 175 ºC and 1500-2000 rpm.

Hydrated lime was used as an antistripping additive. In this study, 1 percent Hydrated lime by total weight of aggregate was added in a 1.5 percent water by total weight of aggregate. Dry hydrated lime was initially added to the dry aggregate. Water was then added then thoroughly mixed to provide a good coating of lime on the aggregate surface. The aggregate was then placed in the oven for drying and heating purposes.

Mix design

The Superpave mix design procedure[10] was used to determine the aggregate gradation and optimum asphalt binder content. The major steps involved in volumetric testing and analysis process are (i) selection of materials; (ii) selection of aggregate gradation; (iii) selection of optimum asphalt binder content; and (iv) evaluation of moisture susceptibility of the design mixture. Three different mix were developed in this study; unmodified asphalt binder (control) mix, rubber polymer modified asphalt binder (RMB) mix and rubber polymer modified asphalt binder with hydrated lime (RMBL) mix.

To select the aggregate gradation, three trial blends were established mathematically by combining the gradations of individual stockpiles into a single blend. This step consists of blending available aggregate stockpiles at different percentages to arrive at aggregate gradations that meet Superpave requirements for each blend. The initial trial content for the three blends was estimated to 4.5%. Two samples from each trial blends were compacted using Superpave Gyratory Compactor (SGC). The SGC compact the samples at an angle of 1.25 gyration, pressure of 600 kPa and a speed of 30 rpm. In this study, the number of gyrations for initial compaction, design compaction, and maximum compaction were N_{ini} = 8 gyrations, N_{des} = 100 gyrations and N_{max} = 160 gyrations were used. Each sample was compacted to the design number of gyrations, with sample height data collected during the compaction process. Superpave gyratory compaction data was analyzed by computing the estimated bulk specific gravity, corrected bulk specific gravity, and corrected percentage of maximum theoretical specific gravity for each desired level of gyration. Superpave mix design volumetric properties criteria such as voids in mineral aggregates (VMA), voids filled with asphalt (VFA), and dust proportion (DP) were established on a four percent (4%) air void content at N_{des} by using the N_{ini} and N_{des} gyration levels previously determined from the design traffic level. The corrected volumetric parameters were compared to the Superpave specification requirements. The design aggregate gradation that "best" meets the criteria was selected for determining the optimum asphalt binder content.

Once the design aggregate gradation was selected from the trial blends, samples were compacted at varying asphalt binders content. The mixture properties were then evaluated to determine optimum asphalt binder content. A minimum of two samples were compacted at the trial blend's estimated asphalt content, at ± 0.5% of the estimated asphalt content, and at +1.0% of the estimated asphalt content. Samples were prepared and tested in the same manner as the samples in the "Selection of design Aggregate Structure" section. The volumetric properties were

calculated at N_{des} for each asphalt binder content. All other mixture properties (%VMA, %VFA, $\%G_{mm}$ at N_{ini}, $\%G_{mm}$ at N_{max} and dust proportion) were checked at the design asphalt binder content to verify that they meet the established criteria. After the trial blend and design asphalt binder content were selected, two additional samples were compacted to N_{max} (160 gyrations) and then compared to Superpave criteria. Superpave specifies a maximum density of 98% at N_{max}. Specifying a maximum density at N_{max} prevents design of a mixture that will compact excessively under traffic become plastic and produces permanent deformation. Since N_{max} represents a compactive effort that would be equivalent to traffic much greater than the design traffic, thus excessive compaction will not occur.

Moisture Susceptibility test

Modified Lottman Test (AASHTO T283) was used to evaluate moisture induced damage of compacted samples. For the compacted samples testing method requires six samples of 150 mm diameter and 95mm height for each mixture which were randomly assigned to two groups of three numbers. One group as control sample (dry conditioning) and kept at room temperature, while the other (second group) was treated through wet conditioning. During conditioning, samples were subjected to 10-26 inHg pressure for 5 to 10 minutes under vacuum saturation. Strength for both Modified Lottman Test was obtained by determined the ratio of mean strength of conditioned samples to the mean strength of dry samples to measure moisture susceptibility of the mixes. The Tensile Strength ratio (TSR) values in the test are an indication of the potential for moisture damage. Higher TSR value indicates greater resistance of the mix to moisture damage. Tensile strength ratio (TSR) was used with 80% as the boundary between mixtures resistant and sensitive to moisture [11].

RESULTS AND DISCUSSION

Aggregate Testing

In Superpave mix, the aggregate was tested in term of consensus and source aggregate properties testing in order to achieve high performance of HMA. The results of the consensus and source aggregate properties testing are summarized in Table 1. Based on the obtained results, the value for both consensus and source properties are acceptable and fulfilled the Superpave mix design criteria. Thus, the sample from HQP Semenyih can be used in Superpave mix design and also suitable for used in the road work.

Table 1: Aggregate Specification Test Results

Reference		Test Method	Results	Criteria
Consensus Properties	ASTM D 4791	Flat or Elongated Particles in Coarse Aggregate	Flakiness Index: 7.71% Elongation Index: 9.16%	< 20%
	AASTHO TP 33	Fine Aggregate Angularity	49.18%	>45%
	ASTM D 2419	Sand Equivalent Test	46.23%	> 45%
Source Properties	AASTHO T 96	Toughness	23.30%	< 45%
	ASTM C88	Soundness Test	Fine aggregate: 4.82% Coarse aggregate: 3.25%	>10% to 20%
	ASTM C142	Deleterious Materials	Clay lumps for each aggregate size: 1.18 mm: 0.4% 4.75 to 9.5 mm: 0.2% 9.5 to 19 mm: 0.2%	>0.2% to 10%

Superpave Mixture Design

This study uses a grading NMAS 19mm and calculations were made based on the average between the upper limit and lower limit of the grading. Three trial blends were evaluated mathematically combining the gradations of individual stockpiles into a single blend gradation to determine the best aggregate structure. The Superpave combined gradation for each blend is shown in Table 2 and the gradation chart for the all blends was plotted and is shown in Figure 1.

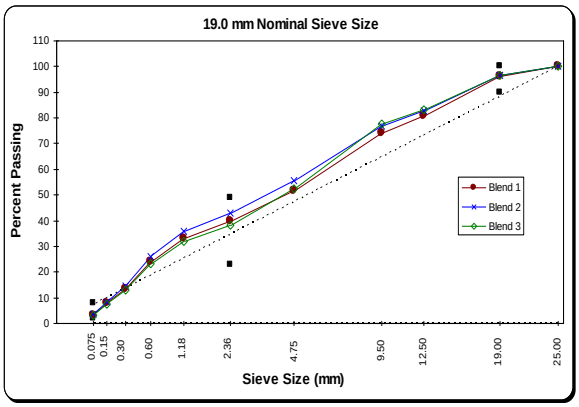

Fig. 1: Aggregate Structure Gradation

Table2: Aggregate Gradation

Sieve size	Individual gradation			Combined gradation			
	#3/4 (a)	#3/8 (b)	Dust (c)	**Blend 1** 39%(a)+ 17%(b)+ 44%(c)	**Blend 2** 35%(a)+ 17%(b)+ 48%(c)	**Blend 3** 34%(a)+ 24%(b)+ 42%(c)	Superpave control points
25.0mm	100.0	100.0	100.0	**100.0**	**100.0**	**100.0**	**100**

75	0.9	1.2	6.2	**3.3**	**3.5**	**3.2**	**2 - 8**

Traffic level was selected based on common traffic level operating on most Malaysia highways. In this study, the traffic will be limited to medium to high roadway application. The initial trial content for the three blends was estimated to 4.5%. Each samples were compacted to N_{design} gyrations and the volumetric properties : Voids in Mineral Aggregate (VMA), Voids

Filled with Aggregate (VFA), air voids (AV) and dust proportion (DP) of the mixtures were determined. Table 3 shows the estimated blend properties. Results indicate that All mix gradations mixtures met the Superpave volumetric requirements and were qualified to become the design aggregate gradation.

Table 3: Summary of Estimated Blend Properties

Superpave mix design properties	Control	RMB	RMBL	Criterion
%Trial asphalt content	4.5	4.5	4.5	-
% Est. asphalt content	5.1	4.9	4.5	4.0%
%VMA	15.05	14.69	15.40	min 13
%VFA	73.4	72.4	74.0	65-76
Dust Proportion	0.8	0.8	0.9	0.6-1.2
%Gmm@Nini	88.4	88.9	88.7	≤89

Determination of optimum asphalt binder content

Further evaluation of this data is to determine the optimum asphalt binder content of the mixtures to achieve 4% air voids (96% G_{mm}) at N_{design}. Selection of the optimum asphalt binder content consists of varying the amount of in the design aggregate gradation to obtain acceptable volumetric properties when compared to the established mixture criteria based on the SGC samples with 4% air voids. The volumetric properties evaluation is one of the major components in determining stability and durability of asphaltic mixtures. The volumetric properties of all mixtures are presented in Table 4 and it can be concluded that all the mixture properties meet the Superpave Criteria. The optimum asphalt binder content of 5.3 %, 5.2% and 4.5% were the values that corresponds to 4.0% air voids at N_{des}=100 gyrations for unmodified asphalt binder (Control), rubber polymer modified asphalt binder (RMB) and rubber polymer modified asphalt binder with hydrated lime (RMBL) respectively. Results revealed that the RMBL mix use less binder compared to Control and RMB. However, all the Superpave volumetric mix design properties for each mixture were found very close to the target value, which implied that the design mixture was good with respect to durability and flexibility.

Table 4: Summary of Volumetric Properties of Superpave Mixtures

Mix design properties	Control	RMB	RMBL	Criterion
% AC	5.3	5.2	4.5	-
%VMA	15.7	15.5	15.5	min 13
%VFA	74.6	72.0	74.4	65-76
%DP	0.7	0.7	0.7	0.6-1.2
$\%G_{mm}@N_{ini}$	88.6	88.8	88.9	≤89
$\%G_{mm}@N_{max}$	96.9	96.5	96.8	≤98

Moisture susceptibility

The last step in the Superpave mix design system is the evaluation of moisture susceptibility of the design mixture. This step is accomplished by performing Modified Lottman test (AASHTO T283) in order to determine the effect of rubber polymer modifier on moisture susceptibility of asphalt mixtures and to determine the effect of hydrated lime as antistripping additive on moisture susceptibility of asphalt mixtures modified with rubber polymer.

Indirect Tensile Strength (IDT)

Table 5 and Figure 2 shows summary of the indirect tensile strength (IDT) results of dry conditioned and wet conditioned sample for subsets with and without antistripping additives. For the dry conditioned samples, rubber polymer modified asphalt binder with lime (RMBL) mix has the highest IDT of 1.416 MPa, followed by rubber polymer (RMB) mix 1.204 MPa, unmodified asphalt binder (Control) mix 1.124 MPa. All the values are reasonable when compared to the result reported by Epps et al., [12] which indicates that dry conditioned tensile strength ranges from 0.54 MPa to 1.88MPa. While, the IDT of the wet conditioned samples ranged from 0.958 MPa to 1.341MPa. The results of IDT of wet conditioned samples showed a similar trend with the dry conditioned samples which showed the RMBL has the highest IDT.

Table 5: Summary of the indirect tensile strength (IDT) results

Mix Design	Unconditioned			Conditioned			TSR (%)
	Air Voids (%)	ITS (Mpa)	ITS_{Ave} (Mpa)	Air Voids (%)	ITS (Mpa)	ITS_{Ave} (Mpa)	
Control	7.4	1.262	1.124	7.5	1.012	0.958	85.3
	6.8	0.972		7.1	0.964		
	7.3	1.137		6.5	0.899		
RMB	6.7	1.112	1.208	6.9	0.977	1.059	87.6
	7.5	1.240		6.7	1.138		
	6.7	1.273		7.2	1.061		
RMBL	7.4	1.537	1.416	6.9	1.224	1.341	94.7
	7.0	1.412		7.4	1.549		
	6.9	1.299		6.9	1.249		

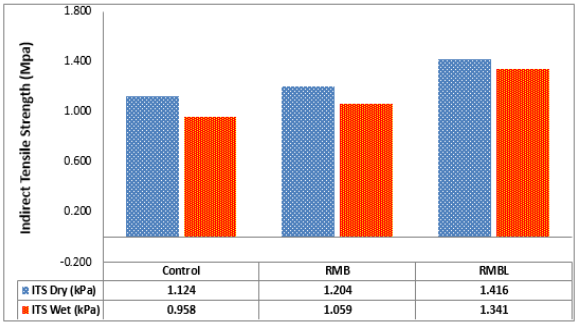

Fig. 2: Indirect Tensile Strength of Dry conditioned and Wet Conditioned samples

Tensile Strength Ratio (TSR)

The Tensile Strength Ratio (TSR) value in the modified Lottman test is an indication of the potential for moisture damage. Higher TSR value indicates greater resistance of the mix to moisture damage. A minimum TSR criterion of 80 percent was adopted for Superpave mix design AASHTO T283. Figure 3 shows the TSR for subsets with and without antistripping additive. The TSR value shows that there is no damage caused by moisture induced for all mixes since TSR

values significantly higher than 80%. The test results show that mixes of RMBL has the highest value of 94.7%, followed by RMB 87.6%, and Control 85.3%.

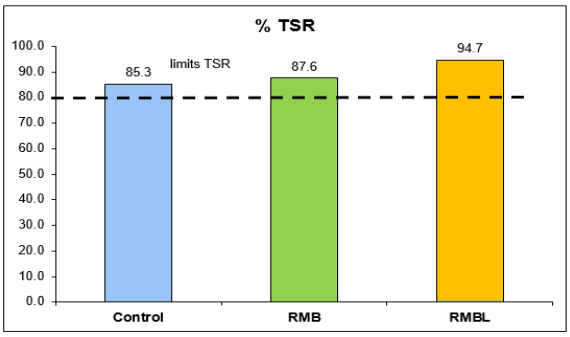

Fig. 3: The Results of Modified Lottman Test (TSR value)

Effect of moisture conditioning on moisture susceptibility of asphalt mixtures

Moisture conditioning has a significant effect on the stripping potential. This was true by the laboratory test results obtained from Modified Lottman test which indicated that the indirect tensile strength (IDT) of the wet conditioned samples was lower than dry conditioned samples. The statistical test analysis was undertaken to look at the effects of wet conditioned strength versus dry conditioned strength for each mixture. A paired sample t-test was done to compare the mean dry conditioned to the mean wet conditioned. The null hypothesis for this analysis was that the mean difference in the mean strength for both dry conditioned and wet conditioned data was equal (H_o: Dry conditioned strength = Wet cconditioned strength). The results of these analyses show the p-values of 0.00 was less than $\alpha = 0.05$, indicate that the null hypothesis was rejected. In other words, the hypothesis that the mean difference between dry conditioned and wet conditioned samples is significant. This analysis indicates that moisture conditioning has a significant effect on the stripping potential of the mixes. This means the environmental conditioning procedures in AASHTO T283 reduced the tensile strength of the mixtures.

Effect of rubber polymer modifier on moisture susceptibility of asphalt mixtures

It could be seen that rubber polymer (RMB) mixes gave better performance compared to unmodified (Control) mixes. It is because the addition of rubber polymer into asphalt binder also enhances the indirect tensile strength towards the moisture susceptibility. The enhancement of the performance to resist the tensile stress is because of rubber polymer reinforcement. The statistical test analysis was carried out to look at the effects of rubber polymer modified asphalt binder (RMB) mix versus unmodified asphalt binder (Control) mix. A paired sample t-test was used to compare the mean RMB mix to the mean Control mix. The results show the p-values of 0.05 was less than the $\alpha = 0.05$. The differences in TSR values of samples made with an unmodified asphalt binder (Control) and rubber polymer modified asphalt binder (RMB) were found to be statistically significant. Therefore, incorporation of rubber polymer as a modifier will improve the strength. This was true because rubber polymer absorbs the asphalt binder that needed to coat the aggregate thus improving the stripping resistance. In general, it can be concluded that mixes prepared using rubber polymer modified asphalt binder showed an improvement in performance and showed better resistance to stripping than mixes prepared using unmodified asphalt binder.

Effect of hydrated lime as antistripping additive on moisture susceptibility of asphalt mixtures modified with rubber polymer

The purpose of adding hydrated lime as antistripping additives was to improve bonding between asphalt binder and aggregate. It could be seen that the rubber polymer asphalt with hydrated lime mixes give better performance compared to the mixes having unmodified asphalt binder. The addition of hydrated lime as an antistripping additive has significantly improved the TSR and the stripping resistance. The enhancement of the performance to resist the tensile strength towards the moisture induced damage might be explained by the fact that hydrated lime contains calcium which increases interaction between aggregate surface and asphalt binder, so it improves the bond between and aggregate. Some States reported that modifications made to hot mix asphalt with hydrated lime will add years to its life [13]. These modifications can reduce stripping, rutting, cracking, and aging. Hydrated lime substantially improves and also works much better in conjunction with polymer additives, helping to create pavement systems that will perform to the highest expectations for many years[14]. The statistical test analysis was undertaken to look at the effects of hydrated lime as antistripping additive on unmodified asphalt binder mix and rubber polymer modified asphalt binder mix. A paired sample t-test was also used to compare the mean unmodified asphalt binder (Control) mix with the mean rubber-polymer modified asphalt binder with hydrated lime (RMBL) mix. The p-values of 0.003 for RPMBL were less than the $\alpha = 0.05$. These results indicate that the null hypothesis was rejected. Rejection H_o indicated that the mean difference between mixes of UMB with RMBL is significant. Therefore, incorporation of hydrated lime in to rubber polymer mix as an additive will enhances the indirect tensile strength towards the moisture susceptibility. It can be concluded that mixes prepared using rubber polymer modified asphalt binder with hydrated lime showed an improvement in performance and showed better resistance to stripping than mixes prepared without hydrated lime.

CONCLUSION

The research had conducted a comprehensive laboratory experimental tests to determine and evaluate the suitability of Superpave system using

local aggregates, to evaluate the stripping performance of rubber polymer modified asphalt mixes and also to evaluate the effectiveness of antistripping additive on the HMA mixes. Superpave consensus and source aggregate properties results showed that local aggregates meet both aggregate properties requirement which indicated that Hanson quarry, Semenyih has a good quality aggregate. Thus, the aggregate and locally aggregate gradations are acceptable and suitable for used in road works. Whereas, for the performance results, the incorporation of rubber polymer modified asphalt binder to bituminous mixes increases the strength. This shows that, incorporation of rubber polymer does improve the stripping resistance. It is also evident from the results, that the introduction of hydrated lime has significantly improved the TSR values of the mixes and reduces the moisture susceptibility of the HMA mixture. In term of knowledge contribution, this study contributes and proof the suitability of the new Superpave system can give better performance especially in reducing pavement failures. The used of hydrated lime and rubber polymer as additives can improved the pavement performance through their ability to improve the properties of the and resulting asphalt concrete mix that is moisture insusceptible.

ACKNOWLEDGMENT

Special thanks to the financial support for this work from Universiti Teknologi MARA (UiTM). The provided experimental facilities and assistance during the work progress were gratefully appreciated.

ABSTRACT

Surface deteriorations such as scaling on concrete happen due to environmental factors such as frost damage and chemical corrosion. Such surface deteriorations in the freeze-thaw test are generally quantified by weight loss and/or decrease of dynamic modulus of elasticity. However, it is difficult to examine these properties of huge concrete blocks such as tunnel lining sidewall. It is hard to quantify local scaling accurately because the current visual inspection methods are based on the slight loss of concrete surface subjected to the scaling. An image analysis has been developed to assess the deterioration of concrete surfaces accurately and efficiently. This image analysis is applicable for quantitative evaluation of the surface quality, including local scaling and surface holes. This study conducted a freeze-thaw test on mortar specimens with artificial surface holes. The paper presents the influence of surface holes on local scaling, which was quantified by the image analysis based on RGB values in the colored photograph. The results indicate that the image analysis is valid to detect and quantify the area of scaling, including invisible micro-scaling. It was concluded that surface holes negatively affect the scaling of concrete. A degradation grade scale based on the area-ratio, including surface holes, is proposed for evaluating local scaling appropriately.

Keywords: Image Analysis; Local Scaling; Bugholes; Freeze-Thaw Cycles

INTRODUCTION

Freeze-thaw (F-T) damage of concrete generally happens by surface scaling and internal damage [1, 2]. Concrete scaling, progressive removal of small flakes or chips of binder [3], is caused by frost damage, chemical sulfate attack, physical salt attack, and pumping effect [4–7].

Conventional evaluation methods for the F-T damage include weight loss and/or decrease of dynamic modulus of elasticity. However, it is difficult to examine these properties of huge concrete blocks such as tunnel lining.

Grading method based on a visual inspection is occasionally used to assess surface quality of concrete. ACI Committee 116 report (ACI 116R) [8] describes concrete scaling as local flaking or peeling away of the near-surface portion of hardened concrete or mortar. According to the report, “light”, “medium”, “severe” and “very severe” are defined by the loss of surface mortar down to depths of less than 5 mm, 5-10 mm, 5-10 mm to 10-20 mm around aggregates, and greater than 20 mm, respectively. ASTM C 672/C 672M [9] gives the visual rating-scale of surface scaling, as shown in Table 1. This grading method provides a quick and convenient way to evaluate surface scaling. However, these visual grading methods may be varied by inspectors, and it may cause subjective and inaccurate evaluation. Both the ACI 116R and ASTM 672/C 672M assess surface scaling based on depth. Most local scaling on concrete surface is caused from the loss of light depth. It may be hard to quantitatively evaluate such local scaling in the general way. Hence, a quantitative evaluation method for local scaling is necessary to assess the deterioration of concrete appropriately.

IMAGE ANALYSIS

Image analysis methods are developed initially to detect deteriorations such as the bugholes. Detailed surveying is a conventional and reliable way to detect bugholes. However, it requires much human resource and takes a long inspection time. Image analyses based on thresholding are generally used to detect and evaluate the surface bugholes, but the detection accuracy of the thresholding method is not always adequate since the stains on concrete. A simple detection method having sufficient accuracy is preferable for the actual application.

The colored image analysis Concrete Vision Evaluation (CVE) developed by our lab is based on red/green/blue (RGB) value of color photographs taken by a commercial digital still camera. Each pixel in a color image consisted of the red (R), green (G) and blue (B) color. Therefore, each pixel has a specific RGB value.

The image analysis to detect and evaluate bugholes is described as follows [10]:

1. Select a typical bughole in evaluated photographic image, and the RGB values of the pixels are determined as reference numbers of red/green/blue.
2. The RGB values of each pixel in the photographic image are compared with the reference number of RGB.
3. When all RGB values of a pixel is low than the reference criteria, the pixel is estimated as an element of the photographic image of the bugholes.
4. When multiple pixels showing a bughole are adjacent to each other, they are combined and estimated as a larger photographic image of the bughole.
5. The dimensions and X-Y coordinates of estimated bugholes are automatically calculated by counting pixels. The reference length is determined by recalculating the pixels of photographic image of a steel ruler in evaluated photographic image.

A comparative test conducted by Yoshitake *et al*. [10] shows that even invisible bugholes (diameter < 1 mm) can be detected in the developed system, whereas such bugholes are hardly detected in detailed visual survey. Further information on image analysis CVE can be found in the previous papers [10, 11].

With the benefits of high accuracy and efficiency, therefore, the image analysis is applicable to detect local scaling deteriorations. This study employs the image analysis to quantify the scaling area-ratio to evaluate the local scaling on concrete/mortar surface.

Table 1 Visual rating scale of ASTM C 672/C 672M

Rating	Condition of surface
0	no scaling
1	very slight scaling (3 mm [1/8 in.] depth, max, no coarse aggregate visible)
2	slight to moderate scaling
3	moderate scaling
4	moderate to severe scaling
5	severe scaling (coarse aggregate visible over entire surface)

RESEARCH SIGNIFICANCE

Bughole often appears on concrete surface. It is considered as an aesthetic problem rather than a durability problem. However, Saorin *et al*. [12] mentioned that the surface finishing of a concrete element might relate to the external and internal porosities with the mechanical and durability properties. Maeda *et al*. [13] addressed that the bugholes reduces the thickness of the concrete cover and probably causes an increase of permeability, which may accelerate the process of deterioration. Hence, it is necessary to investigate the effect of surface bugholes on durability.

A F-T test on concrete blocks (30 cm × 30 cm × 75 cm) was conducted to examine the local scaling of bugholes. In the 300 F-T cycles, concrete specimens were stored in a cooling chamber, and saltwater were sprayed on vertical surface of the specimens. The image analysis was performed to detect the surface deteriorations during the F-T test.

Surface scaling is observed as local flaking of the near-surface portion of mortar. The image analysis emphasizes on the image color of concrete surface and the scaling. This study conducted a F-T test on mortar specimens having artificial holes to confirm the actual application of the color image analysis method for quantitative evaluation of surface deterioration. This paper discusses the influence of surface holes due to the local scaling.

TEST PROGRAM

Mortar Specimens

Mortar materials used in this study were sea sand (density 2.58 g/cm^3) and ordinary Portland cement (density 3.16 g/cm^3) defined in the Japan Industrial Standard (JIS R 5210). Water-cementitious material ratio and cement/sand mass ratio of mortar were 0.45, 1:2, respectively. The mortar had a compressive strength of 45 MPa at the age of 28 days.

To make surface holes, the mortar was cast in a steel mold (150 mm × 150 mm × 60 mm) with wood plates at the bottom having various sizes of round screws, as shown in Fig. 1. Every three of specimens with the same hole size, including hole diameter of 2 mm, 4.5 mm, 6.9 mm, 9.4 mm, 14 mm, and no holes, as given in Table 2. Figure 2 shows the specimens demolded at the age of 1 day. After that, the perimeter of testing surface was covered with an aluminum tape as a dike shown in Fig. 3. In addition, an adhesive was employed to bond aluminum tape to the surface.

Freeze-Thaw Test

All specimens were subjected to 100 F-T cycles. In the F-T test, mortar specimens retained 4 % calcium chloride water of 6 mm depth and were placed in a cooling chamber. The freezing temperature was -15 ^{o}C for 16 hours, while thawing was performed in a natural ventilation condition for 8 hours. A digital camera recorded the surface

16 17 18	14	3.7

conditions with a shooting distance of 400 mm, as shown in Fig. 4.

RESULTS AND DISCUSSIONS

After the F-T test, surface scaling was evaluated by both visual inspection methods and the image analysis method.

Evaluation by Visual Inspection

surface mortar down to depths is less than 5 mm. Moreover, based on the visual rating scale of ASTM C 672/C 672M, all mortar specimens were rated as level 1 because scaling depths were lower than 3 mm. These visual evaluation methods evaluate the local scaling in a general way and ignore the deterioration area.

Evaluation by Image Analysis

Deterioration area-ratio

The deterioration area-ratio r_d is defined as

$$r_d = \frac{S_d}{S}, \quad (1)$$

where S_d is the total area of pixels estimated as holes and scaling, and S is the evaluation area of a graphical image used in the image analysis.

The deterioration area-ratios of test surfaces before and after 100 F-T cycles (r_{d0} and r_{d100}) were performed by the image analysis, and their relationship is shown in Fig. 5. Specimen 1-2, 4-6, 7-9, and 10-11, having the same size of surface holes, respectively, showed less deterioration during the F-T cycles. The observation implies that the degradation of the surface with small holes can be negligible.

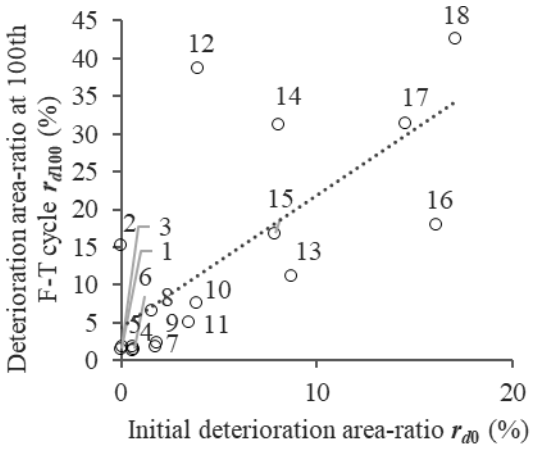

Fig. 5 Relation of deterioration area-ratio before and after 100 F-T cycles

Scaling area-ratio

Scaling area-ratio r_s occurring in the 100 F-T cycles is calculated as follows:

$$r_s = r_{d100} - r_{d0} \quad (2)$$

Figure 6 shows the relation of initial deterioration area-ratio r_{d0} and scaling area-ratio r_s. Specimen 1 and 3-11 indicated slight scaling. On the other hand, Specimen 14-15 and 17-18 had severe scaling around their larger surface-holes. The observations confirm the former F-T test result of concrete. That is, the local scaling may occur at the edge of bugholes subjected to multi-directional frost damages while the surface having fewer bugholes shows hardly local-scaling. Therefore, it can be concluded that the local

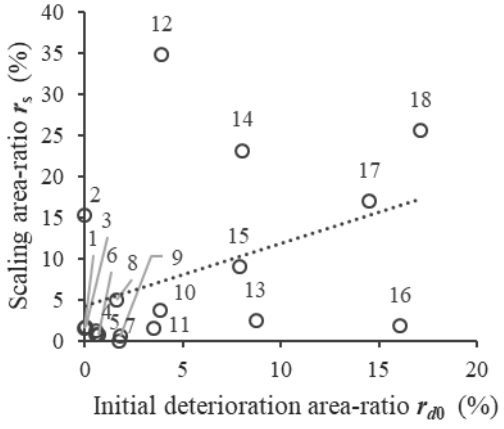

Fig. 6 Relation of initial deterioration area-ratio r_{d0} and scaling area-ratio r_s in 100 F-T cycles

scaling is affected by surface bugholes. The initial surface quality problems such as surface bugholes and spalling, has possible to increase the permeability of concrete and to accelerate the penetration of chloride ion.

Degradation grade scale based on the area-ratio

To evaluate surface deterioration precisely, the present study proposes a grading scale based on the area-ratio given in Table 4.

Table 4 Degradation grade scale based on deterioration area-ratio r_d

Grade	r_d	Surface condition
0	≤ 0.01%	no deterioration
1	≤ 1%	very slight deterioration
2	≤ 5%	slight to moderate deterioration
3	≤ 10%	moderate
4	≤ 20%	moderate to severe deterioration
5	>20%	severe deterioration

For grade 0, deterioration area-ratio under 0.01% is acceptable while the image analysis can detect invisible bugholes and holes caused by the scaling (< 1 mm). The degradation is not so important for the evaluation of the surface quality. The grade 1-4 refer to the hole area-ratio of Specimen 4-6, 7-12, 13-15, 16-18, respectively. For severe deterioration grade 5, scaling area-ratio is over than 20%.

According to the degradation grade scale, the tested mortar specimens were rated in Table 5. It assesses the degradation of specimens concisely and precisely based on the area-ratio. This grading scale is a complement with visual inspection methods by scaling depth though further investigation is needed to validate the application of the proposed deterioration grade scale.

Figure 7 shows the processed image of Specimen 18 before and after the F-T test. The scaling, occurring around holes in a slight depth, was detected by the image analysis. It is confirmed that the image analysis is applicable to quantify surface deteriorations.

CONCLUSIONS

Table 5 Deterioration grade of mortar specimens

Specimen	Before F-T test		100th F-T cycle	
	r_{d0}	Grade	r_{d100}	Grade
1	0	0	1.6	2
2	0	0	15.3	4
3	0	0	1.8	2
4	0.6	1	1.3	2
5	0.6	1	1.8	2
6	0.7	1	1.5	2
7	1.7	2	1.8	2
8	1.6	2	6.6	3
9	1.8	2	2.4	2

18	17.1	4	42.6	5

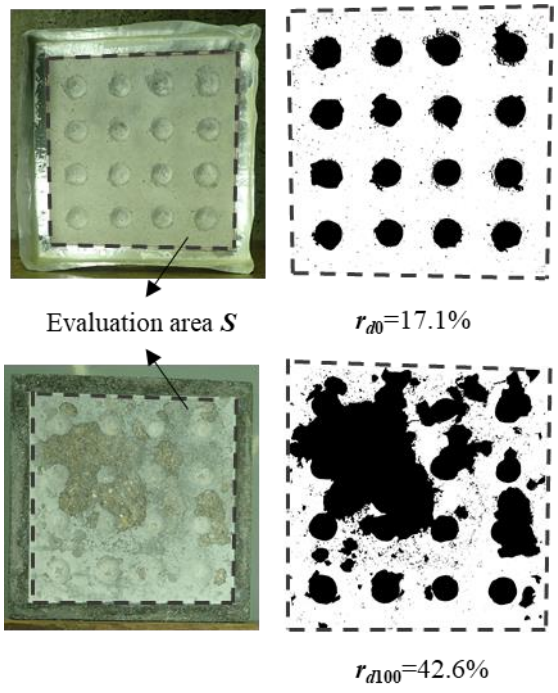

Fig. 7 Processed images of Specimen 18 by image analysis before and after 100 F-T cycles

The conclusions of this study are summarized as follows.

(1) The image analysis provides a quantitative evaluation method for local scaling of concrete surface. It is applicable for detection of the deteriorations including invisible surface scaling under the F-T cycles.

(2) The local scaling is affected by initial surface holes or bugholes before F-T test.

(3) The proposed grading-scale based on the area-ratio is useful for evaluation of surface deterioration.

The image analysis in this study can quantify surface deterioration by using two-dimensional area. It may be a complement for the conventional visual inspection methods by scaling depth. To validate the proposed scale, further research and practical application study are needed.

EXPERIMENTAL STUDIES OF HYDROGEOCHEMICAL INTERACTIONS OF SEAWATER AND CEMENT CONCRETES: IMPACTS ON STRENGTHS AND DURABILITY

Moshood N. TIJANI, Adedayo A. ADESIYAN, John H. ARUWA and Nnamdi OBINI
Faculty of Science, University of Ibadan, Ibadan – Nigeria

ABSTRACT

This study examines the hydrogeochemical processes associated with cement concrete–seawater interactions vis-à-vis strengths and durability of the cement concretes. A total number of 46 samples each of moulded concrete cubes (100mm x 100mm x 100mm) and cylinders (200mm x 100mm) using freshwater with mix ratio of cement, sand and gravel at 1:1:2 were cured in seawater while 32 control samples of both cubes and cylinders were cured in freshwater. Crushing and strength tests were undertaken while hydrochemical analyses of major cations and anions in the curing fresh and seawater were undertaken at the end of the prescribed curing duration of 15, 30, 60, 75, 90, 120, 135, 150 and 180 days. The crushing strength tests revealed a higher compressive strength of 18.6 – 56.9 N/mm^2 and tensile strength 1.4 – 3.2 N/mm^2 for specimens cured in freshwater compared to the samples cured in seawater with compressive strength of 16.3 – 41.8 N/mm^2 and tensile strength of 1.4 – 3.01N/mm^2. The decrease in strengths for seawater cred samples, correspond to decreases in Na^+ from 12,475mg/l to 7,250.4mg/l and decrease in Cl^- from 26,000mg/l to 17,160.2mg/l and at the same time with increase in Ca^{2+} from 382mg/l to 695.4 mg/l and increase in CO_3^{2-} from 122mg/l to 788.1 mg/l; indicative of ion exchange processes. The overall evaluation revealed that ion exchange processes, formation of crystallized chloride salts through ingress of chloride ions into concrete pore system and the formation of gypsum salts through sulphate attack are responsible for the observed strength weakening of concretes.

Keywords: Hydrogeochemical interactions, Seawater, Concretes, Strengths.

INTRODUCTION

Worldwide, the vast majority of infrastructural development has found concrete useful as an important building component. However, concrete are a composite construction material composed of cement and other cementing materials [1]. Generally, the strength of concrete structures (compressive and tensile strengths) depends mainly on the proportion of its ingredient particles i.e. cement, sand, coarse aggregates etc and it is affected by the nature of the mix, water-cement ratio, method of curing, physical properties of coarse and fine aggregates and cement types [2].

Most large cities of the world are situated within coastal settings with massive infrastructural development due to high economic potentials vis-à-vis international trades. However, the durability of concrete structures, i.e. the ability to resist the effects and influences of the environment while performing the desired functions are found to be greatly compromised under such coastal marine environment. This is largely due to the fact that the coastal and offshore concrete structures are exposed to the combined effects of a number of physical and chemical deterioration processes notably: chemical action of seawater constituents on cement hydration products, alkali-aggregate expansion, corrosion of embedded steel in reinforced or pre-stressed members, and physical erosion due to wave action and floating objects [2].

Generally, no matter its composition, water plays a big role in concrete production especially during curing since good curing practice enhances the strength and durability of concrete structures. However, there is a great variability in the concentrations of chemical elements in fresh and sea water, as seawater contains high percentage of chloride, sodium, magnesium, calcium and potassium with total salinity of about 3-5%.

A number of studies had revealed long-term negative impacts of seawater on the strengths and durability of concrete structures in coastal environments [3]–[4]. However, the chemical nature of concrete deterioration is often unappreciated [5] due to lack of detail understanding of chemical interactions between the components of the cement concretes and mixing or curing fluids.

Nonetheless, the combined damaging effects of the chemical action of seawater in form of sulphate attack through crystallization and chloride attack on the steel reinforcement are said to be the major problems associated with concrete structures either built in seawater or cast or cured with seawater [6].

Thus, this paper experimentally, studied the effects of seawater chemistry on the strengths (compressive and tensile) and durability of concretes. This by extension assesses the variations in concrete strengths with recourse to the chemistry of the curing fluids and durations / age to understand some of the controlling hydrogeochemical processes responsible for the strengths deterioration.

EXPERIMENTAL SET-UP

The experimental set-up of this study involved casting of concrete cubes and cylinders using a mix ratio of ordinary Portland cement, sand and gravel at 1:1:2 and cured in seawater and control freshwater in order to assess the possible impacts on compressive strength (Fc) and splitting tensile strength (Ft).

Concrete Mix Design and Strength Tests

A total of seventy-eight (78) concrete moulds` consisting of 46 samples each of moulded concrete cubes (100mm x 100mm x 100mm) and cylinders (200mm x 100mm) at mix ratio 1:1:2 using freshwater were employed in this study. Thirty-two (32) control samples (16 cubes and 16 cylinders) mixed with freshwater and cured in freshwater were also employed (Fig. 1).

Crushing and strength tests, using ELE - Testing Machine (Model ADR-2000), were undertaken at the end of the prescribed curing duration of 15, 30, 60, 75, 90, 120, 135, 150 and 180 days. The fresh water used for mixing and curing the concrete samples was devoid of impurities making them fit for drinking according to ASTM C190, and the seawater containing about 21,000 mg/l of dissolved salts with a pH value of about 8.0 was used.

Fig 1 Moulded cubes and cylinder concrete specimens

All the required materials for preparing concretes were weighed as regards the required proportions while the samples were removed after 24h of casting into the curing liquid until the prescribed testing durations of 15, 30, 60, 75, 90, 120, 135, 150 and 180 days. At the end of the prescribed curing duration, compressive and splitting tensile strength tests were conducted on the cubes and cylinders in accordance with BS 1881 part 116 and 117 (1983) using ELE International-Testing Machine (Model ADR-2000) (Fig. 2).

Fig 2 Loaded concrete cube specimen for Compressive strength test

The respective compressive and splitting tensile strengths in N/mm^2 for the test specimens were calculated using Eq. 1 and 2:

$$\boldsymbol{F_c = P/10} \quad (1)$$

$$\boldsymbol{F_t = 2P/\pi LD} \quad (2)$$

where; F_c = Compressive strength, F_t = Splitting tensile strength, P = Applied load / crushing load, L = length of the sample (mm), D = cross sectional dimensions or diameter (mm).

Hydrochemical Analyses of Curing Fluids

About 600 litres of seawater collected from Aivorji Beach, Badagry, Lagos and freshwater from a borehole at the Department of Civil Engineering, University of Ibadan were tested for their in-situ and laboratory physico-chemical parameters (pH, EC, TDS and major cations and anions prior to concrete moulding and curing.

Furthermore, at the end of each of the prescribed curing durations samples of the curing fluids were collected and tested for physico-chemical parameters and laboratory analyses of major cations and anions. Inductively, couple plasma atomic absorption spectrometry (ICP-AES was used for Ca^{2+}, Mg^{2+} and flame photometer for Na^+ and K^+. Also Cl^-, HCO_3^-, and CO_3^- were determined by titration while colorimeter method was employed for SO_4^{2-} and PO_2^{3-}.

The hydrochemical data alongside the strength test data were subsequently subjected to statistical evaluation, presentations using bivariate plots and interpretations in order to draw reliable deductions/ inferences.

RESULTS AND DISCUSSION

Generally, it was observed that concrete cubes (CU_{SW}) and cylinder (CY_{SW}) samples cured in seawater had darker surfaces compared to CU_{FW} and CY_{FW} (cube and cylinder cured in control fresh

water). Also, crystallized salts deposits were noticed on the surfaces of CU_{SW} and CY_{SW} samples.

Compressive Strength, Fc and Splitting Tensile Strength, Ft of the Concrete Moulds

Table 1 presents the results of the compressive strength (Fc) tests for CU_{SW} and CU_{FW} and that of the splitting tensile strength (Ft) tests for CY_{SW} and CY_{FW} at the end of the different curing durations. The results of the crushing strength tests revealed a higher Fc of 18.6 – 56.9 N/mm^2 and Ft of 1.4 – 3.2 N/mm^2 for CU_{FW} and CY_{FW} specimens cured in freshwater when compared to the CU_{SW} and CY_{SW} samples cured in seawater with Fc of 16.3 – 41.8 N/mm^2 and Ft of 1.4 – 3.01N/mm^2. This is a clear indication of the negative impact of seawater on strengths of the cement concretes. For the Fc, CU_{SW} initially gained strength and reaches a peak value of 32.9 N/mm^2 at 90 days which can be attributed to progressive hydration during setting and curing with resultant improved strength development. However, a decrease in Fc by 120 days (21.7N/mm^2) and 135 days (15.9 N/mm^2) can be associated with interaction of the seawater with the hydrated components of the concrete with resultant disintegration and removal of the lime rich cementing components of the concretes.

Table 1 Compressive and Splitting Tensile Strength results in N/mm^2

Age	Compressive Strength		Splitting Tensile Strength	
	CU_{SW} (N=23)	CU_{FW} (N=16)	CY_{SW} (N=23)	CY_{FW} (N=16)
15	16.30	18.60	1.40	1.40
30	19.40	25.80	1.80	1.90
60	25.70	30.20	2.00	2.10
75	29.60	32.60	2.40	2.20
90	32.90	34.40	2.70	2.40
120	21.70	44.80	1.90	2.50
135	15.90	53.50	1.30	2.60
150	31.80	54.50	1.70	2.90
180	41.80	56.90	3.00	3.20

Comparatively, the rate of increase in Fc for the concrete CU_{SW} specimens were observed to be low relative to CU_{FW}, as strength increases from 18.6N/mm^2 at 15 days to 56.9N/mm^2 at 90 days curing periods (Table 1). This may be due to the less concentration of chloride (242.3mg/l) and sulphate (41.56mg/l) in the freshwater used as curing fluid, hence, the absence of the negative impacts of the curing fluid on concrete strength.

Furthermore, the result of Ft, (Table 1), revealed a similar trend in strengths of CY_{SW} relative to the Fc. The Ft for the CY_{SW} specimens varies from 1.3 – 3.0N/mm^2 while F_t for the CY_{FW} specimens varies from 1.4 – 3.2 N/mm^2. Also the highest Ft of 3.0N/mm^2 and 3.2 N/mm^2 for the CY_{SW} and CY_{FW} respectively were observed at 180 days. However, the highest Ft of 3.2 N/mm^2 for CY_{FW} is most expected as concrete mix ratio of 1:1:2 are known to perform better under freshwater curing fluid without impacts of chloride or sulphate attacks that usually characterized seawater curing medium [3].

Hydrochemical Profiles of the Curing Fluids

Table 2 shows the initial chemical composition of the freshwater and seawater prior to curing relative to the composition of the Atlantic Ocean (Gopal, 2010). Table 3 presents the results of the physico-chemical characteristics of the curing waters at different curing durations.

The initial physico-chemical characters of the curing seawater aligned reasonably well with the Atlantic seawater thresholds with respect to EC, Na^+, Mg^{2+}, Cl^- and SO_4^{2-} concentrations. However, the freshwater exhibited low TDS of 680mg/l and low concentrations of 41.03 mg/l Na^+, 39.0mg/l Mg^{2+}, 134.2 mg/l Cl^- and 41.6 mg/l SO_4^{2-} compared to initially measured concentrations of 12,475 mg/l Na^+, 1,650.2 mg/l Mg^{2+}, 26,000 mg/l Cl^- and 180.0 mg/l SO_4^{2-} for the curing seawater (Table 2).

Table 2 Composition of initial seawater and freshwater (in mg/l) to relative Atlantic Ocean

Parameters	Freshwater	Seawater	Atlantic
Temp.	29	30	-
EC	1,000	32,500	35,370*
TDS	680.0	21,000	-

PO_4^{3-}	20.1	2.59	-

*[7].

As presented in Table 3, the measured pH revealed steady increase for the curing seawater with curing duration from 8.0 to about 12.6 and from 6.9 to 11.9 for the control curing freshwater; suggesting increasing alkaline condition due to the dissolution / leaching of carbonates constituents of the cement concretes especially for those cured in seawater. Such dissolution will obviously lead to loss of cementing properties thereby affecting the strength of the concrete [8].

In addition, EC of the curing seawater also increases steadily from 32,500 to 53,500µS/cm during curing period 180 days. Likewise, for the control freshwater curing medium, the EC also increases slightly from 1,000 to 9,200µS/cm during the curing period. In general, the increase in EC is

clearly an indication of increasing dissolved solids apparently due to the dissolution / leaching of carbonates constituents of the cement concretes and possible reduction in strengths as highlighted earlier. As presented in Table 4, the results of the analysed chemical parameters of the curing fluids revealed varied enrichment and depletion of the dissolved solutes at the end of the different curing duration vis-à-vis the initial freshwater / seawater composition. There are clear decreases in Na^+ from 12,475mg/l to 3,412 mg/l and K from 451mg/l to 305mg/l alongside with decreases in Cl^- from 26,000mg/l to 17,160.2mg/l. This is a clear indication of uptake/ depletion due to reactions with the components of cement concretes.

Table 3 Profiles of the Physico-chemical Characteristics of the Curing Fluids with respect to the Curing Durations

	Cl^-	24,660	22,860	20,360	18,800	17,160	14,556.6	13,483
	SO_4^{2-}	138.8	174.5	267.2	269.2	318.0	324.1	401.3
BCY_{SW}	HCO_3^-	1,980.0	2,500.1	2,756.1	2,968.0	3,256.4	3,976.2	4,135.4
	CO_3^-	244. 2	244.6	264.1	280.5	356.4	392.5	420.6
	Cl^-	18,540	16.672	16,640	15,800	15,640	11,700	9,705.7
	SO_4^{2-}	165.1	183.6	242.20	248.1	272.4	341.4	410.8
BCU_{FW} and BCY_{FW}	HCO_3^-	1,440.1	1900.1	2,040.2	2,064.1	2,252.2	2,688	3,274.7
	CO_3^-	bdl	bdl	bdl	bdl	45.1	46.4	60.0
	Cl^-	128.1	194.30	280.0	340.0	164.8	102.6	82.0
	SO_4^{2-}	42.4	52.40	54.3	74.6	76.3	78.9	80.6

However, Ca^{2+} and Mg^{2+} increased steadily till 90 days curing duration alongside with an increase in CO_3^{2-} from 122mg/l to 788.1mg/l. In addition, SO_4^{2-} ions steadily increase in the curing seawater from 139mg/l at 15days to 412mg/l at the end of 180days curing duration.

Hence it can be inferred that the enrichment of Ca^{2+}, Mg^{2+} and CO_3^{2-} are clear indication of leaching or dissolution of the carbonate components of cement concretes and it is consistent with the observed increase pH from 8.0 to 12.9 of the curing seawater.

Influence of Curing Durations on Strengths of the Concrete Moulds

There is no doubt as to the fact that sulphate and chloride attacks result in expansion, cracking, spalling and loss of bond between the cement paste and aggregate with eventual attendant reduction in strength of concretes [9]. As presented in Figs. 5a and b, there are steady increases in both compressive and tensile strengths until 90days curing duration. This can be attributed to progressive hydration as the concretes slowly set with resultant decrease in porosity and thus increase in strength.

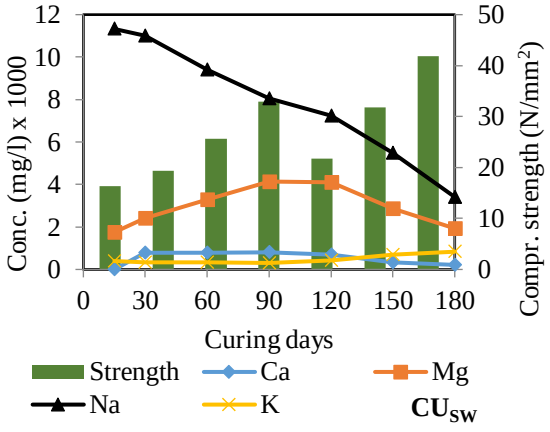

Fig 5a Chemical characters of the curing fluid and compressive strengths against curing durations

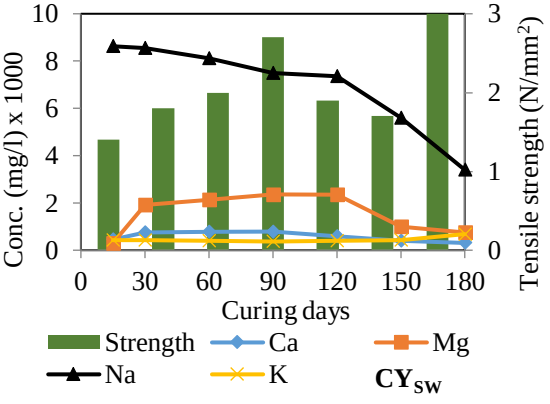

Fig 5b Chemical characters of the curing fluid and tensile strength profiles against curing durations

However, the observed reduction in compressive strength of cubes (CU_{SW}) from 32.9 – 21.7 N/mm^2) and the tensile strength of cylinders (CY_{SW}) from 2.7 – 1.9 N/mm^2 cured in seawater by 90days to 150days of curing (Fig.5a and b) can be attributed to the chemical activity between the components of the concretes and the curing fluids controlled principally by the pH of the medium. This is consistent with the study as in [10] that revealed increase in strengths of concrete when mixed & cured in sea water at early ages and a decrease after a curing period of 28 days and up to 90 days.

In addition, the decreases in strengths by 90days of curing are consistent with the decrease in Mg and Ca, Na, Cl and SO_4 in the curing fluid, which is an indication of alteration of the binding properties of the concretes through sulphate attack. The sulphate attack is related to the formation of expansive *ettringite* with the hydrated calcium aluminates of the set-cement leading to internal cracks and spalling as in Eq. 3:

$$MgSO_4 + CaH_2SiO_4 \cdot 2H_2O \rightarrow CaSO_4 \cdot 2H_2O + MgH_2SiO_4 \quad (3)$$

In summary, it can be inferred that ion exchange processes with attendant leaching of Ca^{2+} and CO_3^{2-} components of the cement concretes and corresponding exchange of Na and Cl ions are responsible for the observed variation in hydro-chemical characteristics of the curing fluid.

Implications of Changes in the Chemistry of the Curing Fluids

The implication of uptake of Na and K ions into the concretes is that after 90 days curing duration and at high basic pH, the presence of Na and K as (NaOH or KOH) will attack siliceous aggregates. This will lead to formation of soluble viscous alkali silicate gel (N-S-H or K-S-H); thus weakening the concrete as stated in Eq. 4.

$$2Na(OH) + H_4SiO_4 \rightarrow Na_2H_2SiO_4 \cdot 2H_2O \quad (4)$$

In absorbing water, soluble alkali silicate gels can swell and induce enough expansive pressure within the core of the aggregates to damage concrete:

Alkalies + Reactive Silica → Gel Product

Gel Product + Moisture → Expansion

However, sulphate (Na_2SO_4 or K_2SO_4 or $MgSO_4$) attacks on concretes are particularly damaging, forming soluble hydroxide ($Ca(OH)_2$; portandite) in the set-cement as in [11] and the resulting reaction to form gypsum which will cause weakening action on the cement paste as in [12] stated in Eq. 5.

$$\boldsymbol{Na_2SO_4} + Ca(OH)_2 + 2H_2O \rightarrow CaSO_4 \cdot 2H_2O + 2NaOH \quad (5)$$

Nonetheless, the implication of chloride attack at higher concentration in curing seawater is the volume expansion and cracking that accompanied

the formation of $CaO{\bullet}CaCl_2{\bullet}2H_2O$ (dicalcium dichloro-hydroxide hydrate) through thermal transformation of the calcium oxychloride salts as in [13] shown in Eq. 6:

$$\boldsymbol{3CaO \cdot CaCl_2} \cdot 15H_2O \rightarrow CaO \cdot CaCl_2 \cdot 2H_2O \quad (6)$$

Hence it can be inferred that under high basic pH of the curing water after 90days of curing, the observed reduction in strengths of test concrete moulds can be attributed to a combination of chloride and sulphate attacks with the resultant formation of crystallize salts within the pore system of the concrete / mortar leading to expansive pressure, internal cracks and spalling [14].

CONCLUSION

This work presents the chemical interactions of the curing fluid i.e. seawater on the compressive and splitting tensile strengths of ordinary portland (OPC) cement-based concretes. The study involved monitoring of the physico-chemical parameters and variations in chemical composition of the curing fluids at specified curing duration vis-à-vis the strengths of the test concrete moulds.

The study revealed that the observed changes in the curing seawater can be attributed to chemical interactions between the components of the cement concretes and the curing seawater. The reduction Na^+ (from 11,325 − 3,400mg/l) K^+ (from 425 − 305mg/l) and Cl^- (from 24,660 − 9,705mg/l) in the curing seawater as curing days progresses can be attributed to the cation exchange processes leading to enrichment of Ca^{2+} (from 462 − 805mg/l), Mg^{2+} (from 300 − 4,140mg/l) and HCO_3^- (from 980 − 4,135mg/l) in the curing seawater due to associated leaching.

In addition, detail evaluation of the controlling chemical processes revealed that the formation of crystallize chloride salts through ingress of chloride ions into pore system and the formation of gypsum salts through sulphate attack usually induce internal cracks and spalling [14]; hence contributed to the observed reduction in strengths of test concrete moulds. The implication is reflected in the observed reduction in compressive strength of cubes (CU_{SW}) from 32.9 – 21.7 N/mm^2) and the tensile strength of cylinders (CY_{SW}) from 2.7 – 1.9 N/mm^2 cured in seawater by 90days to 150days of curing duration.

In addition, this study highlighted that the strength of the concrete tends to increase initially during the early stage of saline attack, but later followed by loss of strength that accompanied the expansion of the set concrete with resultant spalling and cracking [10]. Therefore, there is the need for prior preventive measures such as coating of reinforcement steel /concretes to prevent the risk of seawater attacks on concrete structures in coastal environments.

MULTIPLE PLANTS MULTIPLE SITES READY MIXED CONCRETE SCHEDULE DISPATCHING USING IMPROVED ANT COLONY OPTIMIZATION

Sakchai Srichandum

ABSTRACT

The purposes of this paper were to optimize the schedule of dispatching Ready Mixed Concrete (RMC) trucks with multiple plants multiple construction sites (MPMS) in order to minimize the transportation cost under various construction constraints i.e. limited traveling, casting time, number of truck, allowable weight for transfer and distance from multiple RMC Batch plants to different construction sites using Improved Ant Colony Optimization (IACO). The IACO introduces some additional techniques for improvement of search process such as neighborhood search and re-initializations. The procedures are: firstly, develop the mathematical model of MPMS for RMC truck schedule dispatching in term of optimization problem. After that, use the IACO to solve the optimal schedule dispatching of RMC with MPMS and truck operation. To show its efficiency, IACO is applied to test with two different problems, and its results are compared with those obtained from the conventional approaches such as genetic algorithm (GA) and conventional Ant Colony Optimization (ACO). The experimental results show that the IACO approach is comparatively capable of obtaining higher quality solution, faster computational time and efficiency schedule dispatch

Keywords:Ant colony optimization, Heuristic algorithm, Optimization problem, Ready mixed concrete, Truck dispatching

INTRODUCTION

Recently, the construction industry is continuously growing and developing in term of construction process, methods and materials. In modern construction, Ready Mixed Concrete(RMC) is one of the most popular building materials inconstruction industry due to RMC has several benefits. The advantages of RMC are convenient for management, reducing the labor cost, providing many concrete types for many construction site and high standards. Unfortunately, the RMC delivery has many constraints due to quick solidifying nature of the mixed concrete. RMC trucks dispatching must be scheduled to many requested construction sites continuously under limited traveling and casting time, number of truck, allowable weight for transfer and distance from RMC Batch Plants to many construction sites [1].

Effective and efficient of RMC delivering to construction sites is an important issue to the batch plant manager. The manager has to consider both timeliness and flexibility to develop an efficient schedule of dispatching RMC trucks, which balances the operations at the construction sites and the batch plant. The existing dispatching schedule mainly depends on the experiences and preferences of the dispatcher. A systematic approach to tackle stated problem has seldom been taken due to the complexity and uncertainty involved within the dispatching process. Consequently, there is a need to develop a systematic model that optimizes the schedule of dispatching RMC trucks as a combination optimization problem.

In the past, many studies under the literature reviews dedicated to the RMC production or truck dispatching scheduling based on optimization problems and solved the problem by heuristic algorithms such as Genetic Algorithm (GA) [2], and Bee Algorithm (BA) [3].

Practically, the RMC companies provide the multiple plants for supplying RMC with various types of concrete in different zone to satisfy more customers' demand. It effects to RMC dispatching due to add more complexity to the model.

This paper proposes a new mathematic model of the RMC dispatching problem in case of the multiple plants to multiple sites (MPMS) with 3 types of concrete (floor, column and beam) to minimize total fuel cost of RMC trucks which is considered from shortest route and minimum waiting time of RMC trucks at construction sites. Furthermore, the development of Ant Colony Optimization (ACO) called "Improved Ant Colony Optimization (IACO)" is purposed to solve this problem.The IACO can provide better solution in comparison to the conventional approaches such as GA, PSO and ACO.

PROBLEM FORMULATION

RMC Delivery Process

The RMC delivery process consists of five main components, which are material production, production loading, truck transport, placement and truck return as shown in Fig.1. This process needs to be carefully planned to avoid early concrete setting.Consequently, the RMC production scheduling and the truck dispatching are not only affect delivery efficiency, but also the operating cost. For the truck dispatching, there are many factors need to be considered as follows.

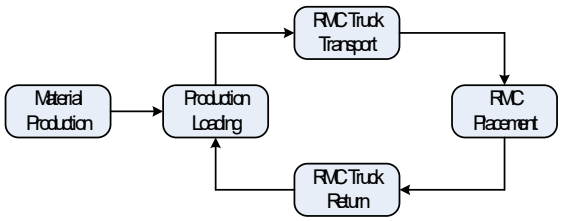

Fig.1. RMC delivery process

RMC dispatching Formulation

In this section, the RMC dispatching formulation in case of multiple plants and multiple sitescan be explained in three parts are dispatching model, feasible solution and fitness function.

Dispatching Model

The dispatching model consists of four components, which are input parameters, decision variables, constraints and system output as shown in Fig.2.

Input parameters: these parameters include the types of required concrete, the number of RMC deliveries, traveling time, pouring duration, mixing duration and allowable buffer duration. The allowable buffer duration presents the maximum duration that the construction site can wait for the arrival of RMC truck.

Decision variable: the sequence of assigning each RMC truck from the different plants to the different construction sites is defined as "dispatching sequence". Therefore, the dispatching sequence of RMC trucks is considered as the decision variable.

Constraints: The continuously pouring requirement restricts the duration that the construction site waits for the arrivals of the RMC truck is smaller than the allowable buffer duration. This constraint is applied to eliminating the infeasible dispatching schedules.

System output: The goal of developing an efficient schedule of dispatching RMC trucks is to minimize the total fuel cost of RMC trucks without breaking off the operation of pouring concrete.

Feasible Solution

The purpose of this study is to find the most efficient and effective sequence of RMC dispatching delivery in case of multiple plants and construction sites. Therefore, the feasible solutions are the sequence of RMC dispatching delivery.

Fitness Function

In order to evaluate fitness function of RMC MPMS problem, we first define indices, parameters and decision variables as follows.

Indices

i : Index of RMC plant, $i \in \{1, p\}$

j : Index of the construction site, $j \in \{1, m\}$

t : Index of RMC truck dispatching sequence from plant i to construction site j, $t \in \{1, n\}$.

Variables

p : Number of RMC plants.

m : Number of construction sites that request RMC deliveries.

n : Total number of the RMC delivery round for all construction sites, $n = \sum_{j=1}^{m} k_j$

NT : Total number of the RMC trucks that all batch plant owns.

D_{ij} : Distance RMC from plant i to construction site j (km).

SCT_j : Start casting time of construction site j.

R_j : Required quantity of the RMC by construction sites j (m^3).

PT_j : Placement type at construction site j. RMC recipe for each type requires pouring time. The pouring time for floor, beam and column is 4, 7, and 9 min/m^3 respectively.

ABD_j : Allowable buffer duration of construction site j (min).

ABT_j : Allowable buffer time of RMC truck (min).

MD_t : Mixed duration of RMC for each placement type for RMC dispatching sequence t which is 2 min/m^3.

CD_t : Casting Duration at construction for each placement type by RMC dispatching sequence t (min), where $CD_t = R_t \times PT_t$.

k_j : Required RMC truck deliveries for the construction site j.

TDG_{ij} : Traveling time from the plant to construction site j (min).

TDB_{ji} : Returning time from construction site j to the plant (min).

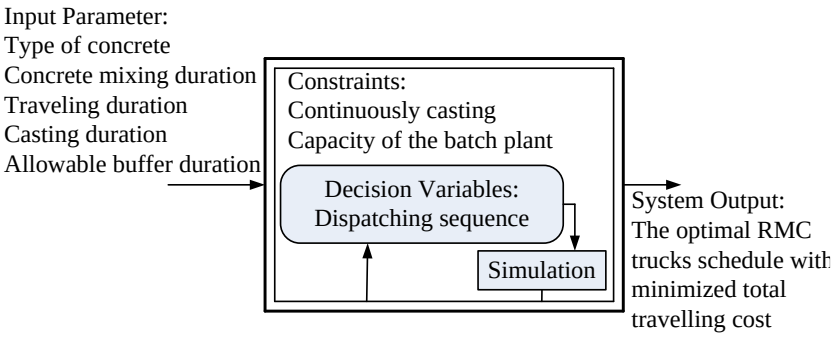

Fig.2. RMC dispatching model

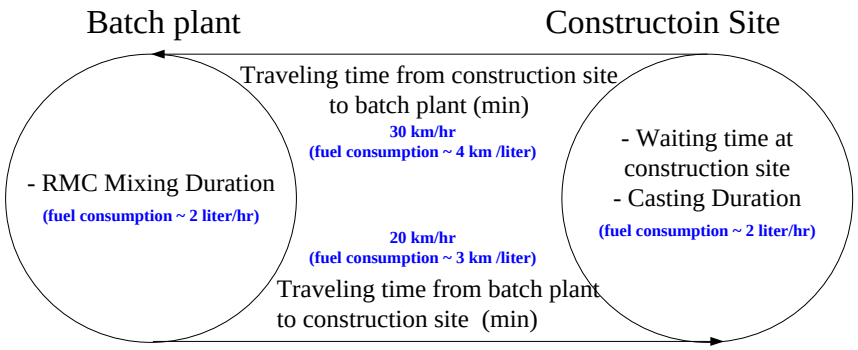

Fig. 3. RMC delivery process and vital variables.

FDT_i : First departing time of RMC truck from plant i .

DT_{it}: Departing time of RMC truck round t from plant i .

SDT_{it} : Simulated departing time of t dispatched truck from plant i .

TAC_{jt} : Arrival time of dispatched truck t at construction site j .

PTF_{jt}: Start pouring time of the construction j if t dispatched truck arrived at construction site j .

$WC_{jt} > 0$: Waiting Duration that dispatched RMC truck t waits at the construction site j .

$WC_{jt} < 0$: Waiting Duration that construction site j waits for the arrival of the dispatched RMC truck t .

LT_{jt} : Leaving time of t dispatched truck from construction site j .

ATB_{it} : Arrived Time of the t dispatched travels back to the batch plant i .

TFC_{ij} : Total fuel cost of RMC truck t for dispatching to construction site j .

The objective of RMC MPMS problem is to minimize fuel cost from multiple plants to multiple construction sites. This duration covers from loading and mixing concrete into RMC truck agitator, travelling from batch plant to construction, waiting time at construction site, casting duration and travelling back to batch plant. RMC truck process flow is shown in Fig. 3. The vital variables in fitness function are travelling speed and fuel consumption in each activity.

Total fuel cost of RMC trucks per minute for each operation is composed of two portions. In this paper, we use the fixed fuel cost of 1.33 $/liter. It is obtained from fuel cost in Thailand.

Firstly, during the transportation of RMC truck: According to the historical data, an average fuel consumption of RMC truck traveling from batch plant to construction site is around 3 km/liter while average traveling speed at 20 km/hr. Thus, fuel cost per minute of TDG_{ij} which is 0.1481 $/min. Meanwhile, average fuel consumption of RMC truck returning from construction site to batch plant is 4 km/liter at 30 km/hr. Hence, the fuel cost per minute of TDB_{ji} is 0.1667 $/min. In this portion, total fuel cost of RMC truck can be minimized by selecting shortest routing from plant i to construction site j .

In addition, the distance (km) from the batch plant to the construction site can be found by using Google map. In this study, the average velocity of RMC truck from batch plant to construction site is

20 km/hr. Therefore, traveling duration from t batch plant to construction site j (in minute), TDG_{ij} can be determined in Equation (1). Meanwhile, the average velocity of RMC truck from construction site back to batch plant is 30 km/hr. Thus, traveling duration from construction site j to batch plant (in minute), TDBj can be calculated in Equation (2).

$$TDG_{ij} = \frac{D_{ij} \times 60}{20} \quad (1)$$

$$TDB_{ji} = \frac{D_{ji} \times 60}{30} \quad (2)$$

Secondary, when RMC truck parks while mixing at the plant: casting at the construction time and waiting for pouring, it is assumed that the average fuel consumption is at 2 km/liter or 0.0444 $/min. This fuel cost could be reduced by minimizing the waiting duration at all construction sites because the mixing and casting times are fixed.

Three truck operations have an impact on the total fuel cost. They are 1) loading/mixing concrete at plant (MD_t), 2) waiting time of RMC truck (WC_{jt}), and 3) Casting time of RMC at construction site (CD_t). These operations occur when the truck parks with agitator rolling at the same time. When the truck is not move, the average fuel consumption is around 2 liter/hr and the fuel cost is 1.33 $/liter. Hence, the fuel cost per minute of MD_t , WC_{jt} , CD_t is 0.0444 $/min. As previously mentioned, an ideal of RMC truck dispatching is just in time delivery. Since mixing and casting times are required, total fuel cost of RMC trucks can be minimized by selecting the RMC truck sequence that have minimum waiting time at all construction sites or the summation of all WC_{jt} .

In summary, the fitness function is equal to the summation of fuel cost per minute multiplied by total duration for each operation of RMC trucks by Equation (3).

$$TC = 0.15 \times \sum_{t=1}^{n} TDG_{ij}^{t} + 0.17 \times \sum_{t=1}^{n} TDB_{ji}^{t} + 0.04 \times \left(\sum_{t=1}^{n} WC_{jt} + \sum_{t=1}^{n} MD_t + \sum_{t=1}^{n} CD_t \right) \quad (3)$$

IMPROVED ANT COLONY OPTIMIZATION

Inspired by the collective behavior of a real ant colony, Marco Dorigo first introduced the ant system (AS) in his Ph.D. thesis in 1992, and the study was further continued by Dorigo et al. [4]. The characteristics of an artificial ant colony include positive feedback, distributed computation, and the use of a constructive greedy heuristic. Positive feedback accounts for rapid discovery of good solutions, distributed computation avoids premature convergence, and the greedy heuristic helps to find acceptable solutions in the early stages of the search process.

A major weakness of conventional ACO algorithm is stagnation that is all ants take the same position. If this problem situation occurs, the algorithm may be trapped in a local optimal point [5]. To alleviate the stagnation problem of conventional ACO algorithms, two improvement procedures are applied in order to improve the ant colony optimization method to guarantee the diversity of ants. This approach is called improved ant colony optimization (IACO). The additional procedures are a specific improvement algorithm (called neighborhood search) and re-initializations.

During searching, the search process gets the repeated solution for a long time. That means the process could not be found the better solutions or escaped from this solution. So this solution could be either a local or global solution. In case the global solution is known, the search process will be stopped as it has been gotten the best solution. On the other hand the global solution is unknown. The algorithm will assume that this solution is a local solution. If the process is stroke on local solution for a long time, the re-initialization process will be applied. This mechanism helps the process to continue searching and find the better solutions. The flowchart of IACO as shown in Fig.4.

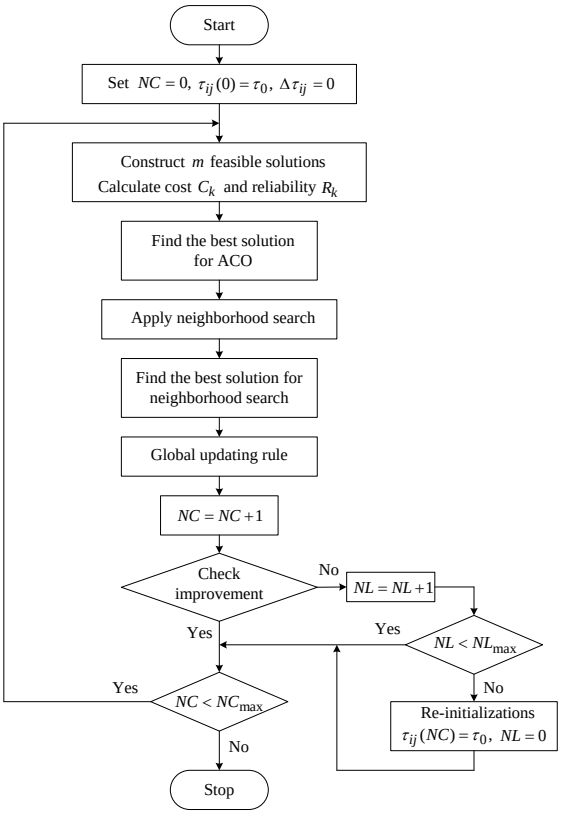

Fig. 4. Flow chart of IACO algorithm

NUMERICAL SIMULATION AND RESULTS

To assess the feasibility of the proposed IACO and the comparison methods i.e. ACO and GA, The different two cases studies are proposed. All methods are performed 30 trials, under the same fitness function and individual definition, in order to compare their solution quality, convergence characteristic and computation efficiency. The software was implemented using MatLab® languages on Intel® Core i5-5200u, 2.20 GHz Laptop with 4 GB RAM under Windows 8.

For case studies, the RMC Company has two batch plants, the first and the second batch plants have three and two RMC trucks, respectively. The Information of dispatching operation is listed in Table 1.

As mention in feasible solutions, There are 1.03×10^{7} and 1.96×10^{12} different dispatching schedules for case study 1 and 2. After solved the case studies with 30 trials, the best solutions for all case studies are shown in Table 2. The *Plant ID* and *Site ID* are determined RMC trucks dispatching sequence. For example in case study 1, the RMC truck starts dispatching from plant 2 in the first sequence of *Plant ID* to construction site 2 in the first sequence of *Site ID* for the first round. Next, RMC truck need to dispatch from plant 2 to construction site 3 and follow this sequence until finished total 8 dispatching orders.

All case studies could be obtained the minimum fuel cost without interruption time by IACO. In addition, the results in case studies 1 and 2 are also verified by exhaustively enumerating all possible solutions.

The interruption of pouring concrete occurs when the duration that the construction site waits for the arrival of the RMC truck is longer than the allowable buffer duration. As shown in Table 2, the best interruptions time is zero that mean without the interruption of pouring concrete.

Comparison of Three Methods

Solution Quality

The results of the IACO method are compared with those obtained by ACO and GA in terms of maximum, average, minimum cost, the standard deviation, and average computational time, as provided in Table 3. Obviously, all methods have succeeded in finding the satisfied solution in all case studies.

In order to demonstrate the efficiency of the IACO method, the distribution outlines of the best solutions of each trial are considered. Fig. 5 and 6 shows the distribution outlines of the best solution of each trial. Almost all optimum costs obtained by the IACO method are lower cost and variation in both case studies. This verifies that the IACO method has better quality of solution.

Computation Efficiency

Table 3 shows average computation time of 30 trials for all methods. The computation time was set running time within 500 seconds per trial. Clearly, the computational time of the IACO method is lowest in comparison to other methods.

Moreover, the convergence characteristics of the IACO, ACO and GA are shown in Fig. 7. The convergences of the IACO to the optimum solution are faster than other methods.

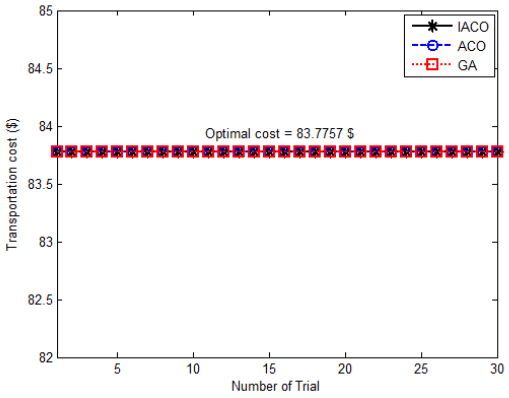

Fig. 5. Distribution of fitness values of all methods of case study 1.

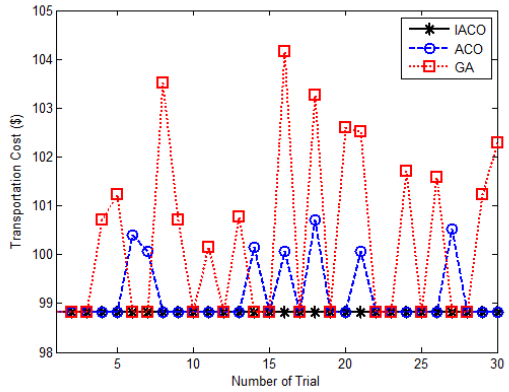

Fig. 6. Distribution of fitness values of all methods of case study 2.

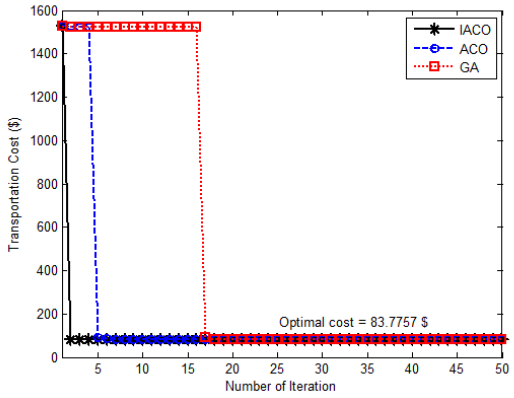

Fig. 7. Convergent graph of fitness values of case study 1.

CONCLUSION

This study presents a systematic approach to modeling the process of dispatching RMC trucks. Results show that by applying the proposed RMC dispatching model to the IACO and the simulation technique, the batch plant manager can quickly generate the efficient and flexible dispatching schedule of the RMC trucks, which not only improves the operations at the batch plant but also promotes the service of the RMC batch plant

EFFECT OF SUGARCANE BAGASSE ASH ON ALKALI SILICA REACTION OF CONCRETE WITH SODA LIME GLASS AS AGGREGATES

Richard De Jesus[1], Giancarlo A. R. Cruz[2], Kendrick B. M. Galang[2], and John D. M. Layson[2]
[1]Faculty, De La Salle University, Philippines; [2] De La Salle University, Philippines

ABSTRACT

Utilization of waste materials for construction use has received much attention lately in the hope of contributing to saving the environment by lessening the impact of construction. This study utilized soda lime glass in concrete as substitute for fine aggregates. However, since soda lime glass promotes alkali-silica reaction, its addition to concrete will not come without risk. Sugarcane bagasse, the unused stalk of sugarcane, when burnt into ash, is a good pozzolanic material. It also has the capability to arrest the expansion brought about by alkali-silica reaction. Therefore, when added to concrete with soda-lime glass, it can lessen the alkali-silica reaction. This study employed sugarcane bagasse ash, as partial replacement of cement, in concrete with soda-lime glass. The amount of soda-lime glass in concrete used in the study ranged from 10-40% replacement of sand, while that of sugarcane baggase ash are 5% and 10% replacement of cement. Compressive strength was determined in 7 and 28 days. Scanning electron microscopy (SEM) was conducted to examine the microstructural change in concrete. To investigate the alkali-silica reaction, measurement of mortar expansion using mortar bar test in accordance with ASTM C1260, was conducted. Some of the significant findings of the study are: (1) addition of soda lime glass, up to 30% replacement of sand, contributes to an increase in compressive strength, and (2) length expansion, due to alkali silica reaction, in concrete with soda lime glass was reduced with sugarcane bagasse ash.

Keywords: Sugarcane bagasse ash, Soda lime glass, Alkali silica reaction, Mortar bar test

INTRODUCTION

The use of glass aggregates in concrete as partial replacement for fine aggregates have been shown to be suitable for use in concrete [1]. Using glass aggregates in concrete is one way of utilizing waste materials and seen as contributing to lessening the impact of waste materials to the environment. Study of [2] have shown that using glass aggregates to replace sand can have beneficial effects on mechanical properties for as long as the replacement is kept below 20-30% of sand since it helps reduce the porosity of concrete. However, the use of soda lime glass (SLG), in particular, does not come without complication as it promotes occurrence of alkali silica reaction (ASR) in concrete due to siliceous content of soda lime glass. They [3] have stated that soda lime glass contains approximately 7-10% Calcium Oxide (CaO) which provides Calcium (Ca) needed for ASR gel formation. In this study, to counter the impact of SLG in causing alkali silica reaction, sugarcane bagasse ash (SBA) is employed.

Alkali-Silica reaction (ASR) is a reaction in concrete when alkali in cement paste reacts with silica present in most aggregates which causes volume expansion that can lead to cracking. This problem in concrete is considered common, and referred to as “cancer of concrete” [4]. One of the most common ways to mitigate ASR in concrete is by adding very fine siliceous material, like pozzolan, silica fume, or fly ash, which results to a controlled pozzolanic reaction during the early stages of cement setting [5]. These siliceous materials safely react with alkali in cement without any formation of expansive pressure because siliceous in fine particles transform into alkali silicate and into calcium silicate without semipermeable reaction rims [6]. They [4] investigated the effect to ASR of employing sugarcane bagasse ash in concrete. They have shown that 10% and 40% SBA replacement of cement resulted to expansion reduction in mortar bar specimens.

Waste glass, in general, contains alkali and silicon dioxide which may lead to ASR [7]. They showed that soda lime glass is composed of 68.4% SiO2, 14.1% Na2O, 9.5% CaO, while the remaining components are small amounts of several compounds. This high amount of silica in soda lime glass, when used as partial replacement of sand in concrete, promotes ASR. Moreover, they showed that ASR risk with an ASR expansion rate of above 0.2% is present in concrete having 30% glass aggregates as sand. Other researches ([2], [8], & [9]) have proven that glass aggregates promote the occurrence of ASR.

Sugarcane bagasse ash (SBA) is a by-product

Table 1. Concrete Design Mix in accordance with ACI 211.1 (for 1-m^3 concrete mix)

Mix ID	Portland Cement (kg)	Course Aggregates (kg)	Fine Aggregates (kg)	Water (kg)	Soda Lime Glass (kg)	Sugarcane Bagasse Ash (kg)
B0G00 (control)	8.40	25.21	16.83	4.25	0	0
B0G10	8.40	25.21	15.15	4.25	1.68	0
B0G20	8.40	25.21	13.46	4.25	3.37	0
B0G30	8.40	25.21	11.78	4.25	5.05	0
B0G40	8.40	25.21	10.10	4.25	6.73	0
B5G00	8.40	25.21	16.83	4.25	0	0
B5G20	8.11	25.21	13.46	4.25	3.37	0.29
B5G30	8.11	25.21	11.78	4.25	5.05	0.29

Note: B – sugarcane Baggase ash; G – soda lime Glass. B5G20 means sugarcane bagasse ash replaces 5% of cement, and soda lime glass replaces 20% of fine aggregates. All replacements were made by weight.

from combustion boilers in sugar industries. SBA is found to be rich in reactive silica giving it a cementitious property, hence, making it a suitable supplementary cementitious material. The use of supplementary cementitious materials (SCM), like sugarcane bagasse ash, is a common method to address ASR [10]. Study of [11] showed that the use of SCM reduces alkali concentrations in concrete hence, reducing the element responsible for producing hydroxyl ions that reacts with siliceous aggregates resulting to ASR. This potential of sugarcane bagasse ash, a waste material, in addressing ASR in concrete is seen as a good compliment for the use of another waste material – soda lime glass in concrete. SBA, through this study, is able to show that ASR caused by employing soda lime glasses in concrete can be mitigated by employing SBA in the same concrete.

MATERIALS AND METHODS

Sugarcane bagasse ash were obtained from local juice vendor. Literatures [12] & [13] have established that the optimal percentage of replacement of SBA to cement ranges from 5 to 10%, hence, this study opted to adopt 5%.

The soda lime glass used in this study was derived from beer bottles, soda bottles, and juice bottles bought commercially. These were crushed manually into bits using a hammer. After crushing, it was sieved to ensure that it is comparable to particle size of fine aggregates. Partial replacement of sand with SLG was done at 10% to 40% replacement by weight, at 10% interval.

Portland cement (Type I) was obtained from local hardware store, along with coarse aggregates, and fine aggregates. Physical characterization of materials (i.e. determination of moisture content, unit weight, and specific gravity) used in producing concrete were made prior to designing the concrete mix proportions and were all conducted in accordance with appropriate ASTM standards. Concrete mix proportion were made in accordance with ACI 211.1 (Table 1).

To figure out the effect of adding soda lime glass to concrete in terms of workability, slump test was conducted on fresh concrete. Justifying the use of alternative materials in concrete requires that the mechanical properties are not compromised. Hence, this study investigated compression and split tensile strength of concrete with 5% sugarcane bagasse ash and soda lime glass which ranged from 10 to 40% at 10% interval. Compressive strength, in accordance with ASTM C39, was tested in 7^{th} and 28^{th} day. Split tensile strength, in accordance with ASTM C496, was tested at 28^{th} day. Three (3) samples were prepared for each mix proportion. All samples were cured in water.

ASTM C1260 is a standard test for determining the potential alkali reactivity of aggregates using mortar bars. Similar to concrete, three (3) specimens were prepared for each mortar mix. The samples were initially immersed in a water bath for 24 hours before it was cured in NaOH solution in an oven for fourteen (14) days. During NaOH solution curing, temperature was maintained at 80 degrees celsius. Length readings were taken three times (3x) daily.

In addition to mortar bar test of potential alkali reactivity, scanning electron microscopy (SEM) was employed to acquire high resolution images of mortar's microstructure to detect the development of ASR gel from the reaction of silica in soda lime glass and alkali in cement.

DATA AND ANALYSIS

Concrete Test Results

Table 2 shows the slump test result for concrete with 0% and 5% SBA, and varying amount of soda lime glass. It shows that the addition of sugarcane bagasse ash reduces slump supporting the claims of [9], and [14] that sugarcane bagasse ash consumes water that is supposed to be for mixing, hence, reducing workability. Another observation

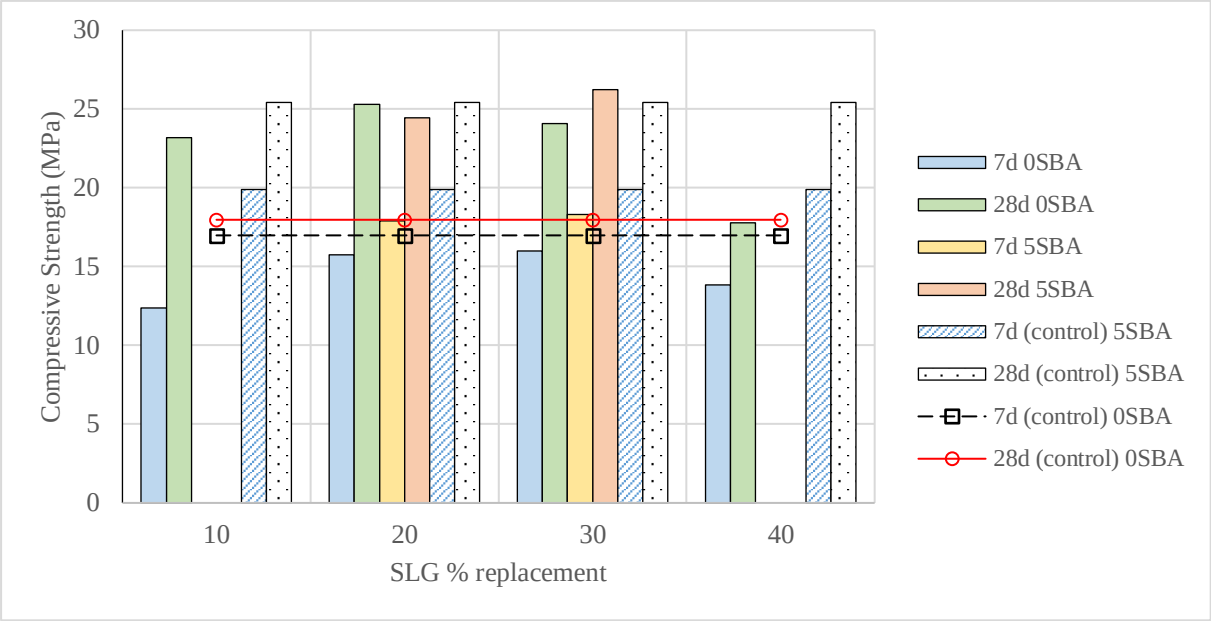

Figure 1. 7th & 28th day compressive strength of concrete with sugarcane bagasse ash and soda lime glass

made was increasing the amount waste glass resulted to increase in slump. This implies that glass aggregates promote workability.

Table 2. Slump test of concrete with SBA & SLG

Mix ID	Slump (mm)
B0G00	86
B5G00	52
B0G20	75
B5G20	56
B0G30	97
B5G30	70
B0G40	112
B0G10	65

Compressive strength test of concrete with SLG and SBA can be seen in Figure 1. Comparison between compressive strength of concrete with and without sugarcane bagasse ash revealed that there is no significant difference between the two. This implies that 5% replacement of cement with sugarcane bagasse ash will not compromise the compressive strength. For both 7th and 28th day strength, the highest strength can be observed at 20% SLG replacement, followed closely by strength values at 30% replacement. SLG replacement appeared to be viable for 20 to 30% replacement as its strength is higher compared to that of control concrete. At 40% replacement, strength fell below that of controlled concrete. All 28-day strength exceeded that of typical normal strength of 21 MPa and that of 28-day control concrete. In this study, it was not established that increasing SLG compromises strength though it was clear that at 40% SLG replacement of sand, strength decreases significantly. Table 3 summarizes the strength results for 7 and 28-day compressive strength and 28-day split tensile strength.

Table 3. Summary of strength results

Mix ID	Compressive strength (MPa)		Tensile strength (MPa)
	7 day	28 day	
B0G00	16.98	17.97	2.92
B0G10	12.39	23.19	1.86
B0G20	15.75	25.30	2.34
B0G30	15.97	24.07	1.87
B0G40	13.84	17.77	1.55
B5G00	19.89	25.42	2.28
B5G20	17.88	24.43	1.29
B5G30	18.29	26.21	1.79

Split tensile strength results showed all samples with SLG have strength lower than that of control sample. Comparison between sample with and without sugarcane bagasse ash show that concrete mix without sugarcane bagasse ash have higher tensile strength. Since this was not observed in compressive strength, it can be stated that for concrete that will utilize tensile strength for a particular purpose, the replacement of cement with sugarcane bagasse ash needs to be investigated thoroughly before application.

Mortar Test Results

The mortar test based on [15] was done to test if the substitute aggregates (i.e. soda lime glass) are potentially reactive to alkali in cement. Length measurement of mortar specimen, using a

Table 4. Length expansion of mortar bar specimens with sugarcane bagasse ash and soda lime glass

Mix ID	Ave. Length Change	Ave. Expansion	Interpretation of Expansion
B0G00	0.663 mm	0.231%	Potentially harmful
B5G00	0.433 mm	0.150%	Safe with slight chance of being harmful
B5G20	0.500 mm	0.173%	Safe with slight chance of being harmful
B5G30	0.537 mm	0.187%	Safe with slight chance of being harmful

length comparator, were done for fourteen (14) days while cured in NaOH solution and kept in an oven to maintain a temperature of 80 degree Celsius. Table 4 summarizes the result of length measurement. Specimen with no sugarcane bagasse ash experienced the highest average length expansion and was found to be potentially harmful with respect to alkali silica reaction. The test also showed that with increasing soda lime glass in concrete, the average length expansion has also increased. This supports the earlier claim that soda lime glass, with its high siliceous content, will contribute more to the occurrence of alkali silica reaction.

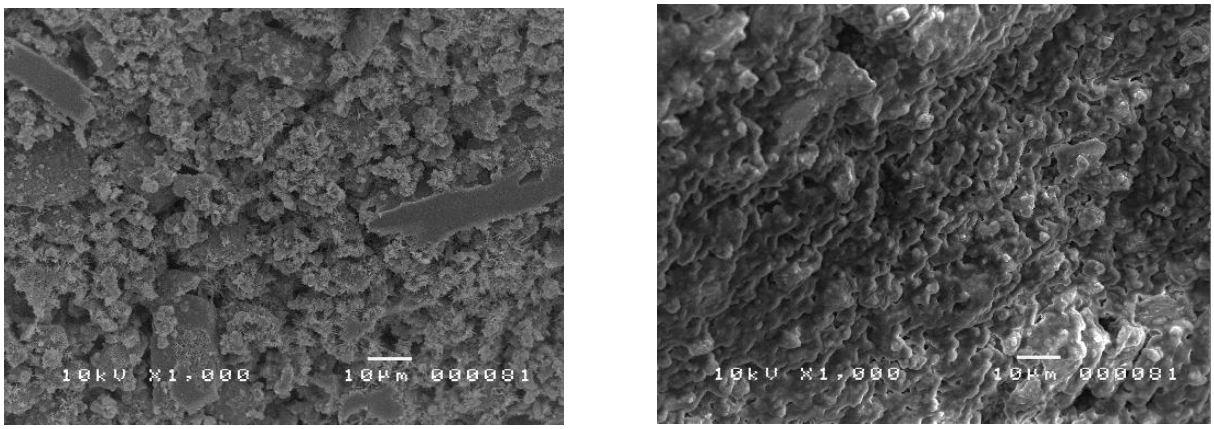

Figure 1a & 1b. B0G00 mortar microstructure before (a) and after 14-day immersion to NaOH (b)

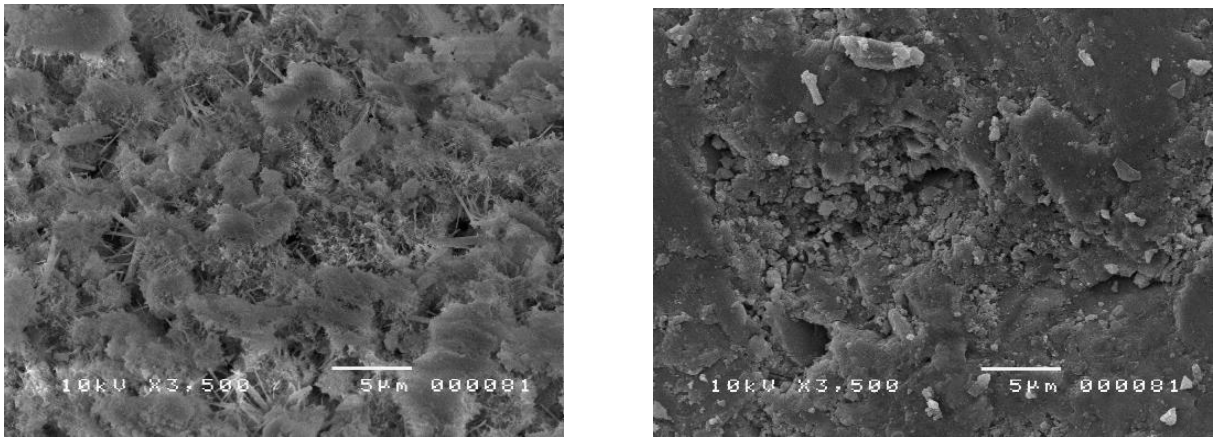

Figure 2a & 2b. B5G00 mortar microstructure before (a) and after 14-day immersion to NaOH (b)

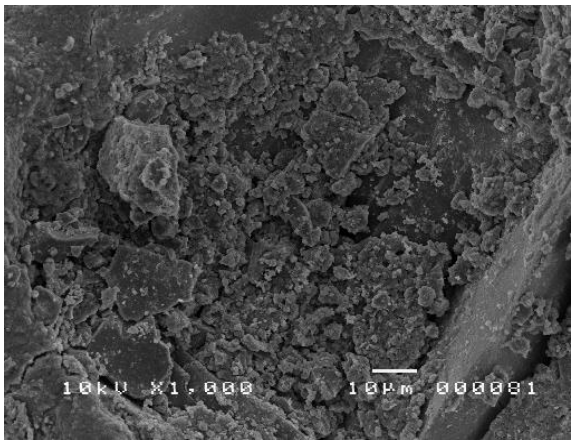

Figure 3a & 3b. B5G20 mortar microstructure before (a) and after 14-day immersion to NaOH (b)

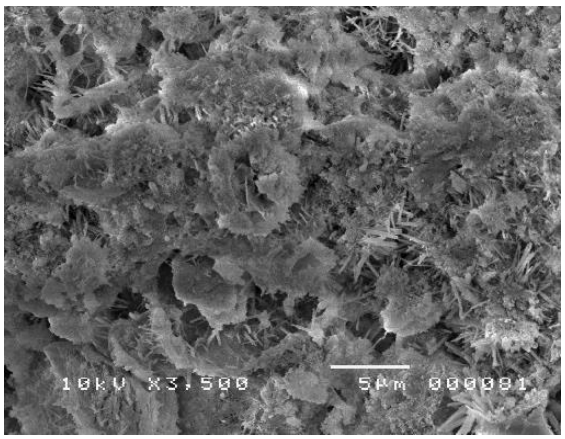

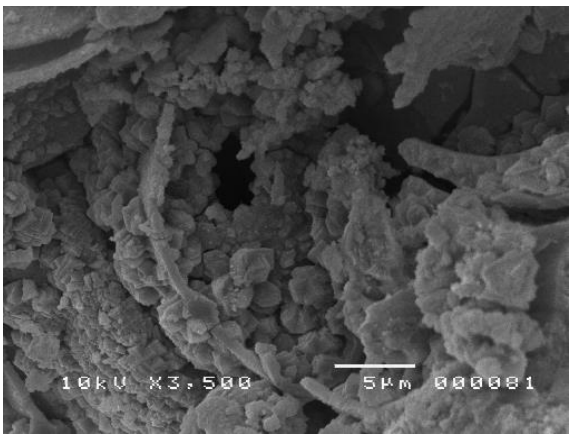

Figure 4a & 4b. B5G30 mortar microstructure before (a) and after 14-day immersion to NaOH (b)

The microstructure of mortar bars was investigated thru SEM before NaOH curing and after 14-day curing in NaOH, as shown from Figure 1 to 4. Common observation from SEM micrographs is the degrading effect of subjecting mortar samples to NaOH after 14 days.

CONCLUSIONS

The call for utilization of waste in construction is getting more loud with times due to continued depletion of resources and the negative impact to the environment. Hence, this study attempted to answer that call by utilizing soda lime glass in concrete by making it a partial substitute for fine aggregates. However, due to high siliceous content of SLG, the potential reaction of silica with alkali in cement pastes must be addressed as it may lead to alkali silica reaction which leads to concrete cracking. So, in order to address ASR, this study employed sugarcane bagasse ash as partial replacement of cement. Sugarcane bagasse ash (a by-product of sugarcane) is another waste where possible utilization in concrete is also being sought in this study.

Mechanical properties of concrete with 5% SBA and varying SLG showed no compromise in compressive strength. Comparison of compressive strength of concrete with increasing SLG amount showed higher values for SLG content not exceeding 30% of sand. 5% replacement of cement with sugarcane bagasse ash will not compromise compressive strength. However, split tensile strength demonstrated lower values for concrete with SLG and SBA. Hence, it is recommended by this study that for concrete applications where tensile strength might be of critical importance, a thorough investigation of tensile strength must be conducted.

Mortar bar test, in accordance with ASTM C1260, was also conducted to determine the potential alkali reactivity of mortar with SLG and to assess whether sugarcane bagasse ash contributes in mitigating the alkali silica reaction. Length expansion measurement showed that increasing SLG resulted to increasing length expansion. Sugarcane bagasse ash reduced the length expansion as compared to specimen without SBA.

Finally, SEM of mortar samples revealed deterioration after exposure to NaOH for 14 days in 80 degree celcius maintained temperature.

LESSON LEARNED IN MAINTAINING THE PRECAST CONCRETE BUILDINGS

Zul-Atfi Ismail
Civil Engineering Program, School of Environmental Engineering, Universiti Malaysia Perlis, Malaysia

ABSTRACT

The contemporary practice of conventional methods in the Precast Concrete (PC) building maintenance entails many issues due to poor service delivery and defect repetition. A key problem impeding the widespread adoption of emerging technologies is the lack of competent contractor supporting the effectiveness of implemented Information and Communication Technology (ICT) than conventional methods and the returns on investment. The shortcomings of conventional methods are assessed from the perspective of PC buildings. Data were collected through a case study of eight PC buildings from two type of design which were high-rise and complex building. The conventional methods had significantly little emphasis on defect diagnosis tools. It had also increased the inadequate strategic decision making to analyse information in improving the maintenance project outcomes for PC building. Building Information Modelling (BIM) tools is suggested from findings and lessons learned as a good practice to reduce the repetition of defect on the design specification used and construction practiced.

Keywords: Maintenance Management, Conventional Method, Maintenance Management System, Building Information Modelling, Malaysian PC Building

INTRODUCTION

Maintenance management is paramount in ensuring the effective and efficient monitoring process of maintenance activities, and Information and Communication Technology (ICT) could play fundamental role in delivering that maintenance management. Precast Concrete (PC) building maintenance depends on the design type (e.g. complex and high-rise building), size and building usability that require quality maintenance in order to achieve life-span prolongation. Structural repairing practice in managing PC building maintenance activities has been a hot issue in recent years due to lack of progress in the area of computer-aided maintenance management and difficulties with accessing information and data in maintenance support systems such as Computerised Maintenance Management System (CMMS) and Computerised Aided Facility Management (CAFM) [1]. Clients and contractors should use the high-quality building information from an emerging application of computerbased technology during the maintenance activities of the PC building's lifecycle. In response to the challenges of dynamic maintenance operations and the need for improving the quality of maintenance process in complex and high-rise structural building components, clients and contractors could change their method from conventional practices to more enabling technology to increase productivity and a new level of interoperability and collaboration. The conventional modus operandi (paper-based reports/unsystematic database), which is commonly being conducted in a sequential manner using CAFM and CMMS tools replaced to new business model which integrates various sources of data and knowledge such as CMMS with the Building Information Modelling (BIM) of the PC building in the maintenance activities [2, 3, 4].

Maintenance staff generally introduces ICT into PC building maintenance management for providing maintenance inspection records and results, including checklists, specification, and maintenance procedure by using software such as CMMS and CAFM. The CMMS and CAFM application provides various paper-based reports (such as inventory confirmation) related to maintenance and repair issues [3]. Furthermore, the traditional 2D Computer-Aided Design (CAD) technology is widely used for maintenance information illustration and even integrating related data for PC building construction design history purposes [5]. Despite the fact that the use of ICT solutions in assessing, planning or process execution takes place at a different scale and function, the emerging trend such as using sophisticated or innovative tools and techniques could improve productivity in PC building maintenance activities and have a great potential to redefine and re-engineer the conventional setting. The conventional method (paper-based reports/unsystematic database) is lack of knowledge support in coordination, maintenance monitoring, maintainability, automation and robot control systems. The PC building maintenance has different training or maintenance information to

address the issue of defects for particular component compared to the conventional building maintenance. The connection of PC component such as by using corbel and PCB need the expert knowledge to improve the quality and reliability of PC scheme in order to avoid any defect repetition in the long-term of life cycle building services. Failure to capture the data acquisition and monitor the defects effectively will influence the assessment process including maintenance planning and execution. This can contribute poor quality, productivity and performance in PC building construction projects [6, 7]. There is also give problematic and inefficient in the handling of information and integration of data of maintenance components within a post-construction site activity [8].

BIM FOR PC BUILDING MAINTENANCE

Recently on PC construction sites, there are many efforts to improve the efficiency of maintenance management activities through the use of more ICT-based systems (i.e. BIM). With the development of emerging technology such as BIM, maintenance management improvements in PC building construction has become possible [9]. Several other industry projects worldwide, for example real estate, waste management, transportation, supply chain and facility management, have been successfully completed by implementing BIM technology [10, 11, 12]. BIM can assist clients to determine the appropriate technology strategy and scope of each deliverable, with the intention of reducing redundancy and rework while improving performance and productivity of an operation and maintenance processes effectively in the future [13, 14]. Whereas BIM related studies mainly focus on utilising sophisticated tool and efficient technique, associating decision making support in diagnosis principles can help in achieving new levels of efficiency in PC building maintenance performance.

CASE STUDY

The case studies on the eight PC buildings were undertaken in order to identify the maintenance management problems, the current approaches to addressing the problems, the ICT implementation, use of emerging technologies and the maintenance management system (MMS) to obtain information relating to the maintenance identification, assessment, planning and execution processes. Eight maintenance clients/contractors are selected based on major problems of using conventional method (paper-based reports/unsystematic database) in the comparison to investigate the maintenance management practices in each PC building. There are around 51 contractors of Industrialised Building System (IBS) building maintenance from a classification of PC system have the highest of IBS building maintenance projects in Malaysia according to CIDB and almost are using conventional method and inadequately use of modern ICT tools. The number is considered very big indicating that the use of modern ICT is still very limited for PC system classification in IBS building maintenance management in Malaysia. The adopted synthesis of good practices of maintenance operations is based on the findings of the interviews and case studies conducted with professional engineers working in PC building maintenance departments [15]. This paper is part of a larger research and will only introduce and discuss the entire finding of the case study. This finding is illustrated in the following sections.

The interviews consisted of two types of PC building, namely, “Residential” and “Non-Residential”. The case study was based on eight cases (Case A-Case H) of PC buildings in Malaysia. There were two case studies (Cases A and E) on “Residential” due to housing maintenance operation such as the Putrajaya Quarters. In addition, six more case studies (Cases B, C, D, F, G and H) were classified as “Non-Residential” which manages the maintenance operation with fully equipped office buildings. The interviews reached a saturated point after the eighth interview session. The justifications for the selected case studies were according to the following main criteria: exposed to the conventional method used and major problems, attempted to implement computerised technology and the willingness of staff to share their experiences in improving the maintenance management processes at the PC building. The differences between the types of the PC building project provided an opportunity to explore variations in maintenance management issues for complex and high-rise PC building projects. The type of PC building under study for maintenance project were all varied from Quarters to Integration News Centre. The summary on the eight case studies is presented in Table 1.

The semi-structured interviews were conducted with the engineers who were responsible for the maintenance management of the entire PC's building structure under the Facility Management and Development Unit (UPPF) and Maintenance and Development Unit (UPS) including maintenance contractor. The interview sessions took around five hours to accumulate the data on the maintenance processes including the demonstration of the current maintenance management system with the implementation of the ICT tools by the engineer. All the data from the interviews were recorded using video camera and transcribed verbatim.

KEY FINDINGS

The eight case studies involved in this research were to identify the maintenance management problems, the approaches to address problems, ICT implementation, use of emerging technologies including the maintenance management system at the selected PC building. The problems identified from the eight case studies revealed that each case study experienced similar problems with defect repetition at the specific component part of PC building and are summarised and presented as below. The discussion involves a cross-case analysis and has been grouped into five main 'embedded units of analysis' identified which are (1) Maintenance Management Problems, (2) Approaches to Address Problems, (3) ICT Implementation, (4) Use of Emerging Technologies and (5) Maintenance Management System.

Table 2 Cross-Case Analysis

Case	Element of Analysis: Maintenance Management Problems
Case A	*Lack of commitment for handling defect* -Report delay and undelivered -Unsystematic database *Less competent contractor staff* -Less engineer competency -Technician's report is in general description -Technician's failure to identify defect problem *Defects repetition (surface cracking, leaking, scaling and jointing)* -Fault design *Poor quality work by contractor* -Less material quality *Poor buildability (M&E coordination)* -Lack coordination between design and maintenance team *Poor maintainability* -Unspecific accessibility to the defect location *Poor waterproofing* -Poor maintenance method
Case B	*Poor quality work by contractor* -Low repair requirements of the structure component *Lack of staff* -Lack of supervision *Limited Budgets* -Budget constraint *Defects repetition (surface cracking and aircond belting)* -Lack of technician -Less defect detection technologies *Less competent contractor staff* -Less engineer/technician competency
Case C	*Defects repetition (surface cracking, leaking and jointing)* -Low quality design control

	Surface cracks due to improper jointing -Less quality of joint material *Deep cracks due to settlement* -Less suitable soil *Less competent contractor staff* -Less engineer/technician competency
Case D	*Defects repetition (leaking and jointing)* -Design performance for concrete durability requirements -Structural installation method *Poor waterproofing* -Poor installation of the waterproof membrane *Poor quality work by contractor* -Lack of uniform standard -Poor material quality *Less competent contractor staff* -Less engineer/technician competency
Case E	*Defects repetition (surface cracking, leaking and jointing)* -Fault design -Poor material quality -Time gap of building repairs *Poor plumbing fitting* -Plumbing installation method
Case F	*Defects repetition (leaking and jointing)* -Design performance for concrete durability requirements *Less competent contractor staff* -Less engineer/technician competency
Case G	*Defects repetition (leaking, jointing and overload current trip)* -Fault design -Contractor ethics issues-Interested in making profits
Case H	*Defects repetition (heavy leaking)* -Poor quality of design -Less technician competency *Deep cracking on structure* -Limited experience by engineer -Poor maintenance method by contractor *Less competent contractor staff* -Less engineer/technician competency
Case	**Element of Analysis: Approaches to Address Problem**
Case A	-Improve the maintenance assessment for the building works did by contractor
Case B	-Provide more quality staff in managing the maintenance of critical defect -To replace the conventional defect detection method (e.g. visual inspection) with the sophisticated ICT application (e.g. CMMS)
Case C	-Improve the maintenance effectiveness for the building works did by contractor
Case D	-Proper supervision of work for the building works did by contractor
Case E	-Improve the building control for the building works did by main contractor
Case F	-Critical plan on maintenance repairs
Case G	-Conduct the maintenance assessment for evaluating the building works performance did by contractor
Case H	-Conduct the maintenance assessment for evaluating the building works performance did by contractor
Case	**Element of Analysis: ICT Implementation**
Case A	*mySPATA*-Data inventory for immobile facilities (e.g. building) *mySPA*-Data inventory for mobile facilities (e.g. furniture) *mySMS System*-for managing complaints
Case B	-Conventional (e.g. MS Word, MS Excel)
Case C	*mySPATA*-Data inventory for immobile facilities (e.g. building) *mySPA*-Data inventory for mobile facilities (e.g. furniture)
Case D	-Conventional (e.g. MS Word, MS Excel)
Case E	-Conventional (e.g. MS Word, MS Excel)
Case F	-Conventional (e.g. MS Word, MS Excel)
Case G	-Conventional (e.g. MS Word, MS Excel)
Case H	*Building Automation System (BAS)*-for detected building's heating, ventilation and air conditioning systems *Supervisory Control and Data Acquisition System (SCADA)*-to ensure that the building systems (e.g. fire alarm) were in good condition *E-Aduan*-for managing complaints
Case	**Element of Analysis: Use of Emerging Technologies**
Case A	-No
Case B	-No
Case C	-No
Case D	-No
Case E	-No
Case F	-No
Case G	-No
Case H	-No
Case	**Element of Analysis: Maintenance Management System**
Case A	-Conventional (e.g. paper-based reports/unsystematic database)

Case B	-Conventional (e.g. paper-based reports/unsystematic database)
Case C	-Conventional (e.g. paper-based reports/unsystematic database)
Case D	-Conventional (e.g. paper-based reports/unsystematic database)
Case E	-Conventional (e.g. paper-based reports/unsystematic database)
Case F	-Conventional (e.g. paper-based reports/unsystematic database)
Case G	-Conventional (e.g. paper-based reports/unsystematic database)
Case H	-Conventional (e.g. paper-based reports/unsystematic database)

SYNTHESIS OF GOOD PRACTICES

Table 3 below represents the suggested solutions from the case studies to improve the current practices on the maintenance management by implementing three approaches at the PC building. Case A, B, C, D, F, G and H suggested improving the transfer of knowledge in the defect diagnosis by combining with the related software technology such as CMMS and CAD. In fact, the problem of knowledge transfer in the defect diagnosis delivery also does affect the other PC buildings to some extent and the significance of this factor is quite obvious. The maintenance contractors will use the inadequate knowledge to handle the defect problem and less detail of the defect source explanation to gather accuracy information record for inspection and planning works. The other suggestion from the client/contractor was to provide the transfer of knowledge to improve the maintenance quality of structure and facility at the PC building (Case A, B, D, F, G and H). All the related cases are facing the impact of problems for the quality knowledge management, which are associated to the defect repetition for handling the defect of structures and facilities with IBS score usage about 70% on its structure development of PC building.

Case C, D, E, F and G suggested on efficient controlling of building performance based design and monitoring the defect diagnostic operation in maintenance through implementation of emerging technology (BIM) on the PC building maintenance. These are also recommended by Case A, B and H to integrate the design/construction and maintenance's database in order to facilitate better decision support and coordination within and across multiple field (e.g. civil, mechanical and electrical) for effective management of the PC building maintenance. This suggested solution is ranked as the most important solution due to suggest from almost case studies in order to manage the large and critical maintenance services for the PC building structure and facility. The using of emerging technology is also the lowest in terms of existing practice for better managing PC building components including mechanical and electrical control systems. As the overall results indicated in Table 3, it was deemed necessary to analyse the use of emerging technology further. Therefore, the systematic system with the emerging technology, defect diagnosis and decision making process should be developed to improve the building structure and facility performance by conducting effective knowledge transfer on the structure component maintenance defects.

Table 3 Suggested Solutions from Case Studies

Case	Suggested Solutions
A,B,C,D,F,G,H	Provide more transfer of knowledge in defect diagnosis
A,B,D,F,G,H	Provide more transfer of knowledge to improve the maintenance quality in maintenance execution
A,B,C,D,E,F,G,H	Implementation of emerging technology (BIM) (efficient control of building performance based design/ monitor the defect diagnostic operation in maintenance)

LESSON AND ENLIGHTMENTS

1) The PC building maintenance and the application of diagnosis techniques should be paid highly attention. Because of the defect repetition of structure components and limitation of understanding about the PC knowledge, the maintenance approach is very important. The application of modern ICT tools such as BIM integration can avoid or alleviate the defect of critical structure.
2) The appropriate modern ICT tools should be selected in assessment areas (diagnosis and decision making process on the design specification used and construction practiced) for PC buildings. The high-rise or complex structure should be given the priority for these types of PC buildings.
3) The maintenance quality of PC buildings should be strictly guaranteed.
4) The deficiency of PC buildings knowledge affected the quality of competent maintenance staff in Malaysia. The future work should be strengthened to guarantee the quality and knowledge in case of defect repetition.

The repetition of defect was frequent at PC building. The maintenance inspection and assessment was not able to address the building structure defect problems at the particular location due to the less knowledge

transfer between all members in maintenance management. Furthermore, the less competent contractor caused the maintenance faults to be increased to encourage the deterioration of the IBS building structure and facility.

In this research, the frontline approaches (new system development with BIM) is intended to counter the maintenance management problems on PC building which are:

a) Defect repetition information and knowledge due to failure to identify the actual reason of structure defect;
b) Defect repetition (leaking, jointing and cracking) information and knowledge due to design defect; and
c) Less competent contractor due to lack of knowledge regarding with materials, method and design of structure repair.

CONCLUSIONS

The data obtained in the case studies revealed that the PC buildings are using the conventional method such as paper-based reports in managing the maintenance processes for building structure and facility. This arise a problematic situation such as defects repetition (leaking, jointing and cracking) and poor quality work by contractor that need sophisticated tools towards a solution. Presently, the implementation of ICT tools in the new system is the better improvement to lead the tremendous saving in budget, time planning and to receive the precise data in handling the defect diagnosis and control. The suggestion for good practices was through the implementation of BIM to reduce the repetition of defect on the design specification used and construction practiced for the building structure and facility.

THE FIRE DYNAMIC SIMULATION IN A FACTORY WITH MULTIPLE STORAGE RACKS

Karin Kandananond
Faculty of Industrial Technology, Valaya Alongkorn Rajabhat University, Thailand

ABSTRACT

The fire protection in a factory is important to the manufacturing of any products since fire can cause a disruption in the manufacturing process and lost in the investment. As a result, the behavior of fire is well understood, the protection will be efficiently enabled. The factory with storage racks was modelled and the fire was simulated with a computational fluid dynamics (CFD) program, PyroSim. The source of a fire was set a corner of the warehouse and other fuel was the pallets and wooden containers. The spread of flame as well as the smoke were simulated and analyzed in a real-time manner. Other factors, e.g., heat flow and temperature, were also considered. Moreover, the capability of fire exhaustion equipment was also assessed. The research results also leads to the recommended design of the factory and the damage protection due to the fire.

Keywords: Computational fluid dynamics, Heat, Temperature, Warehouse

INTRODUCTION

The industrial safety is a critical concern for the industrial personnel and fire is one of the harmful sources which have a significant impact on the safety. Therefore, if the behavior of the fire in the workplace is fully assessed, the proper safety measures for the fire protection will be prepared. In a factory, warehouse is a potential source of fire eruption since there are a lot of materials which is the fire fuel. However, it is difficult to conduct a study by conducting the actual experiment in the real situation. As a result, the fire simulation is a powerful tool used to understand the behavior of the fire in a warehouse.

LITERATURE REVIEW

Pole, Chiu, and Wu [1] studied the airflow in the factory which has a clean room environment. The simulation was conducted to evaluate the effective installation of fans and the airflow when there is a fire and explosion in the factory. The assessment of an open fire in the pesticides storage facility was conducted by Kefalas, Chritolis, Nivolianitou, and Markatos [2] by the computational fluid dynamic (CFD) program. Two factors, fire strength and magnitude of the hear, were studied in order to evaluate the consequence of the fire in the facility. Another study regarding the fire experiment in the factory was carried out by Zhang, Zhu, Wang and Wu [3]. This study focused on the temperature of the fire source and the plant facility where fire broke out. Yang, Tan, and Xin [4] utilized the CFD program to simulate the fire in the storage house where there were shelves. The studied factors were temperatures, fire growth and heat release rate. Another study on fire factory was conducted by Lin, Wu, and Tsai [4]. The scenario is a textile factory in Taiwan. The analysis was based on three factors, temperature, smoke conditions, and smoke layer height.

METHODOLOGY

To understand the fire characteristics, the method of computational fluid dynamics (CFD) is utilized and the Fire Dynamics Simulator (FDS), a CFD model, is used to simulate the fire behavior in the factory. The computation is based on the solution of a large eddy simulation form of the Navier–Stokes equations. In this study, a FDS program, Pyrosim, was utilized to conduct a study.

OBJECTIVES

The objectives are the characteristics study of the fire spread and smoke in the warehouse. These also include how fast the fire can spread in 2 minutes and the studied parameters are temperature, heat release rate, and smoke. Moreover, another objective is the effectiveness study of the fire extinguishers, i.e., sprinkles installed in the warehouse.

SCENARIO

The study was set in a warehouse which consists of multiple storage racks. The size of palette is 1m x 1.2 m x 2 m while the size of the warehouse is 10 m x 10 m x 3 m. The total number of pallets and wooden containers are 21 and its size is 1 m x 1.2 m x 2 m. The pallets and containers were made of pine wood and the thickness of the containers is 2 cm. In this warehouse, there is a single door with the size of 1.5 m x 2 m. Different measuring devices were installed

as follows:

-Thermometer located at x-plane = 8 and y-plane = 2.5.

-Flowmeter located at y-plane = 8, x = [2,3], z =[0,2]

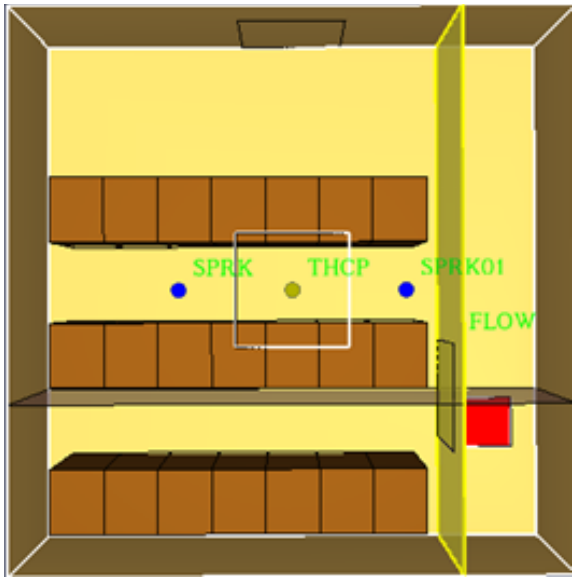

Fig. 1 Layout of the warehouse.

The free space near the first aisle is the place where spare pallets were placed. In this case, it was the potential spot that the fire might be lighted so the simulation was conducted by placing the surface burner with the heat release rate of 1000 kW. The heat release rate (HRR) graph from 0-120 seconds is shown in Fig. 2. The heat release is approximately 1000 kW.

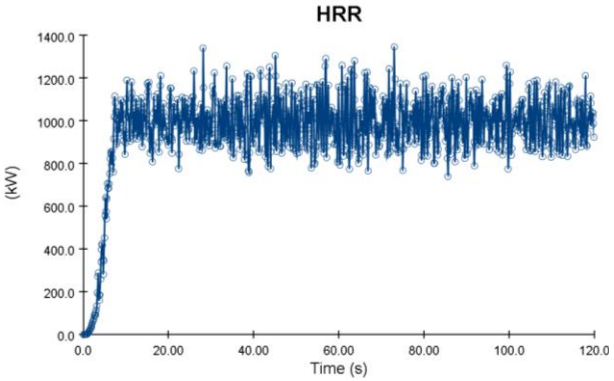

Fig. 2 Heat release from the burner.

RESULTS

The simulation was carried out in Pyrosim, a FDS package, in order to study the characteristics of the fire spread and the effective option to extinguish the fire. The time frame of the simulation is 120 seconds. The results are categorized into two cases, before and after installing the sprinkles in the warehouse.

Before installing sprinkles

The simulation was conducted and the thermometer installed at y-plane = 2.5 was measured at t = 10, 20, and 30 seconds consecutively. The isometric view of the temperature from the thermometer (y-plane = 2.5) was illustrated in Fig. 3. Color codes represent a different bands of temperatures

-red ≈ 155-170 Celsius degree

-orange ≈ 140-155 Celsius degree

-yellow ≈ 125-140 Celsius degree

-green ≈ 80-125 Celsius degree

-light blue ≈ 50-80 Celsius degree

-dark blue ≈ 20-50 Celsius degree)

The thermal images from the thermometer installed at y-plane = 2.5 were simulated at different time t = 10, 20, and 30 seconds as shown in Fig. 4, 5, and 6). Alternatively, Fig. 7, 8, and 9 illustrate the thermal images measured from the thermometer installed at x-plane = 8 for time: t = 10, 20, and 30 seconds.

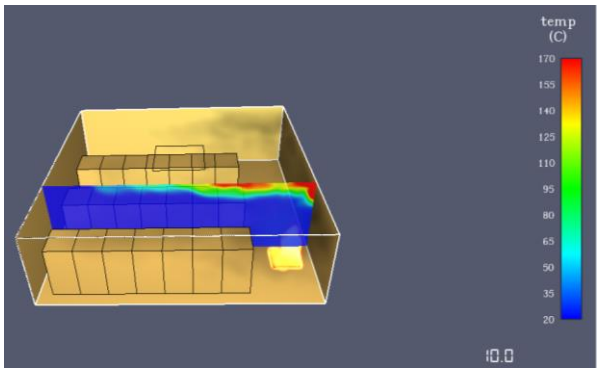

Fig. 3 Thermometer (y-plane = 2.5) at t = 10 sec (isometric view).

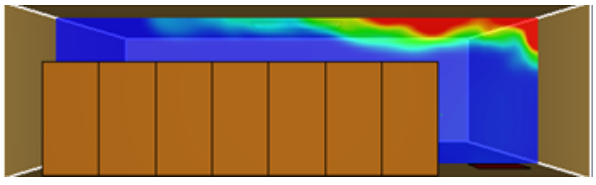

Fig. 4 Thermometer (y-plane = 2.5) at t = 10 sec (front view).

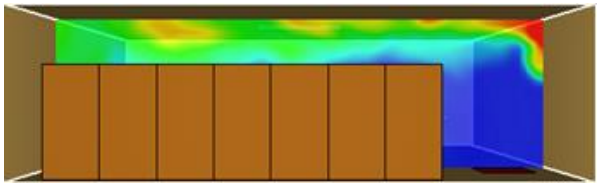

Fig. 5 Thermometer (y-plane = 2.5) at t = 20 sec (front view).

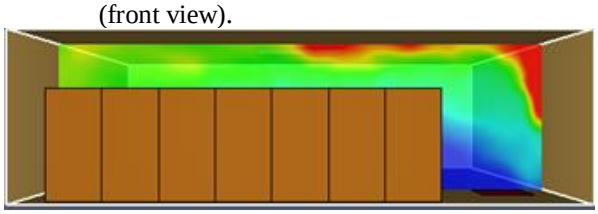

Fig. 6 Thermometer (y-plane = 2.5) at t = 30 sec (front view).

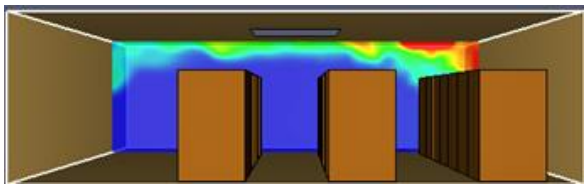

Fig. 7 Thermometer (x-plane = 8) at t = 10 sec (side view).

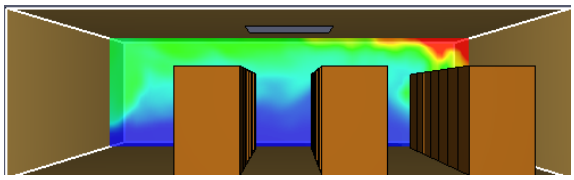

Fig. 9 Thermometer (x-plane = 8) at t = 30 sec (side view).

Fig. 10 Smoke view (front view) at t = 10 sec.

Fig. 11 Smoke view (front view) at t = 20 sec.

Fig. 12 Smoke view (front view) at t = 30 sec.

After installing sprinkles

To study the effect of fire extinguisher, two sprinkles were included in the simulation. They are located at (3, 5) and (7, 5). The orientation of the sprinkle is set at z = -0.01 and it will work at the temperature of 75 Celsius degree. After the simulation was run, the results show that he first sprinkle is activated at the time t = 6.7 second while the second is at time t = 65.2 second.

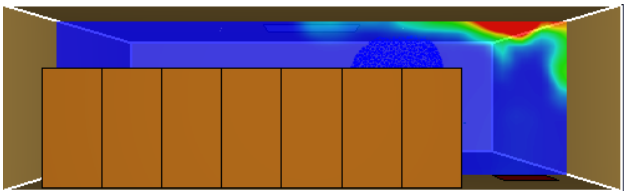

Fig. 13 Thermometer (y-plane = 2.5) at t = 6.7 sec.

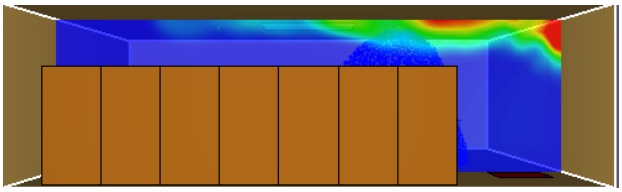

Fig. 14 Thermometer (y-plane = 2.5) at t = 10 sec.

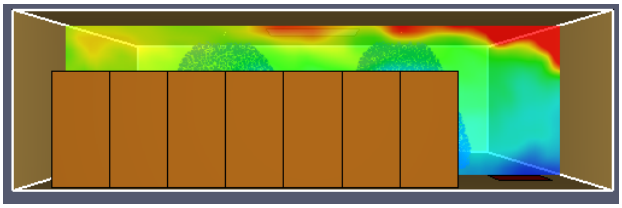

Fig. 15 Thermometer (y-plane = 2.5) at t = 65.2 sec.

The front view pictures of the smoke occurred in the warehouse was shown in Fig. 10, 11, and 12 for different time (t = 10, 20, and 30 seconds). According to Fig. 10-12, the smoke fully covers the warehouse in only 30 seconds.

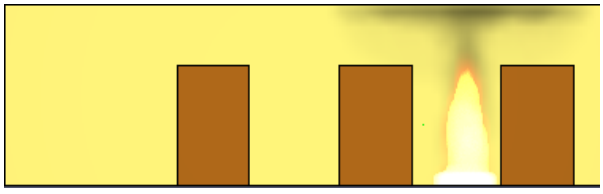

Fig. 16 Thermometer (x-plane = 8) at t = 5 sec.

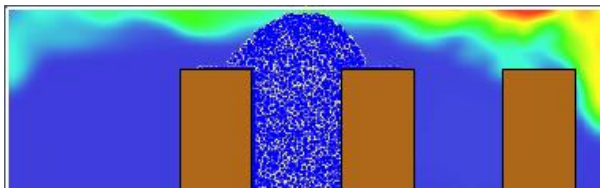

Fig. 17 Thermometer (x-plane = 8) at t = 10 sec.

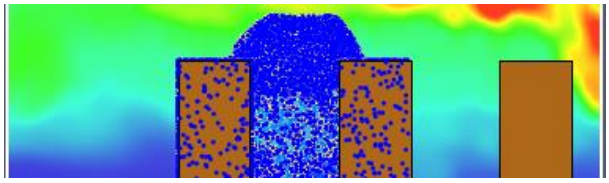

Fig. 18 Thermometer (x-plane = 8) at t = 65.2 sec.

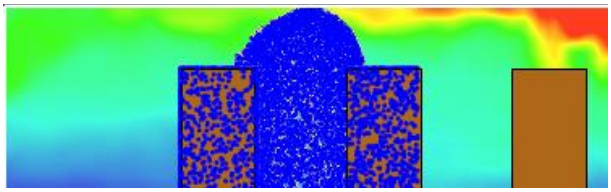

Fig. 18 Thermometer (x-plane = 8) at t = 120 sec.

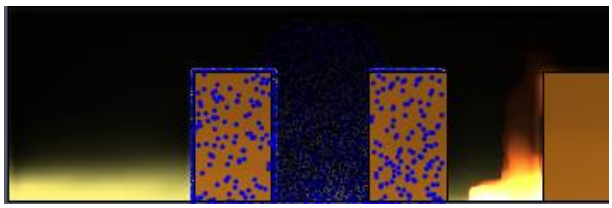

Fig. 19 Smoke view at t = 60 sec

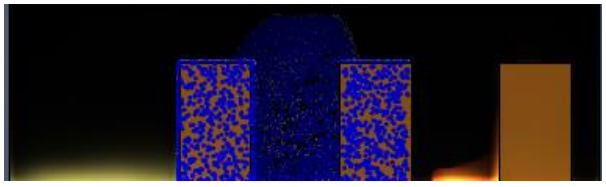

Fig. 19 Smoke view at t = 90 sec

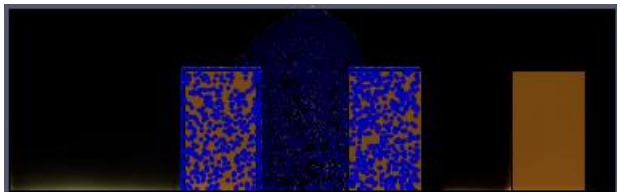

Fig. 20 Smoke view at t = 120 sec

The smoke view in the room at t = 60, 90, and 120 seconds is shown in Fig. 19, 20, and 21. From the smoke view, the fire is almost gone but the room is fully covered by the smoke.

The heat flow measured from the flow meter installed shows that the quantity of heat reaches the highest point (700 kW) at the approximate time of t = 5 second but gradually decreases after time t = 10 when the first sprinkle was activated. The quantity of heat decreases in the form of linearity and was reduced to almost zero at time t = 70 seconds which was after the second sprinkle was activated.

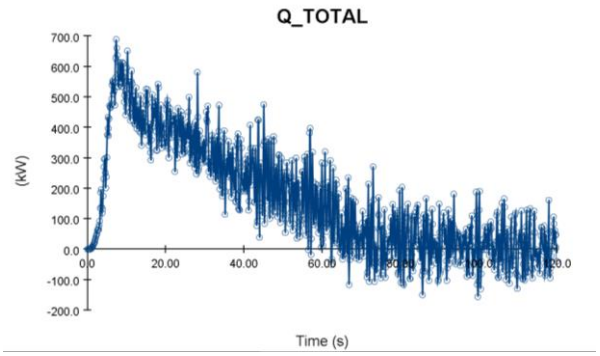

Fig. 20 Heat flow

CONCLUSIONS

The fire simulation was carried out to study the fire scenario in a warehouse. The burner surface with the heat release rate of 1000 kW was set as the fire source. There are 21 wooden pallets and containers in the warehouse. Different measuring devices, thermometer and flowmeter, were included in the simulation program. The period of simulation was 120 seconds. The results show that the fire quickly spreaded since the temperature of the another side of the room swiftly reach 120 Celsius degree in 30 seconds. On the other hands, the smoke also covers the warehouse in 30 seconds. The study also includes the sprinkles as the fire extiguisher. The simulation study show that the sprinkles were activated at time t = 10 and 65.2 seconds consecutively. The results also show that the sprinkle can help to sustainly contain the fire as shown in heat quantity graph. However, although the sprinkle can effectively work but the problem is the smoke which is still in the warehouse.

As a result, the future study should include the effective approach to ventilate the smoke from the warehouse.

FTIR AND UV IN STEEL PIPELINE COATING APPLICATION

Omar Abdelkarim[1], Mohamed Hazem Abdellatif[1], Diaa Khalil[1] and Ghada Bassioni[1]
[1] Faculty of Engineering, Ain Shams University, Cairo, Egypt

ABSTRACT

Different spectrum can be used in characterization and upsetting the performance of our daily application. Fourier transform infrared (FTIR) spectroscopy is used to make structural analysis for materials. The need to have low cost, portable, and suitable size FTIR to be used onsite application is in need. A novel microelectromechanical system (MEMS)-based FTIR spectrometer device is made to solve this problem. Epoxy coating is used frequently to protect steel pipeline from environmental condition against corrosion. Its drawback is that is perform with low resistance for crack initiation and propagation. In addition, the absorption of ultraviolet radiation (UV) deteriorate its properties. Which reduce the lifetime of the coating. Having direct and indirect economical losses. The usage of alumina nanoparticles with small amount of weight percentage 0.25 wt. % can enhance the mechanical properties. The key factor is having good distribution of nanoparticles inside epoxy-resin matrix. The investigation of the mechanical properties, bulk properties as in flexural strength, and surface properties as in erosion resistance and hardness are studied. Furthermore, the effect of 48 h UVA absorption on the performance of these properties with different alumina nanoparticles wt. % is investigated. For the bulk properties, the addition of alumina nanoparticles having insignificant effect, while in surface properties, the effect of UV reduces with the increase in particle wt. %. The MEMS-FTIR has good agreement with mechanical properties. Indicating the distribution of particles inside the system. Supported by environmental scanning electron microscope (ESEM) images. Which shows that MEMS-FTIR is useful instrument used in non-destructive, low cost, onsite material analysis.

Keywords: MEMS-FTIR · Epoxy resin · Alumina nanoparticles · Mechanical properties

INTRODUCTION

Spectroscopy is an important characterization technique that analyze the interaction between matter and electromagnetic spectrum [1]. There are different type of spectroscopy, with wide range of electromagnetic wavelength, ranging from Gamma rays to radio waves [2]-[8]. Fourier transform infrared (FTIR) spectroscopic analysis is one way to analyze the structure of different materials [9]-[12]. The use of portable, low cost, average size near-infrared spectroscopy (NIRS) as a non-destructive testing technique is a major challenge. One way to solve this problem is by using microelectromechanical system (MEMS)-based FTIR spectrometer [13]. This device can be used for practical applications, onsite material analysis, which can save cost and time.

Steel pipeline manufacturing has been developed in the last decades [14]. Continuously increasing strength of pipeline, reducing its thickness that decreases the overall cost has been of major concern. A challenge remains corrosion of steel that depends on environmental and operational factors [15]. Many ways are used for protection including surface coating, which act as a barrier between steel and the environment [16]-[19]. Liquid epoxy coating is one type that is widely used, because of good electrical insulator, adhesion, chemical, and mechanical properties [20]-[26]. A drawback for epoxy coating is that it has a poor resistance for crack initiation and propagation, and surface damage through abrasion ware [27]. Furthermore, epoxy degrades when it is exposed to sunlight for a long time, due to absorption of ultraviolet radiation (UV) [28]. This degradation deteriorates the mechanical and physical properties [29]-[31], eventually causing direct and indirect economical losses [32].

Incorporation of nanoparticles in epoxy systems can enhance the properties at nanoscale. The factors that affect the properties are matrix-to-particle interaction and particle-to-particle interaction [33]. Nanoparticles with high surface to volume ratio tend to reduce its surface energy by interacting with each other to form agglomerates, which deteriorate the properties [34]. This interaction can be controlled through particle disruption, loading, and shape. The interface between matrix and particles, its quality enhances load transfer to nanoparticles, which enhance the mechanical properties [35].

In this study, two different spectra are used to investigate a system composed of epoxy resin with alumina nanoparticles with different weight percentage (wt. %). The effect of ultraviolet radiation A (UVA), which is the main cause for epoxy degradation, on the mechanical and physical properties, and MEMS-based FTIR spectroscopy used for material characterization.

EXPERIMENTAL

Alumina nanoparticles are used due to high

phase and dimensional stability, commercial availability, and hardness. The particles wt. % used are (0 – 0.25 – 0.5 – 0.75 – 1). The UVA exposure is for 48 hours for each sample. The detection of alumina nanoparticles distributed in epoxy-resin matrix in the near-infrared (NIR) range using an on-chip silicon micro-electro-mechanical for the application of coating steel pipelines is also studied.

Materials

KEMAPOXY epoxy-resin, mixing ratio 2:1 (resin: hardener), bought from CMB. α alumina nanoparticles, coated with aluminic ester, with 60 nm particle size, super hydrophobic, bought from US research nanomaterial, Inc.

Mold preparation

Silicon rubber mold is prepared according to ASTM D790. Using steel samples, with the same dimensions as the standard sample, as a positive pattern, then pouring silicon rubber mixture to cure on theses samples, providing the mold used for epoxy-resin/alumina nanoparticles composite samples. The ratio between resin and hardener for silicon rubber is 950:32. A vacuum pump is used to remove any air bubbles inside for 10 min. then poured over the steel samples.

Sample preparation

The epoxy resin is weighed, heated to 50ºC for 10 min to decrease the viscosity, and evacuated from any air bubbles through a vacuum pump for 30 min. Then alumina nanoaparticles with different wt. % are weighed, using sensitive scale, and added to the epoxy resin. The mixture is then stirred, using a magnetic stirrer, for 1 h. Subsequently evacuated for 30 min using vacuum pump. Then the hardener is added to the mixture, stirred for 15 min, evacuated for 5 min, and finally poured into the silicon rubber mold. The nanocomposite is left to cure at room temperature for 24 h, then post curing at 80ºC for 16 h. The samples are then exposed to ultraviolet lamp, in a sealed chamber, for 48 h at room temperature.

Characterization

MEMS-FTIR

The spectrum reflected by the samples is measured using MEMS FTIR spectrometer. Spectralon (diffuse reflectance standard) is used as a background and samples reflectance are measured with respect to it. All measurements are taken with 10 sec averaging time and a resolution of 16 nm. Samples with different concentrations are measured. For each concentration, different positions are tested to identify variation in nanoparticles distribution in the sample. The sample was placed on the source with free-space above to ensure no reflection from objects. The sample was coupled in the spectrometer's fiber.

ESEM

ESEM (Quanta FEG250) is used to take images for the cross-section of alumina/epoxy nanocomposite. Sample size 1 $cm* 1\ cm* 0.4\ cm$ is used. Samples are gold plated first to enhance the conductivity.

Mechanical properties

Bending test: 3-point bending test is used to test epoxy-resin and alumina/epoxy nanocomposites. The load is applied on the middle of specimens, supported by 2 spans. ASTM D790 (2004) specimens' specification. The machine used is 10 Ton LLYOD testing machine.
Erosion test: Sand erosion testing is performed on the samples. After projecting the samples to a stream of abrasive sand particles for 9 minutes, the weight of each sample is measured 9 times, each after 1 min, by sensitive scale, then the slope of the line is calculated as the erosion rate, which is converted to erosion resistance.
Hardness test: The same samples used for the bending test is used to measure the hardness of the composite. Each sample is tested 3 times, at 3 different locations. The test is performed using ZWICK/ROELL testing instrument, to determine the hardness behavior at room temperature.

The prepared samples are subjected to Ultraviolet radiation, before being tested, investigating the effect of UV radiation on the composites. Using a self-assembled sealed chamber, consisting of 3 partitions, UVA, UVB, and UVC is used to expose the specimens to ultraviolet radiation UVA. The exposure duration to UVA is 48 h at room temperature.

RESULTS AND DISCUSSION

Nanoparticles distribution are analyzed using MEMS-FTIR spectroscopy. The spectrum of different concentrations and positions is shown in Fig. 1. The spectrum shows that for the 0.25 wt. % sample, the alumina nanoparticle distribution is well dispersed inside the matrix, no difference with different positions. As we increase the particle wt. %, the spectrum varies from one position to the

other. The variation gradually increases as we increase the particle wt. % with the highest variation in 1 wt. %. These results indicate that agglomeration starts to occur as we increase the amount of alumina nanoparticles inside epoxy-resin matrix as well as the uneven distribution of the nanoparticles inside the system.

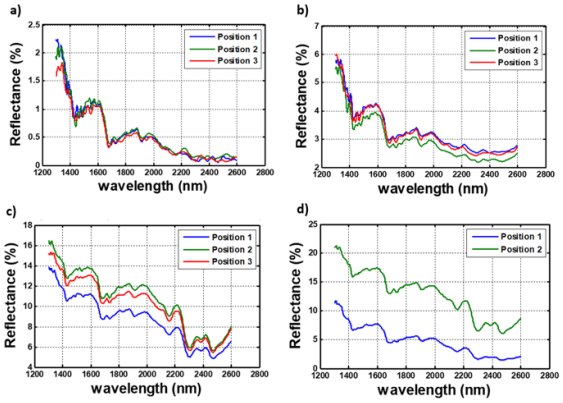

Fig. 1 MEMS-FTIR reflectance spectrum for a) 0.25 wt. % b) 0.5 wt. % c) 0.75 wt. % and d) 1 wt, % of alumina nanoparticles inside epoxy-resin matrix at different positions

The effect of increasing the amount of alumina nanoparticles wt. % on the spectrum is shown in Fig. 2. As we increase the amount of nanoparticles, the reflectance increases, from wavelength of 1300 nm to 1700 nm, then at higher wavelength, there are insignificant changes. These results indicate that the more nanoparticles we add to the system, the more interaction bonds occur between the chains and these nanoparticles. These bonds hinder the movement of the polymer chains during light exposure, and hence increase the reflectance peak for the same wavelength.

The effect of UV on the reflectance spectrum varies from one concentration to another. For pure sample without alumina nanoparticles the spectrum shifts upwards, which indicate that the UV exposure increases the amount of crosslinking inside the system, and hinders the movement of chains. While for the samples with different alumina nanoparticles a different behaviour is observed due to the inhomogeneous distribution of particles inside the matrix, as proven in Fig. 1.

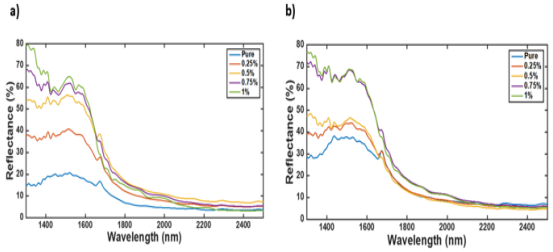

Fig. 2 : Effect of particle wt. % on the MEMS-FTIR reflectance spectrum a) before UV exposure b) after UV exposure

ESEM micrographs of the cross section of the samples are shown in Fig. 3. Those images support the results from MEMS-FTIR, showing the agglomerations that occur in different particle wt. %, in the indicated white circles. The more the particles wt. %, the more agglomeration occurs. From Fig. 1 and Fig. 3, we can conclude that as the amount of nanoparticles increases in the system, more particle-to-particle interaction increases, and more agglomeration occurs.

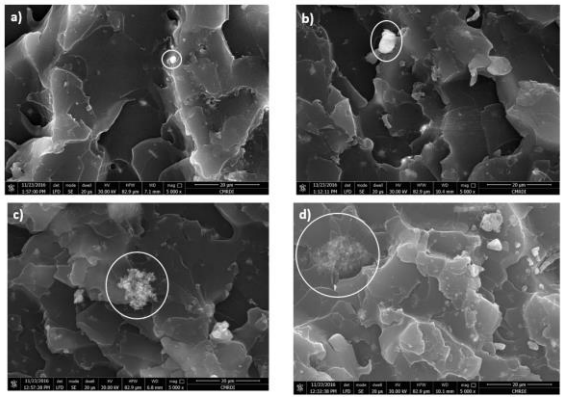

Fig. 3 ESEM microscopy of cross section surface at 20 µm of epoxy alumina nanoparticles composite with a) 0.25 wt. % b) 0.5 wt. % c) 0.75 wt. % and d) 1 wt. %

In order to investigate the effect of UVA exposure on the samples, different tests are performed: Three point bending test, Hardness test, and sand erosion test. All samples are subjected to these tests before and after UVA exposure. The effect of UVA for tests results, comparing before and after UVA exposure, are summarized in table 1.

Table 1 Mechanical properties of epoxy resin reinforced with alumina nanoparticles, difference between before and after exposure to UVA

Alumina Nanoparticles wt.%	Effect of UV on Flexural Strength (%)	Effect of UV on Erosion Resistance (%)	Effect of UV on Hardness (%)

0.00%	-1.11%	-23.0%	-20.4%
0.25%	1.11%	-19.8%	-16.9%
0.50%	-0.61%	-2.5%	-13.0%
0.75%	2.04%	-6.5%	-12.3%
1.00%	-5.06%	10.4%	0.8%

Flexural strength of epoxy-resin samples with different alumina nanoparticles, before and after exposure to UVA, is shown in Fig 4. The flexural strength increases in case of 0.25 wt. % with respect to pure sample with 7% from 77.1 MPa to 83.06 MPa. Then the strength gradually decrease with increasing wt. % till it reaches 62.45 MPa at 1 wt. %, which is 19% decrease compared to pure sample. The reason for increasing the strength is due to the good dispersion of alumina nanoparticles inside the matrix. More particle to matrix interface occurs, which transfers more load from matrix to the nanoparticles, carrying more load, and enhancing the strength of the system. However, further increase in alumina wt. %, increases particle agglomeration, so more particle-to-particle interaction occurs. These agglomeration works as stress concentration parts, which initiate cracks inside the system, lowering its performance. MEMS-FTIR and ESEM in Fig 1 and 3 can be used as a support for this statement.

The difference between the flexural strength, before and after exposure to UVA, is shown in Fig. 4. From these data, there is insignificant difference between the flexural strength before and after 48 h. UV exposure, as shown in table 1.

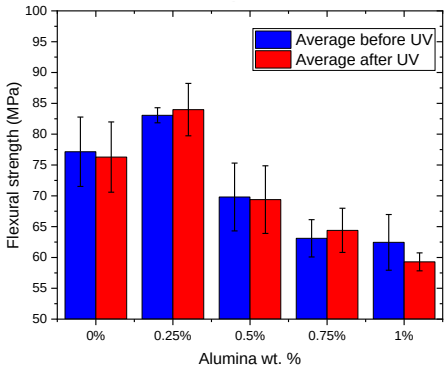

Fig. 4 Flexural strength of epoxy resin reinforced with alumina nanoparticles, before and after exposure to UVA

Erosion resistance of epoxy-resin samples with different alumina nanoparticles, before and after exposure to UVA, is shown in Fig. 5. Similar to flexural strength. The erosion resistance increases in case of 0.25 wt. % with respect to pure sample with 67% from 0.824 min/mg to 2.477 min/mg. Then the resistance gradually decrease with increasing wt. % till it reaches 1.23 min/mg at 1 wt. %, which is 49% increase compared to pure sample. The crosslinking density increases with the increase in particle wt. %, with good dispersion then gradually decreases in case of agglomeration.

From table 1, the increase in alumina nanoparticles reduces the UV effect gradually as we increase the wt. %. Starting from 23% reduction in pure sample to 10.4% improvement in 1 wt. %. These results show that the addition of alumina nanoparticles improves the surface properties of the coating against UV exposure.

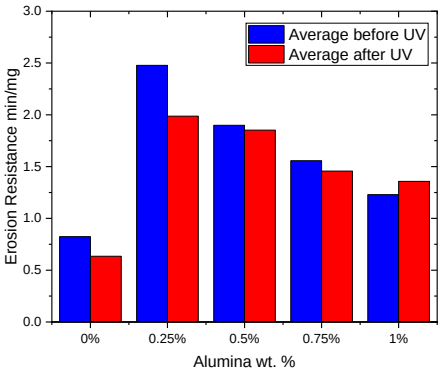

Fig. 5 Erosion resistance of epoxy resin reinforced with alumina nanoparticles, before and after exposure to UVA

Hardness of epoxy-resin samples with different alumina nanoparticles, before and after exposure to UVA, is shown in Fig. 6. In this case, The hardness slightly increases with the increase in particle addition. Starting with 75.6 Shore D for pure sample. Until it reaches 79.3 Shore D for 0.75 wt. %, with 4.9% increase. For 1 wt. %, a reduction in Hardness occur, due to inhomogeneous distribution of the nanoparticles, and Hardness test is a localized test.

The effect of UV on Hardness test is the same as in erosion resistance. As both are surface properties. The increase in alumina nanoparticles wt. % reduces the effect of UV gradually with the increase in wt. %. Staring from 20.4% reduction in pure sample to 0.8% improvement in 1 wt. %.

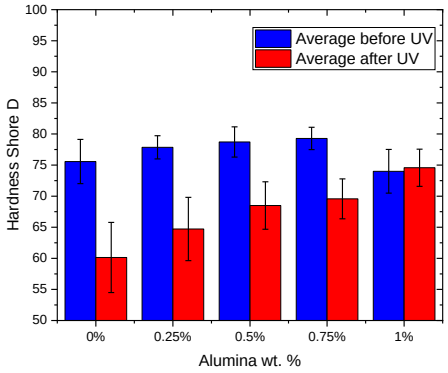

Fig. 6 Hardness Shore D of epoxy resin reinforced with alumina nanoparticles, before and after exposure to UVA

CONCLUSION

As a conclusion for this work a novel MEMS-FTIR method is used to identify the alumina nanoparticles distribution, using different positions, for the same material, in an epoxy-resin matrix. These results are supported by ESEM micrographs. The mechanical properties of different alumina nanoparticles wt. % is investigated before and after UV exposure. For flexural strength, the properties improved with the addition of 0.25 wt.% and reduced with increasing more of wt. %. The improvement is due to good particle dispersion, as indicated by MEMS-FTIR and ESEM. The reduction is due to formation of agglomeration, which reduces crosslinking density and acts as stress concentration points. The erosion resistance properties follow the same trend as flexural strength, while hardness improves slightly with increasing particle wt. %. The effect of 48 h UV exposure is insignificant in flexural strength, indicating that the UV does not affect the bulk properties. On the other hand, in case of erosion resistance and hardness, as surface properties, the addition of alumina nanoparticles reduces the effect of UV with increasing the wt. %.

ABSTRACT

This paper presents the experimental study of a new two types of eco-friendly basalt geosynthetics. Results are evaluated for its bearing capacity with one backfill soil using the California bearing ratio (CBR) test. The test results are compared based on interface mechanical properties of the reinforcements. One backfill sandy soil in combination with two different geosynthetics are tested at various loading conditions in the CBR test. Based on the analyses of the experimental data, the penetration strength and the penetration displacement of specimens due to the variation of the type of geosynthetic and location of embedment are examined. Load-penetration behavior of the backfill soil with the two types of geosynthetic shows a significant increment in the bearing capacity. It is found that the embedment position of the reinforcement affects the ground bearing capacity. Also, for each one of those reinforcements, there is an effective embedment position to reach the maximum bearing capacity. In particular, bearing capacity reached its maximum in the case of using two layers of geogrid on the surfaces of the upper and lower layers of the subgrade soil specimen.

Keywords: Geosynthetics, Sandy Soil, California Bearing Ratio Test, Bearing Capacity.

INTRODUCTION

Earth fill structures offer various advantages and can be used in airfields, highways, and other public facilities, depending on the purpose of the construction. Those structures must be stable under all static and dynamic loadings during construction and in-service [1]. The subgrade soils are generally defined by their resistance to deformation under load and the strong subgrade soil can reduce the cost of the airfield or highway construction. By using reinforced subgrade, which can be very complex depending on the nature and properties of the reinforcement [2] the required thickness of a flexible pavement can be reduced as compared to weaker subgrades. It will, therefore, result in a significant cost saving advantage due to resource-saving and durability [3]. This is the reason that the reinforcing the soft soil using various types of geosynthetics is a well-known technique to improve subgrade soils performance and enhance its bearing capacity.

The performance of the subgrade soils is widely evaluated by using the California bearing ratio (CBR) test which evaluates the strength of subgrade soils, sub-base, and base course material for the design of the pavement thickness. The CBR test often forms the basis of pavement design. For this reason, it finds favor with some design and control methods. Design testing is usually undertaken in the laboratory where the CBR can be measured for a variety of dry densities and soaked or unsoaked, corresponding to the groundwater or drainage conditions foreseen and where surcharges can be added to simulate the effect of construction thicknesses. Once a design CBR has been established, it can be controlled in the field by sampling the placed fill and testing at the site laboratory, or by adopting in situ CBR procedures.

The bearing capacity of reinforced soil with geosynthetics has been investigated using the CBR tests by several researchers. They used various types of geosynthetic materials i.e. polypropylene (PP), High-density polyethylene (HDPE), Polyester (PET) yarns, etc. [4] The present study dealt with a new type of geosynthetics which are made from basalt fiber. A series of CBR tests on the geosynthetic embedded inside one type of backfill soil have been conducted. Based on the test results, the load-penetration behavior of the reinforced subgrade soil along with different mechanical characteristics has been evaluated and discussed shortly.

PURPOSE OF THE STUDY

1. To investigate the relationship between the reinforced subgrade soil moisture content and the CBR value.
2. To investigate the influence of new types of basalt geosynthetics, (its embedding position, and the number of geosynthetic layers) with one backfill soil on CBR value, through a series of CBR tests.

MATERIALS AND METHODS

Backfill Material

One type of soil was used as backfill material in

this study. The soil sample had been collected from Handa area (半田地区), Tsu City, Mie Prefecture, Japan is shown in Fig. 1 and used in combination with geosynthetic materials to evaluate its bearing behavior.

Fig. 1 Soil from Hanada area, Tsu City, Mie Prefecture, Japan.

Fig. 2 represents the gradation curve of the experimental soil. According to the Japanese Geotechnical Society engineering classification system (JGS), this sandy soil is classified as SF.

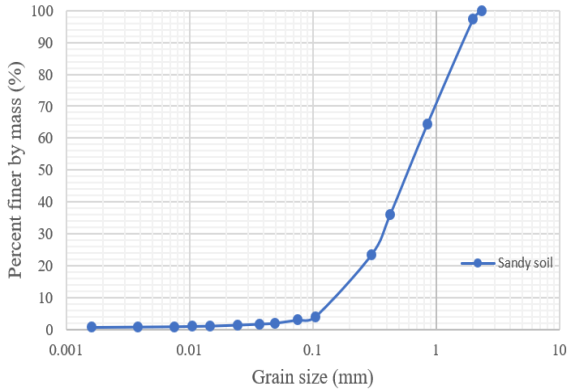

Fig. 2 Backfill soil particle size distribution curve.

The major physical properties of the soil are listed in table 1. While basically, the optimum water content of this sandy soil was 16.7%.

Table1. Backfill sandy soil physical properties.

Properties	Sandy backfill
Soil particles density, ρ_s	2.779 g/cm^3
Optimum water content, $W_{opt.}$	16.7%
Maximum dry density ($\gamma_{\text{dry max}}$)	1.713 g/cm^3
Liquid Limit, LL	36.664%
Plastic Limit, PL	30.587%
Plasticity Index, PI	6.08%
Gravel > 2 mm	2%
Sand (75 µm - 2 mm)	94%
Silt (5 µm - 75 µm	2%
Clay < 5 µm	2%

Geosynthetic Materials

The woven geosynthetics used in this study are made of basalt fiber and provided by Tsuchiya TSCO Co., Ltd. These materials possess the good property of elasticity and stretch tension with good resistance to acid, alkali, heat, and vibration. It has also nonconductive and non-magnetic resistance. The chemical composition and basic characteristics of basalt fiber used for manufacturing these geosynthetics are listed in Tables 2 and 3 respectively. Two types of geosynthetics have been used, one woven geotextile (with soft texture) and one woven geogrid (with stiff texture). For the purpose of discussion, the geotextile is noted as GTX and the geogrid is noted as GGR as shown in Fig. 3.

Table 2. Chemical composition of basalt fiber [5]

Ingredient	Content by weight %
SiO_2	51.6 ～ 59.3
Al_2O_3	14.6 ～ 18.3
CaO	5.9 ～ 9.4
MgO	3.0 ～ 5.3
Na_2O+K_2O	3.6 ～ 5.2
TiO_2	0.8 ～ 2.25
Fe_2O_3+FeO	9.0 ～ 14.0
Others	0.09 ～ 0.13

Table 3. Basic characteristics of basalt fiber [5]

Characteristic		Basalt fiber
Thermal	Operating temperature (heat-resistant temp.) (℃)	-260～650
	Maximum continuous use temperature (℃)	700
	Heat transfer coefficient (W/mk)	0.031～0.038
	Melting temperature (℃)	1450
	Softening temperature (℃)	1050
	Thermal expansion coefficient (×10^{-6}/℃)	10

	Table 3 Continued	
Physical	Density (g/cm^3)	2.67
	Fiber diameter (μm)	10～17
	Tensile strength (Mpa)	1900
	Elastic modulus (GPa)	90
	Breaking elongation (%)	2.2
	Tensile strength thermal change (Tensile strain):	
	20℃ (%)	100
	200℃ (%)	95
	400℃ (%)	82
Electro-chemical	Electric resistance (Ω)	1×10^{12}
	Chemical stability (3h boiling mass loss):	
	2N-HCI (%)	2.20
	2N-NaOH (%)	2.75
	H_2O (%)	0.20

For convenience in drawing CBR specimens and diagrams, the used geosynthetic products were represented by abbreviations and graphical symbols as recommended by the International Geosynthetic Society (IGS) described in table 4.

Table 4. Abbreviations and graphical symbols of the used geotextile and geogrid products

Abbrev.	Geosynthetic Product	Graphical Symbol
GTX	Geotextile	
GGR	Geogrid	

Note: as recommended by the International Geosynthetics Society (IGS) [6].

CBR Test Apparatus and Equipment

In this research many tools have been used e.g. CBR stainless steel Mold (inner diameter 15 cm, height 17.5 cm), perforated base plate, collar (extension ring), spacer disc (diameter 15 cm, height 5 cm), manual compaction hammer (diameter 5.0 cm – mass 4.5 kg – height 45 cm), steel straight edge, balance (Max. capacity of 20 kg, minimum reading 10 g), filter papers, measuring cylinder, plastic squeeze bottle with water, moisture beakers, drying oven, loading plate**s** (split surcharge weight**s**), samples jack (Universal extruder), and CBR penetration testing machine.

For the convenience of the readers, the important components of the CBR penetration testing machine shown in Fig. 10 are numbered numerically starting from top left to down right in the increasing way such as, the number from (1) to (8), where the number (1) are a stainless steel screw columns, adjustable upper crosshead, and nuts, (2) is the proving ring with dial gauge for measuring the vertical load applied, (3) is the standard penetration piston (plunger), (4) is the CBR mold with a perforated bottom plate containing the specimen, (5) are the split surcharge weights outside the mold, (6) is the penetration measuring dial gauge, (7) is a stainless steel top board of a mechanical type jack (8) mechanical type jack manual operating wheel.

CBR Specimen's Preparation

At first, the CBR control specimen (soil only specimen) shown in Fig. 4 was prepared in the CBR mold. To prepare the control specimen layers, soil and water (12% - 13% of the soil weight) were mixed homogeneously. Then the soil was added into the mold after it had been assembled with the perforated bottom plate, spacer disc, and mold extension. While adding soil into the mold the soil was divided into three layers and tamped uniformly 67 times per layer using a manual hammer.

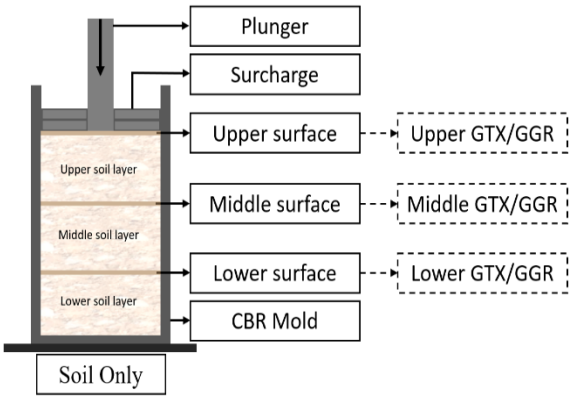

Fig. 4 Typical schematic diagram of CBR control specimen using a divided three layers of soil only with an indication of the surface of each layer where geosynthetics can be laid on.

For the preparation of CBR test specimens, in the same way, the mold had been assembled with the perforated bottom plate, spacer disc and mold extension, the wet soil sample was poured into it. The wet soil sample was divided into three layers then tamped uniformly 67 times per layer with the 4.5 kg hammer.

Fig. 5 GGR sample laid or flattened on a surface of a compacted soil layer inside the CBR mold.

Considering that in these CBR test specimens, the surface of each soil layer was leveled precisely and geosynthetic(s) of the same diameter of the mold were laid or flattened on the surface of a chosen soil layer(s) which had been tamped before to achieve the separation between specific soil layer(s) as shown in Fig. 5 resulting in six patterns of CBR test specimens with a total number of twelve specimens.

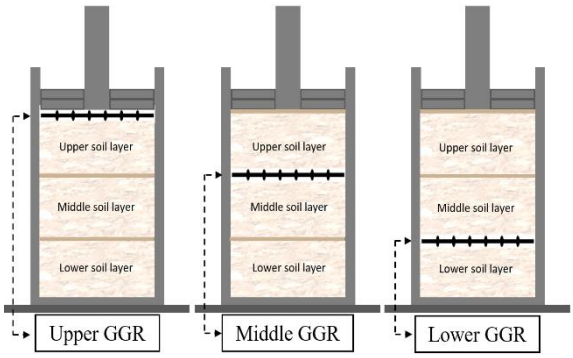

Fig. 6 Three specimens of one-layer GGR embedded in between three layers of compacted soil in three different positions (upper, middle and lower)

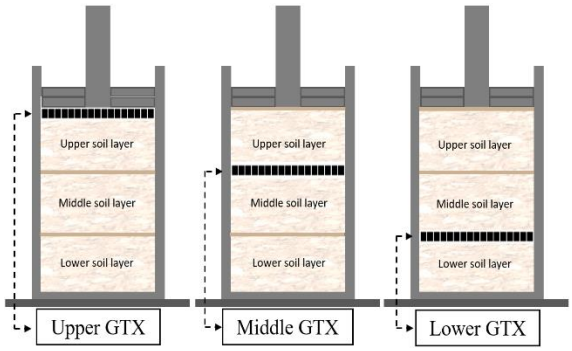

Fig. 7 Three specimens of one-layer GTX embedded in between three layers of compacted soil in three different positions (upper, middle and lower)

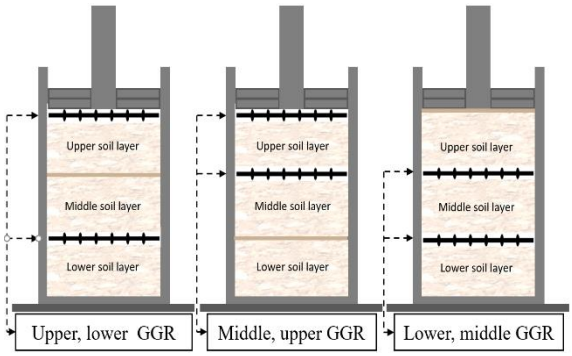

Fig. 8 Three specimens of two layers GGR embedded in between three layers of compacted soil in three different positions (upper and lower, middle and upper, lower and middle)

The six patterns of CBR test specimens were classified into two groups, three of one layer (upper GGR/GTX (pattern I), middle GGR/GTX (pattern II), and lower GGR/GTX (pattern III)) shown in Fig. 6, 7 and three of two layers (upper and lower GGR/GTX (pattern IV), middle and upper GGR/GTX (pattern V), lower and middle GGR/GTX (pattern VI)) shown in Fig. 8, 9.

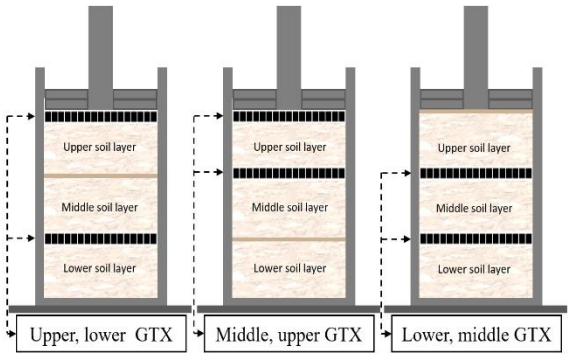

Fig. 9 Three specimens of two layers GTX embedded in between three layers of compacted soil in three different positions (upper and lower, middle and upper, lower and middle)

CBR Test Setup and Procedures

The California Bearing Ratio (CBR) test was developed by the Californian Division of Highways for the design of flexible pavements. The basic procedure of this test was adopted by the Corps of Engineers of the US Army. Certain modifications were made in the test procedure, and now the modified method is adopted by the Corps of Engineers and Regarded as the standard method of determining the CBR. The corps Engineers have developed design curves using CBR values for determining the required thickness of flexible pavements for airport runways and taxiways.

It has been widely used all over the world to evaluate the bearing capacity of soils and subgrades since its invention in 1930 by the California Division of highways, USA [7].

In the laboratory, the CBR test is typically performed on compacted soil samples. In this research, the CBR was calculated as follows:

After the specimen had been set up in the mold then the specimen is placed precisely on the top board of the CBR apparatus jack (No.7, Fig. 10). The required clearance between the split surcharge weights inside the mold (No.5, Fig. 10) and plunger (No.3, Fig. 10) was set by adjustable upper crosshead (No.1, Fig. 10) letting the plunger to touch the upper surface of the specimen freely without applying loads. The tests were conducted in the way of penetrating the specimens using the standard plunger with a constant velocity of 1.27 mm/min (0.05 in/min) by means of screw jack (No.7,8, Fig. 10) under mechanically

manual operated constant pressure.

While operating the CBR testing machine the load (pounds) measured using proving ring dial gauge (No.2, Fig. 10) versus depth of penetration (inches) of the piston (No.3, Fig. 10) as it is being pushed into the soil was recorded using penetration measuring dial gauge (No.6, Fig. 10) considering the penetration depths of 0.5 mm, 1.0 mm, 1.5 mm, 2.0 mm, 2.5 mm, 3.0 mm, 4.0 mm, 5.0 mm, 7.5 mm, 10.0 mm, and 12.5 mm.

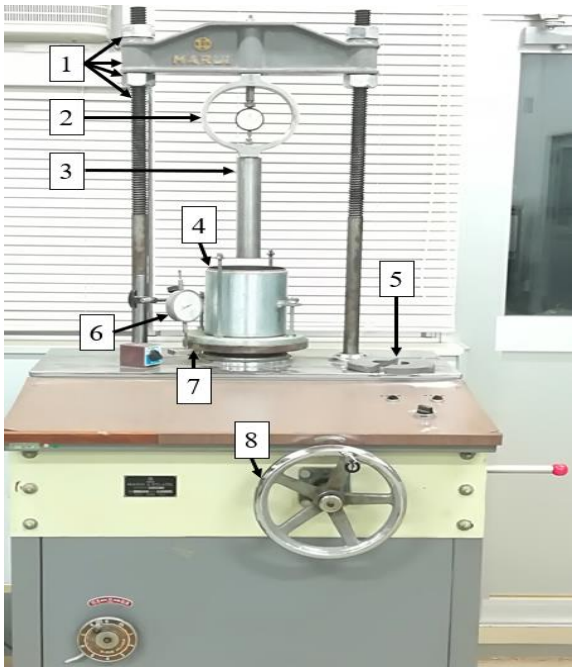

Fig. 10 CBR testing machine and its components

Then the stress (psi) on the piston by dividing the load by the area of the piston was calculated. A graph for the stress (psi) versus the depth of penetration (inches) relationship was plotted. The bearing value is normally the stress (psi) corresponding to a depth of penetration of the piston of 0.10 in. (2.54 mm). if the curve indicates surface irregularities or if the curve is initially concave upward, a correction is applied, in order to obtain the corrected stress for 0.10 in (2.54 mm) penetration of the piston. This bearing value is converted to a ratio by dividing it by 1000 psi, which represents the penetration resistance of compacted standard crushed rock.

This bearing ratio, which is a fraction, is multiplied by 100 and reported as the California Bearing Ratio. Typical CBR values range from less than 5 for soft clays up to 80 for dense sandy gravel.

In the above analysis, the stress corresponding to 0.20 in. (5.08 mm) of penetration should also be determined, and then the bearing value is converted to a ratio dividing by 1500 psi. if this bearing ratio is greater than the bearing ratio calculated for 0.10 in. (2.54 mm) penetration, then the test must be repeated. If, upon rerunning the test, there is a similar result, then the ratio at 0.20 in. (5.08mm) is used as the California Bearing Ratio value. In this study, the CBR tests were carried out for one control specimen and twelve test specimens with their repetitions.

It is vital to take care while interpreting the CBR data, because there is a possibility that the soil might be disturbed and loosened during the construction operations, resulting in a lower CBR than originally measured.

The CBR is defined as the ratio of the resistance to the sinking of a penetration piston having a velocity of 1.27 mm/min (0.05 in/min) into the soil to the resistance shown by a standard crushed rock sample for the same penetration depth [8].

Using this apparatus, the loads were recorded up to a penetration depth of 12.5 mm according to the Japanese Industrial Standards (JIS-A-1211) [9]. The CBR value was calculated according to the following equation:

$$CBR\,\% = \frac{Load\ Strenght}{Standard\ Load\ Strength} \times 100 \quad (1)$$

RESULTS AND DISCUSSION

In the present investigation, two types of basalt geosynthetics (geotextile (GTX) and geogrid (GGR)) were embedded inside soil layers with the purpose of reinforcing the subgrade soil. The reinforcing of subgrade soil by using basalt geosynthetics is expected to be used in infrastructure projects including those in the rural sector (highways, airports, and embankments) that require huge initial investments and low rate of returns on investment [10]. The performance of the non-reinforced and reinforced subgrade specimens was evaluated by using the CBR test. A high CBR value indicates the excellent quality of the material, although other relevant parameters may be necessary to re-confirm the material's performance [11].

In this study, six position patterns forming twelve different CBR test specimens of subgrade soil reinforced with geosynthetic were tested in order to understand their performance response based on CBR values.

The types of test specimens were classified into two groups, in the first group which contains three patterns of six specimens, only one layer of geogrid (GGR) was embedded inside the subgrade soil layers forming three different specimens according to its position which were GGR on upper layer, GGR on middle layer, and GGR on lower layer of the subgrade soil. In the same way, another three specimens using geotextile (GTX) instead of geogrid (GGR) were prepared.

On the other hand, also the second group contained six test specimens of three patterns but in which a combined layer of geogrid (GGR) was

embedded inside the subgrade soil layers forming three different specimens according to its position which were GGR on upper and on lower layers, GGR on middle and on upper layers, and GGR on lower and on middle layers of the subgrade soil. In the same way, another three specimens using geotextile (GTX) instead of geogrid (GGR) were prepared. In addition to the twelve test specimens, there was one control specimen which was a nonreinforced soil sample.

The results for the effects of different geosynthetic type and embedding position(s) at variable depths of soil as a subgrade layer are depicted and a pertinent discussion comparing the results with this control specimen is presented.

Moisture Content and CBR Value Relationship

Analysis in this part included the relationship between the subgrade soil moisture content and the CBR value. A graph had been created where the water content was plotted on the horizontal axis and the CBR value was plotted on the vertical axis as shown in Fig. 11. In Fig.11, a range of around 12 to 13.5% of water content, which is the water content ratio used for the preparation of all the CBR control and test specimens and slightly lower than the optimum moisture content of the used subgrade soil, was shown with a green frame.

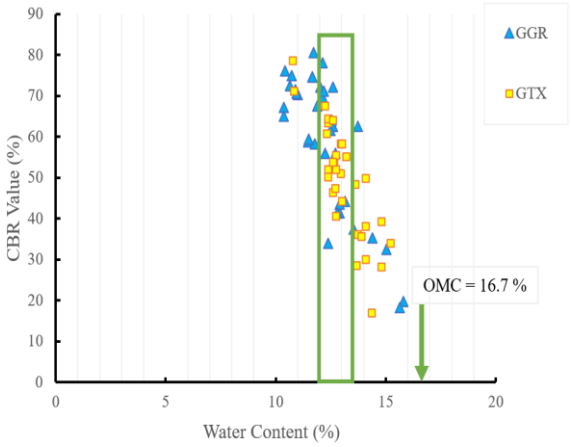

Fig. 11 Subgrade soil moisture content - CBR value relationship chart

Basically, the green frame in Fig. 11 had been picked to show the effect of the water content on the CBR value in the case of the water content is slightly lower than the optimum water content.

The experiments showed that the CBR values were significantly different near the optimum moisture content than in the place where the water content was low. It was found that the CBR value tends to decrease near the optimum moisture content where the water content is slightly high. In contrast, it was found that the CBR value tends to increase as the water content decreased.

While the main purpose of this research is to investigate the effect of embedding different types of basalt geosynthetics inside the subgrade soil layers in different positions at a water content slightly lower than the optimum moisture content on the CBR value, it was found that when the water content ratio becomes low, the CBR value is getting increased drastically. Thus, the CBR value was affected not only by the subgrade soil type, basalt geosynthetic type and/or location but also by the moisture content. And therefore, in this research, the percentage near 12-13.5%, which is slightly lower than the optimum moisture content, was carefully considered.

And that is why, when one is interpreting the CBR data, there is a possibility that the field moisture content of the soil could increase, which could soften fine-grained soils leading to a lower CBR than originally measured.

Influence of Embedding Geosynthetic Inside Subgrade Soil on CBR Value

A series of CBR tests were conducted to obtain the load-penetration relationship of CBR control and test specimens to understand the Influence of geosynthetic type, the number of layers, and position of embedment inside subgrade soil on the CBR value.

Influence of reinforcing the subgrade soil with one layer of basalt geogrid (GGR)

In addition to the CBR control specimen curve, three load-penetration curves obtained from the CBR tests of the three subgrade test specimens containing only one layer of GGR are shown in Fig. 12 in which three different embedding positions were implemented upper, middle and lower. From this figure, it can be seen that all curves follow a typical trend of a CBR test. And also, as the embedding position goes up, the piston load at a given penetration also increases considerably.

The calculated CBR values for the penetration depth of 2.5 mm in the subgrade soil reinforced with one layer of GGR are given in table 5. The results show that the CBR values can be improved by raising the embedding position of the GGR inside the subgrade soil as in the upper layer case, the CBR value was maximized. The CBR values for one-layer GGR reinforced soil in positions of upper, middle and lower layers are 70.89, 60.08, and 42.25% respectively. From these results, also it could be seen that the upper layer is closer to the surface of sinking, indicating more resistance in comparison to the lower layer.

The CBR value of the control specimen (soil only) in this research is 47.93%. This means that CBR values can approximately by 48% higher be achieved by embedding the GGR on the upper subgrade soil layer compared to the CBR value of the control.

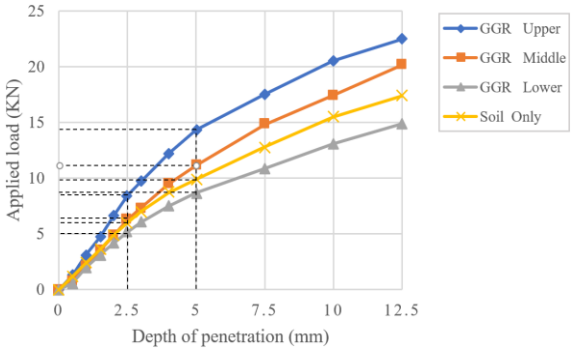

Fig. 12 Load penetration curves of control specimen and three subgrade soil test specimens containing one layer of basalt GGR on the upper, middle and lower soil layer respectively

Influence of reinforcing the subgrade soil with one layer of basalt geotextile (GTX)

The CBR test results for the subgrade soil test specimens containing one layer of basalt GTX on the upper, middle or lower soil layer all together are shown in Fig. 13 It can be seen that, the results of the control specimen (soil only) and the two specimens of soil containing one layer of GTX on the upper- and middle-layer display similar trend before and after penetration depth of 2.5 mm. while the specimen of soil containing one layer of GTX on lower layer showed a different increasing trend.

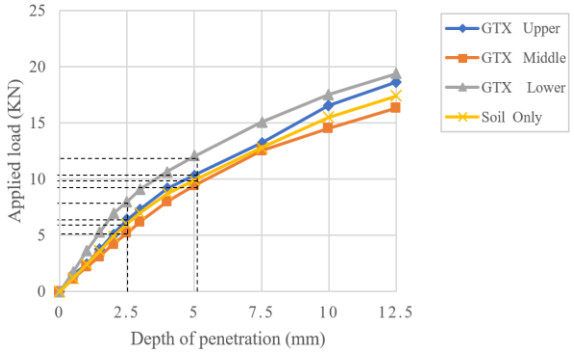

Fig. 13 Load penetration curves of control specimen and three subgrade soil test specimens containing one layer of basalt GTX on the upper, middle and lower soil layer respectively

The CBR test values for penetration depths of 2.5 mm in the subgrade soil reinforced with one layer of GTX are also given in table 5. From this table, it can be observed that in contrast to the GGR one layer the CBR values increase when the embedding position of GTX goes down inside the subgrade soil as in the GTX lower layer case, the supporting force was maximized. The CBR values for subgrade soil reinforced with one layer of GTX on upper, middle and lower layer are 49.72, 45.66, and 59.28% respectively.

This means that CBR values can at most by 24% higher be achieved by embedding the GTX on the lower subgrade soil layer compared to the CBR value of the control.

From Fig. 12 and Fig. 13 where the subgrade soil is reinforced with one-layer geosynthetics only, it is found that in the case of the stiff geosynthetics (as the used GGR), the closer to the upper layer, the sooner the bearing capacity is affected and the CBR value increases drastically. In contrast, softer geosynthetics (as the used GTX) are not immediately affected by the upper layer and are considered to affect significantly the bearing capacity when embedded in the lower layer.

Influence of reinforcing the subgrade soil with two layers of basalt geogrid (GGR)

Fig. 14 describes the relationship of applied load versus the penetration depth in subgrade double layers of basalt GGR upper-lower, middle-upper, and lower-middle. The CBR curves for the GGR double layer in subgrade soil are more pronounced before 2.5 mm penetration in comparison to the previous group of GGR and GTX one layer. It is evident that the penetration load increased for this case.

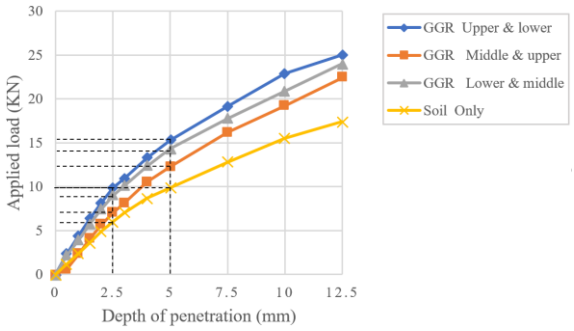

Fig. 14 Load penetration curves of control specimen and three subgrade soil test specimens containing two layers of basalt GGR on the upper-lower, middle-upper, and lower-middle soil layers respectively

The CBR values for the penetration depth of 2.5mm penetration are given in table 5. In comparison to the previous group of one layer of geosynthetic (GTX or GGR), the current CBR results show higher increments especially when the embedding position in the subgrade soil comes in upper-lower, and lower-middle layers. The CBR values for a penetration depth of 2.5 mm for subgrade double layers of GGR upper-lower, middle-upper, and lower-middle are 74.61, 64.48 and, 67.29% respectively.

Influence of reinforcing the subgrade soil with two layers of basalt geotextile (GTX)

The CBR test results for the subgrade soil test specimens containing two layers of GTX on the

upper-lower, middle-upper, and lower-middle soil layers all together are shown in Fig. 15 The CBR curves for the double layer GTX reinforced subgrade soil show close trends before and after penetration depth of 2.5 mm.

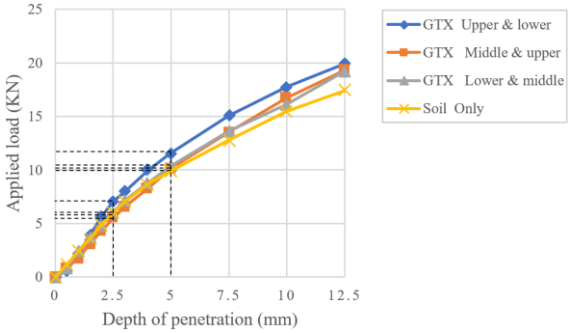

Fig. 15 Load penetration curves of control specimen and three subgrade soil test specimens containing two layers of basalt GTX on the upper-lower, middle-upper, and lower-middle soil layers respectively

The calculated CBR values for the penetration depth of 2.5 mm in the subgrade soil reinforced with two layers of GTX are given in table 5. The results illustrate that the CBR values, in general, had been slightly improved by using two layers of GTX, but this improvement was still less than the increment due to using only one-layer GTX on the lower subgrade soil layer. The CBR values for double layers GTX reinforced subgrade soil in positions of upper-lower, middle-upper, and lower-middle are 55.87 %, 56.07 % and, 52.87 % respectively.

Table 5 CBR values of subgrade soil specimen types

Specimen type or layering pattern		CBR Value	
		GGR	GTX
One layer test specimen	Upper	70.89	49.27
	Middle	60.08	45.66
	Lower	42.45	59.28
Two layers test specimen	Upper & middle	64.48	56.07
	Middle & lower	67.29	52.87
	Lower & upper	74.61	55.87
Control specimen (soil only)		47.93	

Table 5 summarizes the CBR values of the types of control and test specimens with various positions of geosynthetics embedment. It shows that embedding the eco-friendly basalt geosynthetic (geogrid and/or geotextile) inside the subgrade soil has a significant effect on improving the CBR value except in the case of using one GTX layer on the middle layer of subgrade soil and also using one GGR layer on the lower layer of subgrade soil.

Fig. 16 shows a bar graph to compare the difference in the CBR values depending on the geosynthetic layering pattern inside the subgrade soil where the CBR value is plotted on the vertical axis and the specimen type is plotted on the horizontal axis.

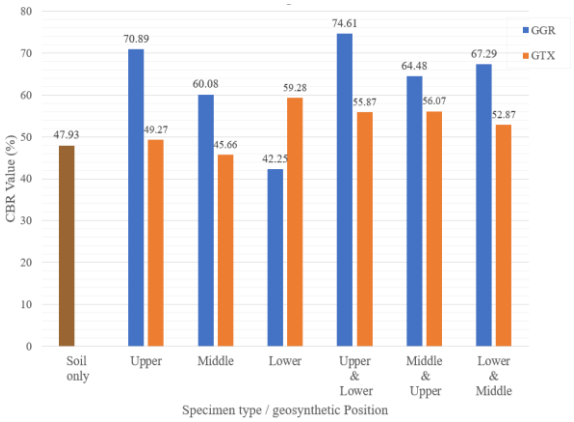

Fig.16 Comparison between CBR values of control and test specimens

The CBR value of one layer of GGR embedded on the lower subgrade soil layer specimen has the lowest value, whilst the specimen of GGR flattened on the upper subgrade soil layer has the highest CBR value among the one-layer GGR pattern. On the other hand, with changing the one-layer GGR pattern into one layer of GTX pattern, the case of embedding the GTX on the middle subgrade soil layer shows the lowest CBR value and on the lower subgrade soil layer the highest CBR value. At one-layer geosynthetic embedment in the subgrade soil, the maximum increment in the CBR value was 48% in the geogrid upper layer case and 24% in geotextile lower layer case.

Further addition of geosynthetic layers inside the subgrade soil layers to turn it into two layers instead of one layer alters the behavior of the ground conspicuously. It is observed that the GGR upper-lower double layers in the subgrade soil gave the highest CBR value compared to the other five double layer cases, whilst the GTX lower-middle double layers showed the lowest CBR value. In the two layers geosynthetic embedment case, the maximum increment in CBR value was 55.7% in the geogrid upper-lower layers specimen and 16.6% in the geotextile middle-upper layers specimen.

It was interesting to note that the GTX double layers embedded inside the subgrade soil layers are not as beneficial as originally expected when compared to a single GTX lower layer. And the effect of embedment was not that large when the number of geosynthetic layers was increased. indicating that there is no benefit in using a double GTX layer for the purpose of reinforcement in constructions. In general, even though the double layer gives the high CBR values, the single layer is more effective and

recommended for field application due to materials scarcity and economic reasons where it has the benefit on the budgeting aspect for design and construction.

This conclusion has certain economic implications for optimizing design and construction using these new geogrid and geotextile. And therefore, it is also recommended that more research be done to outline the correlation between CBR values and shear strength parameters.

CONCLUSIONS

Based on the study results of this paper, it can be concluded that embedding of these new types of eco-friendly basalt geotextile and geogrid inside the subgrade soil layers has a significant effect on improving the CBR value. Since it was found that the CBR value increases by a range from 2 to 55 % from the CBR value of the control specimen according to the layering pattern and the used geosynthetic type.

It could also be concluded that there are effective embedment positions for these geosynthetics according to its type to increase the bearing capacity where the highest CBR value (74.61%) was reached by using double layers of GGR on the upper-lower layers and the lowest CBR value (42.25%) was obtained by using the subgrade soil reinforced with one-layer of GGR on the lower soil layer. It was also interesting to note that the double geosynthetic layers patterns are not as beneficial as originally expected when compared to a single upper layer in the case of using GGR and to a single lower layer in the case of using GTX. This conclusion has certain economic implications for optimizing design and construction using these new basalt geosynthetics.

The increment of water content reduced the CBR value of all types of subgrade soil reinforced with geosynthetics which have been examined. The highest CBR value was achieved by the water content of 10.4%.

For practical and economic reasons, it is recommended to use the pattern of GGR upper layer for the field application. Even though the GGR two layers upper-lower pattern gives the highest CBR value, the upper GGR layer is more effective for field applications due to materials supplied and economic reasons. It has a benefit on the budgeting aspect for design and construction when using this type of geosynthetics.

GREEN CONCRETE HOLLOW BLOCKS UTILIZING BASIC OXYGEN FURNACE STEEL SLAG

Santiago, Karen Joyce B.[1]; and Juan, Jose Arnel P. [2]
[1]Faculty, Mariano Marcos State University, Philippines; [2]Faculty, Mapua University, Philippines

ABSTRACT

This study presented the effects of replacement of fine aggregates with high percentages of steel slag (BOF) on the properties of Concrete Hollow Blocks (CHB). The mix proportions of 1:3:4, 1:4:3, and 1:3.5:3.5 (cement: fine aggregates: coarse aggregates) incorporating various percentages of steel slag were designed. Fine aggregate was replaced 25, 50, 75, and 100 percentages of BOF steel slag by volume of fine aggregate. Elemental and chemical tests were conducted to determine the toxicity of BOF slag to the environment and its use as a partial replacement of fine aggregates thru optical microscopy and xrf spectrometer. Compressive test and statistical inference reveal that inclusion of steel slag as partial replacement with fine aggregates in CHB has a greater compressive strength than the conventional CHB. Moreover, the results of the xrf indicates the presence of calcium and iron oxides. Iron oxides, which are non-toxic, have inert, opaque, and water resistant properties. In raw cement manufacturing, calcium oxide and silica oxides are components and considered to be non-toxic.

Keywords: BOF Steel Slag, Compressive Strength, Green Concrete Hollow Blocks, Toxicity

INTRODUCTION

In the Philippines, Concrete Hollow Blocks (CHB) are commonly used for exterior and interior walls of buildings especially residential projects [1]. It is also used for perimeter fence, tank, septic vault, drainage canal, and many more. Fajardo [2] adds that CHBs are classified as bearing and non-bearing blocks. Load bearing blocks are those which thickness ranges from 15 cm to 20 cm and are used to carry load aside from their own weight. Non-bearing blocks, on the other hand, have thickness ranging from 7.5 cm to 10cm blocks and are intended for walls and partition fences carrying their own weight.

Hua-dong and Liu's [3] study as cited in Yi, Xu, Cheng, Wang, Wan and Chen [4] stated that basic oxygen furnace (BOF) steel slag is a solid waste from steel production. This slag is formed when scrap metals, molten iron, and various fluxes like lime are oxidized by injecting large amounts of pure oxygen into the molten mix to create molten steel and molten slag [5].

In the construction industry, concrete is one of the most commonly used material in variety of environment such as dry, water, underground and even in hot or cold climate zones. One of the advantages of concrete is the material's possibility to change its properties depending on the requirements of the construction project and the price. Concrete consists of three components: binder, filler, and water. Natural aggregates with different proportions are the most common filler. However, the status of depleting natural resources especially on natural aggregates is under question. This led to the conduct of studies using alternatives and replacements of natural aggregates using solid waste.

A global sand importer, Omnico Natural Resources (ONRI), has been exporting construction sand from Ilocos Norte, Philippines to Japan and Singapore since 2009. It has also been importing furnace slag aggregates from Taiwan since 2015 to develop a 112 hectare seaport reclamation project in Currimao, Ilocos Norte [6]. However, the use of this slag for embankment and backfilling materials has been stopped by the Ilocos Norte Provincial Quarry Council due to the alleged toxic slag elements. The council needed the slag to be re-examined in its toxicity and threat to the marine ecosystem of Currimao [7]. Due to the discontinue of the use of the BOF steel slag, which appears like mixed gravel and sand and furnace slag steel, wastes are stockpiled in the northern portion of ONRI seaport complex, measuring as high as 20 meters [8].

Yildirim and Prezzi [9] stated that it is essential to have knowledge of the chemical, mineralogical, and morphological properties of steel slag to utilize BOF steel slag as a replacement material in concrete development to produce green concrete. The use of the Currimao BOF steel slag will take care of the environmental issue as well as the scarcity of the use of natural aggregates for concrete. The use of the slag as a partial replacement for fine aggregates will lessen and eventually eliminate the stockpiled BOF steel slag in Currimao. It will address the problem in industrial waste and apply the recycle, reuse, and recover implementing rules and regulation of the Philippine's Ecological Solid Waste Management Act of 2000 (RA 9003)[10].

The study focused on the utilization of the BOF steel slag as a partial replacement of fine aggregates to produce green concrete hollow blocks. Establishment of proportions for the BOF as a partial replacement of fine aggregates was observed and its possibility as a substitute for natural aggregates.

METHODOLOGY

Concrete Mix Design

Sample design mixes of proportions 1:3:4; 1:3.5:3.5; and 1:4:3 (cement: fine aggregates: coarse aggregates) were used as presented in Table 1. The fine aggregates were replaced by BOF steel slag with various percentage replacement of 25%, 50%, 75%, and 100%, respectively.

Elemental Test by Optical Microscopy

Natural aggregates and BOF slag were collected, sorted, and dried before undergoing elemental analysis using OEM optical microscope.

Table 1. Concrete Mix Design

Mixture (Cement : Fine : Course)	Natural Fine Aggregates %	BOF Slag Aggregate %
1:3:4	0	100
	25	75
	50	50
	75	25

	50	50
	75	25
	100	0

Material Characterization

Natural aggregates and BOF steel slag were pulverized and characterized by the handheld X-Ray Fluorescence Spectrometer.

Slump Test

All procedures and test methods conducted were in accordance with ASTM C143, "Standard Test Method for Slump of Hydraulic-Cement Concrete" specification. Slump was maintained at 5 inches for all mix designs.

Compressive Strength of Cylindrical Concrete Specimens

One hundred fifty (150) 4 x 8 inches concrete cylinders have been tested in the uni-axial compressive test in order to obtain compressive strength. Every five (5) concrete cylinders was tested, respectively, on the same age set to 14^{th} and 28^{th} day period. The development of compressive strength of BOF steel slag aggregate at the age of 14 and 28 days was investigated.

Green Concrete Hollow Blocks Development

BOF steel slag was incorporated in the production of CHB to produce green concrete hollow blocks. Based on the results of the compressive test of the cylindrical samples, the mixture with the highest compressive strength value served as the proportion to be used in the fabrication of the green concrete hollow blocks.

RESULTS AND DISCUSSIONS

Optical Microscopy

The results obtained from the optical microscopy shows that the sample course aggregate had a 12.21mm diameter. This value conforms to the standard size used in concrete mix wherein the usual range employed is between 9.5mm and 37.5mm in diameter. Likewise, the sample fine aggregate had 1.432mm and 1.064mm diameter, respectively. Lastly, the result obtained for BOF steel slag aggregate had 1.218mm and 1.163mm diameter, as shown in Fig. 1. These values of fine aggregates and BOF steel slag conforms to the standard size of fine aggregate used in concrete mix with a range less than 9.5mm.

Figure 1. BOF steel slag

Table 2. Traced Chemical Composition of BOF Steel Slag

Element	PPM	+/-
Ca	37.61%	0.3706%

Material Characterization

Table 2 shows the weight percentage of the element present on BOF steel slag. Its main chemical constituents are CaO, FeO/ Fe_2O_3, and SiO_2. The iron oxide (FeO/ Fe_2O_3) content of BOF slag was 23.99% which could be as high as 31%. This is the amount of oxidized iron that cannot be recovered during the conversion of molten iron into steel. The silica (SiO_2) content of BOF slag was 7.72% ranging from 6.9449% to 8.4951%. The Al_2O_3 and MgO contents were 3.38% and 7.10% ranging from 2.92-3.84% and 0.84-13.35%, respectively. Large quantities of lime were used during the process of conversion from iron to steel; hence, the CaO content of BOF steel slag was 37.61%, which was typically very high (CaO>35%).

In Table 3, Calcium oxides (ranges from 52.25 % to 72.15% parts per million) and iron oxide (ranges from 25.99 % to 42.61% parts per million) are the two major chemical constituent of BOF steel slag. According to Egirani, Latif, Poyi, Wessey and Acharjee [11] as discussed by Ohimain [12], oxides of iron ore are highly values and possess non-toxic, inert, opaque and water resistant properties. Calcium oxide and silica oxides are likewise non- toxic substances since these oxides are raw materials in producing raw cement [13].

Table 3. Oxides present in BOF Steel Slag

	Range Percentage (%)	
Oxides	Low	High
CaO	33.12	72.13
Fe_2O_3	25.99	42.61
SiO_2	13.77	19.26
MgO	1.40	22.15
Al_2O_3	5.52	7.26
MnO	2.38	2.53
P_2O_5	2.99	3.15

Compressive Strength Test

One hundred fifty cylindrical samples were subjected to compressive test. On the 14th and 28th days of curing, the cylindrical samples were tested at the Universal Testing Machine (UTM) to determine their compressive strength. The 150 samples comprised of 3 mixture proportions, namely 1:3:4, 1:4:3, and 1:3.5:3.5 (cement: fine sand: coarse aggregate) with different percentages of fine aggregates replaced by BOF steel slag of percentages 0%, 25%, 50%, 75%, and 100%, respectively.

Five samples on different percentages of slag (0%,25%,50%,75% and 100%) on the different proportions of cement, fine sand, and coarse aggregate (1:3:4, 1:4:3, and 1:3.5:3.5) were subjected to compressive test as presented in Table 4. From Fig. 2, it was presented that the proportion 1:3:4 (cement: fine sand: coarse aggregate) with 25% partial replacement of BOF slag had the highest compressive strength of 4.34 MPa. Furthermore, five samples on different percentages of slag (0%, 25%, 50%, 75%, and 100%) on the different proportions of cement, fine sand, and coarse aggregate (1:3:4,1:4:3, and 1:3.5:3.5) were subjected to compressive test as presented in Table 4 for 28 days curing. It presented that the proportion 1:3:4 (cement: fine sand: coarse aggregate) with 75% partial replacement of BOF slag had the highest compressive strength of 5.38 MPa.

The proportion of 1:3:4 (cement: fine sand: coarse aggregate) significantly presents a higher compressive strength compared to the conventional mix. In the mixture, the 25% BOF steel slag replacement attained the highest value of compressive strength for a 14-day-old concrete while a 75% BOF steel slag replacement attained the highest compressive strength for a 28-day-old concrete. Results indicate that the use of BOF steel slag in the 1:3.5:3.5 proportion yields a lower compressive strength than

those of the conventional mix made from the similar mix proportions.

In addition, there was a difference among the compressive strength of concrete which depended upon the percentage of BOF steel slag it contained. There was also a significant increase of the mean compressive strength between the 14 day age and 28 day age. The highest compressive strength of concrete was considered for the 28 day age since their mean values were significantly higher than the mean compressive strength of the 14 day age. For the mixture 1:3:4, 75% replacement of BOF steel slag showed the highest compressive among the different replacement with the value 5.38 MPa. In the mixture 1:4:3, 50% replacement of BOF steel slag presented the highest compressive strength of 4.39 MPa. While in the 1:3.5:3.5 mixture, 100% replacement of BOF steel slag had the highest mean compressive strength of 5.33MPa. Although the value of the mean compressive strength of the 100% BOF steel slag replacement was high, the values presented in the 1:3.5:3.5 proportions were not recommended since the values were all lower than the compressive strength of the control sample (0% BOF steel slag replacement) which was 5.53MPa.

Table 4. Comparison of Compressive Strength

Mixture	Percentage Replaced by BOF (%)	Compressive Strength, MPa 14 day Age	28 day Age
	0% BOF	2.76	4.84
	25% BOF	4.34	5.28
	50% BOF	3.06	5.31
	75% BOF	2.86	5.38
1:3:4	100%BOF	2.84	4.44
	0% BOF	3.11	3.65
	25% BOF	2.47	4.25
	50% BOF	3.01	4.39
	75% BOF	2.71	4.34
1:4:3	100%BOF	2.47	4.29
	0% BOF	3.21	5.53
	25% BOF	2.32	3.31
	50% BOF	2.42	3.85
	75% BOF	2.57	4.74
1:3.5:3.5	100%BOF	3.31	5.33

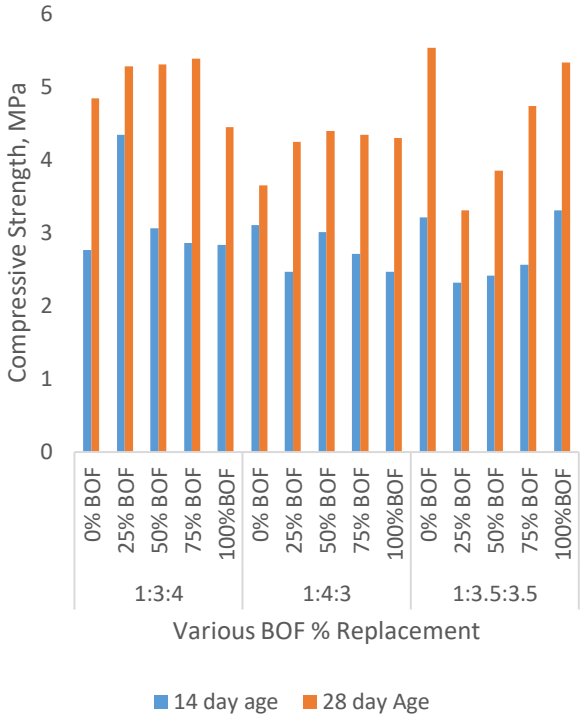

Figure 2. Comparison of compressive strength of various BOF percentages

Statistical Analysis T Test

The t-test analysis with 95% confidence is presented in Table 5. In the design mix 1:3:4, the t critical 2.54 was higher than the t actual 1.20 and the p value of 0.28 was higher than the level of significance. There was no significance between the control mix and the highest compressive strength generated of the design mix 1:3:4. However, this design mix actually generated the highest compressive strength among the mixes. Likewise, the two design mixes of 1:4:3 and 1:3.5:3.5, showed that most of the t actual was greater than the t critical ($t_{actual} > t_{critical}$). Moreover, the p values of these two design mixes were less than 0.05, the level of significance. Hence, the results show that there is a significance difference between the control mix and the fine aggregates replaced by BOF steel slag in the design mix 1:4:3 and 1:3.5:3.5. Likewise, the presence of BOF slag in the mixture of concrete increases the compressive strength of the concrete.

Table 5 Statistical Analysis T test for the compressive strength of concrete of all design mixes

Parameters	Mix Design		
	1:3:4	1:4:3	1:3.5:3.5
Compressive Strength, Control Design Mix, MPa	4.84	3.65	5.53
Highest Compressive Strength, MPa	5.38	4.39	5.33
Fine aggregates replaced by BOF steel slag, %	75	50	100
T actual	1.20	20.91	2.71
T critical	2.45	2.45	2.45
P value	0.28	0	0.04

Figure 3. Green CHB

Development of Green Concrete Hollow Blocks

The proportion 1:3:4 served as the basis for the fabrication of the green concrete hollow blocks since it generated the highest compressive strength of 5.38 MPa. Conventional procedure in the fabrication of hollow blocks was implemented. Fine aggregates were replaced by 75% BOF steel slag. After the molding of green CHB, a maximum of 10 days curing was observed to attain its maximum strength.

CONCLUSION

Green concrete, also known as a sustainable or 'high performance' concrete, uses sustainable materials which are made from recyclable materials or green materials. They are more efficient than the traditional products because they require fewer resources to produce. Green concrete is a material that exhibits better functional performance and capabilities than ordinary concrete. It is considered a maintainable construction material as it consumes less natural resources and less energy and emits a smaller amount of carbon dioxide. The concrete wastes are slag, power plant wastes, recycled concrete, mining and quarrying wastes, waste glass, incinerator residue, red mud, burnt clay, sawdust, combustor ash and foundry sand.

The results obtained from the optical microscopy shows that the BOF steel slag conforms to the standard size of fine aggregate used in concrete mix with a range less than 9.5mm. In determining the elements and oxides present in pure BOF steel slag specimen, it was found out that it contained oxides that had similar elements to the results of the previous studies. Calcium oxides (ranges from 52.25 % to 72.15% parts per million) and iron oxide (ranges from 25.99 % to 42.61% parts per million) are the two major chemical constituent of BOF steel slag. Iron oxides, which are non-toxic, have inert, opaque, and water resistant properties. In raw cement manufacturing, calcium oxide and silica oxides are components and considered non-toxic. Thus it can be concluded that the BOF steel slag treated specimen does not contain any toxic and harmful elements that can harm the environment. The slag can then be used as a suitable material for replacement of natural aggregates and can be categorized as a sustainable material to produce green concrete products.

This study attempts to optimize and develop proportions that can include steel slags as an ingredient for concrete hollow block. BOF slag replaced a certain percentage of fine natural aggregates and the specimens were tested according on the specimens curing days. Concrete hollow block proportion 1:4:3 has the highest value for compressive strength of a fourteen-day old CHB having a value of 4.34 MPa with 50% fine aggregate replacement by BOF steel slag. Likewise, concrete hollow block proportion of 75% replacement from the 1:3:4 proportion governed the value for compressive strength of a twenty-eight-day old concrete hollow block with a compressive strength of 5.38 MPa.

Based on statistical analysis, there was a great significance of the replacement of BOF steel slag in the concrete mixture. There was a significant increase of the compressive strength of concrete as the percentage

of BOF replacement also increases until it reaches its maximum strength. Also, the three mixture proportions were treated independently and presented increase of compressive strength as its age from 14 to 28 days, as well as the addition of BOF steel slag as a replacement of fine sand. As the percentage of fine aggregates replaced by steel slag increased, compressive strength of concrete samples slowly increased.

It can be concluded that BOF steel slag can be used as an aggregate in the manufacture of concrete hollow blocks. It can reduce the solid wastes present in Currimao, Ilocos Norte as well as environmental impacts. Moreover, the use of BOF steel slag makes it possible to reduce the consumption of natural sand which causes potential environmental damage in riverbeds.

CONCRETE STRUCTURES INTERACTING WITH SUBSOIL DEPENDING ON THE USE OF SLIDING JOINT

Michal Kropacek[1], Petr Mynarcik[2] and Radim Cajka[3]
[1, 2, 3]Faculty of Civil Engineering, VSB – Technical University of Ostrava, Czech Republic

ABSTRACT

Article describes the interaction of concrete structure (usually foundation structure or industrial floor) with subsoil, where unwanted friction occurs. Friction can be reduced with sliding joint. This generally known assumption is followed by research described in the article, which determines the effectiveness of sliding joints with respect to concrete volume changes on large-dimensional specimens. Large-dimensional specimens with dimension of 150 x 500 x 6000 mm were placed in the laboratory and outdoor environment, defining different boundary conditions. The research included various concretes in the same strength class and various sliding joints that respect the requirements of construction practice. The paper also describes the comparison of measured results with calculation models from technical standards and regulations, which allow calculation of volume changes on concrete structures. Regarding the subsoil and the sliding joint, this is one of the main long-term goals of the research, since the calculation models do not take these two parameters into account. Deformations from volume changes then deviate significantly from theoretical calculations, as friction in the sliding joint area affects the magnitude and course of volume changes.

Keywords: Concrete, Foundation, Subsoil, Sliding Joint, Volume changes

INTRODUCTION

When designing concrete structures, usually flat foundations and industrial floors, the subsoil has a major impact on the behavior of these structures. This is a well-known phenomenon and is also based on the regulations used to design these structures. In conjunction with the subsoil, a sliding joint is used on the footing bottom to reduce friction (for example, in connection with undermining, prestressing, etc.). The use of sliding joints is a long-term scientific topic of the Faculty of civil engineering, VSB – Technical University of Ostrava, where they are verified by experiments calculations for various types of concrete structures and sliding joints. Various boundary conditions and load methods enter to these calculations. [7], [8], [9], [10], [11], [13], [14], [15], [16], [17], [21], [30], [35], [36]

One of the branches of this research is the use of sliding joint in interaction with volume changes of concrete. From the perspective of concrete structures, volume changes cause unwanted friction on the base-subsoil. These volume changes caused by hydration of cement or also by the ambient temperature lead to stress that can lead to undesirable cracks [2], [3], [28], [29], [31], [32], [33].

For this reason, a sliding joint is used which allows friction to be reduced on this footing bottom. The sliding joint can also be understood as a simple treatment of the footing bottom, as evidenced by the friction coefficients in Tab. 1, where various subsoils and sliding joints are simulated. Mostly, however, the sliding joint is understood as an interlayer composed of one or more layers of different materials providing lower friction. The first option is a composition, where one or more layers are made of foil (PE, PVC) and between them can be, for example, sand or geotextile. The second option is to use asphalt membranes of different thickness and compositon, where viscoelastic properties of asphalt are used.[5], [6], [12], [17], [20], [24], [34]

Table 1 Friction coefficient for subsoil [34]

Base layer	Sliding joint	Friction coefficient
Gravel	No	1,4 – 2,1
Sand	No	0,9 – 1,1
Cohesive soil	No	0,5 – 0,8
Base concrete smooth	1 layer PE foil	0,8 – 1,4
Base concrete smooth	2 layers PE foil	0,6 – 1,0
Base concrete rough	2 layers PE foil	max. 2,0 (h=0,3m) max. 1,3 (h≥1,5m)
Base concrete rough	1 or 2 layers bitumen membr.	avg. 0,45 (h=0,3m) avg. 0,2 (h≥1,5m)

Note: h – thickness of foundation slab

The long-term intention of the author's research is to determine the volume changes of concrete in interaction with the use of sliding joint. Several practical experiments were conducted on this subject, and the results were further used as a basis for comparison by calculation models. From experiments performed on large-dimensional specimens, it was found that even one layer of PE foil can serve as an effective sliding joint (depending on the subsoil) and thus significantly different volume changes of concrete were measured in the laboratory and outdoor environment. The results also differ considerably from calculation models, which are currently the most widely used [22]. It is calculation model from the technical standard EN 1992-1-1 [18], a refined model of regulation Model Code 2010 [23], the American model ACI 209R-92 [1], and the most detailed model of a team Professor Bazant model B4 [4]. All these listed calculation models for determining final concrete shrinkage do not consider the effects of subsoil and possible sliding joint. [25], [26], [27]

EXPERIMENTAL PART

The main part of the experiment was the production of six large-dimensional specimens, which were made of two types of concrete. The first concrete was steel fiber reinforced concrete in strength class C 30/37-X0 and the second concrete was plain concrete in the same strength class C 30/37-XC4. Both concretes have been designed fully in accordance with technical standard EN 206 [19], with the intention that both concretes have the same composition. Minor variations in the composition of the concrete components are caused by the use of steel fibers. This made it possible to directly compare the effect of dispersed reinforcement.

Six large-dimensional specimens with dimensions of 150 x 500 x 6000 mm were made with the emphasis on building practices, where laboratory results on small specimens need to be verified. The dimensions of the specimens simulate the dilatation unit and correspond proportionally to the real structure. Of the total number of specimens, three specimens were placed in a test hall simulating laboratory conditions (hereafter referred to as laboratory) and three specimens were placed in outdoor environment. Two types of sliding joints were chosen for this experiment and the combination with the proposed concrete was as follows. Three combinations were chosen for laboratory and outdoor environments. The first pair of specimens was a combination of fibreconcrete and sliding joint from the asphalt membrane. The second pair of specimens was composed of fibreconcrete and two layers of PE foil with an intermediate layer of geotextile. The last pair of specimens consisted of plain concrete and the same type of asphalt membrane as in the first pair of specimens. The asphalt membrane was selected with a thickness of 4 mm based on modified asphalt (SBS) with sand on the strip surface and PE foil on the bottom. Volume changes, including temperature sensing, were measured inside of specimens using the EDS-20-E string strain gauges. Three string strain gauges were fitted in each specimen at a spacing of 1,5 m from the specimen edge along the length. The strain gauges were at a height of 50 ± 10 mm from the bottom of the specimen, see Fig. 1, where the location of the strain gauges can be seen together with the sliding joint from the asphalt membrane and the prepared formwork.

Fig. 1 Installation of string strain gauges

The concrete was cast into the prepared formworks directly from the truck mixer using a trough and compacted by submersible vibrators. After the concrete was casted, the curing was started immediately. Curing of concrete was performed for 5 days by spraying with water on specimens that were covered with geotextile, see Fig. 2.

Fig. 2 Large-dimensional specimens in laboratory during concrete curing

At the end of the curing, the specimens in laboratory were exposed to conditions with

temperature of 20 ± 2 °C and relative humidity of air 55 ± 5 %, the specimens stored outside the laboratory were fully exposed to ambient conditions.

EVALUATION OF RESULTS

The results were continuously evaluated at time 100 days, which is a sufficiently long period since concrete is usually evaluated in accordance with the regulations for a 28-day period. Since the article describes the interaction of concrete with subsoil, it is not an object to describe in depth concrete technology and processes occurring in concrete during hydration. That is why only graphs showing the comparison of volume changes (shrinkage) of concrete with calculation models are presented in the article and there are no detailed results of individual specimens with boundary conditions. A more detailed evaluation focused on concrete technology will be the subject of another article, but it is certain that specimens in the laboratory undergo different volume changes than specimens in the outdoor environment.

Specimens swell at the start of setting and hardening, and no shrinkage occurs during the curing period. However, since the calculation models do not consider initial swelling, the measured results from the experiment had to be customized. Specimens began to shrink after the end of the curing, which was the time defined as “zero” value, and from that time the volume changes read from the string strain gauges were further measured. The following calculation models were used for comparison with experimental results. Calculation model from EN 1992-1-1, Model Code 2010, ACI 209R-92 and Model B4.

Because of the stable conditions and thus the limitation of the external influences, it is advantageous to evaluate the results separately for the specimens placed in the laboratory and specimens placed in the outdoor environment. Figure 3 shows a graph of the comparison of the results on the specimens in the laboratory with the results of the calculation model. As mentioned above, drying shrinkage occurs in the laboratory after the curing is finished. All other volume changes can be neglected or cannot occur in a laboratory environment. For this reason, the shrinkage curves are continuous and have a regular course. This is important for comparing specimens to each other and for comparison to specimens placed in outdoor environment where more influences enter the experiment and it is not easy (or even possible) to accurately evaluate the volume changes or behavior of the specimens interacting with the subsoil. It can be seen from the graph in Fig. 3 that the combination of plain concrete and sliding joint from the asphalt membrane has the largest shrinkage. This result corresponds to the assumption, since the plain concrete without dispersed reinforcement is to generate the largest shrinkage and the asphalt membrane provides low friction. From the graph describing only shrinkage, the results of fibreconcrete is identical regardless of the sliding joint used. The results show that steel fibers in concrete regulate concrete shrinkage. Compared to calculation models, the measured results are comparable to the model assumptions of the technical standard EN 1992-1-1, which is in line with the requirements of a safe design. In contrast, the measured results differ significantly from the assumption of model B4. The other two models also differ. The results confirm considerably different behavior when using sliding joint.

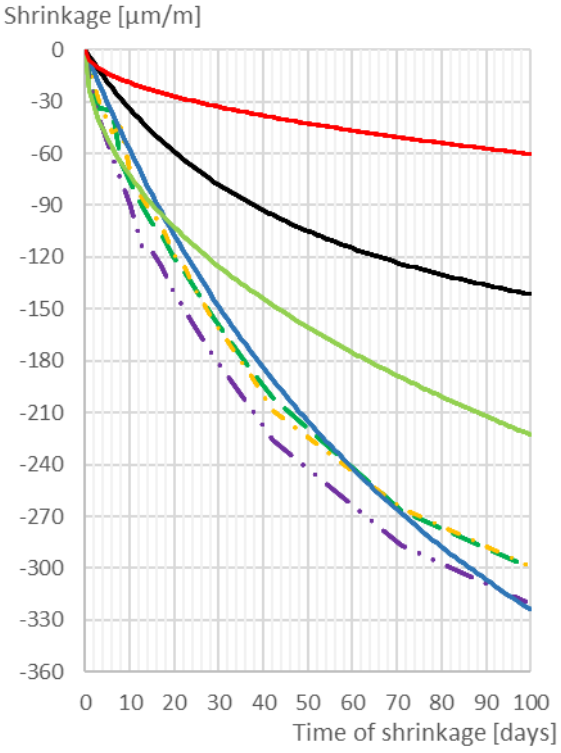

Fig. 3 Comparison of specimens from laboratory with calculation models. Legend: Dashed line – Fibreconcrete / Asphalt membrane; Dashed line one dot – Fibreconcrete / (PE foil + Geotextile + PE foil); Dashed line two dots – Concrete / Asphalt membrane; Blue line – EN 1992-1-1; Green line – MC 2010; Black line – ACI 209R-92; Red line – Model B4

When evaluating specimens from the outdoor environment, the situation is more complicated. Other boundary conditions, such as varying temperature, relative humidity of air and possibly precipitation, affect the measurement. In addition to drying shrinkage, thermal expansion also affects the volume changes. Since the specimens are in outdoor environment, they can be constantly doped with water and the average higher relative humidity of air also

ensures a slower shrinkage of the concrete specimens. Thus, it can be seen from the graph of Fig. 4 that the specimens alternately shrink and swell over time. The shrinkage of concrete is undoubtedly continuous, but shrinkage is outweighed by the expansion of the concrete due to changes in temperature and water supply. An important role is played by the use of a sliding joint that reduces friction and allows the specimen to move horizontally. For the reasons given above, it is very difficult to evaluate any trend, but the largest shrinkage again generates plain concrete in combination with the asphalt membrane sliding joint. The lowest shrinkage (but the largest volume changes) has a specimen of fibreconrete with a sliding joint from the PE foil + geotextile + PE foil. This finding again confirms the trend of laboratory results and the need to use dispersed reinforcement to control concrete shrinkage.

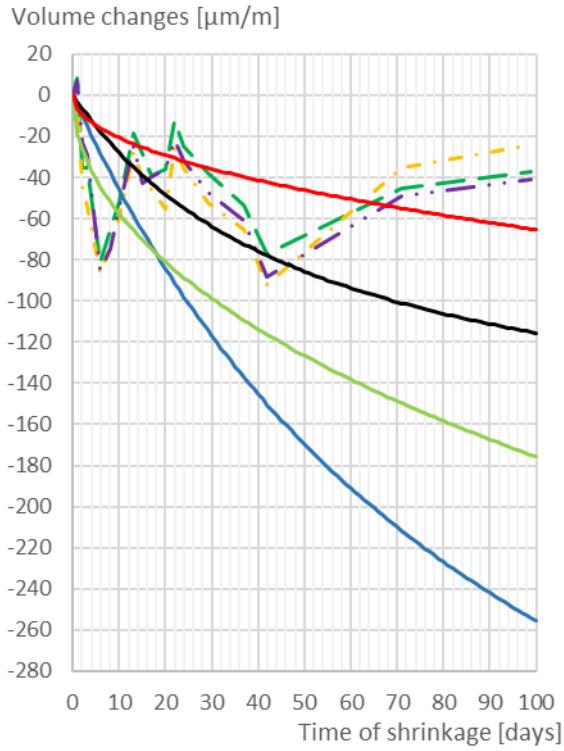

Fig. 4 Comparison of specimens from outdoor environment with calculation models. Legend: Dashed line – Fibreconcrete / Asphalt membrane; Dashed line one dot – Fibreconcrete / (PE foil + Geotextile + PE foil); Dashed line two dots – Concrete / Asphalt membrane; Blue line – EN 1992-1-1; Green line – MC 2010; Black line – ACI 209R-92; Red line – Model B4

Comparison of results with calculation models is significantly different from specimens in the laboratory. Regarding the different behavior of specimens in an outdoor environment, the B4 model is closest to the measured results. Calculation model from technical standard EN 1992-1-1 provides significantly oversized results, but the results are consistent with safe design of concrete structure. These results demonstrate that calculation models do not reflect the effect of sliding joint, which reduces friction and allows the concrete specimen to make volume changes easier.

CONCLUSIONS

An experiment dealing with the interaction of the sliding joint with the concrete specimen provides unique results in several areas. When designing concrete foundations as well as industrial floors, it is always necessary to consider and assess the influence of horizontal forces resulting from the load. However, horizontal forces also arise within the concrete structure through volume changes from hydration or climatic conditions. Large volume changes and high friction at the footing bottom result in high stress inside the structure, which can lead to cracks and weaken the durability of concrete. For this reason, sliding joints are designed in the footing bottom to reduce friction and allow concrete "free" volume changes. The results from experiment show that when using dispersed reinforcement in concrete, the volume changes of fibreconcrete compared to plain concrete are reduced. Steel fibres mixed into concrete have a positive effect on reducing volume changes (mainly shrinkage) in early stages of setting and hardening of concrete. This is particularly evident in laboratory specimens where only drying shrinkage occurs. As mentioned above, the use of sliding joints has its clear reason and importance. In direct comparison of selected sliding joint (and recalculation of results for use with calculation models), the actual use of sliding joint is particularly important. 4 mm thick asphalt membrane and formation of PE foil – geotextile – PE foil do not offer significant differences in friction coefficient.

Comparison of results with calculation models is another separate area to which the author has long focused. Calculation models allow to determine long-term final shrinkage of concrete. The lack of all current models is that they do not reflect initial swelling of concrete during the curing, do not reflect effect of dispersed reinforcement and, above all, do not reflect the influence of subsoil and sliding joint. There are only theoretical sub-calculations that work with a coefficient of friction, but these are not included in calculation models together with other effects such as concrete composition, temperature, relative humidity and time. The results point to the fact that large-dimensional concrete specimens behave very differently from the assumption of calculation models, especially in real conditions of concrete casting and construction conditions. The research of the volume changes of concrete in

interaction with the sliding joint is further focused on high performance and high strength concrete. The results will be further compared with calculation models with an emphasis on friction.

ABSTRACT

A good number of infrastructure projects are implemented in Bangladesh during the last decade and many more are still in pipeline. In the financial year 2017-18 approximately 12.7 million tons of aggregate are used by the construction industries. Local sources could supply only 11% of those aggregate and rest 89% are collected from foreign sources. Due to the wide variation of aggregate sources performance of concrete become unpredictable in some cases. Therefore, in the present study influence of coarse aggregate characteristics on concrete properties are investigated in the context of Bangladesh. To evaluate performance, six mostly used coarse aggregate sources are selected for this study. A series of laboratory test are conducted to evaluate the ACV, TFV, LAA, EI, FI, specific gravity, water absorption and unit weight for all six aggregates. Additionally, chemical composition and petrographic properties are also explored. Keeping the gradation of aggregate constant, two types of concrete mix (w/c ratio 0.3 and 0.4) were prepared to cast concrete cylinders and beams by using six sources of coarse aggregate. Concrete properties including compressive, tensile and flexural strength are determined. The study finds that physical properties of aggregate generally influence the properties of concrete. However the influence is significant in case of concrete requiring compressive strength higher than 50 MPa. The outcomes of the study will help the engineers to select appropriate sources of aggregate depending on concrete strength requirements.

INTRODUCTION

Bangladesh is a developing country where GDP growth rate has hit 7.86 % in the fiscal year 2017-18. It is often said that construction sector is one of the crucial drivers for accelerating economic growth in Bangladesh. Construction sector plays a great role in employment generation, expansion of markets for materials and other commercial activities. Aggregate is one of the mostly used construction materials in all most every construction work. Aggregates have a significant effect on the strength characteristics of concrete in case of high strength concrete. For normal concrete strength may be governed by the interfacial transition zone as it is the strength limiting factor for the case of normal concrete [1], [2]. Characteristics of cement matrix, the interfacial transition zone between the cement matrix and the coarse aggregate usually decide the strength of normal concrete. The usage of water reducing agents in the high strength concrete increases the strength of cement matrix as well as the mechanical properties of interfacial transition zone. Consequently, the properties of coarse aggregate have become dominant in making high strength concrete. In such high strength concrete, the cracks may get initiated either in matrix or aggregate and propagate across all the three phases making the fracture surface relatively less tortuous [3]. Chemical admixtures and some supplementary cementing materials can be used to improve the workability of concrete without negatively affecting hardened concrete [4]. Aggregate shape, texture, and grading have a significant effect on the performance of fresh concrete [4]. Extensive research works on aggregate properties are reported by many researchers including the effect of different types of coarse aggregates such as grey Granite, Anorthosite, Charnockite, Limestone, and Gneiss on the performance of concrete by Vishalakshi et al. [5], effect of maximum aggregate size on the concrete strength by Grabiec et al. [6], the influence of coarse aggregate minerology in mechanical properties of high strength concrete by Oraimi et al. [7], the influence of aggregate type on the elastic modulus of high strength concrete Beushausen et al. [8].

However, detail research work related to the development of high strength concrete using available aggregates in Bangladesh is yet to be completed. In Bangladesh, maximum 6,600 psi

concrete is made but it is not sufficient for making high-rise structures [9]. One of the challenges for making high strength concrete in Bangladesh is non-availability of good quality stone aggregates [10]. Bangladesh has limited sources of naturally occurring rock [11]. Due to shortage of aggregate researchers in Bangladesh are trying to establish recycled aggregate as an alternative. Study reports that by utilizing 100% recycled coarse aggregate and 100% recycled fine aggregate, it is possible to make concrete of strength over 27.5 MPa. Additionally, it is reported that induction furnace slag can be utilized as coarse aggregate for normal strength concrete [12].

Currently, this country depends largely on the various international sources and on few local sources for coarse aggregates. The geological and geo-morphological processes forming the rocks may vary in different locations leading to remarkable variations on the properties of aggregates from different sources. Therefore, it is essential to analyze the characteristics of local as well as known foreign aggregates to be used in various national important infrastructure projects.

In the present study, the influence of aggregate, collected from various sources, characteristics on concrete strength has been studied. A series of physical and mineralogical tests of aggregates have been performed. Concrete cylinders are then prepared and tested for strength evaluation. Finally, a correlation between the concrete strength and aggregate properties has been studied.

MATERIALS

Coarse Aggregate

The coarse aggregate were obtained from six different sources, three from sources within Bangladesh, such as Moddhapara (Mo), Bholaganj (Bh) and Jaflong (Ja) and three from sources outside Bangladesh, namely Pakur – India (PI), Seremban – Malaysia (SM) and Khuong – Vietnam (KV). Samples were crushed as shown in Fig. 1 before delivered by the local supplier.

Pakur Seremban Khuong

Moddhapara Bholagonj Jaflong

Fig. 1 Crushed samples of various coarse aggregates.

Physical Test

Gradation of coarse aggregate varies from source to source and has significant effect on concrete strength [5]. However, in order to study the influence of aggregate on concrete properties it is essential to keep the gradation of coarse aggregate same for all samples. Therefore, for the present study gradation of aggregate is kept constant for all six aggregate samples as shown in Fig. 2.

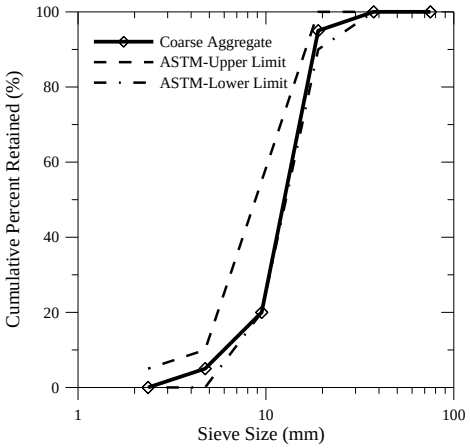

Fig. 2 Constant gradation of coarse aggregate used in this study along with ASTM limits (ASTM C 33).

It is reported that physical properties of aggregate, like strength, shape, size and texture has significant effect on both fresh and hardened properties of concrete [4]. Furthermore, mineralogical composition of aggregate also influences the compressive strength of concrete. Therefore, in the present study a series of physical test, such as aggregate crushing value (ACV), Los Angeles abrasion (LAA), ten percent fine value (TFV), flakiness index (FI), elongation index (EI), fractured face (FF), specific gravity (SG), absorption capacity (AC) and unit weight, has been performed. Properties of various aggregates are summarized in Table 1.

Table 1 Physical properties of coarse aggregate

Properti	PI	KV	SM	Mo	Bh	Ja

es						
ACV (%)	12	17	17	19	20	21
LAA (%)	12	21	16	26	28	32
TFV (kN)	290	220	240	190	210	170
EI (%)	23	23	16	21	19	20
FI (%)	17	15	12	22	19	20
FF† (%)	100	100	100	100	100	100
SG (SSD)	2.88	2.80	2.65	2.74	2.64	2.66
AC (%)	1.19	0.57	0.72	0.83	0.94	0.74
Unit wt. (kg/m^3)	1673	1677	1626	1682	1567	1669

† 100% of aggregates have 3 or more fractured faces

The aggregate crushing value (ACV) and ten percent fine value (TFV) indicate resistance of aggregate against crushing under a gradually applied compressive load. According the ACV result, Pakur-India (PI) has the highest resistance then SM, KV, Mo, Bh, and finally Ja. Based on TFV data, sequence of resistance is PI>SM>KV>Bh>Mo>Ja. Los Angeles abrasion (LAA) test measures toughness and abrasion characteristics of aggregate. Similarly, PI has highest toughness and lowest abrasion, and sequence for the other aggregates is SM>KV>Mo>Bh>Ja.

Elongation index (EI) and flakiness index (FI) represent shape and size of the aggregate. Fractured face signify rough surface of the aggregate and the test results show that 100% of all six aggregate samples have three or more fractured faces. Specific gravity and water absorption capacity of all six aggregates is similar except for PI and KV with slightly higher value. Unit weight of aggregate samples is almost similar apart from Bholaganj aggregate.

Chemical Test

Aggregate mineralogical composition has substantial effect on concrete strength as reported by [7]. Hence, in the current study chemical composition of all six aggregates are determined through a wavelength dispersive X-ray fluorescence (WDXRF) and the results are shown in Table 2. From the test results it is evident that only Khuong – Vietnam (KV) is calcium oxide based and all the other aggregates are silica based. Beside these other major components are ferric oxide, aluminum oxide, magnesium oxide and potassium oxide.

Table 2 Chemical composition of coarse aggregate

Petrographic Analysis

Petrography analysis appraises the quality of course aggregate. In this analysis aggregate particles are initially subjected to geological classification. Analysis is done following ASTM C-295 and the results have been sketched out in Table 3. As shown in the table, parent rock for PI, SM and Mo is igneous type; whereas, parent rock for KV, Bh and Ja is sedimentary. On the other hand, PI is basalt, KV is lime stone and rest are granite type rock.

Table 3 Rock classification of aggregates

Aggregate Source	Origin	Rock Type
PI	Igneous	Basalt
KV	Sedimentary	Lime Stone
SM	Igneous	Granite
Mo	Igneous	Granodiorite
Bh	Sedimentary	Granite
Ja	Sedimentary	Granite

Fine Aggregate

Fine sand are river sand obtained from Sylhet district in Bangladesh. These particles almost entirely passing the 4.75 mm (No. 4) sieve and predominantly retained on the 75 µm (No. 200) sieve. The properties of fine aggregate are shown in Table 4.

Table 4 Properties of Sylhet sand

Name of properties	Ref. Standard	Test Results	Unit

Specific gravity	ASTM C 128	2.61	-
Absorption capacity	ASTM C 128	1.7	%
Unit weight	ASTM C 29	1466	kg/m^3

Cement

For the present study an ordinary Portland cement (OPC) collected from local manufacturer has been used. The OPC cement, also classified as CEM I – 52.5 N, was produced following the Bangladesh Standard BDS EN 197-1: 2003. The physical and chemical tests were conducted in the laboratory and presented in Tables 5 and 6, respectively.

Admixture

In order to maintain the workability at low water-cement ratio a modified polycarboxylate based admixture is used in this study. It is a high range water reducing super plasticizer with negligible sensitivity against aggregate variations. It has a relative density of 1.08 kg/l at 25°C. As per the manufacturer, recommended dosage is 0.5 to 2% by the weight of cement.

CONCRETE MIX PROPORTION AND PREPERATION

It is widely reported that influence of aggregate is insignificant for regular concrete with w/c ratios between 0.4 and 0.7. However, concrete with high compressive strength with low w/c ratio may depend on aggregate properties. Therefore, to study the effect of aggregate properties in concrete performance, two w/c ratios (0.3 and 0.4) has been considered in this study.

Mix design of concrete has been performed according to ACI 211-91. Mix proportions for 1 m^3 of concrete for each aggregate type are presented in Table 7. In total, twelve mix proportions have been considered with six different aggregate types and two different w/c ratios. Concretes were designated with coarse aggregate type and w/c ratio. For example, PI-03 represents Pakur-India coarse aggregate and 0.3 w/c ratio.

Table 7 Mix proportion for 1 cum of concrete

Designation	**Water (kg)**	**Cement (kg)**	**CA (kg)**	**FA (kg)**	**Admixture (ltr)**
PI-03	205	683	1037	501	6.83

Ja-04	205	513	1035	575	3.85

Concrete cylinders, 100 mm by 200 mm, were prepared in two layers with the help of vibrator for compressive strength and split tensile strength. Beside these, concrete beams, 100 x 100 x 500 mm, were also casted for flexural strength test.

RESULTS AND DISCUSSION

At 28 days concrete cylinders were tested for compression and split tensile test in a 3000 kN capacity compression machine; beams were tested

for flexural strength in 1000 kN capacity universal testing machine. Just before the test samples were removed from the water tank and surface dried with rags.

Compressive Strength

Compression test were performed for twelve sets of cylinders for six aggregate types and two w/c ratios. Fig. 3 represents the test results. As shown in the figure, concrete with aggregate from the Seremban – Malaysia (SM) produced the highest compressive strength in case of both w/c ratios of 0.3 and 0.4. On the other hand, concrete with aggregate from Jaflong (Ja) showed lowest compressive strength. Beside these concrete with KV and Mo showed good compressive strength. Except for concrete with Pakur-India (PI) compressive strength concrete is related to strength properties of aggregate, such as ACV, LAA and TFV. Aggregate from PI has shown highest strength compare to other aggregates. However, because of its high elongation index (EI) and flakiness index (FI) the compressive strengths of concrete with PI fall short of the expected results. Furthermore, lime stone aggregate from KV showed good compressive strength despite having relatively high EI value.

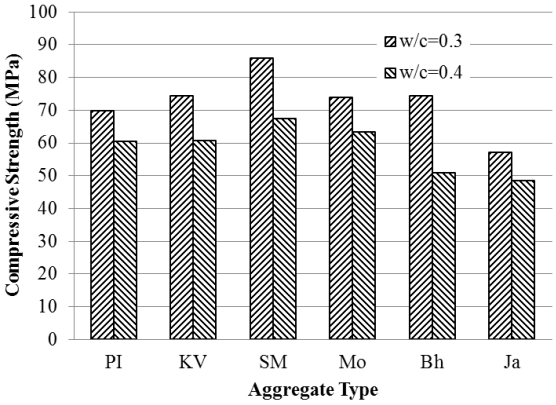

Fig. 3 Compressive strength of concrete with six coarse aggregate types at 28 days age for w/c ratios of 0.30 and 0.40.

Split Tensile Strength

Similar to compression test, split tensile tests were performed for concrete with six aggregate type and two w/c ratios. Fig. 4 displayed the tensile test results. Like compressive strength, concrete with SM aggregate showed the highest tensile strength; whereas, concrete with Ja aggregate gave the lowest strength. Concrete with KV and Mo also performed well.

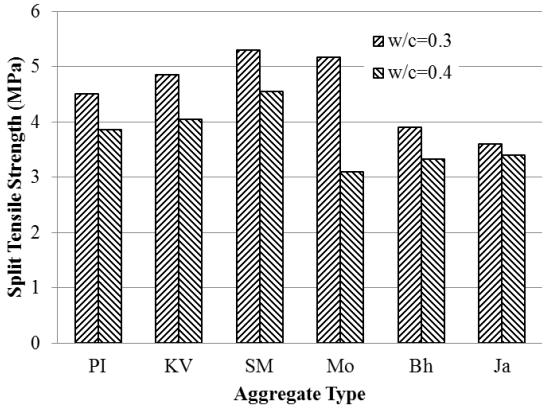

Fig. 4 Splitting tensile strength of concrete with six coarse aggregate types at 28 days age for w/c ratios of 0.30 and 0.40.

Flexural Strength

Concrete beams were tested for flexural strength. Loads were applied at one-third and two-third points and flexural loading capacity were calculated accordingly. Fig. 5 displayed the flexural strengths concrete with aggregate and w/c ratio variations. As shown in the figure, concrete with aggregate from KV and PI have shown the highest flexural strength despite having high EI and FI values. On the other hand, SM, with lowest EI and FI values, based concrete has not yield higher flexural strength. This implies that aggregate shape has very little effect on flexural strength of concrete.

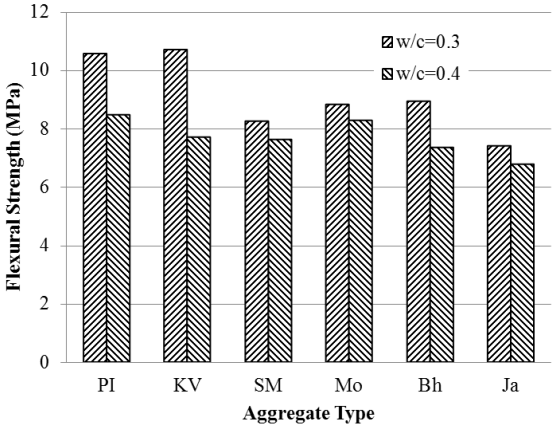

Fig. 5 Flexural strength of concrete with six coarse aggregate types at 28 days age for w/c ratios of 0.30 and 0.40.

Correlation between Aggregate Properties and Concrete Strength

One of the major objectives of this study is to

find a correlation between aggregate properties, such as shape and strength, with concrete strength. Shape of the aggregate is partly depends on the crushing procedure of the rock, and thus, will not be used for direct correlation for concrete strength. However, strength properties of aggregate, such as ACV, LAA and TFV, have significant effect on concrete compressive strength. Fig. 6 – 8 represent concrete compressive strength against ACV, LAA and TFV, respectively except for concrete with aggregate from PI. As mentioned earlier, concrete with PI showed scattered results because of its shape factor of aggregate. The figures also include linear trend lines with r-squared values. In all cases it showed good correlations.

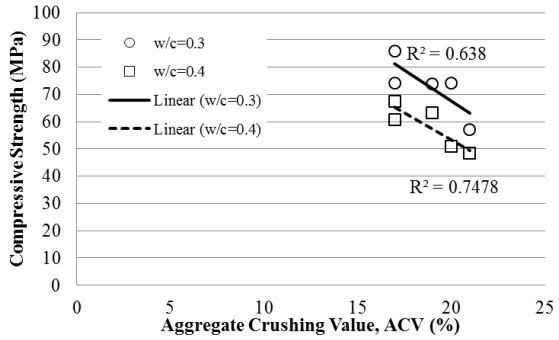

Fig. 6 Compressive strength of concrete at 28 days vs. aggregate crushing value (ACV).

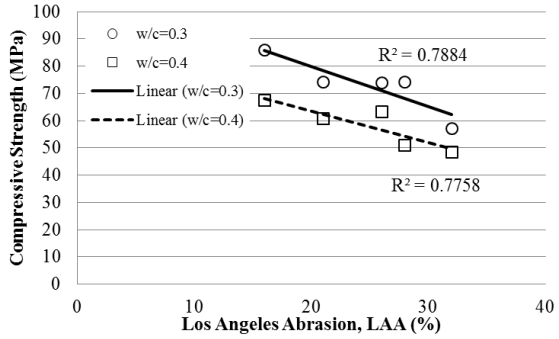

Fig. 7 Compressive strength of concrete at 28 days vs. Los Angeles abrasion (LAA) value.

As shown in Fig. 6, concrete compressive strength reduces with increasing ACV values. Similar is true for LAA values. As described in Fig. 7, higher the LAA values lower the compressive strength of concrete. For TFV opposite trend observed as presented in Fig. 8. With increasing values of TFV concrete compressive strength increases. It is also observed that in all cases influence of aggregate strength become insignificant for concrete with 50 MPa or less.

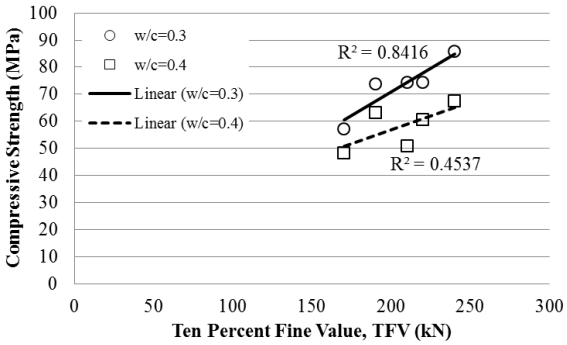

Fig. 8 Compressive strength of concrete at 28 days vs. ten percent fine value (TFV).

CONCLUSIONS

The conclusions that can be drawn from this study are as follows:

- Strength and shape properties of aggregate have significant effect on compressive and tensile strength of high strength concrete. However, for concrete with 50 MPa or less compressive strength this influence becomes trivial.
- Concrete compressive strength increases linearly with decreasing ACV and LAA values and with increasing TFVs. However, this is relation is only valid for 50 to 90 MPa strength and for relatively lower elongation and flakiness indexes.
- Shape of aggregates has insignificant influence on flexural strength of concrete.

ABSTRACT

The collapse of the brick masonry infill in the Reinforced Concrete (RC) structures has been known as one of the causes of the many casualties during the earthquake. This clay brick masonry has been commonly used as the partitions in the RC frame structures in earthquake-prone areas such as West Sumatera, Indonesia. Strengthening the brick masonry infill is expected to be able to increase the performance of the brick masonry against the earthquake motions, which also may improve the seismic performance of RC structures. In this study, four of 1/4 reduced-scale singe-bay and single-story RC frame specimens were prepared and tested under lateral static reversed cyclic loading. The specimens include one specimen of RC frame infilled with brick masonry and three specimens of RC frames infilled with strengthened brick masonry. Strengthening of the brick masonry infill has used three types of wire mesh, namely plastic wire mesh, steel wire mesh, and chicken wire mesh. The wire mesh was tacked on both sides of the diagonal area of the brick masonry infill. The wire mesh was then fastened to columns and beams of RC frame by using chemical epoxy adhesive. The purpose of this experimental study is to define an effective, inexpensive, and easy to apply the strengthening of the brick masonry infill such that may be applied by the local labors in West Sumatera, Indonesia. The structural test results have shown that all the strengthening methods increase the lateral strength of the RC frame and can delay the failure of the brick masonry infill. Even though the strengthening by using the steel wire mesh produced a higher increase in stiffness of the specimen compares to others, however strengthening by using chicken wire mesh performed the most effective strengthening method. The presence of the chicken wire mesh maintains the ductility of brick masonry infill and RC frame as well.

Keywords: RC building, strengthening brick masonry, seismic performance, reversed cyclic loading

INTRODUCTION

The presence of brick masonry as infill in the reinforced concrete (RC) structure has commonly in the earthquake-prone area such as West Sumatera, Indonesia. Based on the results of the post-earthquake investigation after the earthquake and the experimental results of RC frame subjected to static lateral loading showed that the presence of infilled brick masonry in RC frame structures influence the performance of its structures. The presence of brick masonry infill, on one side, increasing the lateral strength and the stiffness of the structure, however, decreases its ductility. On the other hand, the existence of this brick masonry infill may endanger the occupants.

In many cases, the brick masonry infill often collapses during the earthquake shaken and results in a loss of human life [1]-[2]. The studies for investigating the influence of brick masonry infill to seismic capacity and behavior of the RC frame structures have been conducted by many researchers covering various aspects. Tanjung [3]-[4] has examined the use of various types of brick masonry materials commonly used in West Sumatra, Indonesia for evaluating the seismic performance of the RC frame structures with infilled by the brick masonry. The RC specimens were subjected to the lateral static pushover loading only. More detail and complex studied have been carried out by Madiawati [5] Cavaleri [6] and Dautaj [7], where the brick masonry infilled of RC frame specimens were tested under the lateral static reversed cyclic loading. They concluded that the brick masonry infill plays an essential role in the damaged on the RC frame structure during cyclic loading.

One effort to reduce the vulnerability of this brick masonry infill is by strengthening its brick masonry infill with such ductile materials. Obviously, the research on the strengthening of the brick masonry has also been carried out by several researchers. Tanjung [8], for instance, has used the embedded plain steel on bed mortar joint to strengthen the brick masonry infill in the RC frame structure, while Ismail [9] uses wire mesh banded to strengthen the unconfined brick masonry housing in Pariaman, West Sumatera. Leeanansaksiri [10] also used the Ferro-cement for straightening the brick masonry infilled in RC frame structures. More advanced research is carried out by researchers have been well summarized

in the article [11]-[16]. The strengthening methods by using modern materials such as textile-reinforced mortar, welded wire mesh, and Carbon Fiber Reinforced Polymer (CFRP) have also been conducted and proposed by the researchers. Although their test results show that the strengthening materials and methods gave better RC frame construction, unfortunately, the strengthening methods require the relative expensive materials and specialized labor for applying the strengthening. Therefore, these methods are not suitable to apply in the West Sumatra area, since there is no available strengthening material and skilled labors as well.

In this study, the simple method based on the experimental works for strengthening the brick masonry infilled in the RC frame structure is proposed. For this purpose, four of 1/4 reduced-scale singe-bay and single-story RC frame specimens were prepared and tested under lateral static reversed cyclic loading. The purpose of this experimental study is to define an effective, inexpensive, and easy to apply the strengthening of the brick masonry infill such that may be applied by the local labors in West Sumatera, Indonesia.

EXPERIMENTAL PROGRAM

The experimental study explains in this paper was conducted by utilizing the structural testing facilities at Structure and Construction Material Laboratory of Syiah Kuala University, Banda Aceh, Indonesia. Four of 1/4 reduce-scaled one-bay and one-story RC frame specimens were prepared, i.e., one specimen of RC frame infilled with brick masonry and three specimens of RC frames infilled with strengthened brick masonry. The specimens represent the first story of the typical construction of low-rise RC frame structures in West Sumatra, Indonesia. Strengthening of the brick masonry has used three types of wire mesh, namely plastic wire mesh, steel wire mesh, and chicken wire mesh. The materials for constructing these specimens were collected from local markets in Banda Aceh, Indonesia. All the specimens were subjected to lateral static reversed cyclic loading.

The RC Frame Specimens

Figure 1. shows the details of the geometry and reinforcement applied for all RC frame specimens. The columns of the RC frame were detailed to yield in flexure before shear failure. The dimension of the cross-section of columns was 125 mm x 125 mm and reinforced with 4D10 longitudinal bars and ϕ4@50 transverse hoops. We designed the cross-section of the columns by considering the scale reduction. The clear height of the columns was 750 mm. The dimension of top-beam was 200 mm wide, 200 mm deep and 1550 mm long and reinforced with 4D13 longitudinal bars and ϕ6@50 transverse stirrups. The columns were then supported by the lower-beam, which was fastened to the strong-floor by using six post-tensioning rods. The dimension of the lower-beam was 700 mm wide, 150 mm deep and 1650 mm long and reinforced with 12D16 longitudinal bars and ϕ6@50 transverse stirrups.

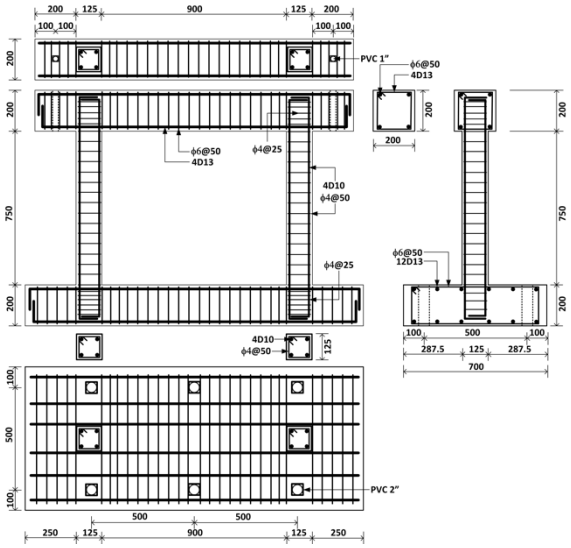

Fig. 1 Reinforcements Details of the RC Frame.

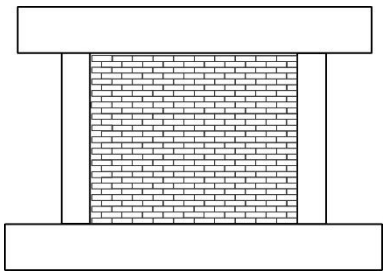
Four of 1/4 reduced-scale singe-bay and single-story RC frame specimens were constructed in this study. The specimens include one specimen of RC frame infilled with brick masonry (IF-SW) and three specimens of RC frames infilled with strengthened brick masonry. Strengthening of the brick masonry has used three types of wire mesh, namely plastic wire mesh (IF-SM-P), steel wire mesh (IF-SM-S) and chicken wire mesh (IF-SM-A). The wire mesh was tacked on both sides of the diagonal area of the brick masonry wall. The wire mesh was then fastened to columns and beams of RC frame by using chemical epoxy adhesive. The RC frame specimen with brick masonry infill is schematically shown in Fig. 2a while the RC frame with strengthened brick masonry infill is presented in Fig. 2.b

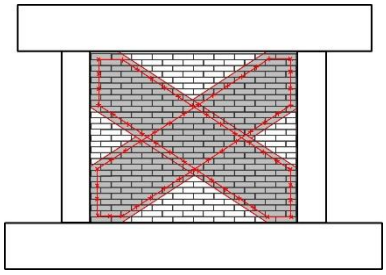
Experimental Setup and Instrumentation

As was mentioned above, during experimental works, the prepared RC frame specimens were subjected to static lateral reversed cyclic loading. A schematically image of the experimental setup for the current study is shown in Fig 3.a. For testing the specimen, at first, its specimen was placed on the rigid-floor. The lower-beam of the specimen was fastened to the rigid-floor by using six post-tensioning rods to keep the specimen remain in its position during the test. A double-action lateral actuator force equipment was attached and fastened to the strong wall by using four post-tensioning rods.

Two horizontal steel beams were used to restrain top-beam of the specimen from preventing the applied force on its top-beam causes out-of-plane deformation occurs during testing. These two horizontal steel beams were connected to the actuator force, which mounted on the strong wall. The displacement transducers (LVDTs) were installed at several points to measure the deformation of the RC frame specimen, as is shown in Fig. 3.b. A displacement transducer which was placed in the middle of top-beam was used as a displacement-control point.



(a) RC Frame with Brick Masonry Infill Specimen



(b) RC Frame with Strengthened Brick Masonry Infill Specimen

Fig. 2 Design of the RC Frame Specimens.

The lateral static reversed cyclic loading applied in current experimental works was conducted by control the lateral displacement of the top-beam with the loading speed of approximately 0.05 mm/s. The procedure follows FEMA461 [17]. The amount of lateral movement of the top-beam was defined based on the drift ratio of the column R=δ/H, where δ is the lateral displacement at a tip of the top-beam measured by the displacement transducer and H is the distance between the transducer and the bottom of the column. The loading program was R=1/800, R=1/400, R=1/200, R=1/100, R=1/50, R=1/25, R=1/12.5 rad., and followed by a pushover to R=+1/10. Except for the first drift ratio R=+1/800, two cycles were applied for each drift ratio. Incremental of the applied lateral static load and the deformation of the specimen were monitored and recorded throughout the tests. An initial crack and its crack propagation were drawn on the RC frame and brick masonry infill in every loading cycle for identifying the failure mechanism of the specimen.

RESULTS AND DISCUSSION

Material Properties

The material properties used for constructing RC frame specimens, including their brick masonry infills, were obtained by standard material testing procedures. The compressive strength of concrete cylinder at 28 days after casting was 30.6 MPa, i.e., the sample of the concrete was cast to the RC frame specimens. The compressive strength of the brick masonry cube was 9.4 MPa. The nominal yield (tensile) strengths of the reinforcements, respectively for Ø4, Ø6, D10, and D13, were 390.2 (574.9) MPa, 346.8 (446.3) MPa, 324.6 (449.5) MPa, and 374.3 (535.4) MPa.

Performance and Failure Mechanism

RC Frame with Brick Masonry Infill

Figure 4. shows the test results of the IF-SW specimen. The ultimate lateral strength was obtained about 93.5 kN at the first cycle of R =+1/100 and 94.5 kN at R=-1/100. An initial crack on the interface between columns and brick masonry infill firstly appeared at R = +1/400 at a load of 30 kN and the initial flexural crack in the column have also been seen at it R= +1/400 due to the lateral load of 47.6 kN. Meanwhile, the brick masonry infill started to crack on it diagonal at the first cycle of R =+1/200 caused

by the lateral loading of 78 kN.

Furthermore, the diagonal crack on the brick masonry infill spreads and widens when the specimen was loaded to 92 kN at cyclic R = +1/100. At the same time, the flexural cracks in the left column also increased. The shear crack on the upper of the left column occurred at the first cycle of R = +1/50, and the diagonal cracks on the brick masonry infill increased become wider than 5 mm. The surface plastering on the brick masonry infill started to peel off at R = +1/50 as it is shown in Fig. 4.b., then the diagonal crack on the brick masonry infill increased more than 10 mm wide when R = +1/25. Finally, the brick masonry infill collapsed at the second cycle of R = +1/12.5, and the transverse hoop in the left column ruptured when the specimen has been subjected a pushover loading to R = +1/10.

Fig. 4 Experimental Setup and Instrumentation.

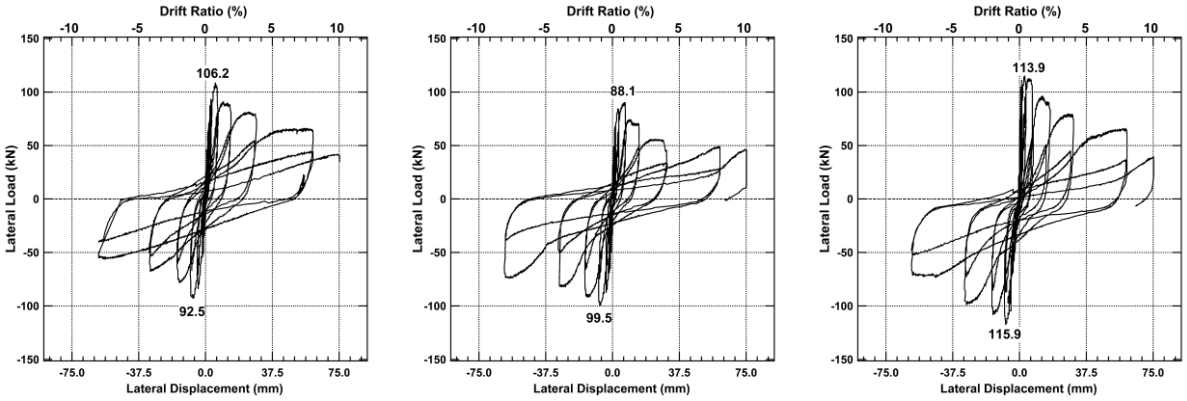
RC Frame with Strengthened Brick Masonry Infill

The comparison of the load-displacement hysteresis curves based on the experimental results for all three strengthed brick masonry infill specimens is shown in Fig. 5. Compare to the test results of the IF-SW specimen, increasing of the lateral strength due to the strengthening of brick masonry infill in IF-SM-P, IF-SM-S, and IF-SM-A specimens are 12.4%, 5.3%, and 22.6%, respectively. Although the increase in its lateral strength is not significant, however, the presence of the strengthed brick masonry infill in the RC frame significantly changed the deformation behavior, crack pattern and the progressive failure of the RC frame specimens.

In IF-SM-P specimen, the plastic wire mesh could not perfectly bond to brick masonry and surface plastering as well. Therefore, the strengthening of the brick masonry infill became imperfect. The initial crack on the wall has seen at the first cycle of R = + 1/400, and the surface plastering of the brick masonry infill has begun to release at the second cycle of R = + 1/200. The interface between the column and the brick masonry infill connected by wire plastic was also the weak area of this strengthening method. The cracks in this area have already appeared at the beginning of loading. The advantage this method is that the use of wire mesh plastic may delay the collapse of RC frame specimen and the brick masonry infill.

The material of the steel wire mesh has better tensile strength compared to plastic wire mesh and chicken wire mesh. Its material may bond to the brick masonry infill as well as to the surface plastering of the brick masonry infill. Strengthening using this steel wire mesh (IF-SM-S specimen) gave an excellent strengthening on brick masonry infill. The cracks that occur on the brick masonry wall were significantly reduced. The strengthening causes increase the stiffness of the brick masonry infill. Unfortunately, increasing of the brick masonry stiffness produced the high force on the diagonal brick masonry infill that compresses the column such that the column damaged relatively faster than other test specimens.

When compared these three types of strengthening materials shows that the strengthening by using chicken wire mesh (IF-SM-A specimen) provided the most optimal result. Although the cracks occurred on its brick masonry infill was more than those of the IF-SM-S specimen, the strengthening using chicken wire mesh can delay the collapse of the brick masonry infill. We noted that the cracks on the brick masonry infill generally occurred outside the area where the chicken wire mesh was installed. The cracks appeared in the columns were dominated by the flexure cracks. This result contrasts to the experimental results of the IF-SM-S specimen where



(a) IF-SM-P Specimen (b) IF-SM-S Specimen (c) IF-SM-A Specimen

Fig. 5 Comparison of the Load-Displacement Hysteresis Curves

(a) IF-SM-P Specimen (b) IF-SM-S Specimen (c) IF-SM-A Specimen

Fig. 6 Comparison of the Crack Pattern of the Specimens at R=1/12.5

the column damage was caused by shear failure. The experimental results were also indicated that the ductility of the IF-SM-A specimen better than other specimens. The images of the crack pattern of the RC frame specimen infilled by the brick masonry are shown in Fig. 6.

CONCLUSIONS

The simple method for strengthening the brick masonry infilled in the RC frame structures has been proposed. A proposed method is defined based on experimental works on several RC frame specimens. Comparing the experimental results of these specimens concluded that the strengthening by using the chicken wire mesh gave the optimal result. The strengthening increase in the lateral strength about 22,6% and delayed the failure of the RC frame and collapse of the brick masonry infill. This proposed strengthening method by using the chicken wire mesh also has good ductility compare to other material. The strengthening material is easy to find in the local markets and is easy to apply by unskill local labor. Therefore, this method will be useful and applicable in the seismic-prone area, such as West Sumatera, Indonesia.

ABSTRACT

On September 28, 2018, Palu city, the Central Sulawesi area suffered the M7.5 earthquake. An epicenter of its earthquake located 77 km from the capital of Central Sulawesi Province, Palu city. The main earthquake followed by a localized 4 to 7 meters high tsunami which swept shore-lying houses and buildings on its way. A large number of damages on reinforced concrete (RC) buildings, houses, and soil liquefaction spread in Palu city were observed after the earthquake. The post-earthquake observation reported in this paper was conducted in order to define the typical pattern of RC buildings' damages. The field investigation was focused on the damaged RC buildings. Several types of damage were detected on RC structures such as collapse due to the soft story, damage to beam-column joint, failure of short column, shear failure of the column, collapsed of brick masonry infills. Two damaged RC frame buildings, one in severe damage and the other in totally collapsed, were furthermore analyzed to define it seismic capacity based on Japanese standard. According to the analyses of the first story in the buildings, the distinct difference of seismic performance of both buildings was discovered.

INTRODUCTION

Indonesia is a country located in the highest seismic region in the world. Indonesia has experienced many strong earthquakes [1]. During the last decades, the series of the intense earthquakes have struck several areas in Indonesia, for instance, Aceh in 2004 and 2016, West Sumatera in 2009 [3,4], Bengkulu in 2007 [5], Yogyakarta in 2006, [6], and Central Sulawesi in 2018. The Earthquake in Central Sulawesi was struck by the M7.5 earthquake on Friday, September 28, 2018, at about 6:03 pm local time in Indonesia and was followed by a tsunami with waves up to 7 m high. According to the U.S. Geological Survey (USGS) [7], the epicenter of the M7.5 earthquake was at 0.256ºS, 119.840ºE with a shallow depth of 10 km and it was 70 km away from the provincial capital, Palu. The earthquake rocked areas around the epicenter is shown in Fig.1.

The Palu earthquake **i**n September 2018, was preceded by series of small-to-moderate magnitude earthquakes over the hours leading up to the big one, the biggest of which was a magnitude M6.1 earthquake that occurred three hours earlier and just to the south of the M7.5 event as reported by the USGS. There was also followed by an active aftershock sequence, with about ten events of M4.7 and it got more significant in the three hours after the earthquake. The earthquake and tsunami destroyed large residential areas of more than 70,000 houses and nearly 3,000 schools. Moreover, the earthquake also triggered soil liquefaction and settlements in Palu, Donggala andSigiareas. Many multi-story buildings were reported being severely damaged as well as collapsed in Palu, for instanc**e**, the Anuntapura Hospital, Palu'sTatura Mall (the oldest shopping centers in Palu), the Roa-Roa Hotel, Fire Station, and Tadulako University.

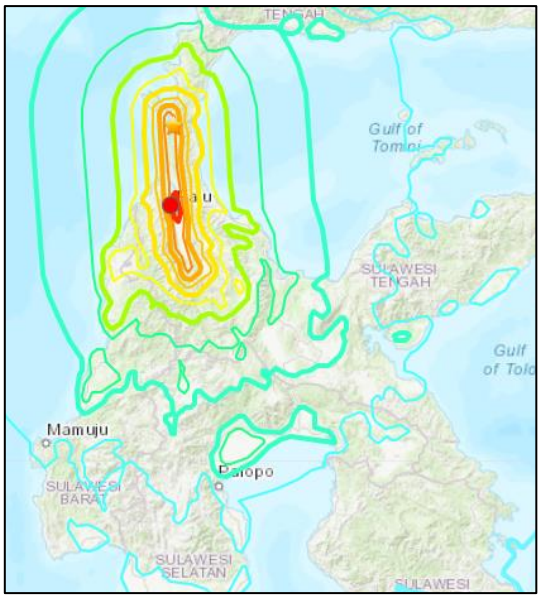

Fig. 1 Shock map of M7.5 Palu earthquake (Source: USGS)

According to the National Board for Disaster Management (BNPB), the earthquake and tsunami caused more than 3,000 death and more than 4,000 injuries in Palu, Donggala, Sigi, and nearby area [8].

This paper presents the report field investigation after Palu earthquake. The observation was conducted from October 4 to 6, 2018, in around Palu city. The investigation was focused on evaluating and discussed on the engineered damaged buildings.

OBSERVATION OF DAMAGED BUILDING

The observation of the damaged RC buildings took place in the areas of Palu, Donggala, and Biromaru cities of Central Sulawesi. Figure 2 shows the map of Sulawesi island dan surveyed areas.

a). Location of Palu city in Central Sulawesi (Source: Google map).

b). Surveyed areas (Source: Google map)

Fig. 2 Map of surveyed areas

The observation was initially done in Donggala, about 40 km west-north of Palu. The ground motion of the Palu earthquake destroyed most of the non-engineered houses, which were built in confined brick masonry wall type. The typical damages of these houses are shown in Photo 1.

Investigation on damaged buildings was carried out in Palu city on the second day. The collapsed RC buildings of Tadulako University (Faculty of Forestry, Faculty of Law, Faculty of political science buildings), building of Universitas Terbuka, The Sya Regency Hotel, Ramayana shopping center, Anuntapura Hospital, Mecure hotel, Fire Station and public apartment and the damaged RC buildings of shophouse and masonry infills were observed**.** Photo 2 shows an example of the damaged buildings observed during the post-earthquake investigation.

In the district Biromoru of Sigi area, the survey was conducted on the third day. In this region, massive liquefaction caused houses to be swept away and damaged public facilities, as shown in Photo 3.

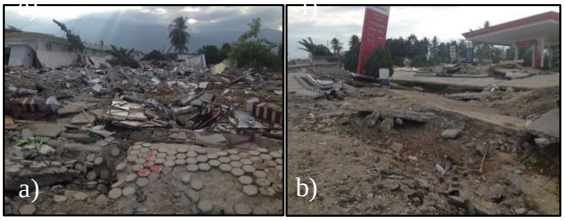

Photo 3 Damage due to liquefaction: a) Swept away homes, b) Damaged fuel station facility

TYPICAL DAMAGE OF RC STRUCTURES

Based on-site investigation, deficiencies were observed on damaged RC buildings according to Indonesian codes of SNI 03-2847-2002 [9] and SNI 03-2847-2013 [10], such as the use of plain round rebars for longitudinal and shear reinforcements of columns and beams, the absence of stirrups in beam-column joint regions, the use of stirrups with 90-degree anchorage on columns and beams, etc. These deficiencies might cause damage to building structures, as follows;

1. The total collapse of the first story that classified as soft-story collapse [11], as shown in Photo 4(a);
2. Failure of beam-column joint due to lack of transversal reinforcements in the joint region, as shown in Photo 4(b);
3. Shear failure of column caused by the use of shear reinforcements with 90-degree hooks, inadequate anchorage of hooks (Photo 4c) and the use of small rebars for stirrups;
4. Columns failed in flexure due to buckling the longitudinal reinforcements (Photo 4d);
5. Short columns failed in shear (Photo 4e);

Photo 4 Typical damage of RC structures: a) The first story collapsed due to the soft story, b) Failure of beam-column joint, c) Shear failure of short columns, d) Shear failure of columns e) Buckling of longitudinal reinforcements of a column

SEISMIC ANALYSIS OF DAMAGED BUILDINGS

Two damaged RC buildings, the Faculty of Forestry of Tadulako University and the Fire Station buildings, were thoroughly investigated. Structural specifics of both buildings were collected through on-site assessments. The Faculty of Forestry building was three-story RC frame structure building located at Jl. Soekarno-Hatta KM 9 Tondo, Mantikulore, Palu which collapsed on the first story as shown in Photo 5(a). The Fire Station building was two stories RC frame structure building located at Jl. Balai Kota Timur No. 1, Tanamodindi, Mantikulore, Palu. The Fire Station building was survived during the earthquake, but most of its columns were damaged, as shown in Photo 5(b). The calculation to identify the damaged grade of the Fire Station building is described as follow.

a). The Faculty of Forestry building of Tadulako University

b). The Fire Station building and damaged columns

Photo 5 The investigated damage buildings

Damage grade evaluation of building

The evaluation was conducted for the first story to identify the damage grade of The Fire Station building. Specifics of the building, correlated to cross-sectional dimensions of structural components, arrangements of reinforcing bars, and damages to columns, were collected on-site investigation. Based on the reference of Nagano [12], damage to the columns was grouped into five classes classified according to Table 1.

Table 1 Damage class definition of RC columns

Damage class	Descriptions of damage
I	– Visible narrow cracks on a concrete surface (crack width of less than 0.2 mm)
II	– Noticeable evident cracks on a concrete surface (crack width of about 0.2–1.0 mm)
III	– Local crushing of concrete cover – Remarkably wide cracks (crack width of about 1.0–2.0 mm)
IV	– Remarkable crushing of concrete with exposed reinforcing bars – Spalling off concrete cover (crack width of more than 2.0 mm)
V	– Buckling of reinforcing bars – Cracks in core concrete – Observable vertical and/or lateral deformation in columns and/or walls – Visible settlement and/or leaning of building

As a result, the damage classes of columns for the first story of the Fire Station building are indicated in Fig.3. The cross-sectional dimension of column C1 was 350x650 mm with 12ϕ19 longitudinal reinforcements and a hoop of ϕ8-100. The damage degree was decided according to the residual capacity index, R, calculated by Eq. (1) [12].

$$R = \frac{\sum_{j=0}^{5} \eta_j . A_j}{A_{org}} \quad (1)$$

where, A_j and A_{org} are the total numbers of columns possessing damage class 0 through V and the total number of the columns, respectively. η_j is seismic capacity reduction factor from Table 2.

Table 2. Damage class definition of RC columns

Damage class	Brittle column ($h_0/D \leq 3$)	Ductile column($h_0/D > 3$)
I	0.95	0.95
II	0.60	0.75
III	0.30	0.50
IV	0.00	0.10
V	0.00	0.00

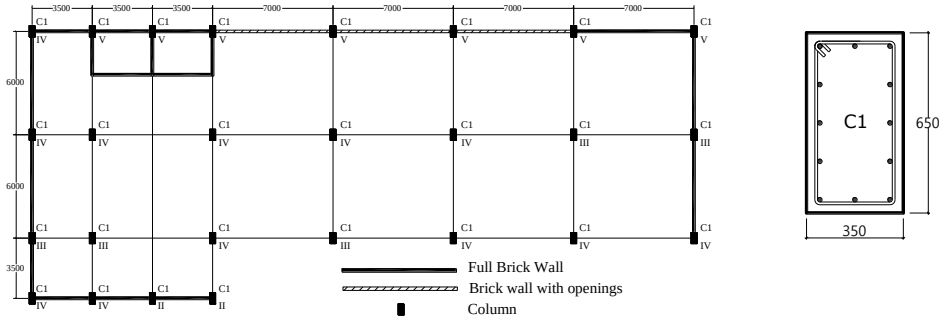

Fig. 3 Floor plan first story and damage class of columns of Fire Station building

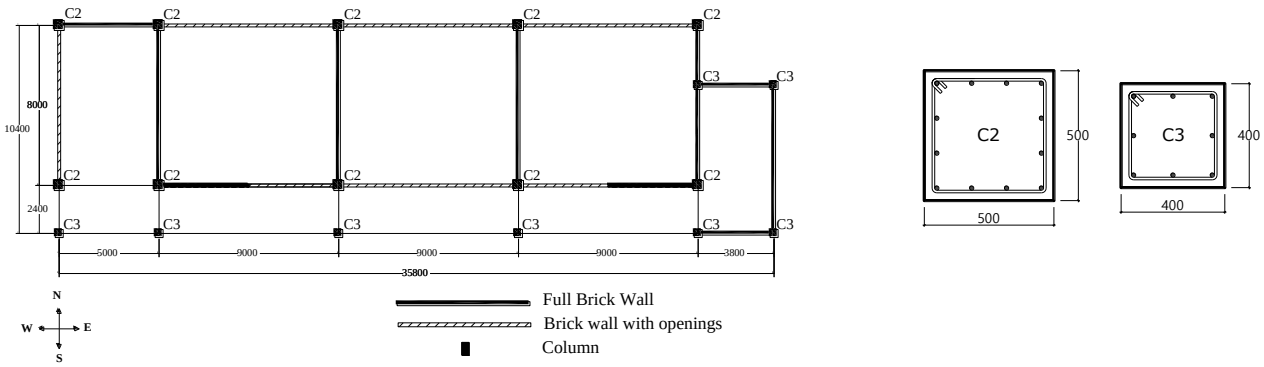

Fig. 4 Floor plan first story of Faculty of Forestry building of Tadulako University

where, h_0 is a clear height of the column, and D is column depth. Based on R-value, that are slight damage with 95 % ≤ R, light damage with 80 % ≤ R < 95 %, moderate damage with 60 % ≤ R < 80 %, heavy damage with R < 60 %, and collapse with R ≈ 0, the damage grade for the first story of the Fire Station building was classified as "a severe damage". On the other hand, the first story of the Faculty of Forestry building was totally collapsed.

Seismic performance of investigated buildings

Seismic performances of the Fire Station building and Faculty of Forestry building were evaluated based on the Japanese standard [13]. The seismic performances of both buildings were analyzed in each direction only for the first story, where the most severe damage was found out to both buildings. The rebars arrangement of the columns of each building is shown in Fig.3 and Fig.4. In the case of Forestry building, the cross-sectional dimension of column C2 was 500x500 mm with 12D22 longitudinal reinforcements and column C3 was 400x400 mm with 8D22 as shown in Fig.4. The stirrups of C2 and C3 were ϕ10-100. The infill walls were neglected in the seismic calculation assuming as non-structure, however, the partial walls were taken into account to calculate the clear heights of the columns.

Based on the reference of [13], the calculated seismic performance of the building was presented in the relationship between the cumulative strength index, C and ductility index, F. The C index was calculated by Eq. (2) [13,14, 15]

$$C = C_i + \sum_j \alpha_j \, C_j \tag{2}$$

$$C_i = \frac{Q_{ui}}{\Sigma W} \tag{3}$$

where, C_i: the strength index of the i-th group of columns having the same ductility index, calculated using Eq. (3), C_j: the strength index of the j-th group having the same ductility index larger than that of i-th group, α_j: the effective strength factor of the j-th group for considering differences between yield deformations of i-th and j-th groups as described in [13]. Q_{ui} is the ultimate lateral load-carrying capacity of the i-th group of columns which is evaluated as the smaller value between the shear force at flexural yielding, Q_{mu}, and the ultimate shear strength, Q_{su}, which are calculated by Eqs. (4) and (6), respectively [13, 14]. ΣW is the total weight of the building.

$$Q_{mu} = \frac{2M_u}{h_0} \tag{4}$$

$$M_u = 0.8\, a_t.D + 0.5N.D\left(1 - \frac{N}{b.D.f_c}\right) \tag{5}$$

$$Q_{su} = \left[\frac{0.053.p_t^{0.23}.(18+f_c)}{\frac{M}{(Q.d)}+0.12} + 0.85\sqrt{p_w.\sigma_{wy}} + 0.1\sigma_0\right] b.j \tag{6}$$

where, p_t is tensile reinforcement ratio calculated ($p_t = a_t/(b.D)$), M/Q is shear span length in which the default value is $h_0/2$, d is effective depth of column, p_w is shear reinforcement ratio calculated by ($p_w = a_w/(b.s)$), σ_{wy} is yield stress of shear reinforcement, σ_0 is axial stress in column (σ_o=N/(b.D)), j is the distance between tension and compression forces, default value is 0.8D. a_w is the cross-sectional area of shear reinforcing bars, s is spacing of hoops. If the value of M/(Q.d) is less than unity or greater than 3, the value of M/(Q.d) to be unity or 3, respectively, and the value of σ_0 is not more than 8 N/mm2.

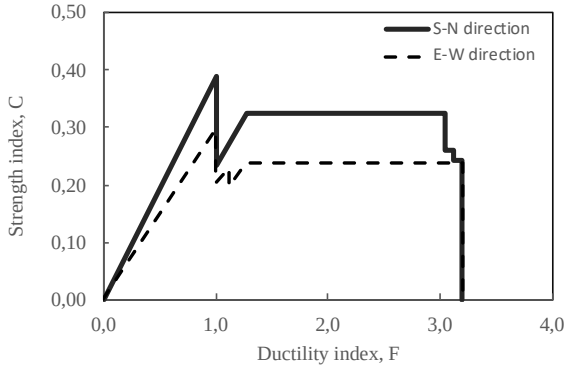
The F index, which represents deformability of column, was calculated by Eq. (7) for the shear column. The F index for the flexural column was determined by Eq. (7) in the case $R_{mu} < R_y$ and by Eq. (8) in the case $R_{mu} \geq R_y$ [13]. This index, excepting extremely short ones, ranges between 1.0 and 3.2, which corresponds to a lateral drift ratio of 1/250 and 1/30, respectively.

$$F = 1.0 + 0.27\,\frac{R_{su}-R_{250}}{R_y-R_{250}} \tag{7}$$

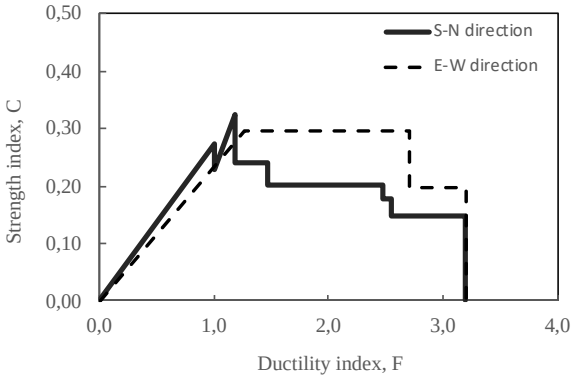
$$F = \frac{\sqrt{2R_{mu}/R_y - 1}}{0.75\left(1+\frac{0.05R_{mu}}{R_y}\right)} \leq 3.2 \tag{8}$$

where, R_{mu} is the drift angle at the ultimate flexural strength of column = (h_0/H_0). ${}_cR_{mu} \geq R_{250}$, ${}_cR_{mu} = {}_cR_{my} + {}_cR_{mp} \leq {}_cR_{30}$, ${}_cR_{mp} = 10(Q_{su}/Q_{mu} - q).{}_cR_{my} \geq 0$, q = 1.0 for S≤ 100 mm, q = 1.1 for S >100 m. s: spacing of hoops, h_o= clear hight of the column, and H_o= height of column from bottom to top of the lower floor slab. ${}_cR_{150}$ = standard drift angle of column (measured in the clear height of column), 1/150. ${}_cR_{250}$ = standard drift angle of column (measured in the clear height of column), 1/250, R_{250} = standard inter-story drift angle, 1/250.

Consequently, a distinct difference in seismic performance was obtained in both investigated buildings, as shown in Fig.5. The maximum strengths are in South-North direction according to the C index of 0.39 and 0.32 for the Fire Station and Faculty of Forestry buildings, respectively. The strengths in the South-North direction of both buildings were dropped first at ductility index F of 0.1 due to failure of short columns. In the case of the Fire Station building, Its strength was maintained about 0.32 of C index after yielding point up to ductility index F of 3.05 as shown in Fig.5(a).



a). Fire Station building



b). Faculty of Forestry of Tadulako University building

Fig. 5 Seismic performance of the investigated buildings

In the case of the building of Forestry Faculty, the strength capacity gradually dropped to 0.15 in the plastic region, as shown in Fig.5(b). Although its strength index of 0.29 was retained up to 2.7 ductility index in E-W direction, these values are low strength capacity and not ductile enough for a building which is located in a high seismic area. This result indicates that the building can be survived during the earthquake when it has strength index more than 0.3 with large plastic deformation.

CONCLUSIONS

According to a post-earthquake investigation conducted after the September 2018 Palu earthquake, several typical damages on building structures and house were observed such as the total collapse of RC buildings, the failure of beam-column joint, the flexural failure of columns, the shear failure of short columns, and the failure of masonry infills. A further analysis was conducted on two damaged buildings, one was survived building, and the other was collapsed on its first story. As a result, the survived building classified as severe damage. The survived building was able to maintain its lateral strength with large deformation. Therefore, it is concluded that the building can survive during the earthquake if such building has high strength capacity in large plastic deformation.

ABSTRACT

Renewable energy is rapidly becoming the alternative to fossil fuel-based energy generation. With new innovative advances in renewable energy technology and the market improving, solar panel prices have become more affordable. Currently more and more countries are opting for solar power energy. Owing to urbanization and population increase on flat terrains, finding flat lands to accommodate this technology is becoming more difficult. Solar installation on slope terrains can provide an alternative solution to this problem. This concept is relatively new with only a handful of companies that have already designed and installed solar panels on slopes. This paper aims to provide a review of current practices used for installation on flat and sloping grounds. Furthermore, the potential effects of solar panel installation on slopes, such as slope instability and a number of foundation design considerations are identified.

Keywords: Slope, Solar panel installation, Foundation design, Slope instability

1. INTRODUCTION

Solar energy generation is a fast and effective way to produce clean energy without causing harm to the environment as seen when using fossil fuel energy generation. Solar energy has also increased in generation as compared to previous years. According to the International Renewable Energy Agency [1], solar energy generation increased 35% in 2017 compared to 2016.

One of the main forms on solar energy generation is using solar PV panels which require land to be utilized. Due to the different terrains solar PV farms can vary from the area of land used. A report done in the United States showed that on average a large fixed tilt PV plant that generates 1GWhr/year requires 2.8 acres or 11.33km^2 [2]. As seen in many solar projects around the world, flat lands are traditionally used because it is easily accessible and does not require landscaping. But now with increasing population and urbanization, most flat lands are being used for other development purposes. Therefore, unused sloping terrains is the answer to solving this problem.

Of course, these inclined terrains need to be thoroughly studied before any solar system is placed on them. The main siting factors include land topography, type of land use, proximity to load demand, accessibility and proximity to existing and planned transmission lines [3,4].

The installation technique and types of materials used for the solar panels also needs to be taken into consideration because sloping terrains pose different problems compared to flat terrains. For example, slope angle and height will play a pivotal difference and may take more time in installing panels.

Finally, a main topic of interest that has little research done is the effect the solar panels play on the slope stability. A failure in a slope occurs when a mass of soil beneath the slope slides or fails [5]. Internal factors such as material composition, physical and mechanical indexes, the topography, rock mineral composition, soil and rocks geological structure surface and slope shape can all influence a slopes stability [6]. The foundation type, position on slope and different parameters of the foundation (depth, load, etc.) for a solar panel may affect the integrity of a slope.

The use of sloping terrains with solar PV systems has only been used in very few countries and little research has been conducted in this area. This paper will review the present state of solar PV panel systems on sloped terrains.

2. CURRENT PRACTICES

There are very few companies who have managed to place solar PV systems on inclined terrains, and so this section will look at some examples from these projects in Japan. While also reviewing the various methods and factors that played a role in the completion of each project.

The first large-scale solar power plant known as the “Dream Solar Higuchi Nagasaki” is located in Togitsucho, Nishisonogi-gun, Nagasaki Prefecture, and construction was completed on September 2015 by the Daiwa Lease Co Ltd (Fig.1) [7]. This solar power plant has an output of about 15MW and is located on the southern slopes of a former hilly golf course.

The initial planning of the solar power plant was carefully taken into consideration, as well as the types of foundations for the solar panels. Since the mountain terrain was previously a golf course the Daiwa Group optimized on the situation and did not

do major landscaping of the slope, instead the company only cut down a few trees on site in order to array solar panels more evenly.

Fig.1: Aerial shot of the "Dream Solar Higuchi Nagasaki" (Source: Daiwa Lease/Daiwa House Industry)

Mortar was also used in some areas to prevent landslides. Water discharge capacity was a major concern for residents living close to the power plant, with landslides posing a risk. Therefore, with this risk in mind, the Daiwa Group maintained all previous water discharge facilities from the golf course and covered all areas under the solar panels with anti-weed sheets. The anti-weed sheets would help in the land's water retaining function because these sheets permeability are almost equivalent to that of previous grass on the ground surface. Next, the company used four different foundation methods in accordance with the slope and terrain of the area (Fig.2).

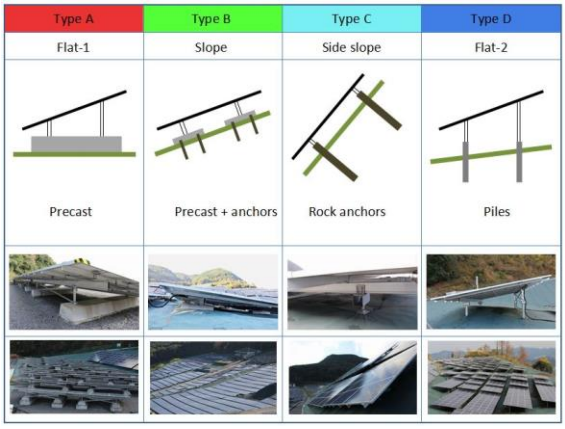

Fig.2: The four types of foundations used in accordance to area and shape of the terrain. (Source: top, Daiwa Lease/Daiwa House Industry; bottom, Nikkei BP; bottom, Photos of Type B Daiwa Lease/Daiwa House Industry)

The first type was a concrete secondary product foundation for flat areas (Type A). Next, on slight slopes a concrete precast foundation was used along with spiral anchors (Type B). For the slopes that were angled even higher a rock anchor foundation was used (Type C). The last type used was the steel tube-based pile foundation, in which a pile driving machine crushed the bedrock and boulders, while driving the pile foundation into the ground (Type D).

Afterwards, installation of the solar panels on the side slopes was done by lifting and supporting the panels with cranes, while the workers, secured by holding fixtures with ropes attached to them, helped to assemble the panels correctly (Fig.3). It should also be noted that the panels were fixed with the mounting system rails in advance before being lifted by the cranes.

Fig.3: Installation of solar panels on side slopes. (Source: Daiwa Lease/Daiwa House Industry).

Another mega solar power plant was constructed at the hills north of Nagasaki Fishing Port on a steep south-facing roadside slope by Sakuranosato Mega Power JV [8]. This solar power plant has 2.141MW output and is known as the "Sakuranosato Mega Power Plant" which was completed in October 2015 (Fig.4).

Fig.4: "Sakuranosato Mega Power Plant" located on a steep south-facing roadside slope. (Source: Nikkei BP)

The main challenge when constructing this solar power system was the angle of the slope which was 30º, a very steep slope. As a result of this steep slope almost no heavy machinery was used in construction. In the middle of the solar power plant there is road that runs east-west and this road was used when heavy trucks and crane vehicles needed to load or offload heavy materials. Transformers and PV inverters were

set up on this road afterwards. Furthermore, a monorail was set up to from bottom to top to transfer construction materials (Fig.5). Portable stairs (newly constructed) and pre-existing lanes running from east-west every 7 meters from the top of the slope were used as well. Next, steel pile foundations were first considered as is seen often on slopes, but due to the unavailability of heavy machinery a new type of foundation installation method was used.

Fig.5: A monorail was constructed to transfer heavy materials. (Source: Toda Corp)

The company decided on using a net as square mold measuring 45 x 45 x 25cm, steel beams were buried in the four corners and center of the square mold (Fig.6). Then mortar was sprayed inside and around forming the foundational structure of each panel (Fig.7). As for drainage capacity, no additional facilities were introduced, the facilities that had been used with the roadside slope was used without modifications.

Figure 6: Foundation method using a net square mold. (Source: Toda Corp)

3. RESEARCH GAP

The interaction between slopes and foundation of solar panels is a complicated topic and requires a great deal of study. Since there is no data on this matter found, deep stabilizing piles embedded in slopes to help reinforce slopes is a good reference to start with this research. Ashour [9], mentions that piles and soil interaction used in slope stabilization is difficult phenomenon due to its 3-dimensional nature and can be influenced by many factors such as the characteristics of deformation and the strength parameters of both pile and soil. As shown in Fig. 8, the driving force that acts along the pile segment above the slip surface is transmitted to the lower (stable) soil layers.

Fig.7: Foundation method of "spraying" mortar in a square mold with buried steel beams was used. (Source: Nikkei BP)

This is the typical reaction seen when piles are used in stabilization of slopes. But piles seen in the above cases do not have the typically long depth which is needed to penetrate the sliding surface.

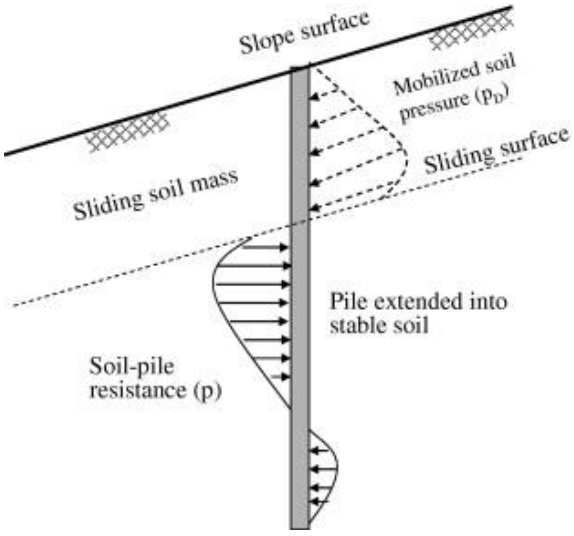

Fig.8: Pressure from the sliding soil mass is transferred to the more stable soil. (Source: Ashour, 2011)

Hence, further information on shallow foundation on slopes and its affects is needed. According to a study on embedded length of piles for slope reinforced with one row of piles [10], showed that the

factor of safety improves as the pile length increases and tends to remain constant after exceeding the critical length. Also, the paper concluded that the critical pile length for slopes with clayey soils is smaller than that for sandy soils for free head piles. There have been other studies as well on the embedded length of piles subjected to lateral soil movements or in unstable slopes. However, there has yet to be research on the short pile length that are in the upper unstable soil and with a load and its effects on the slope.

4. FUTURE RESEARCH

4.1 Proposed Methodology

Further research is needed in order to fully understand the effects of solar panels placed on slopes have on the overall stability of a slope. A proposed methodology for this research could be a numerical simulation with clearly defined parameters for both the slope and piles. The slope would have to have clear measurements such as slope angle, height, slope stability before and after installment of solar panels, shear strength, etc. And the piles would have a given load seen in regular solar panels and various spacing and embedded lengths to see the changes occurred from such variables.

4.2 Research Questions

Some of the research questions that may bring a clearer picture to further research ideas on this topic are presented below:

- What are the best foundation types for solar panels on slopes?
- What is the maximum or optimum slope angle for solar panels to be placed on slopes?
- What is the reduction of lateral capacity of the pile in slope?
- What is the reduction of pull-out capacity of the pile in slope?
- What is the factor of safety before and after installation of solar panels on slope?
- What is the optimum embedded length of pile that would not affect the factor of safety?
- What are the effects of seismic forces that act on the slope with and without the solar panels installed? Is there a difference?

5. CONCLUSION

This paper brings to light that solar panels on slopes is a great way to effectively use sloping land that would otherwise be left idle. After reviewing the current industry practices, a number of research questions were raised for answer in the future. The effect of pile installation on the overall stability of slope and the reduction of pile capacity with respect to the lateral loading and pullout force were identified as the key research items in the near future. This paper has also highlighted the need to bring industry partner and government body to join the research program.

6. ACKNOWLEDGEMENT

The first author would like to express his gratitude to the Japanese International Cooperation Agency (JICA) for providing scholarship to study and research at Mie University, Japan.

ABSTRACT

In designing an effective and economical hydraulic structure for flood control, an optimal design of rain gauge network is important as it produces fast, accurate and important rainfall data. In this paper, the geostatistical method integrated with a hybrid of particle swarm optimization-simulated annealing is used to simulate the optimal locations and number of raingauges station. The simulation process used different generated rainfall data based on real rainfall data. The rainfall data randomly generated based on the exponential semivariogram model and it showed similar characteristics with the mean and standard deviation of real rainfall data. The proposed method successfully obtained the optimal number of rain gauges despite different sets of generated rainfall data. This situation shows that the proposed method is adequate to be applied in another case study, in other places or different data.

Keywords: Rain Gauges, Geostatistics, Particle Swarm Optimization, Simulated Annealing

INTRODUCTION

Numerous water resources management tasks such as water budget analysis and assessment, flood analysis and forecasting, streamflow estimation, and design of hydraulic structures, employed rainfall data provided by a reliable and optimal rain gauge network. Accurate and precise data will help the researchers to minimize the hydrological and economic risk and errors involved in different water resources projects. An optimal and well-designed rain gauge network thus should contain an appropriate number of rain gauges, which reflect the spatial and temporal variability of rainfall in a catchment [1].

Thus, identification and selection of the optimal rain gauge network configuration with optimal number and locations of rain gauge stations is the main objective of the network design. Hence, the optimal rain gauge network should contain the number and locations of rain gauge stations in such a way that it can produce optimum rainfall information and data with minimum uncertainty and cost [1]-[3]. One can approach the problem either by removing redundant stations from the network to minimize the cost or by expanding the network with the installation of additional stations to reduce the estimation uncertainty [4]. Some studies applied the kriging technique in combination with other techniques such as entropy [1] and multivariate factor analysis [5] for the network design. A few studies also combined optimization method based on simulation tools (e.g. simulated annealing) with the kriging technique [2], [6],[7] to obtain the optimal rain gauge network.

A network design methodology was developed in this paper to determine optimal number and locations of the existing stations in the current rain gauge network located in the Johor state, Malaysia using geostatistical and hybrid of particle swarm optimization-simulated annealing (PSO-SA) as an optimization method. A simulation is performed to verify the ability of the optimization method to determine the optimal number of raingauges using randomly generated rainfall data by the semivariogram model selected. The major contribution here is that unlike the work of [2], the developed methodology considered the hybrid of PSO-SA technique as an optimization method which capable of escaping from a local optimum with fast convergence.

METHODOLOGY

Geostatistical Method

The network design problem consists in obtaining the number *N* and the location of rain gauges stations that give the best estimate areal mean rainfall. An estimation variance σ^2 is a basic tool of variance reduction techniques for optimal selection of sampling locations. A semivariogram must be modelled for the application of the variance reduction method to the optimal location of sampling sites.

A semivariogram $\gamma(h)$ is one of the significant functions to indicate spatial correlation in observations measured at sample locations. Semivariogram is represented as a graph that shows the difference in measure with a distance between all pairs of sampled locations. The estimated variance depends on the semivariogram model, the number *N* of rain gauges and its spatial location. Therefore, choosing an appropriate semivariogram model is vital in determining the optimal estimation variance.

Let *h* be the lag or distance, and *Z* be an intrinsic random function and let $Z(x_i)$, for $i = 1,2,\ldots,N$ be a sampling of size *N*. Then the following expression is an unbiased estimator for the semivariogram of the random function:

$$\gamma(h) = \frac{1}{2n(h)} \sum_{i=1}^{n(h)} [Z(x_i + h) - Z(x_i)]^2 \quad (1)$$

Equation 1 is used to compute experimental semivariogram from the data under study. By changing *h*, both in distance and direction, a set of the sample (or experimental) semivariograms for the data is obtained [8].

The exponential semivariogram models are selected to fit the data. The exponential semivariogram model equation is as follow:

$$\gamma(h) = C\left(1 - e^{-\frac{3h}{a}}\right) \quad (2)$$

where *C* is the sill and *a* is the range.

Once the model of the semivariogram is fixed, the estimation variance only depends on the number *N* and the location of the rain gauges. To calculate the estimation variance using ordinary kriging,

$$\sigma^2(x_0) = 2\sum_{i=1}^{k} \lambda_i \gamma(x_i, x_0) - \sum_{i=1}^{k}\sum_{j=1}^{k} \lambda_i \lambda_j \gamma(x_i, x_j) \quad (3)$$

Where

$$\hat{Z}(x_0) = \sum_{i=1}^{k} \lambda_i Z(x_i) \quad (4)$$

Subject to $\sum_{i=1}^{k} \lambda_i = 1$.

This is an algorithm for the ordinary kriging estimation to calculate the estimation variance [9]:

1. Calculate each term in matrix *G*.

   Let x_i 's be the sampling sites of a sample subset of size k, $i = 1,2,\ldots,k$ and let $\gamma(x_i, x_j)$'s be the experimental variogram. Then the *G* is the matrix

$$G = \begin{bmatrix} \gamma(x_1,x_1) & \gamma(x_2,x_1) & \cdots & \gamma(x_k,x_1) & 1 \\ \gamma(x_1,x_2) & \gamma(x_2,x_2) & \cdots & \gamma(x_k,x_2) & 1 \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ \gamma(x_1,x_k) & \gamma(x_2,x_k) & \cdots & \gamma(x_k,x_k) & 1 \\ 1 & 1 & \cdots & 1 & 0 \end{bmatrix} \quad (5)$$

2. Calculate each term in matrix g.

Let x_0 be the estimation location, then the *g* is the matrix

$$g = [\gamma(x_0,x_1) \quad \gamma(x_0,x_2) \quad \cdots \quad \gamma(x_0,x_k) \quad 1]' \quad (6)$$

3. Solve the system of equations

$$GW = g,$$

$$W = gG^{-1},$$

Where $W = [\lambda_1 \quad \lambda_2 \quad \cdots \quad \lambda_k \quad -\mu]$.

4. Calculate the ordinary kriging estimation variance

$$\sigma^2(x_0) = g'W = g'G^{-1}g. \quad (7)$$

Hybrid of Particle Swarm Optimization and Simulated Annealing

The basic idea of the hybrid optimization study in this research is based on running PSO algorithm first and then improving the result by employing simulated annealing. The most significant character of SA is the probabilistic jumping property, i.e. probability to accept a worse solution to be a new solution. Therefore, through the integration of SA to PSO, the proposed algorithm is capable of escaping from a local optimum with fast convergence. Based on the PSO and SA characteristics, the whole procedure of PSO-SA is described as follows:

1. Initialization:

1a. Randomly initialize the *x* particles representing different combinations of *N* rain gauge placements.

1b. Evaluate each particle in the population using the fitness function in Eq. (7) and minimum fitness function is set as *pbest*.

1c. Set all parameters, including c_1 and c_2, $v_{\max}$, initial temperature T_0, cooling rate α.

2. Repeat this step until the stopping criterion is satisfied:

2a. Evaluate the velocity and position of each particle by Eq. (8) and Eq. (9).

2b. Calculate the fitness of each particle, x'.

2c. Calculate $\delta = f(x') - f(x)$ and then randomly generate a number $\theta \in (0,1)$. If $\delta < 0$, as the objective is to minimum, meaning that the new position is improved, then the new position is accepted as the new position of particle *i*. Otherwise, a new position is accepted according to the following criterion: $\theta > e^{\frac{-\delta}{T_k}}$. Proceed to step 2d when the velocity of all particles are determined or return to step 2a for

those particles failing to be accepted and generate new velocities using the same evaluation process.

2d. Renew each particle to the new velocity and position and modify *gbest* and *pbest* by a simple comparison of their fitness values.

2e. When the evolution process has achieved a stopping criterion (or maximum iteration is reached), proceed to step 3, otherwise, modify the annealing temperature and return to step 2.

Output the best solution *gbest* and its fitness value. The output is the optimal number and location of stations with the minimum estimated variance.

Optimization Procedure

The optimization model to determine the optimal number and locations of rain gauge formulated mathematically as below.

Minimize

$$\sigma^2(x) = 2\sum_{i=1}^{k} \lambda_i \gamma(h_{i0}) - \sum_{i=1}^{k}\sum_{j=1}^{k} \lambda_i \lambda_j \gamma(h_{ij})$$

subject to

$$\sum_{i=1}^{k} \lambda_i = 1$$

where

$$\gamma(h) = C\left(1 - e^{-\frac{3h}{a}}\right)$$

RESULTS AND DISCUSSION

The optimization procedure to determine the optimal number of raingauges using the real rainfall data shows 59 raingauges stations, as in [10]. This procedure is performed by using monsoon rainfall data. It is because Johor recorded high rainfall amount during monsoon season. This procedure is needed to be verified by performed a simulation with randomly generated rainfall data.

For the simulation process, the rainfall data randomly generated based on the exponential semivariogram model obtained previously in Eq. (2) The semivariogram model used to estimate the rainfall data for each location as the geostatistics is a method of interpolation itself. The generated rainfall data is shown in Table 1. The true value for mean and standard deviation are 335.37mm and 490.63mm, respectively.

The box and whisker plot has been constructed to determine the variability of the mean and standard deviation of the simulated rainfall data as compared to the real rainfall data from monsoon season. It is due to the boxplot ability to interpret the asymmetric aspects of the data [11]. From Fig. 1 and Fig. 2, it shows that the boxplot manages to accurately capture the mean and the standard deviation of the real monsoon data. Indirectly, this proves that the exponential semivariogram model previously obtained is the best fitted and accurate model to represent the rainfall data. The estimates rainfall data showed similar characteristics to real data with the mean and standard deviation that is almost the same with real monsoon data.

Table 1 Mean and standard deviation for 30 generated rainfall data.

No.	Mean (mm)	Standard Deviation (mm)	No.	Mean (mm)	Standard Deviation (mm)
1	342.97	556.37	16	353.27	538.03

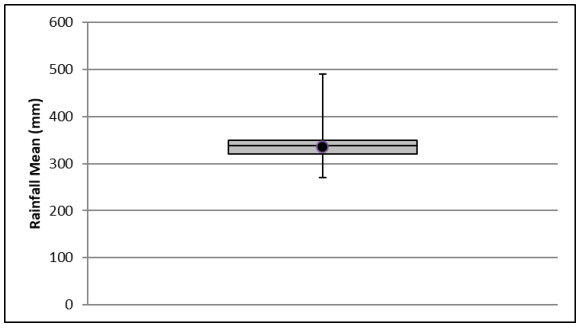

Fig. 1 Box and whisker plot for rainfall mean (mm).

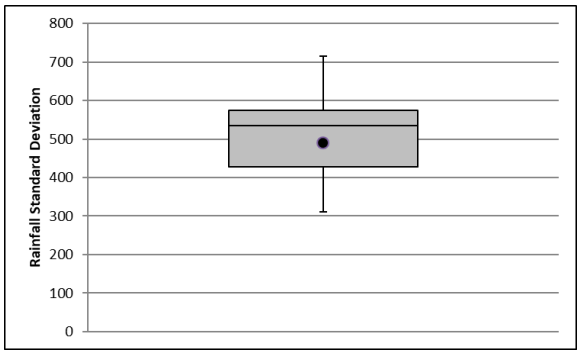

Fig. 2 Box and whisker plot for rainfall standard deviation.

The proposed method has been simulated 30

times, with 30 different generated rainfall data based on monsoon rainfall data. The computing procedure to obtain the optimal number and location for each data are repeated using the proposed method after the rainfall data has been successfully generated. The results are shown in Table 1 below.

The proposed method managed to determine the optimal number of rain gauges for each simulation. The optimal number of rain gauges for each simulation is not the same. This is because of the different generated rainfall data will give a different number of optimal rain gauges.

14	56	29	59
15	56	30	55

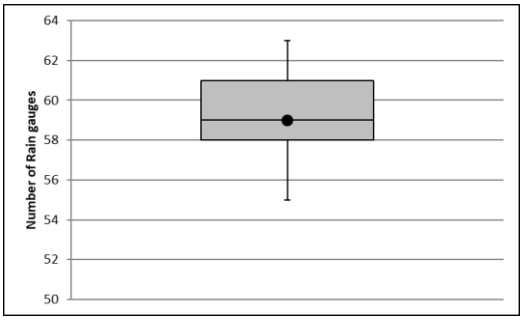

Fig. 3 Box and whisker plot of the number of rain gauges for 30 simulations.

Box and whisker plot (boxplot) used to investigate the symmetry of the results. The form of the box and whisker plot shown in Fig. 3 here is a graphical 5-number summary of a given dataset, which includes: the median, the interquartile range (shown by the box), the maximum and minimum value from Table 2. The distribution is shifted to the right; the mean should be greater than the median. From the plotted boxplot, the minimum number of rain gauges network is 55 rain gauges, and the maximum is 63. The median is 59, same as the results in [10]. In this case, the median is shifted toward the lower portion of the box with a wider range of observations in the upper quartile as compared to the lower quartile [11]. The box and whisker plot manages to capture the optimal value of the rain gauge network very well, and it proves the stability of the proposed method. Overall, the proposed method successfully obtained the optimal number of rain gauges despite different sets of generated rainfall data. The optimal locations of the generated shown in Fig. 4(a) and Fig. 4(b).

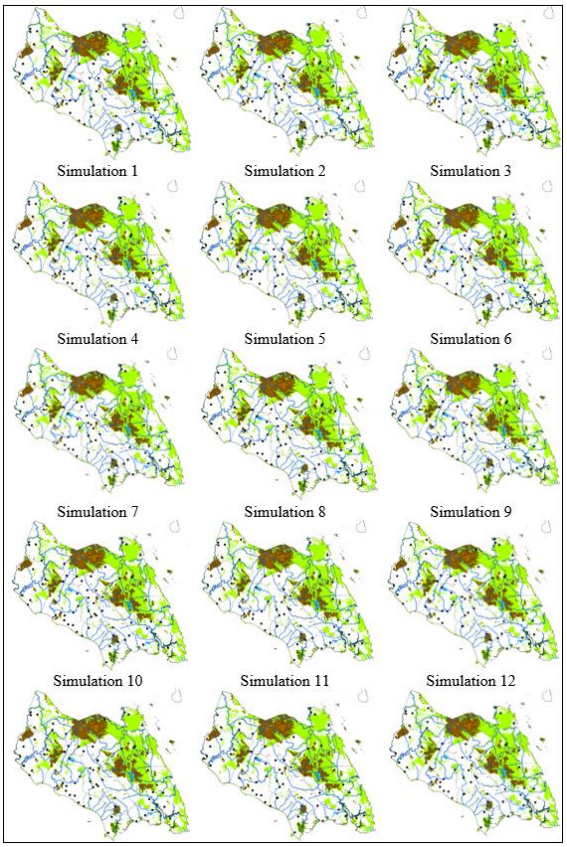

Fig. 4(a) The optimal locations for the raingauges stations.

CONCLUSION

The combination of PSO and SA successfully develop a new optimization method to determine the optimal number and location of the rain gauges in Johor. To this point, the unique characteristic of PSO and SA is utilized to form a PSO-SA hybrid optimization model. PSO ability to change the pace of the optimization procedure and SA ability to find new angles of solution at times when it is trapped in local optima has been a key factor in the optimization process. The simulation results verified the stability of the newly proposed method in determines the optimal number and locations for the rain gauge network. The optimal rain gauges network is essential

in helping understanding the rainfall patterns and acts as a guide in water resource management for extreme events like flood and drought. The optimal rain gauge network also helps us plan responses to droughts and floods, especially in flood prediction, flood warning and flood risk management. Since all of these events frequently occurred during the monsoon season, thus the results of monsoon data are the most appropriate result to be implemented in Johor.

ABSTRACT

The food industry has a lot of wastes from production processes, that are beneficial to the possible when used of by-product to reduce environmental pollution. There were research reports related to the production of various type of cereal drinks by using cereals as raw materials. The objective of this research was to study the optimum ratios of riceberry residues, agar and water on health drink production. There were four experiments: Experiment 1: (control formula) blended riceberry and water 30:70, Experiment 2: blended riceberry and water 15:85, Experiment 3: blended riceberry and water 20:80 and Experiment 4: blended riceberry and water 25:75 were obtained. The results from physical measurement (L*,a and b*) were significantly different ($P \leq 0.05$). The study chemical of measurements, i.e. pH, percentage of acidity and total soluble solid were performed. The results showed that Experiment 2 had the lowest pH and gave the highest percentage of acidity values of 5.96 and 0,28, respectively. The microbiological properties revealed that amount of microorganism in each treatment was not found. The sensory evaluation used a 9-point hedonic scale. The results indicated that Experiment 3 had the highest scores of overall liking. Based on the obtained data, the formulation of beverages produced from residues, there is a high possibility of using the residues from production process. It can be developed health drink to be accepted by consumer, which has increased steadily and reduced the amount of wastes that must be disposed of pollution that is toxic to the environment.

Keywords: Riceberry, Water, Health, Drink

INTRODUCTION

At the present, Thailand food industries generate large amount of wastes or by-products annually from a variety of raw material sources. In that food wastes or by-products are an excellent source of nutraceuticals, bioactives, inherently functional and possess many components that are good for human health. Food industrial wastes or by-products convert to the functional food ingredients, it is the healthy trends in the food industry. The waste management is one of the major parts of food industries. The large volume of the low cost by-product gives economical benefit of its potentially valuable components and environmental benefits. Therefore, the utilization of by-products to health beneficial product and economic benefit to labour and country. Now, as people become increasingly take care of the relation between foods and good health. Consumer attitude towards health foods is promising development and the scope of functional foods is growing very fast in Thailand. Consumers believe that foods are taken directly effects on their health as a good or as a bad. The market for the functional foods has seen a tremendous demand in the recent years. Today foods are not only used to demand our hunger but also to provide major and minor nutrients for human life and these nutrients having the health benefits, protecting and controlling from the diseases [1]. Rice is one of the commonly used stable foods around the world. The distribution of the rice anthocyanins depends on the rice cultivars. The consumption of colored rice varieties is increasing among the people, because of its health benefits. Riceberry is a good example as registered rice variety from Thailand, a cross-breed of Jao Hom Nin (JHN), a local non-glutinous purple rice and Khoa Dawk Mali 105 (hom mali_rice). The variety was created by the Rice Science Center, Kasetsart University, Thailand. The research for nutritional properties, anthocyanin stability, and physical and cooking properties is a deep purple whole grain rice with softness and a palatable aftertaste. Riceberry has been a popular brown rice due to its health promoting properties. Inducing people to consume more brown rice could help ameliorate food-related chronic diseases like diabetes, heart disease, high blood cholesterol, obesity, and cancers [2]. Agar is a mixture of two components: the linear polysaccharide agarose and a heterogeneous mixture of smaller molecules called agaropectin. It forms the supporting structure in the cell walls of certain species of algae, and is released on boiling. Agar has been used as an ingredient in dessert. Agar can be used as a laxative, an appetite suppressant, a vegetarian substitute for gelatin, a thickener for soups, in ice cream, and beverage, as a thickening agent. Agar is the phycocolloid of most ancient origin. Water contributes to the formation of gels in food. Originally, and even in the present times, it

was made and sold as an extract in solution (hot) or in gel form (cold), to be used promptly in areas near the factories; the product was then known as tokoroten [3]. Since this research focuses on the use of food waste residues for added values, therefore, the riceberry residues from the riceberry production process has been utilized since it still contains the necessary nutrients. There are some researches related to the processing of healthy beverages from Homnil rice by studying to optimize a suitable ratio between rice flour and water at 1:20, 1:30 and 1:40 ratios with rice flour extraction temperature at 50°C. The types and amount of sweeteners were 60°Brix sucrose syrup and 60°Brix. The banana syrup at concentration levels of 7 and 9°Brix. and amount of gelatin stabilizer were used at 0.0, 0.1, 0.2, 0.3 and 0.4 percent and suitable period for disinfection at 90°C was studied at 15, 20, 25 and 30 mins. It was found that the most suitable ratio between rice flour and water was 1:30. The batter viscosity was 14.73 centipoises, with pH, total soluble solids, protein content, fat content, and fiber content of 6.71, 1.1, 0.23, 0.05 and 0.83 percent, respectively. The amount of anthocyanin was 0.37 mg/ml. From adjustment of total soluble solids, it indicated that the use of 7°Brix sucrose syrup was most acceptable from testers in taste, texture, and overall liking ($p \leq 0.05$). The use of 0.3 percent gelatin (by weight) resulted in wholeness of the beverage, without layers. The beverage had viscosity of 18 centipoises, pH of 6.4, total soluble solids of 9.8 percent, and anthocyanin content of 0.7 mg/ml. It was also found that with disinfection at the temperature of 90°C for 25 minutes, the beverage could be kept for 15 days at the temperature of 4-6°C with standard amount of microbes [4]. The study on preparation of enhancing GABA in germinated brown rice and its products were conducted during 2008-2010 at Pathum Thani Rice Research Center, Thailand. The results revealed that an appropriate method was malting of selected healthy brown rice in a closed container at room temperature for 20 hours after the seeds being washed with clean water and steeped for 4 hours. This freshly malting rice can be used for making blended drinks of germinated brown rice by pre-boiling with intermittently stirring the mixture of ingredients as germinated Khao Dawk Mali 105 : germinated black glutinous rice: overnight steeped soy bean: roasted white sesame: water at a ratio of 1: 0.5 : 0.3 : 0.3 : 20 by weight for 20 mins. Filtering the mixtures twice and adding 5 g of sugar per 100 ml of the mixtures. The processing of instant germinated brown rice was also conducted by pre-preparation of soy milk from a mixture of overnight soaked soybean: roasted white sesame: water at a ratio of 1 : 0.8 : 14 by weight. Rice starch mixture was then prepared by mixing germinated Khao Dawk Mali 105 : germinated black glutinous rice: soy milk at a ratio of 7:3:9 by weight and wet milling. The mixture was dried with a double drum drier then ground to fine powder. Eight g of germinated rice powder were then mixed with 5 g of fine sugar, 4 g of maltodextrin and 2 g of non dairy cream packed in aluminium foil sachet. The another experiment was conducted at Ubon Ratchathani Rice Research Center using cooked germinated Khao Dawk Mali 105 and water at a ratio of 1 : 1 by weight. The mixture was slurred and drum dried prior to ground into powder. The powder was then packed with pre-cooked soy bean and job tear powder which were prepared by overnight soaked and steamed cooked before drum dried and ground to powder. The ingredient contained 7 g of dehydrated germinated brown rice, 2 g of dehydrated soy bean, 2 g of dehydrated Job's tear, 6 g of non dairy cream, 4 g of dairy powder and 10 g of sugar [5]. From above related researches, but there was no information about the formulation of riceberry residues juice mixed with agar and water. For this reason, of riceberry residues and agar advantages, the researchers are interested in producing water-based riceberry residues juice, agar and water with the healthy drink by studying and development an appropriate amount of riceberry residues, agar and water ratios on the physical, chemical, microbiological quality and sensory acceptability of the panelists, which help with the quenching of thirst and help relax or make the body. The data obtained from this research was an alternative to make riceberry residues juice as by-products and agar for beverage production to improve the quite appearance characteristic, nutritional quality, acceptability test and good health of consumers also solve the problems of bringing by- products from various food industries that are being commercially used in functional food ingredients for human consumption with higher values.

METHODOLOGY

The research was carried out at the Division of Food Science and Technology, Faculty of Agricultural Technology, Rajamangala University of Technology Thanyaburi. (RMUTT) Pathum Thani Province Thailand. The samples used in this study were purchased from Rangsit Market which located in Pathum Thani Province Thailand. This research was performed as four experiments)three replications(: 1) (control formula) blended riceberry and water 30:70; 2) blended riceberry and water 15:85; 3) blended riceberry and water 20:80 and Experiment 4: blended riceberry and water 25:75 details as the Table 1 [6].

Riceberry Juice Preparation

The riceberry was soaked in amount of water in a

stainless steel pot according as shown in Table 1. Then, allowed to mix homogeneously. The aliquot was filtered through a white cloth and again an aliquot was clarified. The aliquot was heated, then 50g of sugar was added and allowed to dissolve homogeneously after which pandan leaf juice was gradually added. An aliquot of this was heated at 65°C for 30 mins, then the temperature was reduced and the liquid poured into a sterilized plastic bottle [6],[7].

Preparation of Riceberry Residues Agar

Weigh 8.3 g of agar powder and 100 ml of water were placed in a stainless steel pot and heated to 90 °c for 6 mins until allowed to dissolve homogeneously. Then 100 g of sugar to simmer until it dissolved until a homogeneous aliquot. Then, put 30 ml of pandan juice was added and allow to dissolve homogeneously and then cooled at room temperature. (This step should add pandan juice before lifted down from the stove, because the aliquot of simmering for too long affecting on the pandan leaf color causing separation from each other). Put them in the prepared mold, then add the boiled rice berry residues from the riceberry juice (as 2.1), then let it cooled to be mixed well [6],[7].

Recording of Data

Collect and record numerical data from experiments (three replications) and calculate data and statistical analysis. The Experimental design for physical and chemical quality analysis were evaluated by using a completely randomized design (CRD). A randomized complete block design (RCBD) for sensory evaluation was used with analysis of variance. Analysis of the mean differences of experiments was performed using Duncan's new multiple range test [8].

Physical Measurement

The color brightness (L*), color as red (+a*) and yellow (+b*) were measured by using Minolta CR-10 [9] and recorded as values adapted from [9]. The sedimentation was detected by using eye detection adapted from [9].

Chemical Measurement

The pH, total soluble solid (TSS) and percentage of total acidity (calculated as citric acid) were measured by using pH meter OHAUS ST3100-F, using hand refractometer and titration with 0.1N sodium hydroxide (phenolphthalein as indicator) as values, respectively adapted from [10].

Microbiological Measurement

The total microbiology was measured as total plate count by using plate count agar adapted from [11].

Sensory Evaluation

The sensory evaluation was carried out by 30 untrained panelists in Rajamangala University of Technology Thanyaburi (RMUTT), Thailand. Panelists were asked to analyze their level of preference for each treatment by using a 9-point hedonic scale test based on the attributes of color, odor, taste, body, clarify and overall acceptability. A randomized complete block design was used with analysis of variance. Analysis of the mean differences of experiments was performed using Duncan's new multiple range test [12].

RESULTS AND DISCUSSION

Physical appearances of blended riceberry residues juice and agar

From the Fig 1, the study of the outside appearance of the riceberry products mixed with riceberry, agar and water. The images could be seen that the red color in all experiments were not significantly different. As a result of the ratio of riceberry juice, agar and water. When considering the appearance, it was found that all the experiments were suspended, which is the pulp of riceberry, which is derived from riceberry, agar and others. When considering the color, revealed that all the samples were dark brown as the color results of the anthocyanin [13]. The anthocyanin is water-soluble vacuolar pigments that, depending on their pH, may appear red, purple, blue or black. Food plants are abaundant in anthocyanins include the blueberry, raspberry, black rice, and black soybean, among many others that are red, blue, purple, or black. Some of the colors of riceberry are derived from anthocyanin. The color of anthocyanin is quite distinct and different chemical compositions and structures in riceberry. The color characteristics can be seen that when the amount of water is much, the color was pale. When considering the appearance, it indicated that the Experiment 1 gave a lot of suspended sediments of riceberry residues than the other experiments. The odor was varied with the amount of increased riceberry and the decreased amount of water which compared to control samples. The taste indicated that all experiments were little sweet and little salty taste. This is due the increasing proportion of riceberries, whereas reducing the amount of water that results in dilution effects caused the flavor to not be concentrated [14].

Physical Measurement

Table 2, The results showed that all of L*, +a* and +b* values and physical appearance depending on different ratios of riceberry residues, agar and water. The results showed that all values were different ($P \leq 0.05$). The physical characteristics of blended riceberry residues, agar and water, comparing the differences between the experiments of color values L*, +a* and +b*, they revealed the brightness value (L*) was of 33.3, 29.0, 31.2 and 32.1, respectively. The color values (+a*) was 4.1, 3.1, 3.6 and 2.5, respectively. The color values (+b*) was of 10.59, 12.13, 12.51 and 13.55, respectively [15]. Riceberry had a deep purple color. This may be caused by the ratios between riceberry residues, agar and water with different amounts due to each experiment to have different values. The experiment with a large amount of riceberry residues ratio had a darker color and more brightness than the experiment with ratio of the less amount of riceberry residues [16]. One possible reason ricebeery has a anthocyanin as a main pigment, a pigment that is red color and soluble in water well. The proportion of the amount of riceberry that increase redness will increase according to the amount of riceberry, but increasing the amount of riceberry residues results in an increasing trend of all values [17].

Chemical Measurement

Table 3, The results revealed that the pH, total soluble solid and percentage of total acidity in riceberry juice products with agar and water, depended on the different ratios. The result was found that the measured values (percent of acidity) were statistically significant differences ($P \leq 0.05$) while pH and total soluble solid were not statistically different. This value depends on the increasing riceberry residues, agar and water ratio, resulting in lower pH values (more acidity). The results indicated a tendency for the percent of total acidity decrease low values in comparison with the control samples. The analyzed values were consistent with the percentage of total acid content in the form of citric acid that is higher with organic acid (such as citric acid). The total soluble solid was not significantly different ($P > 0.05$). The anthocyanins are the most important water-soluble pigments that belong to the flavonoid group and are accountable for the different color in plant tissues [18]. The pH is one of the most influencing factors of stability, and color of the anthocyanins. The anthocyanins are more stable in acidic condition than in the alkaline condition. This reason be due to anthocyanin may be used as pH indicators because their color changes with pH; they are red or pink in acidic solutions ($pH < 7$), purple in neutral solutions ($pH \approx 7$), greenish-yellow in alkaline solutions ($pH > 7$) and colorless in very alkaline solutions, where the pigment is completely reduced. [19]. Apart from this, there was some main compounds of total phenolic content in riceberry. Therefore, if the riceberry was heated to a high temperature level and took too long time, it did not affect in pH change of riceberry. This can be seen that the pH value might not be very low. Because the heat was used to boil, it took short time, so the amount of pH was not very low [20],[21].

Microbiological Measurement

Based on the analysis of total microbial counts by using the total plate count method in blended riceberry residues, agar and water. the results showed that microorganisms were not found in all experiments. One reason possibility was due to the completed pasteurization process of blended riceberry residues juice agar and water before packaging. This processing is a thermal processing method with the main purpose to destroy pathogenic microorganisms, including microorganisms and enzymes that cause food degradation [22],[23].

Sensory Evaluation

Table 4, the results of the sensory analysis showed that there were differences in all experiments ($P \leq 0.05$) [24],[25],[26]. Based on the color, odor, taste, body, clarify and overall acceptability values. Experiment 1 had the greatest odor and taste from panelists due to the highest amount of riceberry residues being added [26],[27]. One possible reason might be due to the highest proportion of riceberry resiudes and the lowest of water. Color values showed that Experiment 4 was the most acceptable, but Experiment 2 gave the highest body score value. This may have been due to the riceberry residues and water ratios level resulted in preferred acceptance level or the panelists preferred the color of the drink containing reddish purple color of riceberry. The experiment with the highest clarify and overall acceptability were the Experiment 3. For one possible reason, the increased amount of water, if increased too much, caused the color and appearance to appear paled color. The amount of total soluble solids decreased as a result of dilution, causing the panelists did not accept it [28],[29].

Table 1 Different Ratios of blended riceberry residues juice agar and water

ingredient	Experiment			
	1	2	3	4
riceberry (g)	210	105	140	175
filtered water (ml)	490	595	560	525
sugar (g)	50	50	50	50
pandan leaf juice (ml)	52	52	52	52

E1 E2 E3 E4

E1: blended riceberry and water 30:70
E2: blended riceberry and water 15:85
E3: blended riceberry and water 20:80
E4: blended riceberry and water 25:75

CONCLUSION

1. The uses of different ratios of by-products as raw material preparation had effects on the quality of mixed riceberry residues, agar and water.

2. The results of the physical properties analysis showed that all values were statistically significant differences (P≤0.05).

3. The results of the chemical analysis showed that the percent of total acidity (except pH and total soluble solid) were significantly different (P≤0.05).

4. Blended riceberry residues, agar and water 20:80 gave the most overall acceptability of 6.91 values from the panelists.

5. The results of total plate count indicated that the microorganism in each experiment was not found.

6.. Based on this research, researchers will be able to launch new health drink products in the future for functionalities and health benefits of food by-products and their functional ingredients.

ACKNOWLEDGMENTS

The researchers would like to thank the 4 the grade students and officials of the Division of Food Science and Technology, the Faculty of Agricultural Technology Rajamangala University of Technology Thanyaburi (RMUTT), Pathum Thani Thailand that contributed some parts in the research. The Faculty of Agricultural Technology provided support facilities and budgets for the research.

MICROPLASTICS INGESTION BY FRESHWATER FISH IN THE CHI RIVER, THAILAND

Pattira Kasamesiri[1] and Wipavee Thaimuangphol[2]
[1,2]Faculty of Technology, Mahasarakham University, Thailand; [1,2]Research Unit of Excellence for Tropical Fisheries and Technology, Mahasarakham University, Thailand

ABSTRACT

Microplastic pollution mainly emanates from terrestrial sources but studies of plastic contamination in freshwater ecosystems remain limited. Consumption of freshwater fish is widespread throughout all regions of Southeast Asia. Contamination of microplastics in fish is an important issue which leads to human health risk. Common freshwater fish in the Chi River, Thailand were caught by local fishermen and investigated for abundance, size, color and shape of microplastics. Eight fish species were investigated. Results showed that 72.9% of the collected fish were polluted with microplastics at mean abundance of 1.76±0.97 particles per fish and was no significant difference of abundance between species. Percentage occurrence of microplastics was highest in omnivorous fish *Puntioplites proctozysron* (86.7%) with the most common size of microplastics ingested by fish at over 0.5 mm (47.5%), of which 56.9% were blue color and 86.9% were fiber shaped. Results revealed that fishing nets and fish cages were major sources of microplastic contaminants in the Chi River.

Keywords: Microplastics Pollution, Freshwater fish, Ingestion, Aquatic Environment

1. INTRODUCTION

Plastic production has continually increased since 1950, reaching 332 million tons in 2015 [1]. Increasing plastic debris has become a serious pollution problem in the aquatic environment. The amount of plastic debris is now 10 times greater than a decade ago on the shores of South Atlantic islands [2]. Plastic debris is widely distributed over ocean shorelines and has also become a major component of riverine pollution [3]-[5], which impacts to aquatic animals such as zooplankton, aquatic invertebrates, fish, marine reptiles and mammals by ingestion [6]-[10].

Microplastics are small plastic items with particle size <5 mm which can be classified into primary microplastics (pellets, plastics used in cleansing, cosmetic products and manufactured plastic products) and secondary microplastics [11]. Secondary microplastics originate from degradation and fragmentation of large plastic items and enter the aquatic environment through different pathways [1], [12]. Microplastics are easily spread with wide distribution because of their small size, light weight and durability [13]. Oceans and many urban rivers are contaminated with microplastics [14].

Direct effects of pollution by microplastics on aquatic organisms hamper their ability to ingest natural prey by obstruction of the digestive tract [6] and reduction of swimming velocity which affects resistance time of fish when swimming against the water flow [15]. Microplastic ingestion also leads to neurotoxicity and oxidative damage in marine fish [16] and reduction in photosynthetic activity and chlorophyll *a* of algae [17]. Moreover, various chemical substances are contained in all plastic products such as styrene, toxic metals, polychlorinated biphenyls (PCB), bisphenol A (BPA), polycyclic aromatic hydrocarbons (PAHs) and phthalates for improving polymer properties [18]-[19]. Microplastics deliver these chemical substances to aquatic organisms and act as mediators for other chemical contaminants in aquatic environments [20].

Microplastics transfer from primary consumers to higher trophic levels via a trophic food web and, finally, may contaminate humans [12], [19], [21]. Thus microplastic contamination is a crucial issue for food safety and human health [19]. Reports concerning microplastic contamination in fish have mainly concentrated on oceans and shorelines with the minority assessing the effects in freshwater environments [22]-[27]. Thus, this study assessed the abundance, size, color and shape of microplastics ingested by freshwater fish in the Chi River. Results will provide useful data for fishery and aquaculture food security.

2. MATERIAL AND METHODS

2.1 Samples Collection

Fish samples were collected from four sampling stations along the Chi River in the northeast of Thailand (Fig. 1). The Chi River is the longest river flowing within Thailand at 765 kilometers and runs

Table 1 Species and number of fish samples caught in the Chi River

Species	Habitats	Feeding features	Total Length (cm)	Weight (g)	Total Number
Labiobarbus siamensis	benthic	Detritivore	9.6±0.7	8.0±2.3	15
Puntioplites proctozyson	midwater – benthic	Omnivore	11.1±3.2	20.4±17.7	6
Cyclochelichthy repasson	midwater – benthic	Omnivore	11.8±2.6	18.7±11.4	15
Henicorhynchus siamensis	midwater	Omnivore	12.4±1.2	20.1±6.1	27
Labeo chrysophekadion	benthic	Detritivore	17.0±2.8	57.5±23.7	14
Mystus bocourti	benthic	Carnivore	14.9±2.7	21.1±9.2	20
Hemibagrus spilopterus	benthic	Carnivore	20.4±3.9	56.7±27.2	6
Laides longibarbis	pelagic-benthic	Detritivore	15.8±1.3	22.5±2.4	4

through seven provinces. The four study sites were located along the middle region where the river flows through urban areas of Maha Sarakham Province. Sources of plastic pollution were composed of fishing activity, aquaculture, agriculture, and sewage from industrial factories and residential areas. Fish were caught by local fisherman using gill nets during the late rainy season (October 2018) and stored at -20°C prior to examination for microplastics.

2.2 Microplastic Extraction and Analysis

Fish samples were weighed and measured for total length to an accuracy of 0.1 g and 0.1 cm, respectively. After dissection, fish stomachs and intestines were placed in 50 ml Erlenmeyer flasks and 30% H_2O_2 was used to digest the organic matter (Jabeen 2017). Volume of H_2O_2 was based on weight of stomach and intestine samples (approximately 30 ml/sample). Extracted samples were placed in an incubator at 65°C for 24 h. A saturated NaCl solution (approximately 300 g/L) was filtered and added into the flasks to separate microplastics by flotation. The saline solution was kept for 12 h at room temperature and then the supernatant was pipetted and filtered through a glass microfiber filter (Whatman GF/C 1.2 μm pore size). The filter paper was placed on Petri-dishes to record the numbers of microplastic particles, and colors and physical characteristics were divided into fibers, rods, fragments, and pellets under a stereomicroscope (Nikon SMZ745/745T). Microplastics were measured for their longest dimension

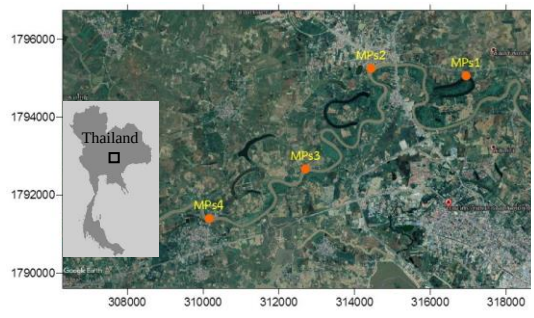

Fig. 1 Location (UTM; 48Q) of the sampling stations at Chi River, Maha Sarakham Province, Thailand

2.3 Statistical Analysis

Significant differences of microplastic abundance in fish gut among sampling stations and fish species were analyzed by Independent-Samples Kruskal-Wallis Test. Significant difference was set as p-value less than 0.05.

3. RESULT AND DISCUSSION

3.1 Abundance of Microplastics Ingested by Fish

A total of 107 individual fish were identified into 8 species (Table 1). We observed microplastics inside the gastrointestinal tract of 78 individuals (72.9% of total fish samples). Percentage occurrence of microplastics in each species ranged between 50.0-86.7% with the highest in *Puntioplites proctozysron* (Smith's barb) (Fig. 2). All feeding types (omnivore, carnivore, detrivore) showed high occurrence of microplastics (>50%) but less than planktivorous fish (77%) from Tokyo Bay, Japan [30]. Proportion of ingested microplastics was higher than fish in the English Channel (36.5% from 10 fish species) [22], islands in French Polynesia (37.2% from 4 fish species) [23] and estuaries of Brazil (9% of 69 fish species) [25]. Microplastics ingested by the fish samples varied from 1 to 2 particles per fish with an

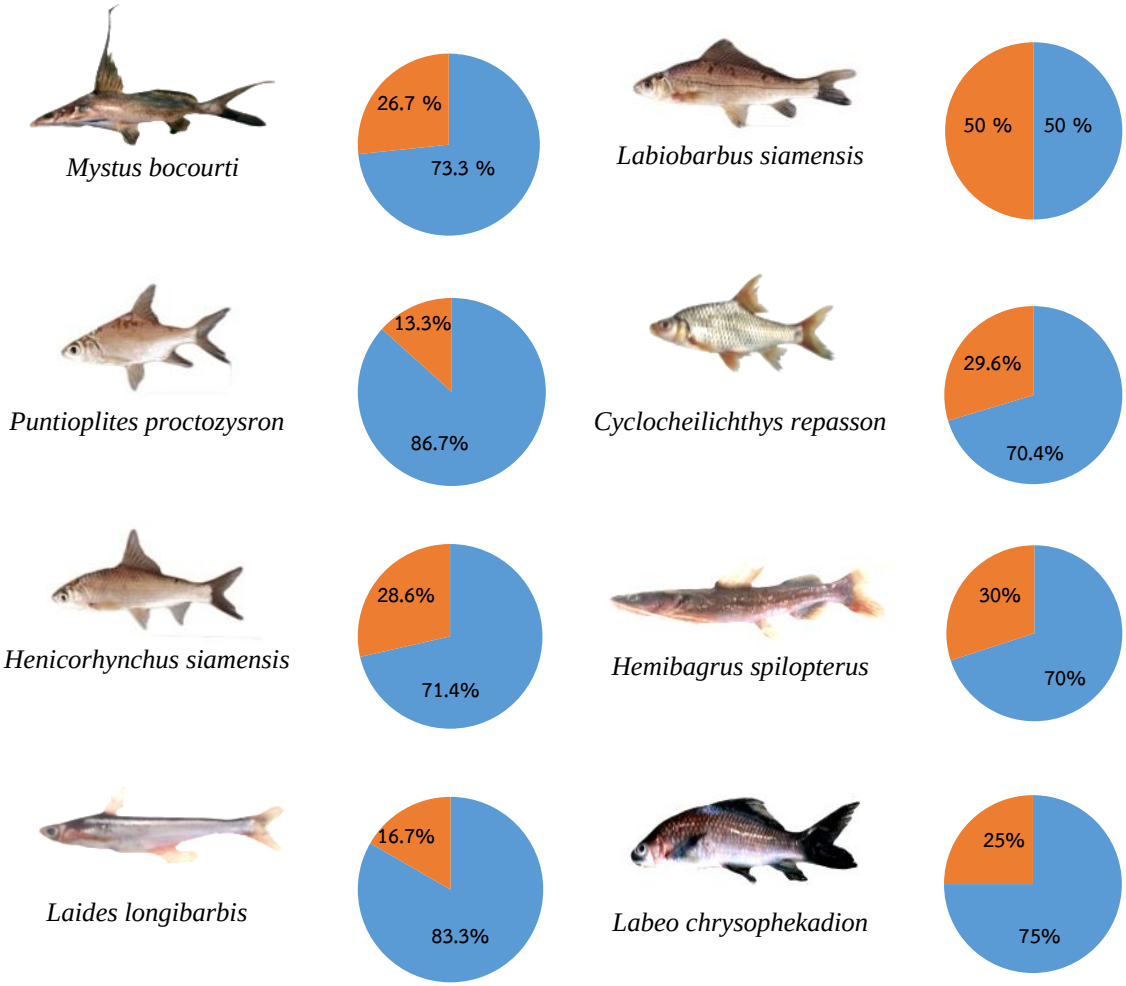

Fig. 2 The percent occurrence of microplastics ingested by fish in each species

average of 1.76±0.58 (Fig. 3). There was no significant difference in abundance of microplastics ingested between species (Kruskal-Willis Test, p-value=0.849). Omnivorous fish in intertidal zones of Chile recorded significantly higher numbers of microplastics than herbivorous and carnivorous fish [26], showing that occasions to ingest microplastics of feeding types were similar in present study. Abundance of microplastics was relatively high compared with fish from tropical estuaries of Brazil that affected from the anthropogenic pressures (0.12±0.37 particle per fish) [25]. Conversely, abundance of microplastics was lower than fish in the Pajeu River of Brazil (3.6 particles per fish) [7], possibly due to different flushing efficiency from river catchments and diverse microplastic sources [5], [12].

3.2 Colors, Shapes and Size of Microplastics Ingested by Fish

Six colors of microplastics were found in fish gut as blue, red, black, white, transparent and brown. The most common color was blue 56.9% (Fig. 4A). Most abundant color results concurred with former studies [8], [13], [28]. Variety of colored microplastics was higher in *Mystus bocourti* and *Cyclocheilichthys repasson* (Fig. 5) as carnivorous and omnivorous species, respectively. Fish may ingest microplastics as a result of visual confusion between prey [28] but our results gave similar color patterns between different feeding types.

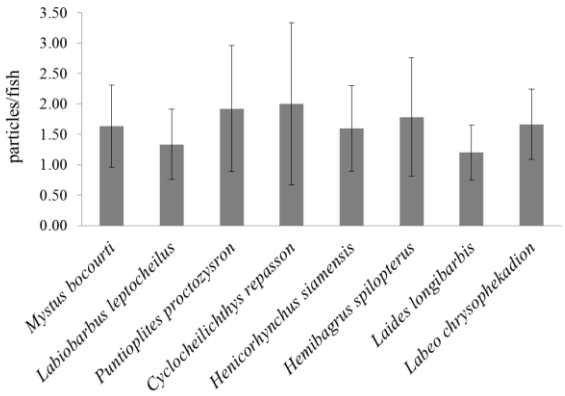

Fig. 3 The average number of microplastic ingested by fish (particles per fish) in each species. (Mean±SD)

Four shapes of microplastics were presented in fish gut (Fig. 6). The most abundance shape was fiber followed by rod-shaped, pellet and fragment, respectively (Fig. 4B). Fiber shape was a major type ingested by fish [7], [13], [28] and related to human activities [12]. An important source of fiber microplastics is from degradation of fishing gear, fish cages or nylon ropes [8] and sewage from washing clothes [29].

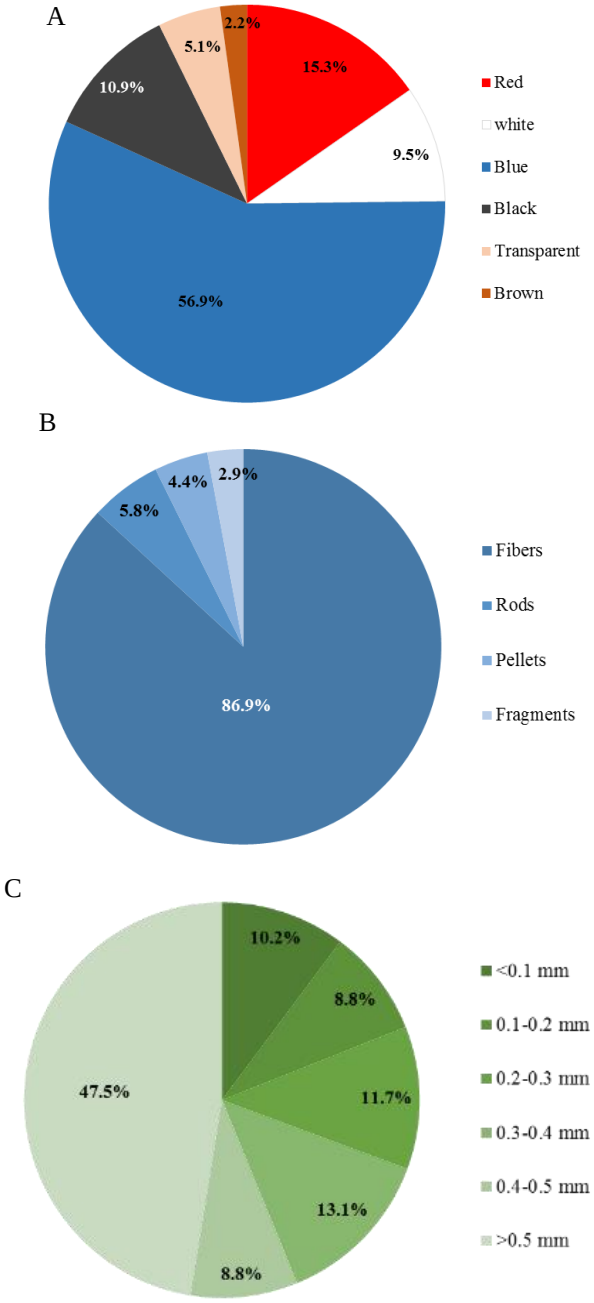

Fig. 4 The percentage of the total number of microplastics ingested by freshwater fish of color (A), shape (B) and size (C).

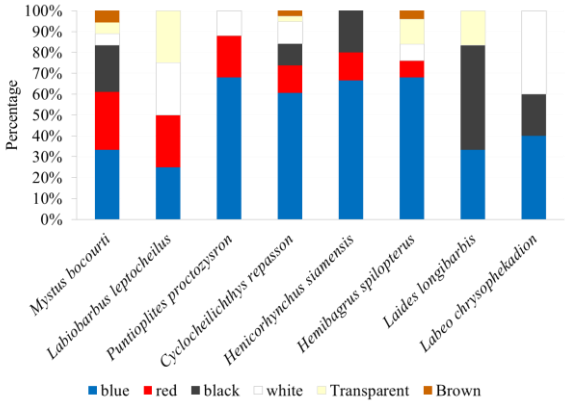

Fig. 5 The percentage of microplastics colors in each fish species.

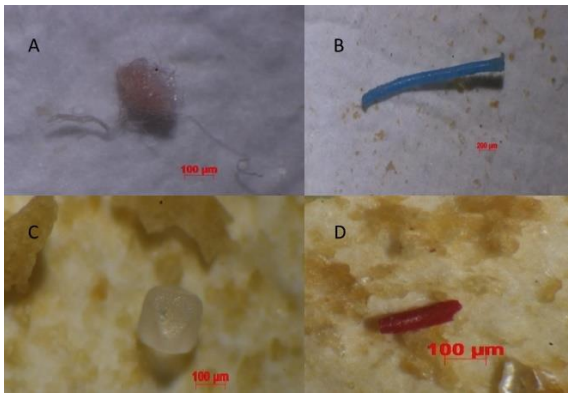

Fig. 6 Shape of microplastics found in gastrointestinal tract of fish: fiber (A), rod (B), pellet (C) and fragment (D).

Size distribution of microplastics ranged between 0.03-3.84 mm. The most abundant size was over 0.5 mm (47.5% of the total number of plastics) (Fig. 4C). Large particles were common in fiber type. Our results were similar to a previous report on surface water in reservoirs of China which found microplastic sizes ranging from 1 to 5 mm as more abundant [31]. Fish from coastal and freshwater areas of China contained microplastics ranging from 0.04-5 mm (76.3%) [13], while in our study, particles smaller than 5 mm were 100% of total number of plastics ingested by fish.

Size of plastics larger than 0.5 mm are used in fishing ropes or lines [30], indicating that the source of microplastics in the Chi River emanated from fishing gear and equipment used in aquaculture. The Chi River is an important fishery resource in the northeast of Thailand with abundant fishing activities [32]. Local fisherman usually use transparent or black gillnets to catch fish [32]. Blue fiber fish cages in Nile tilapia aquaculture may also be an important source

of microplastics ingested by freshwater fish in the Chi River. Plastic materials are used in fishing gear such as nets, traps, hooks and lines. These are commonly made from polyamide (PA) and polyethylene (PE) [1]. Polyamide is a low-density polymer that is found in both pelagic and demersal fish [22]. Results confirmed that the percentage occurrence of microplastics ingested by each fish species was not related to vertical habitat zonation but concerned feeding activities.

CONCLUSIONS

The abundance of microplastics ingested by fish in the Chi River indicated middle-level contamination in aquatic animals compared to results of previous studies in both freshwater and ocean fishes. Opportunities to convey microplastics through the food chain into the human body remain limited. Shapes of microplastics indicate their origin as mainly from fishing gear such as nets and synthetic fibers from clothing.

ACKNOWLEDGMENTS

The joint conference was supported by Mahasarakham University Development Fund. Laboratory operations were supported by the Research Unit of Excellence for Tropical Fisheries and Technology. We would like to convey our special thanks to Padchara Bupphahao and Pattarawut Kothaisong for assisting with field operations and ensuring project success.

CURRENT SITUATION EVALUATION OF TAKASAKI CITY BY FORMULATING MODEL OF URBAN POWER

Toshikazu Nishio[1], Tetsuo Morita[2] and Shinya Tsukada[3]
[1] Takasaki Technical High School, [2] Maebashi Institute of Technology, Maebashi City Office [3]

ABSTRACT

The aim of the present study is to indicate objective position of a local city other than the prefectural capital location by formulating model of urban power and current condition evaluation. Specific methods are as follows: 1) formulate a model of urban power; 2) evaluate the current situation of Takasaki City; and 3) clarify direction to tackle in order to improve Takasaki City in the future by formulating model of urban power and current condition evaluation. The results obtained in the present study can be summarized as follows: 1) In order to maintain urban power of local cities, it is necessary to industrial activities that create bustling communities such as commerce; 2) It is indispensable to enhance transportation system such as Shinkansen, railway and expressway, and to enhance the bases of home center and department store; and 3) The annual sales of goods value of Takasaki City is larger than that of Maebashi City, the prefectural office location in Gunma, and is considered to be contributed by department store, Shinkansen, and expressway.

Keywords: Provincial city, urban power, Takasaki City

INTRODUCTION

City data pack 2018 version is conveying movement of town of the whole country. [1] Toyo Keizai is published a livability ranking in July 2018. The purpose is to clarify urban power of each city area based on public statistics in various fields. The 16 indicators are based from 5 in terms of peace of mind degree, convenience degree, comfort, high-net-worth level. Deviation value for the 50 average values is calculated for 16 indicators. The overall rating is the calculation each average and the deviation value of the 5 point of view. The rankings of all 814 city blocks in 791 cities and 23 wards of the country are introduced on 2 pages each. For example, Inzai City is a livability ranking overall rating 1 of 2017. It is located in the northwestern Chiba, in a population of 92,000 people, accounting for more than half of the area of Chiba New Town. It is comfort third place, in the convenience of 10-position. Mori Memorial Foundation urban strategy Institute is published a "Japanese cities characterization" in October 2018. Six areas as elements that make up the city are economy, business, research and development, culture and exchange, living and living, environment, transportation and access. In each field, 26 indicator groups and 83 indicators are selected. Each index data is indexed as maximum value 100 and minimum value 0. The average value of each index group is summed up by field, and it is considered as the score of each field. The total score is calculated by adding up the six fields. For example, Kyoto City is a ranking first in culture and interaction, and second in research and development, and first in the total score of urban characteristics in Japan.

The present study is to formulate a model of the city force, intended to evaluate and organize the current state of Takasaki City (summary will be described later).

PREVIOUS STUDIES

As research on urban power, Ishikawa considers urban power to be a comprehensive value of seven indicators: production rate, population growth rate, land price rate, yield rate, lighting rate, tax rate, and savings rate. [2] Sakurai focuses on milk marketed in Tokyo. There is explained urban power from the milk producing area in the metropolitan area, the amount of milk transported from the milk producing area to Tokyo, the transportation distance, transportation means, and transportation route. There is clarified that the city's milk area connecting Tokyo from milk producing area was formed in Showa era. [3] Takano defines urban power as the total number of employees of the establishment targeting 23 urban areas in Aichi. Urban area index is the ratio to the total residential population. There is high in large cities like Nagoya and in developed areas of the industry. It is low in other areas. [4] Yoshisaka et al. define a numerical value corresponding to urban power in order to quantitatively grasp the size of the city the force index. A comprehensive index is obtained by multiplying the population concentration area population (DID population) by the population concentration area

(DID area). [5] Sawada uses the total value of the six indicators of the number of shops, the number of shop workers, the number of goods sold, the number of factories, the number of plant workers, and the amount of industrial shipments as urban power. [6] Yoshisaka et al. define urban power index corresponding to urban power from the road distance in the population concentration area. [7] Yoshisaka et al. consider the composition of a block from the city power index and the area corresponding to urban power. [8] Sakurai et al. define urban power as the force produced as a result of accumulation of urban functions. It is target within a radius 5km area of central area in Yokohama City. There is defined urban power as a comprehensive value of the active force produced in 4 function of residential, commercial, business, industry. In order to simulate the situation of city change and transformation in advance, there is formulated by multiple regression analysis. Objective variable is urban power. [9] Noda defines the urban power as a state that the transform the world, the quality of life, and the economic power are achieving balanced growth. The three areas are measured by intellectual capital / innovation, technology maturity, gateway function, transportation/ infrastructure, health/ safety/ security, sustainability and natural environment, population composition/ livability, economic influence, ease of business, the cost of industrial and life. [10]

In the field of urban planning, urban power is seen to have been professionally defined as a comprehensive indicator of quantitatively competitiveness between cities.

THE PURPOSE OF THE PRESENT STUDY

Urban power is professionally defined as a comprehensive indicator that quantitatively indicates the competitiveness between cities from the past research in the field of urban planning. Each item of indicators makes up urban power as a comprehensive evaluation, and there are variety previous studies. Therefore, a problem from the point of view of regional policy is to formulate a model of urban power by an objective analysis technique. It is necessary to be formulated on the model of urban power, evaluate and organize the current state of the specific city by case studies.

The aim of the present study is to reveal the state objectively the position of regional cities other than prefectural office location by modeling formulation of urban power and evaluating current. It is formulated a model of urban power by the objective analysis technique. Moreover, it is evaluated and organized the current state in Takasaki City as a case study (set reason will be described later). Based on the above-mentioned results, it reveals the direction that should be addressed in order to improve the future Takasaki City. That is, there is created a model that can be represented metrically on the scale of urban power. Based on the above-mentioned results, there is addressed the direction in order to improve the urban through case studies.

The specific method is as follows.

(1) There is described the concept of urban power model. There is selected a multiple regression analysis from the statistical analysis technique. From this, the evaluation index X is to formulate a model of urban power to predict the impact directly to the comprehensive evaluation Y.
(2) As a study area to expand the case studies, there is set Takasaki City, and described an overview of Takasaki City.
(3) There is organized and evaluated the current status of Takasaki City from the model of urban power formulated by predicting that the evaluation index and the general evaluation are related.
(4) There is revealed the direction that should be addressed in order to improve the future Takasaki City from the current state evaluation of the results.

URBAN POWER MODEL FORMULATION

Urban Power Model Concept

Model concept of urban power in this study are as follows. Urban power is able to capture and quantify the status of the city. Outlines of the analysis procedure are modeling of urban power, and prediction of urban power by simulation using model formula.

Prerequisites for Modeling

A prerequisite is to the following two assumptions to model construction for expressing to meter urban power.

[Assumption 1] To make city unit city.
[Assumption 2] To quantify the situation of the city at a certain point.

Model Formulation

Among various urban activities developed in a city, the base function and the transportation system are taken up as two representative functions. The total value of activity generated by these two functions is the annual product sales value. This is urban power. Annual sales of goods is based on 2016 economic general survey-activity investigation Table 1, the number of the establishments according to city and

Table 1 Index and Item of Urban Power
(Created by the author)

Index	Item
base function	1. number of household appliances, furniture, and home center 2. department store association merchant number
transportation system	3. Shinkansen stop station 4. number of railway station 5. number of interchange

Table 2 Statistics of multiple regression analysis
(Created by the author)

Index item	Partial regression coefficient	Standard partial regression coefficient	T value	Judgment
X1	18,918.076	0.303	3.548	**
X2	206,940.793	0.248	3.463	**
X3	190,712.134	0.142	2.085	*
X4	5,455.218	0.120	1.549	
X5	32,650.959	0.166	2.366	*
Constant term	128,625.126		1.656	
F value			22.577	**
Multiple correlation				0.679

**: the t value does satisfy the significance level for 1 %.
*: the t value does satisfy the significance level for 5 %.

district, the industrial classification subdivision, the number of the employees, the annual sales of goods. There is selected the number of household appliances, furniture, and home center, and department store association merchant number for the base function. Similarly, there is selected the presence or absence of Shinkansen stop station, the number of railway station, the number of interchange for the transportation system (Table 1). Therefore, objective variable is "annual sales of goods(Y)". Explanatory variable is "the number of household appliances, furniture, and home center(X1)", "department store association merchant number(X2)", "the presence or absence of Shinkansen stop station(X3), "the number of railway station(X4)", "the number of interchange(X5)". When formulated by multiple regression analysis, regression equation of formula (1) is obtained a precision shown in Table 2. In addition, the cities used for model creation are population of 150,000 or more excluding all ordinance-designated along with 790 cities in Japan based on the 2015 census.

$$Y=18918.076X1+206940.793X2+190712.134X3 +5455.218X4+32650.959X5+128625.126\cdots(1)$$

The results of the test for significance of regression equation is shown in Table 2. The results of the analysis of variance, the degree of freedom of the F value molecule is 5, and the denominator of freedom of the F value molecule is 132. F distribution of the upper side 1% is 22.577>F (5, 132, 0.01) =3.17. It is 1 % level of significance. The null hypothesis that the obtained regression equation is not useful for the estimation of Y is rejected. The F value is also large enough. Therefore, the resulting regression equation can be determined to be valid. Further, the multiple

Table 3 Annual sales of goods [13]
(Created by the author)

Population rank	Prefecture	Municipalitie	Annual sales of goods (one million yen)		
			Actual value	Estimated value	Difference
51	Nagano	Nagano City	1,685,006	1,290,507	−394,499
52	Aichi	Toyohashi City	1,089,863	1,162,887	73,024
53	Osaka	Suita City	1,919,875	497,317	−1,422,558
54	Gunma	Takasaki City	3,057,010	1,405,140	−1,651,870
55	Wakayama	Wakayama City	1,133,258	1,080,768	−52,490
56	Nara	Nara City	602,695	898,894	296,199
57	Osaka	Takatsuki City	555,036	796,800	241,764
58	Saitama	Kawagoe City	766,096	593,032	−173,064
59	Fukushima	Iwaki City	869,814	841,205	−28,609
60	Shiga	Otsu City	469,139	1,280,467	811,328
61	Saitama	Tokorozawa City	520,941	692,807	171,866
62	Hokkaido	Asahikawa City	1,063,246	708,319	−354,927
63	Saitama	Koshigaya City	822,471	456,038	−366,433
64	Kochi	Kochi City	972,508	1,193,206	220,698
65	Gunma	Maebashi City	1,147,867	1,015,305	−132,562
66	Fukushima	Koriyama City	1,402,963	1,114,169	−288,794
67	Okinawa	Naha City	849,364	639,226	−210,138
68	Akita	Akita City	1,147,819	1,076,333	−71,486
69	Mie	Yokkaichi City	993,011	894,490	−98,521
70	Aichi	Kasugai City	696,654	602,737	−93,917

correlation coefficient between the actual observed values with the theoretical value calculated by applying the regression equation of the object variables is 0.679. Therefore, as shown in Table 3, there is a difference between actual values and estimated values in the annual sales of goods, but resulting regression equation is valid.

Table 2 is clear that the number of household appliances, furniture, and home center, department store association merchant number, the number of interchange, and the number of railway station affected annual sales of goods, the t value does satisfy the significance level. Among them, the number of railway station and the number of interchange are a significant impact on annual sales of goods can be seen. On the other hand, although the t value does not satisfy the significance level for 5 %, “the number of railway station (5,455.218)” is also an important index item judging from the magnitude of the parameter (partial regression coefficient).

Based on the above-mentioned results, it is considered that the number of household appliances, furniture, and home center, department store association merchant number, the presence or absence of Shinkansen stop station, the number of railway station, and the number of interchange are important to capture urban power from the viewpoint of base function and traffic system.

STUDY AREA AND TAKASAKI CITY

Setting of study area

A city that represents the prefecture is generally prefectural office location. Even if Maebashi City is appeared in the national statistics in case of Gunma, Takasaki City is hardly found. However Takasaki City is merged with Haruna town, becomes a population of 340,000 in October 2006, exceeded

Fig. 1 Takasaki Station West Exit
(Photo taken by the author)

Fig. 2 Takasaki Station East Exit
(Photo taken by the author)

Maebashi City which has been merged with the previously Seta County area, etc. Takasaki City is the city with the largest population in Gunma. April 2011 or later, Takasaki City is a core city. In recent years, Takasaki City's position has been objectively shown throughout Japan. According to Takasaki Chamber of Commerce and Industry, Takasaki City has been posted on the city ranked by economic magazine in recent years. Happiness ranking with 42 core city nationwide of the Toyo Keizai newspaper is third across Japan, Nikkei city rankings with a vitality of the business is the 29 across Japan in 2016. According to statistical data, the urban population is 55th in the whole country (2015), the industrial scale is 31th in the national scale, commercial sales is 15th in the national scale, and the industrial shipments are 88th in the national scale. [11]

From above, the present study is set area the Takasaki City as local cities other than prefectural office location.

Summary of Takasaki City

According to Takasaki City Directory, Takasaki City is a commercial city that flourished as a strategic point of traffic. There is expanded exchange area by development of high-speed transportation network. Prefecture population in sphere that can travel in two hours from Takasaki City is said to be 46 million people. The annual 200 million 6,000 million people visit in Gunma. Visitors to Takasaki City are the most frequent in Gunma. Near Takasaki Station is accumulation of accommodation, is a base for businessmen and tourists. Headquarters of the consumer electronics retailer's largest and a broad-based sales offices nationwide company are integrated. The department stores and attractive commercial premises in the nucleus, town building has been carried out and full of bustle and vitality in the center city. Advanced use of Takasaki City center is progressed by urban redevelopment projects. Takasaki Station connects with large commercial facilities, office buildings and hotels via an air corridor called pedestrian deck. Castle district which is continuous from Takasaki Station West Exit (Fig. 1) commercial area is an integrated areas of public facilities such as the city hall and Medical Center, Gunma Music Center. Takasaki City is established a "Takasaki Cultural Arts Center (tentative name)" new music hall as the base of art and culture in Takasaki Station East Exit (Fig. 2) area, is planning a large-scale complex facility with commercial premises and industrial development function. [12]

CURRENT EVALUATION

Assuming the annual product sales amount as urban power, evaluation Takasaki City is formulated urban power model of formula (1). More specifically, the current state of Takasaki City is organized from the point of view of annual sales of goods, the number of installed university, department store association merchant number, the presence or absence of Shinkansen stop station, the number of railway station, and the number of interchange. It is evaluated by comparing with Maebashi City, the prefectural office location in Gunma.

Current Situation of Takasaki City

(1) Annual sales of goods

Wholesale trade is 2 trillion 569.2 billion yen, the retail industry is 487.7 billion yen in Takasaki City, 2016. Annual sales of goods which is their total amount are 3 trillion 57 billion yen. Takasaki City ranks 15th in the national ranking and 1st in the core city. The cities in within the 20th place are all designated cities except for Takasaki City. In the city in Gunma, Maebashi City is 1 trillion 147.8 billion yen (46th) (See Table 4, the same is true for the following.).

(2) Number of home center and so on

The number of household appliances, furniture, and home center are 24 shops, in the case of Takasaki City, as of March 2019; Yamada Denki, Cainz home,

Table 4 Current Situation of Takasaki City
(Created by the author)

Item	Current Situation
Annual sales of goods	1 trillion 147.8 billion yen
number of household appliances, furniture, and home center	24 shops
Department store association merchant number	2 shops
Shinkansen stop station	Takasaki Station
number of railway station	16 stations
number of interchange	4 places

Sekichu, Nitri, Super Viva Home, Tokyo interior furniture, Bic camera, and so on.

(3) Department store association merchant number

Department store association merchant number are 2 shops, in the case of Takasaki City, as of March 2019; Takasaki Takashimaya, Suzuran Takasaki store.

(4) Shinkansen stop station

The presence or absence of Shinkansen stop station is Takasaki Station, in the case of Takasaki City, as of March 2019. Takasaki Station gets into Joetsu Shinkansen and Hokuriku Shinkansen of JR East that have served.

(5) Number of railway station

The number of railway station are 16 stations, the case of Takasaki City, as of March 2019, JR Takasaki Line Takasaki Station, Kuragano Station, Shinmachi Station, JR Joetsu Line of Takasaki-tonyamachi Station, Ino Station.

(6) Number of interchange

The number of interchange are 4 places, in the case of Takasaki City, as of March 2019; Takasaki Tamamura SIC, Takasaki IC, Maebashi IC of Kanetsu expressway, Yoshii IC of Joshinetsu expressway.

Comparative Study of Maebashi City

In order to show the position of regional cities other than the prefectural capital objectively, as compared with Maebashi City, there is evaluated the estimated value of annual sales of goods of Takasaki City.

Substituting a numerical value into urban power model of formula (1); the number of household appliances, furniture, home center of X1=24, department store association merchant number of X2=2, the presence or absence of Shinkansen stop station of X3=1 (Yes), the number of railway station of X4=16, and the number of interchange of X5=4, the estimated value of annual sales of goods of Takasaki City is 1 trillion 405.1 billion yen.

Substituting the estimated value into urban power model of formula (1); the number of installed university of X1=12, department store association merchant number of X2=1, the presence or absence of Shinkansen stop station of X3=0 (no), the number of railway station of X4=19, and the number of interchange of X5=2, the estimated value of annual sales of goods of Maebashi City is 1 trillion 15.3 billion yen.

Compared to Maebashi City, there are 3 shops less than the number of household appliances, furniture, and home center, there are 3 stations less than the number of railway station, and there are acting on the negative. However, there is a Shinkansen stop station, there is 1 shop more department store association merchant, there are 2 places more than the number of interchange, and there are acting on the plus.

Based on the above-mentioned results, it is considered that the number of interchange, Shinkansen stop station, and department store association merchant number of Takasaki City contribute to the results above the estimated value of annual sales of goods of Maebashi City, the prefectural office location in Gunma.

CONCLUSIONS

The aim of the present study is to reveal the direction to be addressed in order to improve the future Takasaki City by urban power model formulation and present situation evaluation. The results obtained in the present study can be summarized as follows:

(1) It is considered that the number of household appliances, furniture, home center, department store association merchant number, the presence or absence of Shinkansen stop station, the number of railway station, and the number of interchange are important to capture urban power from the viewpoint of base function and traffic system.

(2) It is considered that the number of interchange, Shinkansen stop station, and department store association merchant number of Takasaki City contribute to the results above the estimated value of annual sales of goods of Maebashi City, the prefectural office location in Gunma.

(3) From (1) and (2), it is possible to show objectively indicate the position of a local city other than the prefectural capital location by formulating model of urban power and current condition evaluation. In order to maintain urban power of local cities, it is necessary to industrial activities that create bustling communities such as commerce. For that reason, it is considered that it is indispensable to enhance transportation

system such as Shinkansen, railway and expressway, and to enhance the bases of home center and department store. The annual sales of goods value of Takasaki City is larger than that of Maebashi City, the prefectural office location in Gunma, and is considered to be contributed by department store, Shinkansen, and expressway.

SUBJECT FOR NEXT STUDY

(1) Our future goal is creation of time consumption type sightseeing to create bustle of town. Tourism resources such as landmarks, sightseeing spots, and hot springs are indispensable to increase the residence time of tourists. It is difficult to make tourists stay for more than half a day with tourist resources such as historic sites and city parks, and invite them to local consumption. Therefore, it is considered that experience-type tourism such as farming experience, and making of daruma at a tourist farm, and leisure tourism by eating and drinking utilizing special products such as Takasaki pasta.

(2) Maebashi City is the 12th largest agricultural city in the country according to the 2016 agricultural production estimate. Therefore, in the future, it is necessary in Maebashi City to put emphasis on the sixth industrialization of agriculture which is processing and sales of agricultural products.

ABSTRACT

Managing historic environment and cultural heritage are important not only from the conservation of cultural assets and local environment but it is also necessary to consider the perspectives from the community. This paper aims to examine a case study focusing on houses and local resources in the center of Kudoyama, known as the gateway town to the World Heritage Site, Koyasan in Wakayama, Japan. Study methods used are field observations and literature reviews. From the results, characteristics of the town center of Kudoyama became clear as follows; around a half of all houses have been built with single or semi-second story houses to form relatively reduced height of skylines. Thus, it creates viewpoints to surrounding mountains within the town center on undulating landform. In terms of local resources, a variety of natural and historic elements have been found to create a historic environment in town center of Kudoyama. In addition, some traditional design of houses is representing the similarities with surrounding areas of the World Heritage Sites of Yoshino and Koyasan. In future, managing cultural landscape may be necessary to balance the needs of the community and tourism.

Keywords: Historic environment, Cultural heritage, Cultural landscape, The World Heritage

INTRODUCTION

The Definitions of Cultural Landscapes

Managing historic environment and cultural landscape are important not only from the conservation of cultural assets and local environment but it is also necessary to consider the perspectives from the community. There are number of studies regarding on valuing cultural heritage and landscapes can be seen [1]–[2]. Melnick suggests the importance of 'viewing the landscape from a variety of perspectives' [1]. For instance, 'documented cultural imprints such as battles and literary connections' are well known by the 'outsiders', however, 'customs and experiences that may only be appreciated by the 'insiders'' [3]. Therefore, meaning to the people living in the area becomes important when it comes to consider thorough comparison which may deny what has been important to those people [1]. In terms of determining priorities, 'the level of significance', whether world, national, regional, and local 'does not reflect the absolute significance of the landscape' [1]. Moreover, cultural landscapes can be described from a wider scale to clarify the characteristics from the human and other species behavior patterns and understanding of mixture of variety of 'species, places and environmental conditions' in complexity [4]. Thus, it is necessary to focus on the diversity and identity of cultural landscapes in rapidly changing landscapes and the society to find out the importance of 'coherence between small composing elements in a broader spatial context' and to be able 'to tell the story of the place' [5]. Furthermore, it is suggested the needs of balancing between three aspects as follows; 'distinctive landform and cover, the indivisible multiplicity of functions, and the embedded fabric of stories and memories' [3]. Therefore, this study defines the meaning of cultural landscapes to be a variety of cultural landscape including value and meaning for the community in a wider scale than current situations of different levels of registrations as cultural properties for conservation.

The Aim of the Study and Study Methods

This paper aims to clarify characteristics of cultural landscape focusing on houses and local resources in the center of Kudoyama, known as the gateway town to Koyasan in Wakayama, Japan. It is one of the sites registered as the World Heritage Site by the UNESCO, Sacred Sites and Pilgrimage Routes in the Kii Mountain Range in 2004, and additional minor boundary modifications in 2016. The town has a World Heritage Site, Jison-in temple and Nyukanshofu shrine, along with pilgrimage routes of Choishi-michi and Kuroko-michi (added in 2016) to Koyasan, as well as a variety of cultural landscape managed by community. Study methods used are field observations and literature reviews regarding on cultural landscapes.

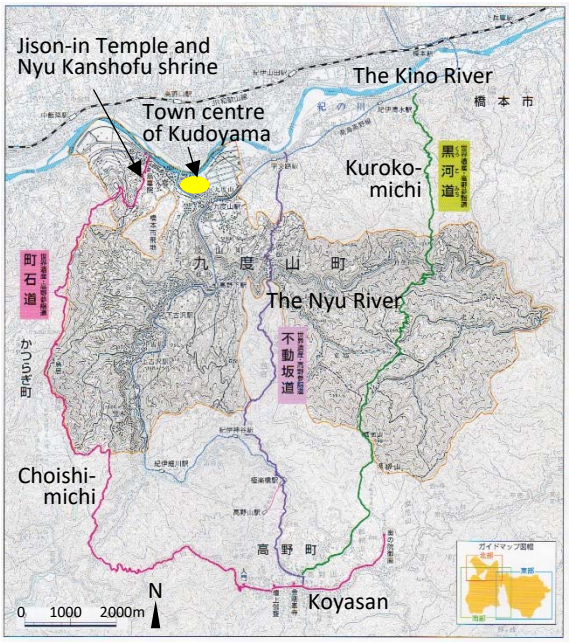

Fig. 1 A map of town of Kudoyama [6] with some amendments

Fig. 2 Undulating landforms and narrow streets

The Outline of the Case Study Location

The town is located at the northeastern part of Wakayama Prefecture. The town of Kudoyama is located along The Kino river which has been a major transportation route by ship between the town of Yoshino, Nara Prefecture and the Wakayama city to carry goods. Therefore, it became a center of a transportation and commerce as a place of unloading at Funato in the town of Kudoyama to Koyasan and surrounding areas since 1601 [7]- [9]. The town center of Kudoyama is located at the foot of mountains to Koyasan, therefore, it became a gateway town and the pilgrimage routes has been developed (Fig. 1). Choishi-michi has been completed in 1285 [10]. Kuroko-michi is documented as the route has been used by one of the famous warriors, Hideyoshi Toyotomi to run down with a horse from Koyasan in 1594 [11]. It is also known to be a place lived by famous warriors of Masayuki and Nobushige Sanada.

The town center has a characteristic of undulating landforms and traditional houses with narrow streets

Fig. 3 Traditional houses creating townscapes

placed on the independent plateau surrounded by two rivers [12], the Nyu river down the mountains of Koya which joins the Kino river (Fig. 1-3).

A CLASSIFICATION OF HOUSES IN THE TOWN CENTRE OF KUDOYAMA

The town is located at the regions of Koya, known as the World Heritage Site, as well as architectural characteristics of using steep sloped sites which can be seen in the neighboring Yoshino region [13]- [14]. It is also surrounded by towns and villages with architectural characters at local scale, i.e., village landscapes at Koya paper making villages [15], and townhouses at cities of Hashimoto [16] and Gojo [17].

A Classification by Numbers of Levels

Single story houses were found at 103 with 32 percent, semi second story houses at 50 with 15 percent, and second story houses at 175 with 53 percent out of 328 houses in total (Table 1, Fig.4). To sum up single and semi second story houses becomes about a half of all houses, which can be recognised to be built in traditional styles (Table 1, Fig.4). Single story houses can be found around the Sanada temple, while semi second story houses are located along the

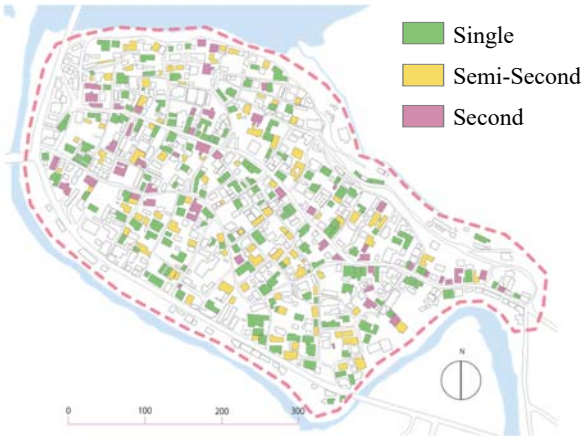

Fig.4 A map of Classification by Numbers of Levels [18]

second main street near the Sanada temple. Second story houses can be found throughout the town center (Fig.4) [12].

Table 1 A Classification by Numbers of Levels [18]

Items	numbers	percentages
Single story houses	103	32%
Semi second story houses	50	15%
Second story houses	175	53%
Total	328	100%

Characteristics of Traditional Houses

A significant number of single-story houses are plastered on the wall. To include partial plaster, it sums up to 50 houses. Semi second story houses can be divided into higher and lower height on the second floor which reflects architecture styles of different time. On the second floor, a window style called 'Mushiko' (refer to as an insect cage) was found at 14 houses, and 13 houses are plastered into a square timber like shaped. Second story houses are relatively newly built. However, some houses are built in the traditional style, i.e., lattice, plaster, etc [12].

A building style of 'Yoshinodate' was found at four houses. The building style can be seen around the region of Yoshino, Nara Prefecture. It utilizes steep slopes to create basements by adjusting to landforms, therefore, a bottom of basements became limited and a foundation are created by terraced stone walls [13]- [14]. Thus, it may be one of the reasons to utilize undulating landforms in town center of Kudoyama.

A Classification by Roof Styles

The results are as follows; gable roofs can be seen at around a half of all houses, at 173 with 53 percent, gambrel roofs are at 102 with 31 percent, and hipped roofs are at 35 with 11 percent (Table 2, Fig.5). Therefore, gable roofs are commonly seen, which

Table 2 A Classification by Roof Styles [18]

Items	numbers	percentages
Gable roofs	173	53%
Gambrel roofs	102	31%
Hipped roofs	35	11%
Semi-Gambrel roofs	8	2%
Flat roofs	4	1%
Thatched roofs	2	1%
Others	4	1%
Total	328	100%

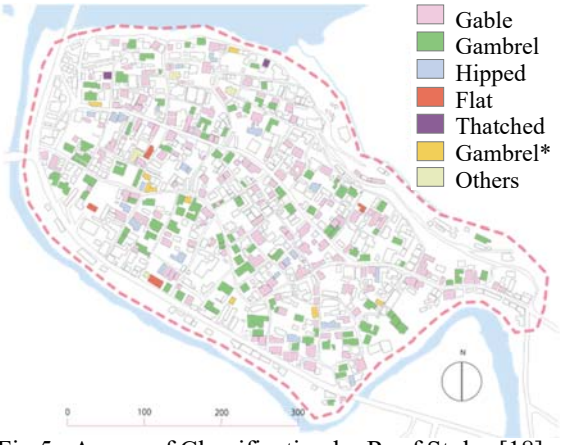

Fig.5 A map of Classification by Roof Styles [18]
Gambrel*: Semi-Gambrel

may be one of the reasons to build houses on the limited land with an independent plateau with higher density in comparison to surrounding areas, such as neighboring district of Nyugo. Gable roofs can be seen along the Sanada high street, and particularly concentrated around the Western area. On the other hand, gambrel roofs are located at the Southern area, along the Sanada temple (Fig. 5). Thatched roofs do exist although at a very limited numbers with two houses. It used to be thatched before, but now has been covered by the tin roofs [12]. This represents the traditional housing styles with the drawings in sites of interests of Kii area in the late Edo period [7].

A Classification by Ridge-end Tiles

The results are as follows; Ornamental borders are commonly seen at 190 with 65 percent, ogre shaped are seen at 63 with 21 percent, and jewel shaped are at 16 with 5 percent (Table 3, Fig. 6). Some ogre shaped are designed with other tiles and plasters. Some houses are decorating ogre shaped tiles in the entrances or gardens; therefore, it is possible to imagine that is used to be placed on the roof top in the past times. Ornamental borders can be seen throughout the town center, whereas ogre shaped are seen along the Sanada street (Fig.6) [12].

Table 3 A Classification by Ridge-end Tiles [18]

Items	numbers	percentages
Ornamental borders	190	65%
Ogre shaped	63	21%
Jewel shaped	16	5%
Family crest	2	1%
Others	22	8%
Total	293	100%

Notes: No ridge-end tiles at 28, and Unidentified at 17.

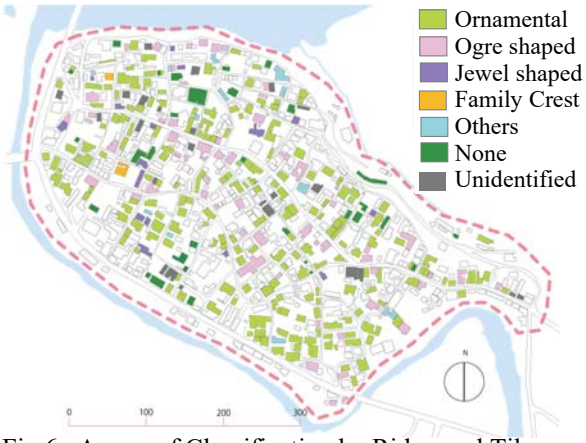

Fig.6 A map of Classification by Ridge-end Tiles [18]

Fig.10 A map of Classification by Uses of houses [18] Merchant*: Merchant houses

Fig. 7 A lattice under the eaves

Fig. 8 A traditionally designed window

Fig. 9 A chimney on a roof with tiles

Details of the design of houses

Traditional houses in town center of Kudoyama have details of the design, such as, lattices (Fig.7), traditionally designed windows called 'Mushiko' (Fig. 8), chimneys on a roof with tiles (Fig. 9), and wooden bars on the edge of the eaves. Houses with lattices were found at 35 houses. This may be due to keep privacy and surveillance from narrow streets with high density of houses in town center [12].

Traditionally designed windows were seen at 14 houses with semi-second story houses, and most of them were designed in square shapes to illustrate the characteristics of timbers. Chimneys on a roof with tiles were found at 5 houses, which can be seen in traditionally designed houses. Wooden bars on the edge of the eaves were seen at 15 houses, which is a common design feature in towns and villages around Koyasan [12].

A Classification by Uses of Houses

The most common uses of houses were residences, and merchant houses have been built along the Sanada street (Fig. 10). Some of residences at present have been built with a signboard architecture, so that it is possible to imagine the houses have been used to be merchant houses in the past. In addition, some merchant houses are single story or semi-second story houses, and it have been built with a traditional design. Moreover, a few factories have been confirmed. According to the interviews to the residents, a saw-tooth roof textile factory used to produce cotton fabrics and had been sold at the Sanada street in the past. From the above, these houses and buildings remaining at present can be said to be the important which represents the history and people's life of the town center [12].

LOCAL RESOURCES IN THE TOWN CENTRE OF KUDOYAMA

In this section, it aims to clarify the characteristics of local resources from a classification and a distribution in town center of Kudoyama. Local resources also reflect natural and historic environments of the area, and it may be necessary to examine the management and conservation as well as houses and buildings [19]. Miyayama and Kamihogi introduces the concept of local resources represented by 'natural elements' to inherit the local history and culture, i.e., landforms, rivers, and streets; and 'historic elements' of monuments and sights of interests, as well as the wider understandings of landscapes and spaces [20]. Therefore, this study aims to clarify natural elements and historic elements.

Characteristics of Local Resources

From the results, a variety of local resources have been become clear and managed by people in the area. In terms of classification, natural elements were found at 224, and historic elements were at 7. Natural elements can be divided into leveling at 115, pine trees at 94, and wells at 15. Historic elements were found with shrines for residences at 4 and monuments at 3 (Table 4-5) [19].

Levelling are largely formed with stone walls particularly along the Kino river and the Nyu river to

Table 4 A Classification of Natural Elements [19]

Items	numbers	percentages
Leveling	115	51%
Pine trees	94	42%
Wells	15	7%
Total	224	100%

Table 5 A Classification of Historic Elements [19]

Items	numbers	percentages
Shrines for residences	4	57%
Monuments	3	43%
Total	7	100%

Fig. 11 Stone walls forming townscapes

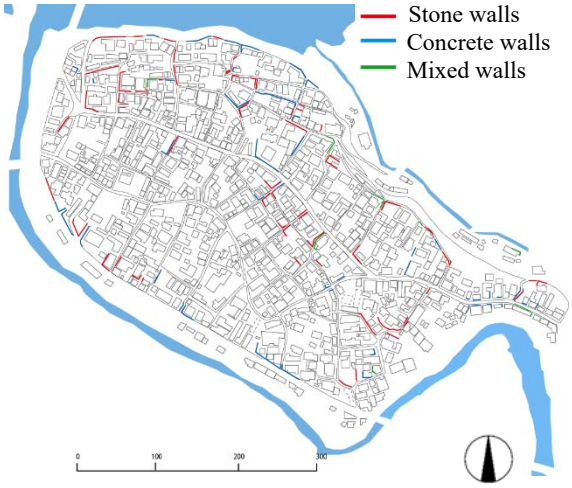

Fig. 12 A map of Levelling [21]

Fig.13 A map of Pine Trees [21]

Fig. 14 Pine trees creating townscapes

represent characteristics of undulating landforms. Chlorite schist, a locally produced stone, has a half of the numbers of all levelling with a count of 62 (Fig. 11, 12). Pine trees can be found in the gardens or entrances of houses (Fig. 13). There are a variety of sizes of pine trees from potted plants to large trees. Several trees planted nearby, and large trees are becoming as landmarks to create characteristics of historic environment and townscapes (Fig. 14) [19].

From the above, a variety of local resources can be seen in town center of Kudoyama which is managed

regularly by people in the area.

CONCLUSIONS

From the results, characteristics of the town center of Kudoyama became clear as follows; around a half of all houses have been built with single or semi-second story houses to form relatively reduced height of skylines. Thus, it creates viewpoints to surrounding mountains within the town center on undulating landform. In terms of local resources, a variety of natural and historic elements have been found to create historic environments in town center of Kudoyama. In addition, some traditional design of houses is representing the similarities with surrounding areas of the World Heritage Sites of Yoshino and Koyasan. In future, managing cultural landscape may be necessary to balance the needs of the community and tourism.

ACKNOWLEDGEMENTS

The authors would like to express our gratitude for the financial support provided by the cultural heritage utilization and community activation project from the Agency for Cultural Affairs.

RESIDENTS' EVALUATION AND CONTINUITY IN THE CASE OF SHIKISHIMA OPEN GARDEN IN MAEBASHI CITY

Shinya Tsukada1, Kazuya Tsukada2, and Tetsuo Morita3
1Maebashi City Office, Japan, 2Seikei University, Japan,, 3Maebashi Institute of Technology, Japan

ABSTRACT

Living while feeling various green effects is considered an effective tool to adapt to the situation of declining population and the aging population or to live an environmentally friendly life. To realize this, it is necessary to have a green zone management policy through cooperation between the administration and residents. Particularly, open gardens (* OG) as one of the private greening areas are expected to have great effects on the viewpoint of town planning. In the task of OG, "trigger and form of activity", "increase participants" and "increase awareness" are soft issues in sustainability. We thought that these could greatly influence the citizen's future activities. Therefore, we focused on this research. Therefore, to solve the above three major problems, this research grasped "situation of efforts by administrators and OG organizers in the case of OG of Maebashi City" and "perception of neighborhood residents' OG activities". The purpose of this research was to obtain basic knowledge for improvement of "issues for the sustainability". As a conclusion, "Shikishima OG" was not a limited activity of merely a favorite group, but more than half of the residents were recognized in the area around Shikishima Park. In addition, 80% of those inhabitants regarded positively as "Shikishima OG contributes to local community development". Furthermore, we could grasp that "improvement of the landscape of the district" was the most expected by these inhabitants in terms of "community development".

Keywords: Open Garden, Actual Situation, Actual Evolution, Continuity

INTRODUCTION

In today's Japan, Japan's financial resources are constrained by the declining population, the aging of the population, and the increase in infrastructure stocks. Under these conditions, to promote environment-friendly living environment improvement and regional development, urban planning that fully demonstrates the various benefits of green and open space is required.

To carry out city planning that fully demonstrates the diverse benefits of greenery and open spaces, it is important that the government and residents work together to make greening activities in accordance with the characteristics of the area and the needs of the residents.

Japan's greening policy can be broadly divided into two. The first is greening of public facilities, which is led by the government. The second is greening of private land, which the residents take the lead.

As one of the private land reforestations, open garden is expected to have great effect based on the point of town development. The open garden (hereinafter referred to as OG) is an activity to open private garden into public. The purpose of this activity is to make citizens enjoy the garden of an individual. This is a greening activity developed in Japan at the late 1990s.

The pleasure of showing the owner's garden to the visitor and the pleasure of the visitor watching the owner's garden can be expected to have the effect of fostering exchanges and communities via flowers.

VIEWPOINTS

Previous research

Research on OG in Japan was accumulated as the activities of OG in Japan were developed.

For example, a study of features and problems in Obuse Town, Nagano Prefecture, conducted by Mr. Nonaka [1]. Another study conducted by Mr. Hirata focused on the impact of the open garden on the regional economy [2]. These are researches on the cause of OG introduction in Japan, and the effect and significance of activities.

After that, with the spread of the activities of OG in Japan, the research conducted by Nonaka "Focus on the behavior of the viewer at the time of the green event [3]", the research brought about by the open garden conducted by Sambuichi and Iwatomo et al. [4] [5] etc. These researches on the visitor's behavior and the actual activity concerning OG was conducted.

Viewpoints of this research

As a study of OG today, a study [6] was conducted focusing on the actual condition and continuity of the

open garden activities conducted by Park. In this study, 73 OGs in Japan were classified into three groups of 9 years or more, 5 years or more and less than 9 years, and 5 years or less. Because of the research, it is necessary to secure the parking lot on the hard side for the continuity of the activity of OG. In terms of software, it has been suggested that it is important to increase activity awareness, form of activity, increasing human resources to conduct activities, and to increase awareness of OG.

As mentioned above, although the research about OG has shown the subject in the activity actual condition and continuity of OG, there are few researches, which examined these subjects more deeply. In addition, “triggers and forms of activities,” “increase the number of participants,” and “increase awareness”, which are the software issues in OG's continuity of activities, are particularly important for promoting future activities. However, conventional research focusing on this has not been seen.

In this study, the above three major issues are summarized as "The issues of OG activity continuity". Then, for the open garden in Maebashi City, we conducted a questionnaire survey 1) on the status of efforts by administrative personnel, and 2) 0on the awareness of OG activities by nearby residents. In addition, it was considered as the originality of research to obtain basic knowledge for the improvement of "problem to OG continuity".

SHIKISHIMA OPEN GARDEN

In this study, OG (hereinafter referred to as Shikishima OG), which has been continuously addressed for 10 years at Shikishima area in Maebashi City, Gunma Prefecture, is used as an example. Firstly, in order to investigate the actual conditions and characteristics of "Shikishima OG", the actual situation was grasped by interviews with the administrative staff who were continuously involved in the work of open garden.

Figure 1 shows the location of the open garden being tackled in Maebashi City. The open garden that has been held continuously for 10 years in the central area of Maebashi City is "Shikishima OG." The "Shikishima OG" began when the National Urban Greening Gumma Fair was held in March 2008 in Gunma Prefecture. Shikishima Park is selected as the main site of the afforestation fair, and the open garden that residents of the adjacent Shikishima area have been working on is the "Shikishima OG Festival" (Fig. 2).

Before the National Urban Greening Gumma Fair

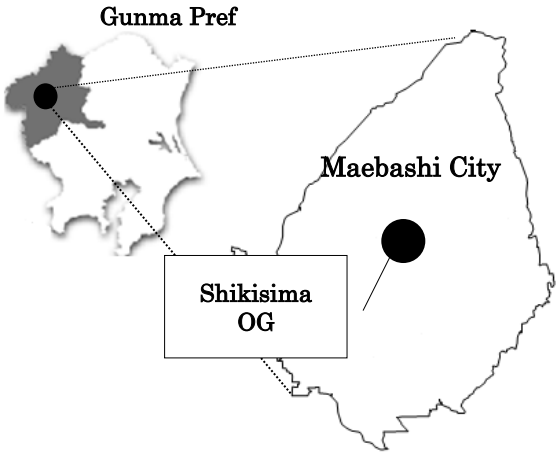

Fig. 1 Location map of Shikishima OG

Fig. 2 Shikishima OG Festival

In 2005, Maebashi City planned an open garden to promote the development of flowers and greenery with the participation of residents in conjunction with the holding of the urban greening fair.

First, in Maebashi City, a lecture was given by a lecturer by Katsue Suma (113 participants) to promote the project. Next, the gardening course and the flowerbed of the Shikishima Town Park were implemented as an approach for the practice of OG.

Shikishima Town Park is a familiar block park in Shikishima Town.

The administration (Maebashi government office) offered the block park of the district as a place of the flowerbed making practice, and there was a desire to want to plan the improvement of the facility environment.OG. Those who wish to participate had a desire to promote their activities to the district residents widely by utilizing the local block park. The interests of both the administration and OG participants agreed.

Gardening course was established in 1971 and was held in greening enlightenment business of

"committee to make town green" with citizen activity organization with history. By holding "seeding class" and "cutting tree class", the opportunity to discover flower lovers was established.

The first open gardening workshop was held in April 2007 at the “Fukaya Flower Festa” site (18 participants). In June of the same year, an open garden gardening class and a planting class for Jade Garden were held (19 participants).

By the time the greening fair was held in 2008 (about 1 year), OG practice classes were held 15 times and open garden gardening classes were held 3 times. Technology training and human resource development for the implementation of the open garden were carried out roughly once or twice a month. This training resulted in the participation of approximately 20 fixed flower lovers.

National Greening Gumma Fair Conducted-After

In the first "Shikishima OG Festival" in conjunction with the holding of " National Urban Greening Gumma Fair " on March 29-30, 2008, "Shikishima Park Flower Friends" with 18 participants are organized and the members' private garden is It was released.

The “Shikishima OG Festival” has been continued every year during the implementation period of the Rose Garden Festival at Shikishima Park after the greening fair (Fig. 3).

In 2019, the 10th "Shikishima Open Garden Festival" was held. Nineteen proud gardens were opened during the two days of the Rose Garden Festival.

As for the administrator, the lecture for citizens promoted citizen enlightenment for OG business is the reason that the activity of "Shikishima OG" continued for 10 years continued. Flower lovers gathered from interest to gardening course and maintenance of flower bed of Shikishimacho Park. In addition, flower lover activities such as open garden inspection training and the implementation of open garden practice classes led to OG. Furthermore, the findings obtained through regular inspection training were used for OG practice. It was evaluated that the continuous approach by such PDCA cycle was the starting point.

For the "Shikishima OG" approach, inspection training sessions and technical training increased the number of activities and participants. In addition, it was evaluated that the use of the block district park familiar to the district residents as a place of OG practice was effective in raising the awareness of the residents.

CITIZEN EVALUATION OF OPEN GARDEN ACTIVITY

Fig. 3 Implementation status of the Shikishima OG Festival

Table1 Neighborhood Resident Questionnaire Survey

Area	within 2.5 km Around Shikishima town
Target	Kawahara town Aramaki town Kamikoide town Shikishima town Midorigaoka town Iwagami town
Duration	2016.8.18～2016.8.31
Method	Posting
Distribution	1,800
Sample	472

The questionnaire survey shown in Table 1 was conducted in order to investigate the residents' evaluation of the activities of "Shikishima OG", which has been working on OG continuously for 10 years. The survey area was 6 towns around Shikishima Park where open gardens are being conducted (within 2.5 km around Shikishima town).

The land use of 6 cities is in the urbanized area in the Maebashi urban planning area, and the use area of the residential area from the first-class low-rise residential area occupies over 80% of the area.

In addition, around Shikishima Park is designated as scenic area. Table 2 summarizes the personal attributes of respondents. According to the table, although there is no significant difference in gender, by age 50 or more accounted for 77.3%. In terms of occupation, "no-employment (34.7%)" was the most frequent, followed by "company employee and public employee (28.0%)." In the family structure, the total of "one generation household" and "two generation household" accounted for 72.2% of the whole.

The residence type was "single-family house (85.2%)".

Table2 Respondent Attributes of the Neighborhood Resident Questionnaire

Sex	Men:56.1% Women:41.9% N.A.:1.9%
Age	19 under:0.2%、 20～29:2.8%、 30～39:6.6%、 40～49:12.1%、 50～59:17.2%、 60～69:25.8%、 70 more:34.3% N.A.:1.3%
Employment	Company employee and Public employee 28.0% Company-owner: 7.4% engage in agriculture: 0.0% housekeeper: 14.4% Student: .6% Part-time: 7.2% No-employment: 34.7% Other: 6.1% N.A. : 1.5%
composition of a family	Single-person household:16.5% One generation household:35.8% Two generation household:36.4% Three generation household:6.6% Other: 3.4% N.A.:1.3%
Habitation	Single-family house: 85.2% Cluster housing: 13.1% Other: 0.4% N.A.: 1.3%
Residence year	0～9: 20.8% 9～19: 17.8% 20～29: 12.9% 30～39: 15.9% 40～49: 14.8% 50～59: 8.1% 60～69: 3.4% 70～79: 3.0% 80～89: 1.1% N.A: 2.3%

Table 3 shows the outline of the questionnaire survey. 55.5% of respondents answered that they knew the activity of "Shikishima OG" and 44.5% answered that they did not know. The following questions were answered by 262 respondents who said, “I know”.

Table3 Results of Neighborhood Resident Questionnaire Survey

Q1: Do you know the Open Garden activities around Shikishima Park?	
They knew the activity	262(55.5%)
They did not know	210(44.5%) (No questions to follow)
Q2: Do you have visited Shikishima Open Garden activities, have you ever seen it?	
visited	87(33.2%)
Seen it	154(58.8%)
N.A.	21(8.0%)
Q3: What changes do you think the area around Shikishima Park will be due to Shikishima Open Garden activities?	
I think that the landscape of the district improves	137
I think that the greenery and flowers of the district will increase	124
I think that the greenery and attachment of the area will increase	84
I think that the community activity will be active	64
I think that nothing changes in particular	35
Do you think that Open Garden activities contribute to community development in the community?	
I think	206(78.6%)
I do not think	50(19.1%)
N.A.	6(2.3%)

Firstly, 33.2% of the respondents answered that they "visited" when I asked the question "Do you have visited Shikishima OG, have you ever seen it?". Next, I asked them to answer the question "What changes do you think the area around Shikishima Park will be due to Shikishima OG activities?"

As a result of the answer, "I think that the landscape of the district improves (137)" was the most frequent. The fact that the neighborhood residents most hoped for the improvement of the landscape of the district by the open garden activity was realized. Then "I think that the greenery and flowers of the district will increase (124)", "I think

that the greenery and attachment of the area will increase (84)", and "I think that the community activity will be active (64). In addition, when asked about "Do you think that open garden activities contribute to community development in the community", 78.6% of the respondents answered, "I think".

From the above, "Shikishima OG" was not just a limited activity of a lover's group, but activity was recognized by more than half of the residents in the area around Shikishima Park. And about 80% of the people who recognized it were positively regarded as "contributing activities to community development in the community".

In addition, in "the town development of area", expectation was most raised for "the scenery of district improves". From this result, the recognition of the activities of the nearby residents and the expectation for the community development were one of the factors that "Shikishima OG" could be continued.

CONCLUSIONS

In this research, we examined three aspects of open garden "motive for activity", "increase participants" and "increase awareness" as a problem of activity continuity, taking "Shikishima OG" as an example. Park's previous research [6] suggests that open garden activities tend to be continued toward activities starting with "a gathering of flower lovers" rather than "recommendation of administration."

"Shikishima OG" originated from the recommendation from the administration (Maebashi City Hall). I. I made an opportunity of activity centering on training of training courses and practical skills. After that, they voluntarily recruited participants of flower lovers' gatherings. II. The area block park familiar to the district residents was used as a place of practice. As a result of the above, the awareness of the residents was raised, and as a result, OG activities could be continued.

"Shikishima OG" was recognized by more than 50% of the respondents in the results of the questionnaire survey on the neighbors. In addition, more than 80% of the recognized residents were rated as "contributing to the area", and it was possible to know "the situation what they most expected these activities to create a local landscape"

The Shikishima OG, which has continued for 10 years, is considered to have received favorable evaluations from nearby residents as a result of working on activities characterized by the issue of activity and the issue of increasing the number of participants, which are the issues of activity continuity.

We will quantitatively verify the basic findings obtained in this research on the subject of activity continuity. In addition, I think that it is necessary to do a concrete study to solve the problem of activity inheritance.

ABSTRACT

The Kaizou-Gawa River is a middle size of the river which flows down to Ise Bay though the northern part of Yokkaichi city. Recently, in the catchment area of the river many pig farms and a semiconductor factory were constructed, In order to identify the influences on them, investigations were carried out over 5 years. High levels of pollution of nutrients and fluorine compounds were found. These pollutions are considered to be related with wastewater of the semiconductor factory and pig farms.

Keywords: Water, Pollution, IC industry, Pig farm, Waste-water

INTRODUCTION

The Kaizou-Gawa River is a middle size of the river which flows down from Komono-Cho town to Ise Bay though the northern part of Yokkaichi city[1)]. The river is situated in a rural area, and is well known by many citizens as the place of ECO-Activities because of its landscape and biological diversity. In the catchment area of the river, vast rice field is spread, and the river enacts an important roll as the source of the irrigation water. However, recently, some big pig farms were constructed upstream from them, and a semiconductor factory was constructed at the upper stream of the branch river. In order to identify the influences of both, an investigation was carried out[2)].

METHOD

Time and investigation site

The investigation was carried out in the years 2015 to 2018 at the stations St0 to St11 (12 stations, shown in Fig.1). In order to identify the source of the pollution, waste water discharged from the pig farms was also investigated.

Monitoring site

The feature of the monitoring sites are mentioned below.
St0: most upstream of the Heta-Kawa river, where has no influence of the semiconductor factory, St1: downstream of the discharge point of the semiconductor factory, St2: downstream of the Heta-Kawa river. St3: irrigation canal, which flows down to the mouth of the main stream. St4: situated at the most downstream of the river. St5: Eda-Gawa, one of the branch river, St6: Taketani-Gawa (branch river), St7: midstream of the main stream. St9: small irrigation canal which leads to the Taketani-gawa. St8: Ooguti-Gawa, branch river, near of Sato-pig farm, St10: upstream of St8, St11: situated at the most up-stream of the main stream, where no typical inflows of the pollutants.

Parameter and analytical methods

Parameter and analytical methods are shown in Table1.

RESULT AND DISCUSSION

At St 0 a high concentration of NO_3-N was found which was considered to be affected by the farm land around there. At St1, St2 and St4, high values of EC, Cl-ion, F-ion were found (Fig.4), these high pollutants level are considered to be due to the influence of the wastewater from the semiconductor factory. The pollution is considered to become significant because of the volume of the wastewater compared to the small original flow rate of the river. In order to solve the matter, much stricter waste water control will be needed. At the St3, some-time relatively high values of F-ion was found which is related to the introduction the irrigation water from the Heta-Gawa river.

At St8 and St9, high values of COD, NO_3-N, NH_4-ion and PO_4-P were found (Fig.2 and Fig.3). At St8, low values (2mg/L to 6mg/L) of DO were also found which is considered to be an influence of the pollutants. These pollutants are considered to be the influence of the wastewater from the pig farms around there. Many pig farms in the area have some waste water treatment facilities,

Table 1 Parameter and analytical methods

Parameter	Method	Parameter	Method
p H	Glass electrode method	NH_4-Ion	Indophenol method
EC	Plutonium electrode method	PO_4-P	Molybdenum color method
DO	Winkler method	F-Ion	Lanthanum-alizarin complexone method
COD	Acidic Manganese titration	CL-Ion	Silber nitrate titration
NO_3-N	UV absorbance		

Fig. 1 Investigation Site

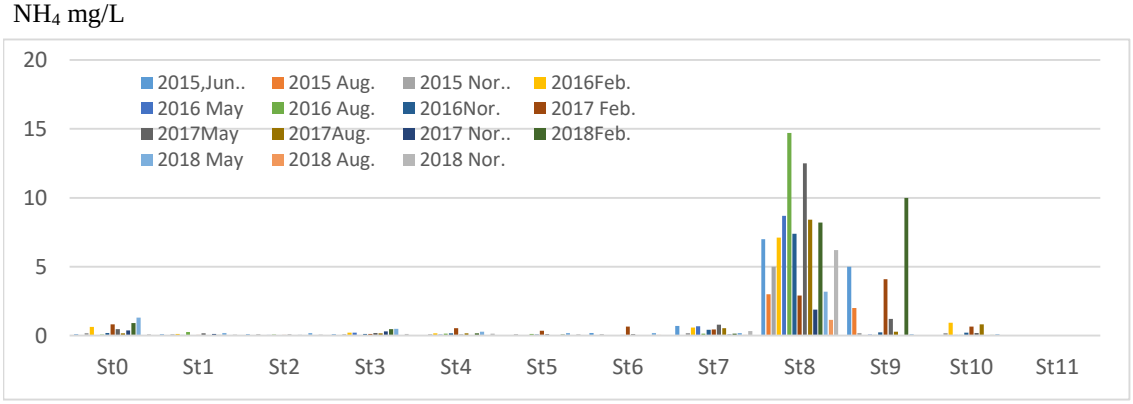

Fig. 2 Features of the NH_4-Ion

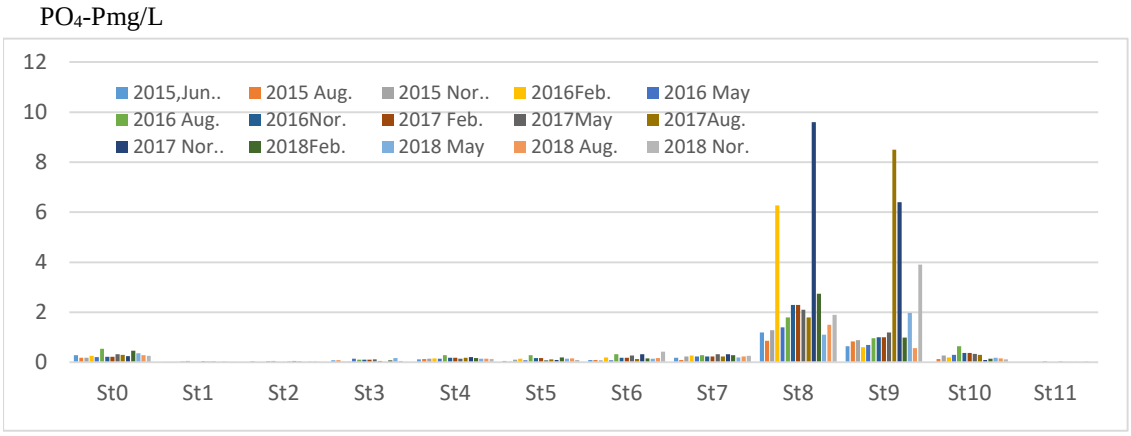

Fig.3 Features of the PO_4-P

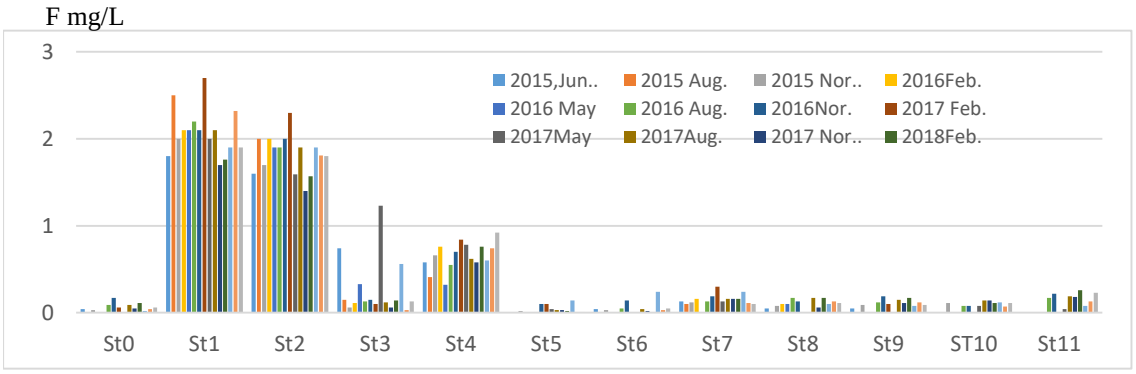

Fig.4 Features of the F -Ion

but these measures are not enough, and influences to the river cannot be ignored. The pollution tends to be lower toward the downstream of the river due to the dilution of the branch river.

At the other monitoring sites, no remarkable pollution was found, and water quality was maintained as pH value distributes around 7 to 8, and DO value 8mg/L to 11mg/L, and the river is judged to be a slightly polluted river like other rivers in this district[3].

CONCLUSION

In order to identify the degree of the pollution, investigations were carried out over 5 years on the Kaizo-gawa river. At the Heta-gawa (branch river), high concentrations of F-ion , Cl-ion was found, and also high values of EC was found. These pollution levels are considered to be due to the influence of the waste water from semiconductor factory near of the river. At the Ooguchi-gawa and Taketani river, (other branch river) high concentrations of COD, PO_4-P, NH_4-N were found which are considered to be caused by pig farms near of the river. At other monitoring sites, unusual levels of pollution was not found.

ACKNOWLEGEMENT

The authors wish to express their appreciation to Dr. Eric Bray (Professor of Yokkaichi University) for his advice on making the article.

ABSTRACT

The solid tire performance can be characterized by the contact patch. The footprint is the particular method to achieve the contact patch between a tire and pavement. The flat surface is often equipped to support a pressure measurement film which is pressed by the tire tread. This derivative patch illustrates characteristic seems the probable result to predict tire performance. Practically, the contact patch happens by the rolling tire. To understand the patch characteristic, the contact patch between the rolling tire and pavement was studied. The 3D finite element model of solid tire which pressed on three different surfaces was developed. The experimental footprint on the flat surface was carried out to validate the finite element model. The contact patch of solid tire tread on the drum surface was investigated to discuss the effect of supporting floor of the testing method. The stress distribution in the solid tire model is the exceptional criteria to clarify the contact patch on the road. The developed models will be used to design the tire tread and pavement in the future work.

Keywords: Solid tire, Finite element method, Ride Contact patch, Pavement, Tread

INTRODUCTION

The solid tire has an excellent performance for supporting the heavy load. To develop solid tire performance, the tire testing is carried out to provide the physical behavior of tire. The tire stiffness testing is used to study the tire characteristic under the compression load which compose of the vertical stiffness and contact patch. Liang et al., [1] had been used the tire static loaded machine and tire pressure measurement system (Tekscan) to studied the footprint geometry. The footprint shape was described in order to build the relationship between the footprints and tread wear. Nowadays, the engineering design technology has been employed popularly to develop the tire performance. The computer aided design (CAD) and computer aided engineering (CAE) can be used to develop the solid tire. The performance testing by the stiffness tester is the compressing on flat surface which performed on solid tires to create benchmark for validation of the solid tire deformation models [2]. Alkan V. et al. [3, 4] had been investigated the static tire enveloping characteristic by experimental setting and 3D finite element model. The finite element method had been used to design tires popularly. The vertical stiffness of the rolling pneumatic tire was studied on a flat surface. To develop the tire safety and effective driving action, the carcass stiffness was studied [5]. The pneumatic tire was compressed on flat surface in laboratory. The carcass stiffness was carried out from experiment to validate the FE model. Subsequently, the FE model which can provide the gradient of contact stress was used to study the effect of carcass stiffness. Practically, the tire is used in the rolling state. The drum testing method is ideal for rolling tire testing in laboratory [6]. Then, the drum testing method which mimics the tire rolling on flat road was widely used to investigate the mechanical behavior of rolling tire. Phromjan J. and Suvanjumrat C. [7] had been carried out the drum testing method with a diameter of 1.7 m to study the vibration behavior of solid tire and pneumatic tire. The rolling velocity and compression load on tire was controlled. Wei C. and Olatunsun O. A. [8] were studied the effect of different height obstacle on pneumatic tire behavior traversing by finite element method. The drum testing method with a diameter of 2.44 m was performed in order to examine the transient dynamic responses of a pneumatic tire rolling over road obstacles and to validate the FE pneumatic tire model. Moreover, the drum testing method was modeled in 3D finite element model to develop the accurately simulation of pneumatic tire rolling over cleat by transient dynamic model [9]. The transient dynamic response was studied in time and frequency domain. The tire rolling speed gave the remarkable influence while the change of the tire inflation pressure only produced the remarkable variation in vertical dynamic force. Both flat and curvature surfaces were used to support tires under the performance testing without proofing its effect. Consequently, the effect of curvature of drum on tire/road contact is interesting.

In this research, the 3D finite element model of

solid tire was developed to study the contact patch characteristic by the compression on three tendentious difference pavements.

THE TIRE TESTING METHOD

The 6.00-9 inch solid tire was interesting to study in this research. The characteristics of solid tire are described in Table 1. According to the tire standards, the tire testing was set to characterize the tire performance. For example, the tire stiffness testing was performed in order to achieve the tire deformation, tire stiffness and tire-pavement contact patch by steel flat surface. On the other hand, the drum testing method which was performed by cylindrical steel surface provided the tire rolling characteristic. The curvature of steel drum surface might be effects to the rolling solid tire which was provided the deformable behavior as like as the tire testing on flat surface.

Table 1 The characteristic of solid tire.

Size (inch)	Rim Size (inch)	Tire Dimension (mm)		Weight (kg)
		Width	Outside Diameter	
6.00-9	4.00E-9	145	523	27

The tire stiffness testing

The tire stiffness testing has been performed by mounting a solid tire on axle of the tire stiffness tester EKTRON TEK model: PL-2003 of Research and Development Center for Thai Rubber Industry (RDCTRI) as shown in Fig. 1. The stiffness characteristic of solid tire was measured by loading the solid tire on measurement table which had a pressure measurement film. In order to investigate the contact patch, the solid tire was pressed by three different loads which were comprised of 400, 800 and 1200 kg. Fig. 2 shows the contact patch on pressure measurement film which illustrates contact area (CA) and footprint area (FA). The FA was calculated by a×b while the contact area was presented in red color. Moreover, the contact pressure distribution on pressure measurement film was presented by color intensity. The vertical force and deformation were measured by a load cell and position transducer while the measurement table was driven by hydraulic motor to lift and press the stationary solid tire.

The drum testing method

The mechanical behavior of rolling tire was investigated by mimicking rotation state of the tire. The drum testing method is an ideal testing in the laboratory. It is exclude the various factors such as road surface and vehicle system which are not the effect of the tire. The drum testing method has been performed by mounting a solid tire on a mounting arm which is driven by hydraulic motor to move and press the solid tire onto rolling steel drum as shown in Fig. 3. The solid tire was pulled to roll at the same velocity with the rolling steel drum by the friction between the contact areas.

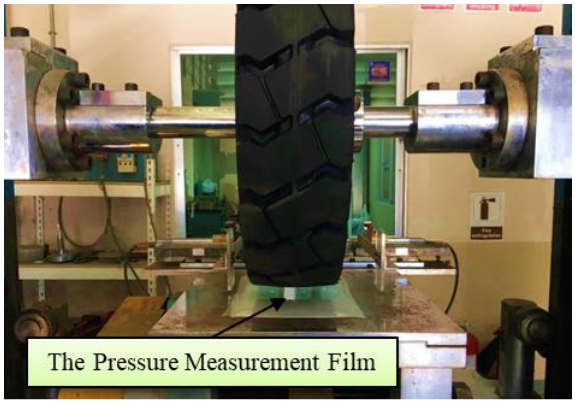

Fig. 1 The tire stiffness testing.

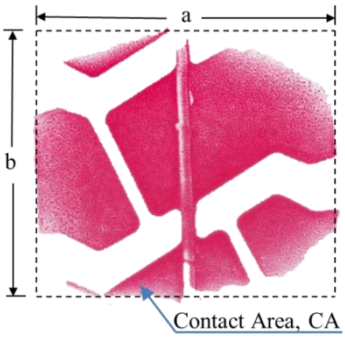

Fig. 2 The contact patch on pressure measurement film.

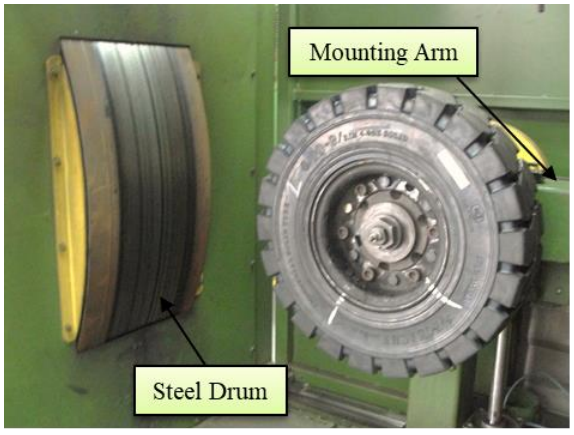

Fig. 3 The drum testing method.

FINITE ELEMENT METHOD

The finite element analysis (FEA) of the solid tire testing is governed by Eq. 1.

$$m\ddot{u}_i + c\dot{u}_i + ku_i = F_i \tag{1}$$

where u_i is the time-dependent displacement field, c is the damping coefficient, m is mass, F_i is the total force.

The Eq. 1 can be transformed into the form of system total work which balanced the work per unit element as shown in Eq. 2 [10]. Hence, V and s is the element's volume and element's surface, respectively.

$$\int \{\delta u\}^T \{f_i\} dV + \int \{\delta u\}^T \{\Phi\} ds + \sum_{i=1}^{n} \{\delta u\}_i^T \{p\}_i = \int \left(\{\delta u\}^T \rho \{\ddot{u}\} + \{\delta u\}^T c\{\dot{u}\} + \{\delta\varepsilon\}^T \{\sigma\} \right) dV \tag{2}$$

where f_i is body force, Φ is surface force, p is determined force, ρ is mass density, ε is strain, σ is stress and n is the number of nodes.

The solution of transient FEA can obtain by the Housbolt method. The general form of the single-step Housbolt is written in Eq. 3-4 [11].

$$\dot{u}_{n+1} = \dot{u}_n + \gamma \Delta t \ddot{u}_n + \gamma_1 \Delta t \ddot{u}_{n+1} \tag{3}$$

$$u_{n+1} = u_n + \Delta t \dot{u}_n + \beta \Delta t^2 \ddot{u}_n + \beta_1 \Delta t^2 \ddot{u}_{n+1} \tag{4}$$

where β_i is the constant and γ_i is the defined parameter.

In case of large strain, the hybrid formulation is effective for the analysis of rubberlike material [12]. The FEA of the solid tire testing was governed by the following equations which the strain energy density per unit volume, ${}_0^t\bar{U}$ is defined in Eq. 5.

$$d\,{}_0^t\bar{U} = {}_0^t\bar{S}\, d\,{}_0^t\varepsilon_{ij} \tag{5}$$

where $d\,{}_0^t\bar{U}$ and ${}_0^t\bar{S}$ are incremental potential energy and Piola-Kirchhoff stress which computed only from the displace field.

The integral form of total Lagrangian formulation is shown in Eq. 6.

$$\int_{V_0} {}_0^t S_{ij} \delta\, {}_0\varepsilon_{ij} dV_0 = R \tag{6}$$

The general form of principle of virtual work which written in the total Lagrangian formulation is given in Eq. 7.

$$\delta\left(\int_{V_0} {}_0^t U dV_0 \right) = R \tag{7}$$

where ${}_0^t U$ is the incremental potential which can be modified to include the effect of interpolated pressure by adding to the term of the displacement based total element pressure.

Material properties

The solid tire which is studied in this research is comprised of the three rubber layers and 4 steel wires (Fig. 4). The rubber layers were built by different formula of rubber compounds. The internal layer (M058) was hardest, the middle (M047) and the tread layer were softer, respectively. The material property of each rubber layer of solid tire was obtained by the tensile testing according to ASTM D412 standard. The stress-strain curve from the tensile testing was fitted by linear regression method. The Ogden hyperelastic constitutive model (Eq. 8) which is the strain-energy density function was the most suitable to represent the solid tire deformation behavior in all rubber layers [13]. The values in Table 2 are the constant of Ogden constitutive model of three rubber layers. The steel wire was specified with elastic modulus and Poisson's ratio of 200 GPa and 0.3, respectively.

$$\mathrm{U} = \sum_{\mathrm{i}=1}^{\mathrm{n}} \frac{\mu_i}{\alpha_i} (\bar{\lambda}_1^{\alpha_i} + \bar{\lambda}_2^{\alpha_i} + \bar{\lambda}_3^{\alpha_i} - 3) + 4.5K(J^{1/3} - 1)^2 \tag{8}$$

and $\bar{\lambda}_\mathrm{i} = \mathrm{J}^{-1/3}\lambda_\mathrm{i}$, $\mathrm{J} = \lambda_1\lambda_2\lambda_3$.

where λ_i is the deviatoric principle stretches, J is the Jacobean determinant, K is the initial bulk modulus, and μ_i, α_i is constant.

Solid tire finite element model

The solid tire model was created in three dimensions using data from the 3D scanner (Artec 3D, Eva) and CAD software. The solid tire model was meshed by hexahedral elements. Consequently, the internal, middle, tread layer and steel wires are created using 16,623, 8,448, 14,366 and 7,040 elements, respectively (Fig. 5). The element of steel wire, internal, middle and inner tread layer are connected together with conjunct node while the outer tread layer is connected with the inner tread by glue contact condition as presented in different color as shown in Fig. 6.

The finite element model of tire stiffness testing

The finite element (FE) model of solid tire which was described in above section was compressed on a rigid flat plate according to the physical tire stiffness testing. Fig. 7 shows the boundary conditions of FE solid tire testing model which the RBE2 elements were defined to link the axis of solid tire model as the steel wheel. The fixed boundary condition was assigned on wheel fixed point as same as the solid tire mounting on the axis of the stiffness tester. The contact boundary condition between the solid tire model and rigid flat plate was specified with 0.8 of static friction coefficient. The vertical loads were assigned on a rigid flat plate to lift and press the solid tire model. Subsequently, the solid tire model was compressed by three different loads which were 400, 800 and 1,200 kg, respectively.

The finite element model of drum testing method

The cylindrical steel drum was created using the curvature rigid element with a diameter of 1.7 m according to the size of the drum testing machine, KAYTON; model: DTM-350PC of RDCTRI. It provided the diameter ratio of 3.25 between the diameter of drum and tire. First, the vertical load was assigned on a rigid drum to move and press the solid tire model by three different loads, 400, 800 and 1,200 kg. Next, the rigid drum was rotated with a constant velocity of 20 km/h. After that, the solid model was pulled by the rolling drum with the dynamic friction coefficient of 0.5 which referred to the principle of drum testing machine. The implicit dynamic transient with single-step Houbolt was used to operate the rolling solid tire finite element model. The constants for analysis were 1.5 and -0.5 for γ_1 and γ , respectively. Fig. 8 presents the boundary condition of rolling solid tire on steel drum to study the effect of curvature surface on contact patch by FEM. MSC. Marc software which was installed in a personal computer with a Core-i7 processor and 8 GB RAM memory had been used to process finite element method of solid tire testing.

RESULTS AND DISCUSSIONS

The results of compressed solid tire (size 6.00-9 inch) on rigid flat plate model were compared with the stiffness testing. The contact patch of compressed solid tire on rigid flat plate model found to be in agreement with the experimental result under compression loads of 400, 800 and 1,200 kg. Table 3 presents the contact patches of all studied conditions which observed at the same tread pattern position with experiment. The vertical deformations increase by the increase of compression loads as shown by graphs in Fig. 9. The comparison graphs in Fig. 10 also indicated that the footprint area of solid tire on measurement table under various compression loads by experiment is smaller than footprint area of compressed solid tire model on rigid flat plate. The maximum stress which happens on the tire tread can illustrate by FEM as shown in Fig. 11. The maximum normal stress happened at the contact area between solid tire model and pavements. At the same time, the concentrate stress also happened between glue contact area of inner and outer tread. This phenomenon affected to the poor distribution of contact patch. The better stress distribution of solid tire model compression on rigid flat plate provided the lower vertical deformation and maximum stress than stationary drum because of contact with the smooth curvature cylindrical drum surface. The maximum normal stress which happened on solid tire under rolling drum was higher than the rigid flat plate. The lateral force of rolling contact affected to the

increase of maximum stress. Fig. 12 shows the comparison graphs of maximum stress between the flat plate and the curvature rolling drum. The contact patch was affected by drum pulling and then some of solid tire elements were deformed extremely. However, the contact coefficients (CA/FA) which represent the adhesion and wear behavior of solid tire were similar. Fig. 13 shows the comparison graphs of the contact coefficients. The average contact coefficient of experiment of solid tire stiffness testing, FE model of solid tire stiffness testing, FE model of loaded drum and FE model of rotated drum were 0.70, 0.70, 0.67 and 0.68, respectively. The error of contact coefficient of solid tire models on the rolling drum surface from the flat plate was less than 2.71%.

CONCLUSIONS

The contact patch which was used to characterize the solid tire perfomnce was studied by finite elememt method. The solid tire model was compressed on three different pavement with various loads which composed of 400, 800 and 1,200 kg. The contact patch characteristics, vertical deformations and maximum normal stresses were obtained by finite element anslysis (FEA). The results of FEA on rigid flat plate had a good agreement with the experiment under the error of 0.52%. The footprint area of solid tire model on drum was less than on rigid flat plate bacause of the curvature of cylindrical drum. Consequently, the stress distribution of solid tire on flat plate was better than drum. On the other hand, the contact coefficient of solid tire which was compressed on flat surface and drum were similar. It indicated that the contact patch characteristic on flat surface by stiffness testing can repesent the adhesion and wear behavior of rolling solid tire. The developed models will be used to design the tire tread and pavement in the future work.

DEVELOPMENT OF DYNAMIC FINITE ELEMENT MODEL FOR RIDE COMFORT EVALUATION OF NON-PNEUMATIC TIRE

Chakrit Suvanjumrat[1,2] and Ravivat Rugsaj[1,2]
[1]Department of Mechanical Engineering, Faculty of Engineering, Mahidol University, Salaya, Nakhon Pathom, 73170, Thailand; [2]Laboratory of Computer Mechanics for Design (LCMD), Department of Mechanical Engineering, Faculty of Engineering, Mahidol University, Salaya, Nakhon Pathom, 73170, Thailand

ABSTRACT

The non-pneumatic tire (NPT) has design potential to have desired mechanical characteristic upon usage requirements. The NPT also has no restriction on inflation pressure, maintenance, and less damage possibilities due to flat while driving. The optimum design of NPT to have required load carrying capacity and vertical stiffness can be easily achieved by mean of static finite element method (FEM) with appropriated material models. However the models to predict dynamic response such as tire structure to road pavement interaction, shock absorption and ride comfort are still needed. This paper aims to develop FEM to study dynamic characteristics and evaluate the ride comfort property of the NPT. The FEM of NPT, which composed of Tread band and Spokes, was model using 3D hexagonal and 2D Quadrilateral elements respectively. The rebar elements and tying equation were used to model steel belt layers of the NPT. The visco-hyperelastic constitutive model was used to model the mechanical behavior which depends on time of the NPT's components. The FEM of NPT was then assigned to traverse across cleats with different heights to study the effect of obstacle on tire-road interaction and dynamic response of NPT. The impact force history and deformation behavior of NPT at any given time was analyzed. The results were compared to discuss the validity of the model to capture important dynamic characteristic that considered useful in designing of NPT to have ride quality challenging the commonly used pneumatic tire.

Keywords: Non-pneumatic tire, Finite element method, Tire-road interaction, Ride Comfort, Impact force

INTRODUCTION

The basis function of pneumatic tire, which is an important vehicle component, is to provide the vehicle to road interface, to support vehicle load, to provide road surface friction, and to absorb road irregularities. In that regards, the design of pneumatic tire requires some performance parameters such as the riding comfort, handling and traction criteria to be engineered to meet desired characteristic. However, the pneumatic tires have several disadvantages since the tire possess the risk to undergo severed damage or flatted if the tire traversing across various types of critical obstacles [1]. The non-pneumatic tire (NPT) or airless tire was developed to overcome these disadvantage. The NPT was designed to exhibit desired characteristics of the pneumatic tires without requirement of the inflation pressure. The first available commercial NPT is TWEEL developed by Michelin. The Tweel, consists of two main components which are 1) circular shear beam and tread 2) elastic spokes which connected to a hub. The NPT can be designed to have required vertical stiffness and contact pressure upon spoke geometry and material without limit to size and pressure, unlike traditional pneumatic tire. The non-pneumatic tire's lateral stiffness which affects handling and cornering can also be independently optimized with vertical stiffness which affects the riding comfort [2].

The vehicle stability and ride comfort is important tire performance especially on off road vehicle which traversing over various type of irregular terrain and obstacles. The transient dynamic characteristic of a tire has significant effect on vehicle handling stability. However the transient dynamic effect is difficult to study due to its highly non-linear behaviors. The effects of obstacle geometric factors during tire-obstacle collision was study using soil-bin facility equipped with a single-wheel tester. The various obstacle shapes along with different depth were varied in the experiments which operation condition of wheel traversing such as speed and load were controlled. The maximum and minimum induced impact force were observed from highest triangular shape and trapezoidal shape obstacle respectively [3]. Normally transient dynamic characteristic of the rolling tire can be determined by using drum testing method. However the drum testing method has limitation if the effects of pavement surface, roughness, or obstacles such as cleat or ditch are interested. The finite element method (FEM) can be used to simulate the tire behavior during rolling under critical conditions. A FEM of tire was developed to perform tire enveloping tests in transverse obstacles

of different sizes using explicit dynamic solution in finite element software ABAQUS. The tire transient dynamic behavior was investigated by analyzing the effects of tire rolling velocity and obstacle height on spindle force, dynamic stiffness, and tire deformation. [4]. The 3D FEM based on dynamic transient approach of mechanical elastic wheel (MEW) traversing over a ditch was developed to study transient dynamic characteristic of MEW. The radial stiffness and footprint of MEW were analyzed and compared with the experiment to validate the model accuracy. A dynamic analysis of MEW over a ditch was conducted using ABAQUS. The equivalent stress and contact stress was analyzed to study effects of rolling speed over the ditch [5].

The tire, which is considered as viscoelastic material, undergoes cyclic deformation during rolling on the road surface. The stress and strain field under cyclic loading exhibit phase delay between strain and stress time histories, which is the cause of hysteresis energy loss [6]. Thus, the development of thermomechanical model with viscoelastic material is required to predict the dynamic characteristic of the rolling tire. NPT, which components are made from low viscoelastic energy loss materials, can be a good option for developing tires with low rolling resistance. The thermo-viscoelastic model of NPT with a lattice spoke was developed to predict rolling energy loss and the corresponding heat generation of NPT components. The Yeoh hyperelastic model was obtained from the tension and compression tests, while viscoelastic material properties were obtained from dynamic mechanical analysis (DMA) test. A 3-D stress analysis was performed using steady state rolling analysis, then the cyclic strain energy was converted into heat to obtain temperature and compared with temperature distribution from the experiments [7]. The effects of static and dynamic loading of NPT with honeycomb spoke was investigated using FEM. the three types of NPT with constant cell wall thickness but different cell geometries were numerically simulated to study the effects on deformation modes, stress distribution, load carrying capacity, and rolling resistance. While on dynamic loading, the effects of friction coefficient and angular velocity on rolling resistance were also studied. The maximum stress in spoke under dynamic loading was observed to be higher when compared to static loading [8].

Design of NPT is needed to consider the tire performances which dynamic characteristic such as tire–road interaction, rolling resistance, and riding comfort, play an important factor. This paper aimed to develop the 3D FEM of NPT based on viscohyperelastic material model that can be used to predict NPT performances regarding dynamic characteristic.

FINITE ELEMENT MODEL OF NON-PNEUMATIC TIRE

The commercial NPT Tweel 12N16.5 SSL ALL TERRAIN airless radial tire developed by Michelin (Fig. 1), which is the first available NPT, was selected to study the mechanical behavior and characteristic of NPT. The FEM of NPT was modeled using the FE software MSC.Patran. The NPT model composed of 4 main components which can be concluded as follows: 1) tread, 2) shear band, 3) belt layers, and 4) polyurethane spoke. The FEM of NPT along with its overall dimension and components is shown in Fig. 2, 3, and 4 respectively. The hybrid formulation or Hermann formulation was used to model the tread and shear band elements of NPT. The formulation utilized the separated integration of pressure and displacement field, which can be used to prevent volumetric locking that may occur during loading of rubber material elements. The thick shell approximation is used to model the spoke. The details of elements which are used in modeling of NPT which shown in Table 1. The thickness of each shell elements was assigned differently based on the actual thickness distribution measured from the real spoke. The thicknesses at outer and inner ring of the spoke were 6 and 7 mm, respectively, while the averaged thickness of the spokes could be calculated relating to the spoke weight that was 5.8 mm.

The belt layer consisted of four main layers which were 1) the outer layer, 2) the 1st middle layer, 3) the 2nd middle layer, and 4) the inner layer. The outer layer was composed of three sublayers while the inner layer was composed of two sublayers. The belt layer model was developed using reinforce bar or rebar element [9]. The rebar elements of the belt layer were embed into the rubber element using tying equations. The value of the degrees of freedom of the nodes in host body element was tied based on their isoparametric location in the elements. The cross section of shear band of the FEM and real TWEEL along with the embed belt layer position is shown in Fig. 5. The details of the elements using in each layer are described in Table 2.

HYPERVISCOELASTIC MATERIAL MODEL

The Ogden hyperelastic constitutive model was used to model nonlinear elastic behaviors of rubber tread, shear band, and polyurethane spoke.

The general form of Ogden hyperelastic model [10] can be expressed as Eq. (1):

$$ {}^{t}_{0}\tilde{W} = \sum_{n=1}^{3} \frac{\mu_n}{\alpha_n}\left(\lambda_1^{\alpha_n} + \lambda_2^{\alpha_n} + \lambda_3^{\alpha_n} - 3\right) \quad (1) $$

Where λ_i are the principal value of the stretch tensor ${}^{t}_{0}U$, μ_i and α_i are material constants. The inelastic behaviors of NPT components were modeled using the generalized Maxwell viscoelastic material model. The generalized Maxwell viscoelastic model can be express as Eq. (2), (3).

$$ G(t) = G_0 - \sum_{i=1}^{n} G_i\left(1 - e^{-t/\tau_i}\right) \quad (2) $$

$$ \tau_i = \eta_i / E_i \quad (3) $$

Where $G(t)$ is Shear Relaxation Modulus, G_0 is Shear Modulus at time, *t=0*, G_i is i[th] term of Shear Modulus, τ_i is i[th] term of Relaxation Time (sec), E_i is Modulus of Elasticity, and η_i is viscoelasticity.

The parameters of Ogden hyperelastic and generalized Maxwell material model of tread and PU spoke, which are obtained and validated from mechanical testing in the previous research, are shown in Table 3 and 4, respectively [7, 11]. The compressive testing and tensile testing was performed on the cylindrical shape and dumbbell shape specimens, which were prepared from NPT's tread and spoke respectively. In addition, steel the belt layers were modeled using linear elastic material with modulus of elasticity (E) of 200 GPa and Poisson's ratio of 0.3.

FINITE ELEMENT ANALYSIS OF OBSTACLE TRAVERSING

The FEM of NPT was combined with road surface model for obstacle traversing analysis of NPT. The tread and shear band was assigned to be in contact with the road surface with friction coefficient of 0.8. The Coulomb's friction model was used to evaluate the friction force which occurred between the tire and road surfaces. The cleat surface was attached to road surface for the purpose of obstacle traversing simulation. Three size of rectangular shape cleat surface was selected in this research to study the effects of obstacle geometry to dynamic behaviors of NPT. The schematic diagram of installation and placement of NPT FEM onto the road and cleat surface along with its boundary conditions is shown in Fig. 6. The cleat surfaces are varied in height, which the schematic diagram of each cleat dimension is shown in Fig. 7 and are summarized in Table 5. The hub of NPT was modeled as rigid surface, which was assigned to be perfectly glued contact with the inner ring of spoke. The vertical load of 5 kN was assigned to the center of rigid hub, which was also applied to move forward at the speed (v) of 10 km/hr with corresponding angular velocity (ω) of 3055.6 rad/sec.

B	500	50	20
C	500	50	30

The dynamic transient analysis was performed using finite element software MSC.Marc, The analysis was divided into 2 main stage, which was 1) loading stage, and 2) rolling stage. At 0 < t < 1 sec., the NPT was assigned to be loaded with force gradually increase from zero to maximum force of 5 kN while the tire was assigned to be stationary. At 1 < t < 1.4 sec., after the NPT was fully loaded, the tire was assigned to be rotated and moved forward while the maximum force was still applied. The force and displacement history were collected after the analysis was complete at t = 1.4 sec to study the tire-road interaction and dynamic behaviors of NPT. The stress and deformation of NPT FEM at t = 1 sec., which is when the vertical force is fully applied, is shown in Fig. 8. It should be note that the analysis at this stage was corresponding to vertical stiffness testing of tire at maximum force 5 kN, which the vertical stiffness was founded to be 648.7078 N/mm. In addition, the spokes at the upper portion of NPT was observed to be in tension, while the spokes at lower portion was observed to be in bending mode. The tire-road interaction and deformation at various time t are shown in Fig. 9.

The impact force and vertical displacement history at hub center were collected, which the vertical displacement was normalized to exclude

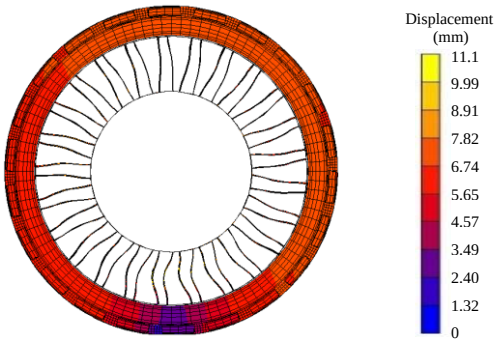

Fig. 8 Displacement and deformation result at t = 1 sec and F = 5 kN.

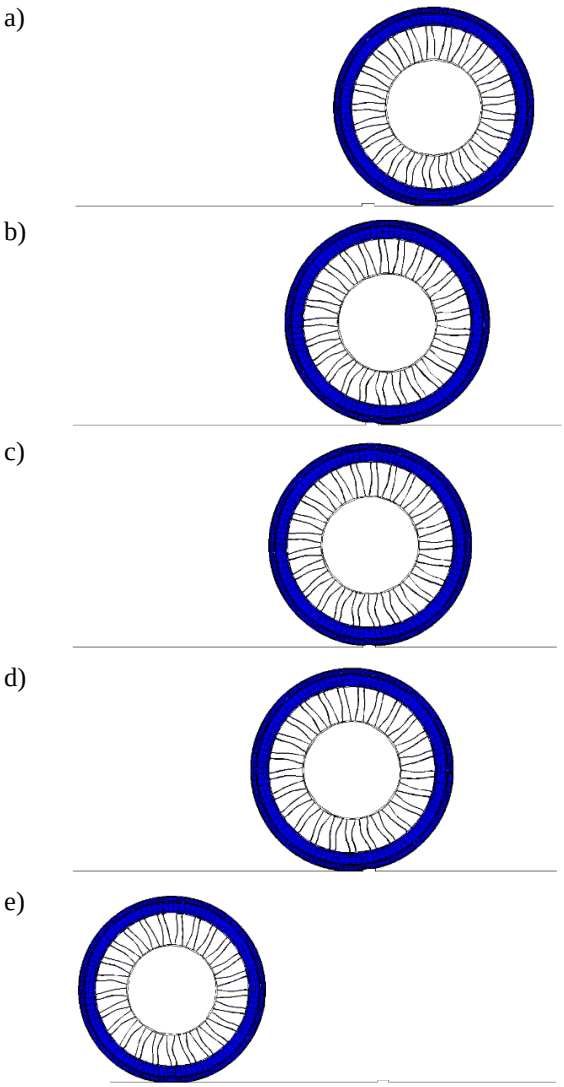

Fig. 9 Deformation and tire-road interaction of NPT at a) t = 1 sec, b) t = 1.72 sec, c) t = 1.88 sec, d) t = 1.14 sec, and e) t = 1.40 sec.

initial displacement due to deformation at t = 1 sec where the load was fully applied. The normalized vertical displacement of tire center and impact force at various time are shown in Fig. 10, 11 respectively. The average vertical displacement of tire center and average impact force along with their maximum values can be concluded as shown in Fig. 12 and Fig. 13, respectively. The summarization of average normalized displacement at tire center and average impact force can be concluded as shown in Table 6. The NPT model with highest cleat (height = 30 mm) was shown to yield greatest value of both average vertical displacement of tire center and average impact force. However the oscillatory response after the NPT rolled down a cleat was scant when compared with pneumatic tire [12-15]. Considering the observed underdamp characteristic of the oscillatory, the NPT has potential to be optimized the ride comfort properties for the vehicles.

C	30	5.617848	30.87236

CONCLUSIONS

The FEM of NPT was developed to study dynamic characteristics and evaluate the ride comfort property of the NPT. The FEM of NPT, which composed of Tread, shear band and Spokes, was modeled using 3D hexagonal and 2D Quadrilateral elements respectively. The rebar elements and tying equation were used to model steel belt layers of the NPT. The validated Ogden hyperelastic material model and generalized Maxwell viscoelastic material model were used to model nonlinear elastic and inelastic behaviors of NPT components. The FEM of NPT was then assigned to traverse across cleats with different heights to study the effect of obstacle on tire-road interaction and dynamic response of NPT. The impact force history and deformation behavior of NPT at any given time was analyzed. The results were compared to discuss the validity of the model to capture important dynamic characteristic. The FEM of NPT with highest cleat (height = 30 mm) was shown to yield greatest value of both average vertical displacement of tire center and average impact force at 5.617848 mm and 30.87236 N respectively. The underdamped oscillatory behavior was observed from vertical displacement and impact force, which shown that NPT has potential to be optimized regarding ride comfort properties. The analysis results shown that the devloped hyperviscoelastic dynamic FEM of NPT can be used in designing of NPT to have dynamic characteristic such as ride quality for challenging the commonly used pneumatic tire.

ABSTRACT

The seismic resistance design of buildings in Indonesia is usually performed based on the most recent Indonesian Seismic Code (ISC). Improvement of the ISC will sometimes produce different (increasing or decreasing) earthquake forces for building design. This paper describes the study of building evaluation by conducting a modified site response analysis (SRA) with a modified incoming earthquake force direction. The modified SRA was performed by means of an in-complete soil boring investigation through the bedrock elevation, using 30 m (soil boring investigation) and 50 m (microtremor investigation) soil profile models. The earthquake force towards the building is analysed using a pair (North-South/NS and East-West/EW) of ground motion models. Due to the unpredictability of incoming earthquake forces, these models are improved by adjusting the ground motion direction to the building by rotating a pair of ground motion from 0^o to 180^o at 10^o intervals. The ground motion is developed based on the Probabilistic and Deterministic Seismic Hazard Analysis (PSHA and DSHA). The analysis was performed by evaluating the moment capacity ratio of the building's existing column reinforcement in resisting the earthquake force. The ground motion and spectral accelerations developed using the 50 m model is slightly greater (10%) than the ground motion and spectral accelerations developed using the 30 m model. In terms of the moment capacity ratio, the existing column reinforcement of the building is strong enough to resist seismic earthquake scenarios, and the minimum value is observed when the ground motion is rotated by 40^o.

Keywords: Site response analysis; Microtremor; Ground motion; PSHA; DSHA

INTRODUCTION

The seismic resistance design of buildings is usually performed by applying a seismic or earthquake force model in terms of spectral acceleration. For design purposes, the Indonesian Seismic Code describes an easier method for preparing the spectral acceleration. The spectral acceleration can also be developed using online software prepared by the Ministry of Public Works and Human Settlements of Indonesia, and is developed based on the updated earthquake data collected from all earthquake events in the whole of the country.

Seismic resistance design and evaluation can also be performed using surface ground motion in terms of acceleration time histories developed from the accelerograph data of a specific earthquake. To develop surface ground motion that can be used for structural analysis requires information of the bedrock elevation and all the soil deposit data from the bedrock up to the surface elevation. The bedrock elevation measurements can be performed using single or array microtremor tests. The soil deposit data can be obtained by conducting soil boring investigations and laboratory measurements.

A soil boring investigation is usually performed when preparing foundation design requirements. The depth of the soil boring investigation data has a direct correlation with the type of foundation used and the bearing capacity requirements of the foundations. Usually the soil boring investigation has no correlation with the bedrock elevation. For a building located on a soft soil layer having a bedrock elevation more than 100 meter, time and money will be needed to prepare soil deposit data, compared to the normal soil boring investigations used for foundation design purposes.

The spectral acceleration data applied to building structure design is usually obtained for two directions perpendicular to the building's position (X and Y, or 0^o and 90^o directions). As the building's position relative to the seismic source is unknown, it is difficult to ensure the seismic force direction for building structure design. This paper describes an example of structural analysis performed using modified ground motion or seismic force directions. The analysis is conducted by first improving the depth of the soil deposit model for SRA by taking a 30 m soil deposit model adapted

from a soil boring investigation. The spectral acceleration and the ground motion are then compared to the same analysis using a 50 m soil deposit model developed from microtremor investigation data. The purpose of this analysis is to obtain the differences between the surface ground motion and surface spectral accelerations developed based on the two models in order to improve them.

The second improvement is conducted by gradually modifying the two perpendicular directions of earthquake forces in terms of ground motion (NS and EW) from 0° to 180° at 10° intervals relative to the building position. The purpose of this second improvement is to obtain the minimum moment capacity ratio of the existing column reinforcement and the correlation between the moment capacity ratio and ground motion direction.

METHODOLOGY

The modified structural analysis in this research was conducted at the Diponegoro University Semarang (Indonesia) building (40.75 x 16.2 m^2 and 43.2 m height). The building was first open on March 10 2017 and was designed and constructed based on the Indonesian Seismic Code 2012 [1].

Soil Investigations

Two types of soil investigations were performed in the building area. The soil boring investigation was first performed to design the foundation system to support the upper structure and was conducted down to a 30 m depth. According to the N-SPT data obtained on site, the building was found to be located on medium site class soil/SD ([1] - [3]).

The second soil investigation was related with the measurement of the predicted bedrock elevation and was performed using single station three-component microtremor at 22 positions surrounding the building position. Fig. 1 shows the site plan of the study area, the building position, soil boring position and microtremor test positions. Fig. 2 and Fig. 3 show the microtremor results analysis in terms of the shear wave velocity profile. As can be seen in these figures the bedrock elevation is predicted at 40 to 50 m below the surface level. This prediction is based on [1], with a shear wave velocity ranging from 750m/s to 1500 m/s.

Site Response Analysis (SRA)

The SRA is conducted based on two different soil profiles. The first profile is applied using the actual bedrock elevation (50 m) and the second profile using the 30 m soil deposit model [4]. The second model is adjusted in this research due to incomplete data or soil boring investigation data from the bedrock elevation. The soil boring investigation data was performed until a maximum 30 m depth due to the requirement for the foundation design of the structure and the minimum requirement for site class calculation [1]. Fig. 4 shows the first soil profile model (Model-1) using the actual bedrock elevation. Fig. 5 shows the second soil profile model (Model-2). The Vs (shear wave velocity) values embedded in these two profiles (0-30 m) are developed using three empirical correlation proposed by ([5] - [7]) and the microtremor data. The actual bedrock elevation is predicted at 50 m below the surface level.

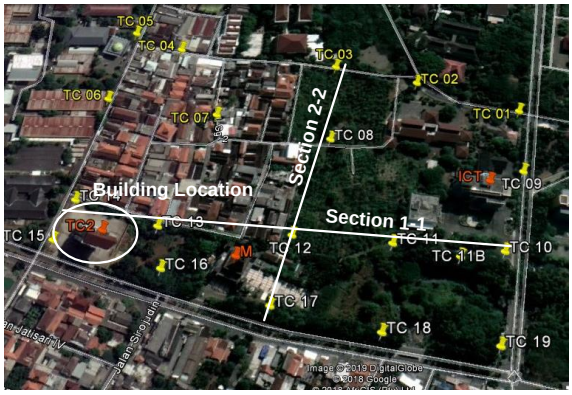

Fig. 1 Study area and building position.

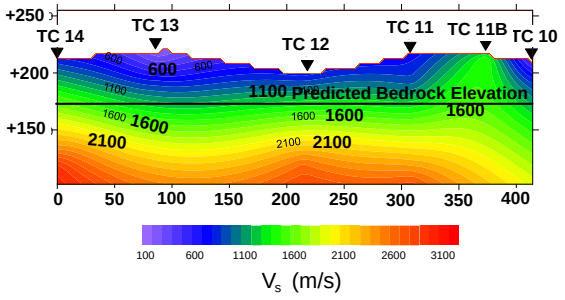

Fig. 2 Vs profile of Section 1-1.

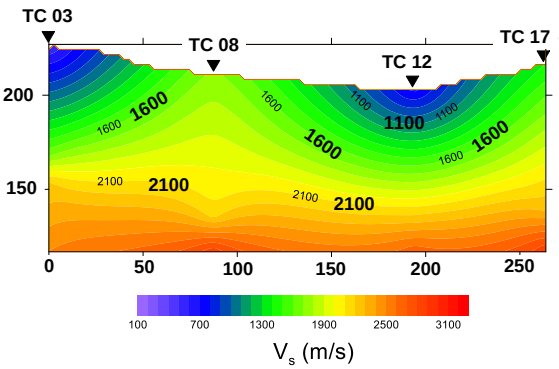

Fig. 3 Vs profile of Section 2-2.

The SRA is developed using two directions of ground motion (NS and EW) collected from a 6.52 Mw earthquake event with an epicenter distance of 5.07 km. To perform the SRA, two different response spectral targets are developed in this study

based on two different types of seismic hazard analysis: Probabilistic Seismic Hazard Analysis (PSHA) with a 2% probability of exceedance in 50 years (2500 years return period) and Deterministic Seismic Hazard Analysis (DSHA). The modified ground motions are then calculated using response spectral matching analysis. Fig. 6 shows the two spectral targets used for spectral matching analysis in order to obtain the modified ground motion at the bedrock elevation. The modified ground motions are used for SRA for obtaining the surface ground motion and spectral acceleration. The PSHA spectral acceleration target was developed based on the 2017 Indonesian Seismic Hazard Map [8]. However the DSHA spectral acceleration target was calculated using three different attenuation functions ([9]–[11]).

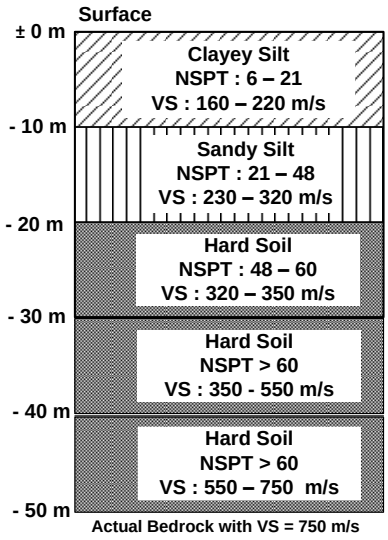

Fig. 4 Soil profile using 50 m soil deposit (Model-1).

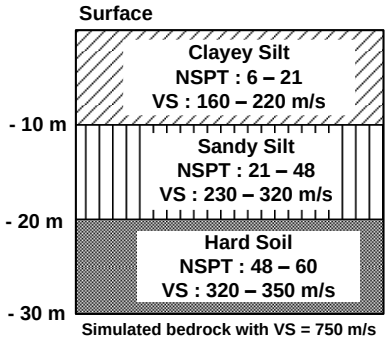

Fig. 5 Soil profile using 30 m soil deposit (Model-2).

The two directions of modified ground motion (NS and EW) developed using the PSHA and DSHA spectral acceleration targets are then used for the SRA using two different soil profile models as shown in Fig. 4 and Fig. 5. Fig. 7 and Fig. 8 shows the two different modified ground motions (NS and EW) developed based on the PSHA and DSHA spectral acceleration targets. As can be seen in those two figures the ground motion developed using PSHA has a peak acceleration almost equal (slightly greater) to the ground motion developed using DSHA. Based on the response spectral matching analysis, the ground motion developed using PSHA is used for SRA.

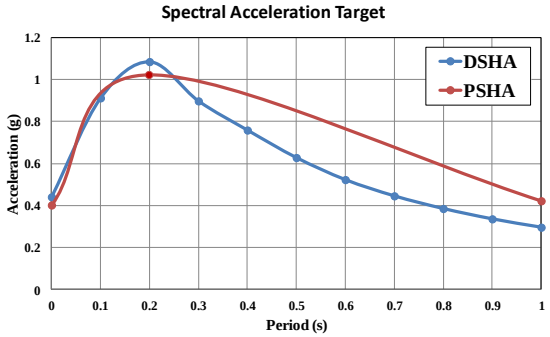

Fig. 6 PSHA and DSHA spectral acceleration target.

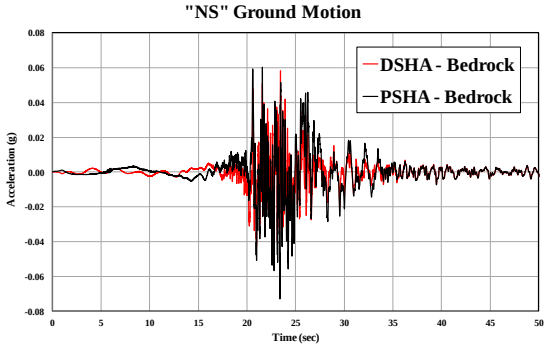

Fig. 7 Modified NS direction ground motion developed from response spectral matching analysis.

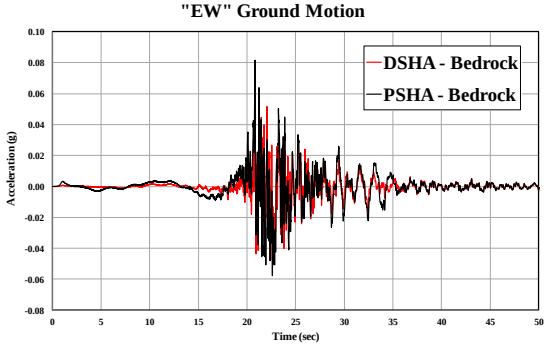

Fig. 8 Modified EW direction ground motion developed from response spectral matching analysis.

Structural Analysis

The earthquake forces model used and applied to the structures is based on surface ground motions in two directions, NS and EW obtained from SRA analysis. The NS direction is perpendicular to the

EW direction. Both ground motions directions are then gradually rotated from 0º to 180º at 10º intervals. The existing columns are evaluated to obtain the moment capacity ratio of longitudinal concrete column reinforcement. The moment capacity ratios for all earthquake force directions are then evaluated and compared to obtain the correlation chart between the earthquake force direction and moment capacity ratio. The minimum moment capacity ratio in terms of the force direction can be obtained using this chart. Fig. 9 shows the model of the earthquake directions used for the structural analysis.

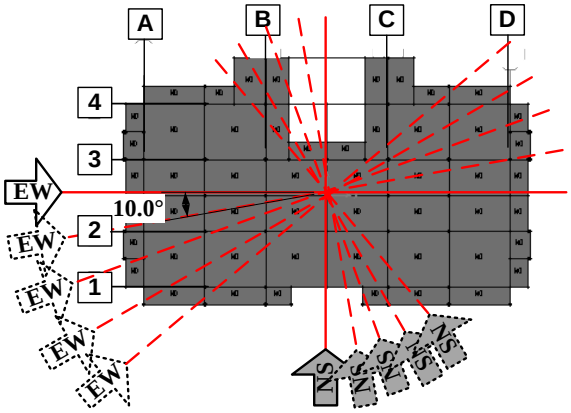

Fig. 9 Improvement of ground motion directions used for structural analysis.

RESULT AND DISCUSSIONS

Surface ground motions are developed using two different soil profile models, Model-1 and Model-2. According to the analysis performed for both models by employing the two different ground motions directions (NS and EW), the surface ground motions developed for the two models are almost equal. Fig. 10 shows the difference of the NS surface ground motions developed using the two models. As can be seen in Fig. 10 the absolute maximum acceleration developed using Model-1 is 0.22 g while the absolute maximum acceleration developed using Model-2 is 0.21g.

Fig. 11 shows the difference of the EW surface ground motions calculated using the two different models. The absolute maximum acceleration developed using Model-1 is 0.18 g and the absolute acceleration developed using Model-2 is 0.16 g. Based on the two different soil profile models developed for the SRA, the maximum surface acceleration for the NS and EW directions is almost equal. Fig. 12 shows the four different surface spectral accelerations developed using the two different SRA models and that the EW and NS spectral accelerations developed using the two models are almost equal.

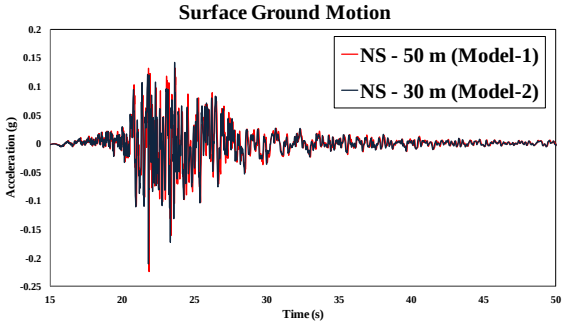

Fig. 10 Surface NS direction ground motion developed using two SRA models.

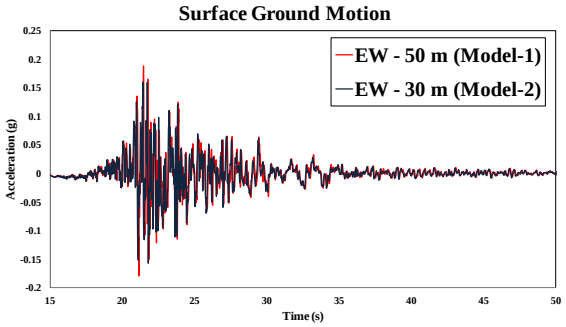

Fig. 11 Surface EW direction ground motion developed using two SRA models.

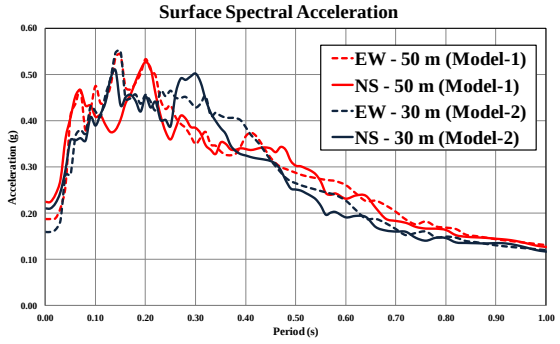

Fig. 12 Surface spectral acceleration developed using two SRA models.

Fig 13 shows the difference of the peak ground acceleration (PGA) profiles developed using the two different SRA models. The PGA values developed using Model-1 is greater than those calculated using Model-2. All the PGA profiles developed using the two models are almost equal (coincident) with maximum differences of surface PGA of 0.03 g (16%) for the NS direction and 0.01 g (5%) for the EW direction. The average surface PGA difference of Model-1 is 10.5% greater than Model-2. Table 1 shows the difference of the surface PGA developed based on the two models. Based on the analysis for developing surface ground motions using the two models, the 30 m soil profile model (Model-2) can

be used as an alternative for developing the surface ground motion. The second soil deposit model (Model-2) used for the SRA is based on the maximum soil boring investigation.

Table 1 Peak ground acceleration of two models

Model	Elevation (m)	PGA-NS (g)	PGA-EW (g)
Model-1	0	0.19	0.22
	50	0.07	0.07
Model-2	0	0.16	0.21
	30	0.07	0.07

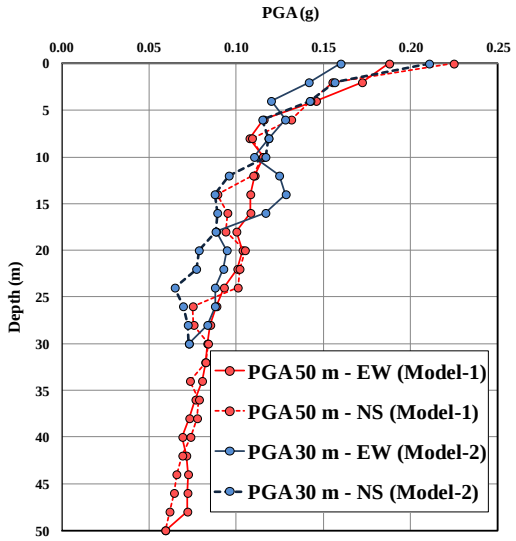

Fig. 13 PGA profiles developed using two different models.

The surface ground motions, EW and NS, used for structural analysis are two perpendicular ground motion developed based on SRA Model-2. Both ground motions are gradually increased and rotated from 0° through 180° at 10° intervals. The example column elements used for structural analysis have dimensions of 700x700 mm^2 and 700x900 mm^2 and longitudinal reinforcement 32D25 and 48D25 respectively. Fig. 14 shows the 700x700 column's longitudinal and transversal reinforcement. Fig. 15 shows the 700x900 column's longitudinal and transversal reinforcement.

The moment capacity ratio (ϕMn/Mu) is calculated for all element structures. Fig. 16 shows the moment capacity ratio of the 700x700 and 700x900 columns. The moment capacity ratios are calculated in terms of the earthquake force directions towards the structure. As can be seen in Fig. 16, the minimum moment capacity ratios for the 700x700 and 700x900 column are observed at earthquake force directions of 40°. The minimum moment capacity ratio for the 700x700 and 700x900 columns are 2.361 and 1.998 respectively. The minimum moment capacity ratios for the 700x700 column are 12.5% to 17.7% smaller than the moment capacity ratios calculated for 0° and 90°, while the minimum moment capacity ratios for the 700x900 are 14.5% to 20.7% smaller than the moment capacity ratios calculated for 0° and 90°.

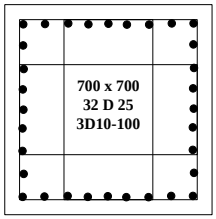

Fig. 14 Reinforcement of 700x700 mm^2 column.

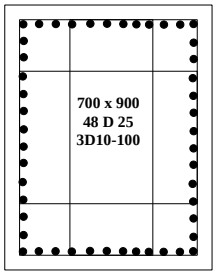

Fig. 15 Reinforcement of 700x900 mm^2 column.

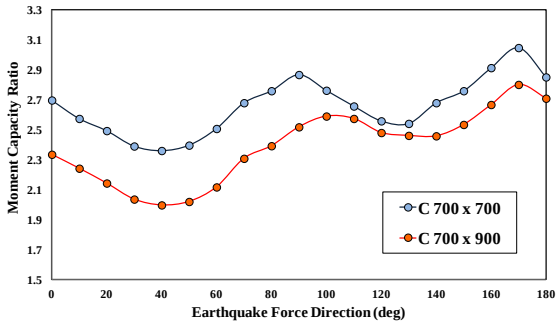

Fig. 16 Moment capacity ratio curves in terms of earthquake force directions for 700x700 and 700x900 columns.

Based on the analysis of moment capacity ratio for the 700x700 and 700x900 columns, the existing column size and reinforcements have a minimum moment capacity ratio of 1.998, greater than 1. All the exiting column reinforcements are predicted to be save enough to resist earthquake forces having a magnitude of 6.5 and a minimum distance 5 km. Table 2 shows the moment capacity ratio calculated for 0 and 90° (the X and Y directions usually used for building structural design) compared to the minimum moment capacity ratio obtained at the 40° direction of ground motion as can be seen in Fig. 16.

Table 2 Moment capacity ratio of 700x700 and 700x900 columns

Column Size	Force direction (°)	ϕMn/Mu	ϕMn/Mu minimum
700x700	0	2.698	2.361
	90	2.868	
700x900	0	2.336	1.998
	90	2.519	

CONCLUSIONS

An improved of SRA is conducted in this study for developing surface ground motion. Two different models of soil profiles, 50 m and 30 m soil deposit above the bedrock elevation are performed in this study. The surface peak ground acceleration developed using the 30 m soil deposit model is approximatelay 10% less than the real 50 m soil deposit model.

The modified SRA can be adjusted by using a 30 m soil deposit model instead of the real soil deposit model developed using the real bedrock elevation. The modified SRA can be applied whre there is in complete data from the soil boring investigation or when the bedrock elevation is greater than 30 m.

An improved analysis of the incoming earthquake force toward the building position was performed in this research by adjusting the earthquake directions from 0° to 180°. In terms of the moment capacity ratio of the column reinforcement, the minimum moment capacity ratio is at the 40° earthquake direction, and is reduced to approcximately 15% less than the normal X and Y (0° and 90°) directions.

ESTABLISHMENT OF RESIDENTIAL FLOOD DAMAGE FUNCTION MODEL FOR KUANTAN, MALAYSIA

Noor Suraya Romali[1] and Zulkifli Yusop[2]
[1]Faculty of Civil Engineering Technology, Universiti Malaysia Pahang, Gambang, Malaysia; [2]Centre for Environmental Sustainability and Water Security, Universiti Teknologi Malaysia, Skudai, Malaysia.

ABSTRACT

Flood damage estimation is an essential element in the assessment of flood risk. However, the study on flood damage in developing countries is limited due to the scarcity of historical data. An attempt has been made to derive residential flood damage function models and flood depth-damage curve for the year 2013 flood in Kuantan, in the state of Pahang in Malaysia. A field survey was conducted to gather information regarding the flood event based on face to face interview technique. The education background, household income, and construction materials had significant influence on the variation of structural flood damages, whereas the content damage was found to be depended mostly on the types of occupation, household income, and house type. The flood depth-damage curves obtained in this study are satisfactory as content and structural damage show R^2 above 0.80 for both, and can be used for future studies on flood damage assessment of the study area.

Keywords: Flood damage estimation, Flood damage function, Flood depth-damage curve, Residential, Malaysia

INTRODUCTION

Flood risk assessment consists of two main parts i.e. a hazard and vulnerability assessment. Flood hazard is normally illustrated in flood inundation or flood extend maps, while flood vulnerability emphasizes the impact of flooding in flood damage map. Flood vulnerability is associated with the assessment of flood damages. Estimation of economic loss is essential to help the development of new housing away from the flood disaster area and reduce the damage loss.

The assessment of flood damages can be done using two methods; either evaluated directly from existing database or by using modeling approach. The modeling of damage estimates is either using unit loss model or a model that relates the flood damages with other factors that have linkage effect on the damages such as economic factor, the nature of damage, and possible relations between damage and flood parameters [1]. Unit loss method is defined as a property-by-property assessment of potential damage [1] and it uses the relationship between flood characteristics and damages to a unit [2]. In the latter method, three well known flood damage estimation models are FDAP (Flood Damage Analysis Package), ANUFLOOD and ESTDAM. Although various different approaches had been used to estimate flood damages, the estimation concept is basically the same, which considers the combination of flood hazard (hydrological characteristics), exposure, value of elements at risk, and the susceptibility of the elements at risk to particular hydrologic conditions which can be represented by a flood damage function curve [3]-[5].

Flood damage function curve is the plot of flood damages to flood parameters [6]. It shows the relationship between the flood parameters with the level of flood damage [7]. Examples of commonly used flood damage influencing factors for flood damage functions are flood depth, flood duration and velocity [1]. However, according to Thieken et al. [8], damage influencing factors consist of two types i.e. the impact parameters and the resistance parameters. The impact parameters reflect the specific characteristics of a flood event such as water depth and flow velocity, while resistance parameters represent the properties of the affected assets such as building type or materials and the emergency measures used.

Flood damage curve can be derived using two methods depending on the availability of the data. The first is based on damage data of past floods or also known as empirical method, and the second is termed as synthetic method, which is based on hypothetical analysis [1]. The curve based on empirical method, or also known as historical curve [10] is derived from historical loss data of actual flood events. While in the latter method, the development of synthetic flood damage function curve does not rely on the actual flood damage information, but derived from hypothetical analysis based on land cover and land use patterns, type of objects, information from questionnaire survey, interviews and expert judgements [1], [11], [12]. This synthetic method had been adopted by researchers who experienced data scarcity problem [10], [11].

Although the first research on flood damage

assessment field can be traced back almost forty years ago, there is still a lot of works to do related to few issues. In developing countries, especially Malaysia, the study on flood vulnerability assessment is still limited especially on flood damage estimation. There are many methodologies for estimating the flood damage worldwide. However, there is no common methodology applied to estimate flood damage in Malaysia. The effect of resistance parameters to the degree of flood damages are usually neglected in damage modelling, as most studies select more influencing parameters such as flood depth. In fact, flood risk assessment should cover all damage dimensions to obtain an extensive description of flood damages [13]. Therefore, with the aim to assist in the assessment of flood vulnerability, the purpose of this study is to investigate the relationship between flood damages and the local condition of the study area and to establish a residential flood depth-damage curve for future flood risk assessment works in Kuantan.

METHODS

Case Study Area

The Kuantan River Basin (KRB) was selected as the location for this case study because it is known for its frequent flooding. KRB has a catchment area of 1638 km^2 and the length of the river is approximately 93.44 km. Kuantan River is the main river in KRB where it flows from Mukim Ulu Kuantan through the Kuantan city and ends at the Perkampungan Tanjung Lumpur before flowing out to South China Sea. In the last few decades, the Kuantan River has experienced severe flood in 2001/02, 2011/12, and recently in 2013. There were major damages to properties, infrastructures and traffic, while around 14,044 people were evacuated during the 2013 flood [14]. The map of KRB displays the area, main river, tributaries and the streamflow station which is Kenau Flow Station is shown in Fig. 1 [15].

A few flood risk studies had been done [16]-[18] for flood mitigation at Kuantan River. However, to date, none flood vulnerability assessment has been studied within the river basin. Hence, a study on the assessment of flood damage is compelling to assess the impacts of flood to properties and the society of Kuantan.

Questionnaire and Field Survey

A field survey using face to face interview technique was conducted to gain a clearer picture of the 2013 Kuantan flood. A questionnaire was developed and distributed among the flood affected residence twice, with the initial survey was conducted in March 2018 and the second survey being conducted in February 2019.

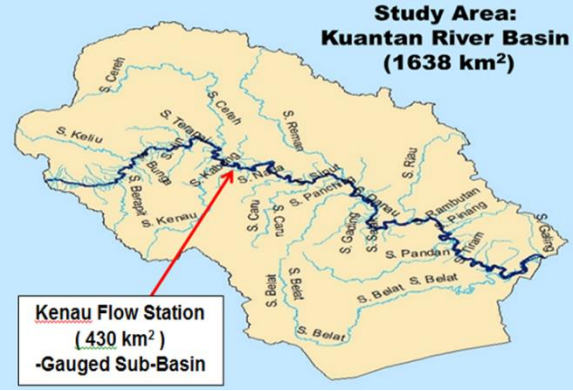

Fig. 1 Residential flood depth-damage curve for structural damage

The questionnaire was designed according to three scopes; demographic data, information on residential property and damage data. There are two sections; Section 1 and Section 2. Demographic and residential property were considered in Section 1, while Section 2 gathered information on the damage experienced by residents during the 2013 flood. Under demographic, various factors, such as gender, age, race, education level, occupation, and household income data were collected, whereas the price of the house, year bought, ownership status, house's type, numbers of storeys, house's material, house's insurance, and the estimated price of the house contents (furniture, gate etc) were investigated under the residential property scope. To gain information on damage, the flood depth and duration were considered, as well as the cost of damage to fabric/structural, cleaning, content damage, vehicle damage and loss of wages.

This survey used randomly selected sampling in the flood prone area of Kuantan to collect a representative sample, as suggested by Win et al. [19]. Information about the flood prone areas was collected from Drainage and Irrigation Department (DID) Kuantan, Kuantan Municipal Council and available flood maps. By using this information, a few 2013 flood affected village in Kuantan area were selected for the survey i.e. Permatang Badak, Sungai Isap, Bukit Rangin, Bukit Setongkol, Kampung Sungai Soi and Kampung Galing Besar. In each village, interviews were conducted randomly at different location and end up with a total of 201 samples.

Multiple Regression Analysis

A multiple regression model was used in this study to model the relationship between flood and various flood damage influencing variables. This method had been adopted by several previous researchers to analyze flood damage and its determinants [19]-[21].

In this study, every value of the independent

variable (flood influenced factor, *x*) is associated with the value of the dependent variable (flood damages, $Flood_D$). The dependent variable covers the level of property damages in terms of structural and content damage. While the independent variables are divided into two categories i.e. demographic and property characteristics. The demographic variables are gender, age, race, education background, occupation and house income, whereas the properties variables are ownership, price of properties, properties type, number of storeys, building material, and flood insurance status. The general regression equation is as Eq. (1) below:

$$Flood_D = f(x_{i1}, x_{i2}, x_{i3.} \ldots\ldots\ldots + x_{ip}) \quad (1)$$

The transformation of the functions for model in Eq. (1) resulted a regression model as shown in Eq. (2):

$$lnFlood_{Di} = \beta_0 + \beta_1 lnx_{i1} + \beta_2 lnx_{i2} + \cdots + \beta_p x_{ip} + \varepsilon_i \quad (2)$$

Where i = 1, 2, 3, …….n while p and ε refer to the numbers of independent variables and error term respectively. *lnFlood* is the logarithm of flood damages from surveys.

The analysis observed the value of coefficient of determination (R^2) and p-value (significance level), where a 5% significance level ($p < 0.05$) is used.

Flood Depth-Damage Curve

Flood damage function curve is the relationship between flood damages (in percentages) against flood parameters. The level of damage was measured according to flood depth and was taken as the ratio of overall replacement cost to the estimated total replacement value of the building. The damage percentage (D_p) was calculated according to the definition by Pistrika et al. (2014) as in Eq. (3):

$$\mathrm{D_p} = \frac{\text{Overall Replacement Cost}}{\text{Market Value of Properties}} \times 100 \quad (3)$$

The overall replacement is the expenses spent by the flood victim to mend their properties after flood, either at their own cost or compensation from the government or insurance company. The damage replacement was estimated for the structural, content, stock and equipment damage. The flood parameter chosen in the establishment of the damage curve is flood depth. Based on previous published work, inundation depth is considered as the principal factor and found to be the major variable for assessing direct tangible damages [1], [7], [22]. Furthermore, Chang et al. [23] suggested that the flood depth alone is sufficient for flood damage estimation without considering other factors.

The curve is plotted using Microsoft Excel and the curve fitting process was performed using trial and error. Curve fitting is the process of constructing a mathematical function that best fits to a series of data points [12]. The logarithmic trend line was selected as the type of trend line best fitted the data and the curve shape is similar with other damage curves from previous studies [1], [12], [14]. The average value of flood depth and percentages of damage was used in the construction of the damage curve.

RESULTS AND DISCUSSION

Survey Results

The field survey data collection yielded a wide range of useful parameters that may help in the assessment of flood damage [19]. Based on the primary collected data, more than 54% of the respondent were male while the rest were female. The average age of the respondents was 45 years old.

The house type that is mostly observed in Kuantan area is brick since 62% of the house interviewed during the survey are brick wall house. Further, 29% of the houses are built as the combination of brick and timber materials, whereas wooden houses are observed to be only 9% of the survey samples.

Most of the house sample was terrace (69%), while only 6% was semi-detached house, 9% was bungalow and 16% was other than these house types. Almost 97% of the house was one storey house.

Flood Damage Function Models

Structural Damage Functions

The relationship between structural damage and demographic and property variables is explained by Equation (4) with the regression results shown in Table 1. The R^2 obtained is low i.e. 0.19. However, the value is acceptable for cross sectional data and it is in agreement with the result observed in Poussin et al. [25] which relate the flood damage mitigation behavior amongst households in France where the R^2 was between 0.19 to 0.31.

$$Flood_{struc} = -10974 - 1422EDU + 1799\ln INC + 1066MAT + \varepsilon \quad (4)$$

where ε is error term and $Flood_{struc}$ is the structural flood damage in RM (Ringgit Malaysia) with the following influenced factors;

EDU	=	Education level of the respondent
INC	=	Household income of the respondents

MAT = Construction material of the houses

Table 1 Regression analysis results on the impact of demographic and property variables on structural flood damages

Variable	Coeffi-cient	Std. Error	t	p-value
EDU	-1421	467.24	-3.04	0.003
lnINC	1799	368.92	4.88	0.000
MAT	1066	458.44	2.33	0.021
Constant	-10974	2803	-3.92	0.000

The results in Table 1 show that the value of residential structural damage is positively correlated with the house material and household income but is negatively correlated with the respondents' education background. Assuming that all other variables are unchanged, a unit increment in household income will result in RM1799 increment in the structural damage when a linear relationship is assumed. These define the affordability of the high income respondent in buying more expensive house or wall furnishing, gate, etc., thus cause greater damage.

Meanwhile, the structural damage decrease by RM1421 if the respondent's educational background is at higher level. This result is consistent with Panic et al. [26] and Morrisey [27] who found that education also plays a crucial role in influencing the flood damage. The people with better educational background is more knowledgeable, hence tend to be more aware and prepared for any natural disaster event [20]. Based on the observation from survey, most of residents with high education level works at private sector or owns a business. Similarly, people with better occupation tend to be more exposed with advance mitigation options and well prepared. On the other hand, the damage increased by RM1066 if the house is built from concrete. This is in agreement with the finding by Win et al. [19] who stated that the rate of flood damage is commonly related to the total of household, household income, and building materials variables.

Content Damage Functions

The R^2 value is 0.19 which is similar with the structural damage model in Eqn. (4). The results for content damage are summarized in Table 2. The occupation and household income was found to have significant positive relationships to the total amount of content damage. However, the content damage is negatively related to house type. Assuming that all other variables are unchanged, a unit increment in household income will result in RM1586 increment in the structural damage when a linear relationship is assumed. The content damage increase by RM3157 if the respondent is businessperson. Respondent with better occupation may owned a high quality and expensive furniture thus experienced high damage if their house content is affected by flood. The content damage decrease by RM3396 for terrace house. This can be justified by the content of terrace house may be cheaper than the content damage of semi-detached house or bungalow.

$$Flood_{content} = -4040 + 3157OCCU + 1586\ln INC - 3396\ln TYPE + \varepsilon \quad (5)$$

where ε is error term and $Flood_{content}$ is the content flood damage in RM with the following influenced factors;

OCCU = Occupation of the respondents
lnINC = Household income of the respondents
TYPE = Types of the houses

Table 2 Regression analysis results on the impact of demographic and property variables on structural content flood damages

Variable	Coeffi-cient	Std. Error	t	p-value
OCCU	3157	1251	2.52	0.012
lnINC	1586	651	2.44	0.016
TYPE	-3396	858	-3.96	0.000
Constant	-4040	5143	-0.79	0.433

Flood Depth-Damage Curves

The flood depth-damage curve for structural and content damage is shown in Fig. 2 and Fig. 3 respectively. Both graphs show a significant correlation, where the percentages of damage increase with the flood depth, with R^2 values of more than 0.8 for all categories. This is in agreement with Pistrika et al. [12] for residential area, R^2 of 0.78.

The result shows that the 2013 flood victims experienced content damage higher than structural damage. Content damage estimates as high as 50% are expected at 6 meters' flood level, compared to 12% for structural damage. The finding is consistent with the observation by Pistrika et al. [12] in Greece where all the flood-affected buildings required only minor repair.

The percentages of content damage are quite low which is between 2% to 12% for a flood depth up to 6 meters. The study by Pistrika et al. [12] obtained a similar low percentages damage, range from 9% to 18% also for up to 6 meters inundation depth.

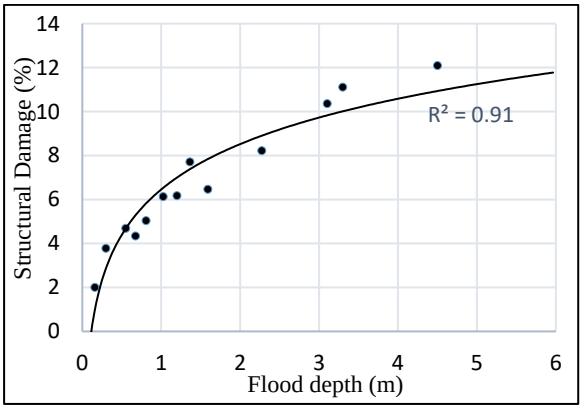

Fig. 2 Residential flood depth-damage curve for structural damage

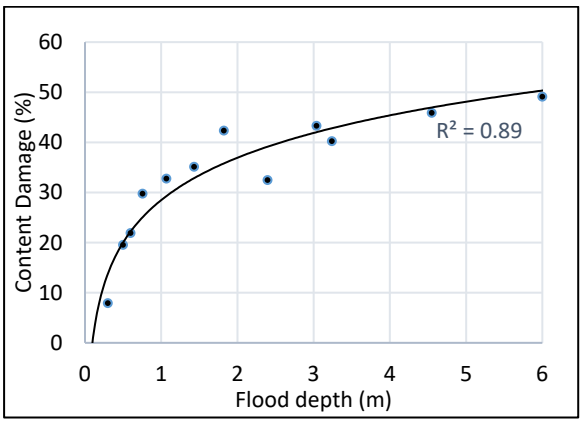

Fig. 3 Residential flood depth-damage curve for content damage

CONCLUSIONS AND RECOMMENDATIONS

Flood damage function model was developed based on interview survey data. The model considered the effects of demographic and property characteristics variables to the level of flood damages.

From this study, the structural damage was found to be depended mostly on the education background, household income, and construction materials, whereas the content damage was found to be depended mostly on the types of occupation, household income, and house type.

Flood depth-damage curves shows that the residents of Kuantan River Basin experienced content damage more than the structural damage during the 2013 flood. For the flood depth up to 6 meters, the percentages of content damage are in between 9% to 50% while the structural damage is in the range 2% to 12%. The damage curves obtained in this study is good enough with R^2 0.91 and 0.89 for structural and content damage respectively and can be applied in future flood damage assessment works at the study area.

A number of recommendations for the future flood damage assessment works are derived. An additional data collection is suggested to improve the flood damage function model, in terms of the coefficient of determination (R^2). Besides damage assessment for residential category, future works should also include commercial and industrial categories. These categories are rarely investigated as getting reliable damage data for the commercial and industrial category is expected to be more challenging. However, the damage assessment of these categories is compelling as it may show the effect of urbanization to the study area.

COMPOSITIONAL CHANGES IN SEA SLUDGE SAMPLES FROM HIDAKA PORT IN WAKAYAMA, SOUTHWEST JAPAN, COLLECTED MONTHLY FOR A PERIOD OF 16 MONTHS

ABSTRACT

The composition of sea sludge varies from location to location and from time to time, since it is affected by various external environmental factors. In this study, we analyzed the organic and inorganic contents of sludge samples collected for 16 months from the Hidaka Port in Wakayama. Weight-loss analyses for 16 months indicates that the highest inorganic content was in July 2016 (99.11%), and the lowest in June 2017 (94.42%). We then conducted EDX Spectrometry analyses on the samples, focused on Si, Al, Fe, and S. Our result indicated that while the dynamics of total inorganic content is naturally synchronized inversely with that of the organic content, it is not completely reflected in the dynamics of individual inorganic elements. For example, S is relatively stable throughout the year, and Fe changes are not congruent with the changes of the total organic and inorganic contents. However, Al and Si show a possible agreement with the changes of total inorganic and organic contents. From these results, we deduced that the dynamics were probably caused by environmental factors such as weather and water temperature, and the activities of living organisms such as diatoms, alga, and microbes.

INTRODUCTION

Sedimental sea sludge is formed through the deposition of organic and inorganic matter brought in to the sea by river, rain, and sea currents, resulting in viscous mud-like sediment piling on the seafloor. Because of the organic material and sulfide compounds, sea sludge has a dark color and bad smell [1]. Information on the chemical compositions of sea sludge is important, since such information will help us to understand the interaction between different environments related to the formation of the sedimental sea sludge, but also about the interactions between the organisms living in the sea sludge as the matrix of their habitats. Such information might also bring insights about the effects of human activities on seafloor environment. However, the inter-relationships and interactions among climate and weather dynamics and other external environmental changes, and the dynamics of chemical compositions of the sea sludge, are rarely studied.

Several studies reported the compositional aspect of sea sludge samples collected from single sampling localities. For example, we have reported the chemical compositions of samples from the Funabashi Port in Chiba as 23.61% [2], and the Hidaka Port in Wakayama as 7.27% [3]. Although lacking detailed information, insights from such studies have allowed for the formulation of a generalized definition of the sea sludge [1]. However, since sea sludge composition itself is influenced greatly by small differences in the environs of the location, to do an objective and standardized comparison of sludge collected from different locations is difficult [1] [4].

To our knowledge, there was no report about sea sludge content changes collected in a time series from one particular sampling point, until our previous study reporting changes of the organic content in time-series samples collected from Hidaka Port in the Gobo coastal area [1]. The result of that study indicates that environmental data such as weather condition and water temperature might explain such dynamics, while possible influence of anthropogenic and microbial activities to such dynamics were also discussed.

In this study, we focused on the changes of inorganic content over time on samples collected from Hidaka Port for 16 months (samples collected

for 12 months analyzed in our previous paper plus additional samples collected in the following 4 months), from July 2016 to October 2017, besides also revisited and reanalyzed the organic content dynamics data from our previous study [1].

MATERIALS AND METHODS

1. Sea sludge sampling

Wet sea sludge from Hidaka Port in Gobo City (33°52'55.3"N, 135°09'10.7"E) in Wakayama Prefecture was collected manually. Details about sampling method and post-sampling oven treatments followed our previous study [1]. Sea sludge samples were collected once a month for 16 months from July 2016 to October 2017 from one sampling location at three different loci. The sludge from the three loci were mixed together for further analyses, in order to avoid compositional bias.

2. Analysis of total organic and inorganic contents

Thermo-Gravimetric (TG) analyses were conducted on oven-dried samples in order to obtain the information of organic content. TG analyses were conducted in three conditions: (1) the original dried sludge sample, (2) dried-up sample further burnt at 100ºC in order to obtain information about both inorganic and organic contents, and (3) dried sample burnt twice, first at 100ºC and later at 600ºC, to get rid of the organic matter completely. The mass lost after burning can be considered as the total mass of organic content. Inorganic content of a sample was inferred by calculating the mass left after burning at 100ºC and 600ºC, considering sample (1) (the solid/dried soil sample) as the standard.

The total organic and total inorganic contents analyses were conducted on all samples collected for 16 months.

3. Main elements analyses using EDX

We measured silicon (Si), aluminum (Al), iron (Fe), and Sulfur (S) in surface of sludge using the energy dispersive X-ray spectrometry (EDX) (SEM-EDX; Miniscope TM-3000; Hitachi Ltd.). Sample preparations were as follow: First, wet sludge samples were dried in an oven at 100ºC for 10–15 minutes. Dried sample clumps were then crushed to turn them into coarse powder. The powder were mounted on carbon stage using carbon tapes, were analyzed using the SEM-EDX. From the analysis, values in percentage showing proportions of the four elements analyzed relative to one another were obtained. For each sludge sample, three mounted powder samples were prepared and analyzed in order to avoid sampling bias.

We were unable to do EDX analyses for August and October, 2016, because of insufficient amount of samples for those two months. Therefore, we obtained only the information of total organic and inorganic contents for those two months.

4. Environmental data

Weather condition and rainfall precipitation data of the three consecutive days before and on the day of sludge collections were collected from the homepage of the Japan Weather Association (http://tenki.jp/) and from the homepage of the Japan Meteorological Agency (http://www.dta.jma.go.jp/obd/stats/etrn/index.php), respectively. Information of seawater mean temperature for the week of the sampling date was obtained from the homepage of the 5th Regional Coast Guard Headquarters (http://www1.kaiho.mlit.g o.jp/KAN5/).

RESULTS

1. Additional analysis of total organic content

a) The dynamics of total organic content

We have reported the dynamics of organic content in a set of time-series sludge samples collected for a year previously, from July 2016 to July 2017 [1]. In this study, we added the results obtained from more samples collected from the same sites in Gobo/Hidaka coast, for another three months (August–October, 2017), totaling in a series of samples showing monthly organic contents for 16 months. When we reconsidered our results to include the values for the whole 16 months, we saw a possible cyclical pattern of the organic content changes. The highest organic content was 8.82% in August 2017 (different from our previous study [1] = in June 2017, 3.93%), while the lowest value was 0.89% in July (similar to our previous study [1]).

b) Weather condition and weather temperature

The highest water temperature was observed during the sampling week of August in 2016 and 2017, after gradually increasing, and then gradually decreasing in other months. Interestingly, when the trends of organic content dynamics vs. water temperature changes during the months of July to October in 2016 vs. 2017 were compared, we observed that organic content decrease happened simultaneously with the gradual decrease of water temperature. Our data indicated that the organic content in 2016 started to decrease about a month

after water temperature decrease, while in 2017 the decrease started in the same month.

We also observed a possible relationship between weather condition and the changes in organic content, in agreement with our discussion given in our previous report [1]. Weather patterns in the months of August and September 2016, and June and August of 2017, heavy rains fell 1–3 days before the sampling date of each month. In these summer months, weather conditions around the sampling dates were similar. Interestingly, organic contents of the sea sludge samples from these months were observed to be relatively high. This observation is also in agreement with water temperature changes mentioned previously.

2. Analysis of inorganic content

a) The dynamics of total inorganic content

The dynamics of the total inorganic content of the time series samples correlate inversely with those of the total organic content. We found that the sea sludge collected from Hidaka Port is composed mainly of inorganic materials (mean percentage for 16 months = 97.96%). The maximum value of the total organic content was 99.11% in July 2016, while the minimum value was 91.18% in August 2017.

b) SEM-EDX Results of the four major elements (Si, Al, Fe, S)

We conducted SEM-EDX analyses to identify the compositional changes of the four main inorganic elements of a sea sludge: Si, Al, Fe, and S. The average value of Si for all samples collected for 16 months is 67.47% (maximum value: 69.18%, October 2017; minimum value: 62.82%, August 2017). The values for all months besides the maximum and minimum values are all more than 60%. When the low organic content mentioned previously (average value: 2.24%) is also considered along with the high Si content, it can be said that the sludge from Hidaka Port is very close to sand. Meanwhile, the average value of Al is 20.82%

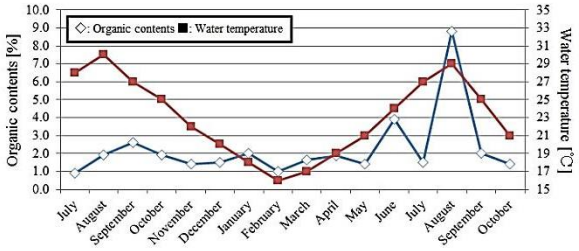

Fig. 1: Analysis of total organic content and water temperature

(maximum value: 22.33%, November 2016; minimum value: 19.59%, June 2017). This makes the composition of Si to be three times of Al (Si : Al ≒ 3 : 1). This compositional ratio is very close to the materials of cement such as blast-furnace slag [5] and fly ash [6].

Fe and S are the elements thought to affect the colorations and smell of sea floor sedimental sludge and mud. EDX analyses of our samples showed the average value of Fe to be 8.52% (maximum value: 11.19%, February 2017; minimum value: 6.73%, June 2017). Meanwhile, the average value of S is 0.90% (maximum value: 1.45%, July 2017; minimum value: 0.49%, November 2016). This composition could explain the gray color and slight rotten-egg smell of the sludge from Hidaka Port.

While random dynamic changes of compositional ration of Fe in the samples were seen, only slight changes of S were observed. Because the changes of S are very small, in order to confirm the stability of S, we conducted log approximation. We obtained the formula below to express our results:

$$Y = 0.286 + 0.298 \ln(x) \quad (1)$$

The result (Fig 1) showed that the changes of S across the whole observation period are very low, which means that for the whole 16 months, the composition of S is relatively stable.

4. DISCUSSIONS

1. Possible external factors affecting the organic matter composition dynamics of the seafloor sludge from Hidaka Port

In a previous study, we suggested that the change in the organic matter content in the sea sludge from Hidaka Port was probably caused by environmental factors such as water temperature and weather conditions, and biological factors such as living organism activities and life cycles [1].

In our present study, we conducted additional analyses on samples taken in the months of July to October 2017, making the total samples to be 16 months. The addition of the measurement results of the organic content has made comparisons among the corresponding months of 2016 and 2017, possible. The comparisons indicated a congruency of fluctuations between the corresponding months of 2016 and 2017 (July, August, September and October) for which data are available. The data showed that in both years, a decrease in the organic content rate was observed a month after the water temperature peaked in 2016, whereas in 2017 the organic matter decrease happened with the samples collected at the end of the month when the water

temperature peaked (Fig. 1). This probably suggests that during the hot months of summer, the warm water temperature might have caused microbe proliferations [7], which might then cause an increase in organic matter deposition. Meanwhile, a decrease in organic matter composition of the sludge samples collected when water temperature dropped at the end of summer might probably be explained in two ways. While warm temperature of water might cause an increase in microbial activities, temperature decrease might have caused microbial activities to also decrease. The decrease in organic content could be caused by it. Besides that, warm water is known to leach organic matter [8]. During summer months, increased microbial activities might replenish the leached out organic matter in the sedimental sludge. However, when microbe activities decrease, the replenishing pace might not be able to catch up with the leaching pace, hence the roughly one month time lag of the decrease of organic content. In our previous report [1], we also discussed possible contributions of the presence and absence of seaweed (a and b in Fig. 2, as change by season, in Hidaka port) caused by its life cycle [9] [10].

In this study, we found that our hypothesis about a possible correlation among microbial activities, water temperature, and seaweed life cycle, is not rejected. We observed that rain fell several days prior to the sampling dates. This might have contributed to the increase of organic content, which was probably caused by leached inland organic matter brought in to the sea by the river. However, while we found no contradiction with what we proposed in our previous paper [1], we are unable to decisively pinpoint any strong correlation between rainfall and the dynamics of organic content. Accordingly, further studies to specifically see if rain affects compositional changes of sea sludge must be conducted in the future.

2. Possible external factors affecting the inorganic matter composition dynamics of the seafloor sludge from Hidaka Port

In order to investigate the factors of change in the main components of inorganic matter, we conducted EDX analyses using the Scanning Electron Microscope (SEM) on the time-series sludge samples on the four main elements known as the main components of sea sludge: we compared fluctuation in organic matter and Si (Fig. 3), Al (Fig. 4), Fe (Fig. 5), and S (Fig. 6). We surprisingly found out that S is stable throughout the year, and Fe fluctuations are uncorrelated with any content changes. Therefore, at least in this study, we are unable to connect the stability of S and the irregular fluctuations of Fe during the whole sampling period with changes in organic components, or environmental factors. Further studies must be conducted to pinpoint the possible causes such as anthropogenic, biological, or environmental factors, and the mechanism.

We also noted that the average percentage of S of the Hidaka Port samples is very low (0.90%), when compared to samples collected from the

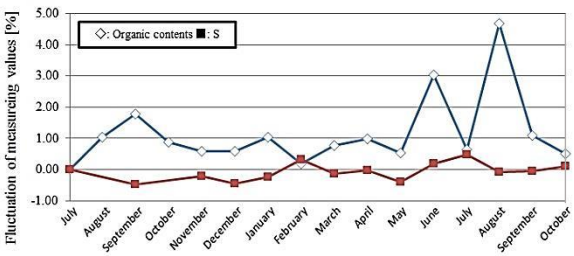

Fig. 6: Comparison with organic content and S

Funabashi Port in Chiba (10.29% [3]). A study of sludge collected from the Funabashi Port in Chiba [11] showed that the amount of dissolved oxygen (DO) is higher in sludge with lower content of sulfide. Therefore, the low S in Hidaka Port sludge might indicate high DO. Further studies, however, will be needed to confirm this suggestion.

In our present study, the changes of Si across time were found to be highly dynamics. When we looked at our non-EDX SEM data, we found traces of the phytoplankton diatoms (Fig. 7 a, b) from the sludge sample of the month October 2017, which is the time when we observed an increase in Si percentage (Fig. 5). Diatoms are classified as a type of algae, members of the superphylum Heterokonta. One of their main characteristics, besides their ability to photosynthesize, is their dense and heavy cell wall made of silica (SiO_2), which is also the cause of their non-motility. Because they are non-motile, they depend on water flow and turbulence to stay suspended in water with enough sunlight, and sink to the bottom of the sea when no external force keep them afloat [12]. As phytoplankton,their life cycle depends on water temperature and the availability of sunlight [12] [13].

A previous study focused on the abundance of diatoms collected from various depths in the Nada-Kumano coastal area, which is adjacent to our sludge-sampling location [14]. The study reported that diatoms from the area at the depth of 200 m are abundant during the months of April, August, and at the depth of 1000 m in October. This observation result sits very well with our results, which showed that Si percentage is high during the months of September 2016, May 2017, and August 2017 (Fig. 5), which means that high Si contents were observed on the month, or a month after diatoms high abundance was reported at the depth of 200 m. Takeuchi had reported the presence of an upwelling current from the bottom to the surface in the sea of the area [15]. Ishikawa et al also suggested that this upwelling could explain the abundance at different depths on different times, similar to previous studies in other areas [14] [16] [17]. Our samples were collected from shallow/surface waters (ca. 30 cm depth) at the Hidaka Port. Taking everything into account, a possible explanation of the relationship between the abundance of diatoms and high Si contents can thus be conceived. Probably, the upwelling brought many of the diatoms to the surface water level. Later, since the diatoms are non-motile, they settled down on the seafloor sludge close to the surface, contributing to the high Si content of the sludge. The one-month time lag between the abundance of diatoms at 200 m depth reported by Ishikawa et al [14] and peaks of Si content in the samples could be explained as the time the diatoms needed to move up from the depth of 200 m to the surface, and then to settle down on the shallow seafloor sludge.

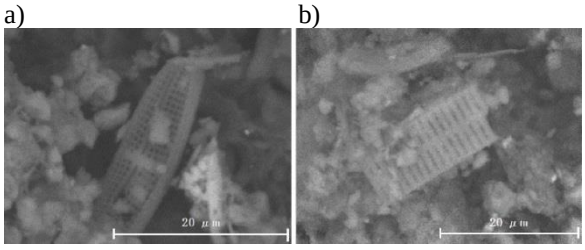

Fig. 7: phytoplankton diatoms in sludge samples

We also found that in our data, Si changes and fluctuations were in agreement with those of the total organic content (Fig. 3), indicating a possible connection. However, further studies to pinpoint the underlying connection are needed. When based on our present result only, however, we might hypothesize that changes in total organic content might be affected by the changes of Si content in the sludge, which most likely is caused by the abundance of diatoms in shallow water. This relationship might also explain the inverse relationship between Si and the amount of organic content (Fig. 3).

Al content fluctuations were found to be congruent to Si. Although we are unable to pinpoint a possible cause, this "synchronized" dynamics of Al to Si have caused the proportion of Si : Al to be relatively stable at 3 : 1. This also makes that both Si and Al changes are in agreement with the dynamics of total inorganic content of the sludge samples across the whole 16 months (Fig. 3, Fig. 4). Future studies will be needed to elucidate the reasons and mechanisms behind the changes and maintenance of the Si : Al proportion.

CONCLUSION

By adding data for three additional months, we were able to confirm our hypothesis conceived from our observation in the previous study [1]. That is, (1) the dynamics of the organic contents over time are probably directly and indirectly affected by external environmental factors such as water temperature, and weather condition. (2) The direct influence of water temperature and weather condition could involve warm-water leaching of organic content, (3) and organic materials from inland areas brought in by rain and river flow. (4) Indirect influence might be related to the presence of microbes and other biological agents such as seaweed and diatoms, which life cycles and biological activities probably depends on water temperature and weather. We also cannot rule out causes of anthropogenic origin, such as farming, contributing to the dynamic changes of sea sludge compositions.

We also concentrated on changes of percentage of some elements composing the inorganic content of sea sludge. Our result indicates that S content did not fluctuate over time, and Fe changes were

probably random and thus inexplicable with our present result. Meanwhile, Si changes are probably be connected to the presence/abundance of diatoms. Al changes were seemingly synchronized with those of Si across time, causing the ratio of Si to Al to be stable at 3 to 1. However, we were unable to pinpoint what exactly the cause of the dynamics of Al in the sludge samples.

We plan to continue our study in order to obtain more information across longer time span, in order to confirm the presence or absence of a cyclical pattern. More studies are needed to pinpoint the exact actual cause of organic content changes, most likely by using other methods including those of microbiology and molecular genetics, such as flow cytometry and eDNA. Similar biological methods can also be used to pinpoint the changes in Si content. Other studies to closely monitor the effects of rain and water temperature must also be conducted in the future.

ACKNOWLEDGEMENTS

HH would like to thank Gobo City municipal government for their cooperation during sampling collection. HH and DHES were partially supported by the National Institute of Technology, Wakayama College Competitive Internal Research Grant for Education and Research 2016.

PUBLIC ACCEPTANCE OF MINING COMPANIES IN INDONESIA

Einde Evana[1], Lindrianasari[2], Hamartoni Ahadis[3], Yuztitya Asmaranti[4]
[1,2,4]Faculty of Economics and Business, University of Lampung, Indonesia;
[3]Ph.D. Student of Environmental Science, University of Lampung, Indonesia.

ABSTRACT

This study aims to provide empirical evidence on community acceptance of mining sector. The survey involved in particular the Department of Environment in all Regencies / Cities in Lampung Province. This survey model is very effective in obtaining data that is suitable for target participants, relatively faster because access to mining locations is easier, and cheaper. The questionnaire was compiled using simple sentences to avoid the possible maturation in a prolonged survey. There are seven variables measured in this study. First is governance, measured by the existence of rules and legislation. The assumption is that these rules and regulations can ensure companies carry out mining activities according to the rules and the government can guarantee the accountability of mining companies. The second is mining acceptance, measured by tolerance, accept, approve, and embrace. Third is living cost, measured by how much the community sacrifices to fulfill basic needs. Fourth is environmental costs, measured by environmental quality (low pollution). Fifth, improving infrastructure, measured by improvements and facilities in supporting economic activities. Sixth is the impact of other industries, measured by the growth of other industry sectors, and the seventh is increasing welfare and greater employment opportunities for the community. The study found empirical evidence that public acceptance of mining companies is influenced by several factors, including the cost of living, quality of the environment, community involvement, improved infrastructure, the impact of other industries, and public welfare.

Keywords: Regulation, Governance, Mining, Public Acceptance, Environmental Cost, Living Cost.

INTRODUCTION

Lampung Province's spatial planning rules have been prepared through Regional Regulation No. 1 of 2010 concerning Lampung Province Regional Spatial Planning for 2009-2029, and Regional Regulation Number 1 of 2018, concerning the Zoning Plan for Coastal Areas and Small Islands of Lampung Province for the period 2017- 2037. The location of the mining area has also been established as shown in Figure 1.

The right to a healthy environment and is well contained in Article 28H of the 1945 Constitution, Article 9 Paragraph (3) of Law No. 39/1999 concerning Human Rights and Article 65 Paragraph (1) of Law No. 32 / 2009 concerning Environmental Protection and Management. Thus, the state (government) and business actors are obliged to respect, protect and fulfill these rights. Article 66 of Law No. 32/2009 states that anyone who fights for the right to a good and healthy environment cannot be prosecuted in criminal or civil suit (https://www.mongabay.co.id/2017/05/17/ damage - environment-effect of coal-mining-continuous-what is the solution /).

Therefore, the community and / or environmental institutions have the right to fight for these rights. Not only to obtain a decent living environment for now, but also to ensure the sustainability of the ecosystem for future generations.

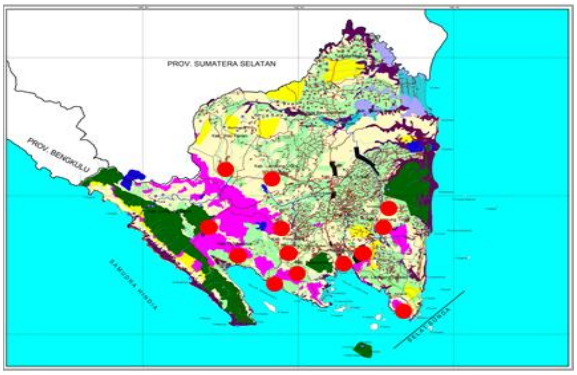

Fig. 1 The spatial layout of the Lampung Province.

Based on Law Number 23 of 2014, since 2015 the authority to administer government affairs in mineral and coal mining has been transferred to the Province. The purpose of transferring this authority to the Provincial Government is to control many conflicts that occur when the ownership rights of mining permits are in the hands of the Regional Head. Conflicts in various dimensions often occur, even though the reason of triggering the conflict is to prosper the community. But in fact, people always become victims of the conflict in the mining area (https://setkab.go.id/konflik-tambang-dan-manfaat-dana-desa/).

This research involves community participation in assessing environmental management in mining areas.

This assessment will provide relevant information for policy making related to the existence of mining. Data on reclamation guarantees, and post-mining guarantees recorded in the Provincial Government of all mining companies active in Lampung Province show that the compliance of mining companies in fulfilling the company's responsibility for the environment is very low.

The low awareness of mining companies to provide guarantees of reclamation and post-mining, is shown in Figure 2. From figure 2, it can be seen that there were only 36% of mining companies out of a total of 168 companies that paid collateral for reclamation. Meanwhile, companies that pay post-mining guarantees are only 18%, and all of them come from companies that also pay collateral for reclamation.

This study successfully confirmed both theories, legitimacy theory and stakeholder theory, that in its operational activities, companies must pay attention to the interests of their stakeholders. Community acceptance of mining companies is one of the keys for companies to perform and continue operations in a sustainable manner.

LITERATURE REVIEW

Social research in the area of the environment, using these two theories, namely the legitimacy theory and stakeholder theory. Both theories can explain that companies must carry out responsibility activities to society and the environment. In this study also uses these two theories and enriched with regulatory theory.

The Legitimacy Theory

Legitimacy was states that legitimacy is important for organizations because it explains the limits of emphasis on social norms and values [1]. Legitimacy is also a response to the importance of analyzing organizational behavior that takes into account the environment. The company's legitimacy will be obtained if there are similar results expected by the community from the company, so that there are no demands from the community. Companies can make social sacrifices as a reflection of the company's attention to society [2]. In order to gain legitimacy, companies must improve their image [3] by communicating their environmental activities with the disclosure of the social environment [4].

Legitimacy theory explains that companies must carry out operational activities in line with the expectations of the surrounding community [5: 8]. If the company's activities are contrary to the expectations of the community, then the company will not get the legitimacy of the community. This is what further tends to cause conflict between the company and the community [6].

The Stakeholder Theory

In general, stakeholder theory explains that a company is an entity that not only operates for its own interests, but also must provide benefits to stakeholders. The stakeholder theory also explains that each stakeholder group has an unequal impact on the environment. This explanation also indicates that all stakeholders have the right to obtain information about company activities so that their diverse decision-making can be used [7]. Consequently, the company has an obligation to fulfill all its obligations to stakeholders. Stakeholders have different expectations from the company [8]. To pursue this expectation, stakeholders can put pressure on the company directly or indirectly in making environmental disclosures. To deal with this, the company is required to always work with stakeholders so that the company's vision is in line with them. However, stakeholders can also choose not to use information and cannot play a role directly in the company [9].

This study attempts to confirm whether the legitimacy theory and stakeholder theory are in line with the real conditions of mining companies in Lampung Province. Where the two theories predict that in its operational activities, the company must pay attention to the interests of its stakeholders. If the company's activities are in line with the interests of stakeholders, the company will be legitimized in the community.

The Public Interest Theory

Public Interest Theory was introduced by Arthur C. Pigou in his book entitled The Economics of Welfare in 1932. Regulation refers to the availability and enforcement of legal instruments, such as laws and other government rules. In general, the Public Interest Theory explains that regulation provides protection and benefits to the wider community [10]. In the case of mining, the theory of public interest leads to the assumption that the legal instruments issued are to provide a balance of allocation of these scarce resources, for all parties. Communities that are powerless stakeholders and who cannot be sacrificed from mining activities. To provide protection to the public, regulation is needed.

Previous Research and Hypothesis Development

Mining companies are types of companies whose operations are very sensitive to the environment. This type of industry is very easy to generate profits, but on the other hand also has a negative impact on humans and the environment. Zhang and Moffat [11] conducted a study that aims to examine how people around mining companies evaluate the benefits and

negative impacts of mining, and from this evaluation data is obtained about the extent to which mining activities in Australia affect community acceptance of mining activities.

Conflicts between companies and communities (including indigenous peoples) are an integral part of the mining area. The frequency of this conflict occurs, resulting in mistrust of indigenous peoples in the government [12]. The Center for Social Responsibility in Mining (CSRM) also recognizes that conflict is an inherent part of the mining community throughout the world. Conflicts that occur in mining areas occur in various elements of society, on several scales, concerning a number of problems; politics, economy, socio-culture, and environment [13], [14].

The study conducted by Zhang and Moffat [10] found that the role of government can play a role (moderating) in public acceptance of the impact of mining activities. Literatures that discuss impact assessments especially on social impact assessments also find positive and negative impacts on mining activities on, especially on a small scale [15]. Islam [5] explains that one form of corporate social responsibility is assessed from the welfare of the community.

Meanwhile, Boyd and Banzhaf [16] explain that the explanation in ecosystem services must involve environmental costs. This explanation is quite a reason for the importance of research to assess the acceptance of people around the mining area for the impact caused by the company's activities. The hypothesis formulated is the role of government can play a role (moderating) in public acceptance of the impact of mining activities. Prolonged conflicts that occurred in the mining area, one of which was the conflict between diamond and mining areas (titanium oxide) in the Sierra Leone region. This conflict between the company and the people of Sierra Leone eventually contributed to the formation of the Revolutionary United Front (RUF) and civil war in Sierra Leone [17]. Conflict in the mining area is one of the centers of economic, social and environmental problems that are key to the country's development, therefore, the impact of the mining sector needs to be seriously assessed [18].

The rules issued by the Indonesian government through Law No. 23 of 2014, effectively valid for 2016, are essentially in favor of the public interest (see Public Interest Theory). So that the policy of business practices should properly create regional economic growth. In relation to mining companies, the law has the potential to reduce poverty and improve the quality of human development [19]. This explanation is quite a reason for the importance of research to assess the acceptance of people around the mining area for the impact caused by the company's activities. For theoretical explanations and previous research, the research hypothesis formulated: Government governance can play a role (moderating) in public acceptance of the impact of mining activities.

RESEARCH METHOD

This study will use a questionnaire survey to measure community acceptance (including indigenous peoples) of mining companies, by involving Regency / City / Province of Lampung. Government involvement will greatly influence the achievement of this research, because the government has easy access to meet people in mining areas. The participative design is very effective in order to obtaining data from participants, and also relatively faster because access to mining locations is easier, and cheaper. In addition, the government should also show concern for the community for the possibility of corporate irregularities in existing rules and regulations. Thus, the government has an interest in achieving the objectives of this research.

The surveys conducted are manual (not on-line) related to the condition of the community surrounding mining companies that may not have WIFI access. Even if they have WIFI access, their expertise in taking orders and filling out online surveys is predicted not to be as expected in this study. Questionnaires were built using research designs that had been carried out in previous studies [10], with adjustments as needed. This adjustment is considered important because of the different natural and community conditions between Australia and Indonesia.

Through the local government, this research will spread questionnaires to the community including indigenous peoples in the area where the mining company is located. Furthermore, the role of local governments to determine respondents (residents around the mining area) will greatly simplify the survey method of this study. At the end of the 20th century indigenous peoples were excluded from any important role in the management of the resource development environment in traditional lands [11].

The instrument of this study adopted the previous research instrument [10]. All variables used in their study were also measured in this study, with some modifications, if needed. Governance is measured using two question items, laws and government guarantees [20], [21], [10]. Participants were given 22 questions (consists of 8 criteria of questions) with a 7-point scale (1 = strongly disagree / very bad / very unsatisfactory, 7 = very agree / very good / very satisfying). Acceptance of mining was measured using four items of questions that tolerate / Accept / Approve / Embrace [22].

The questionnaire was compiled using simple sentences to avoid the possible maturation in a prolonged survey. There are seven variables measured in this study. The respondent group was

divided into two groups. The first group is the Regency / City, where the mining company is located, and also and Lampung Province (the first variable). The second group is community groups who live around mining companies (second-seventh variables).

The **first** is mining acceptance, measured by tolerance, accept, approve, and embrace. **second** is living cost, measured by how much the community sacrifices to fulfill basic needs. The **third** is environmental quality, measured by environmental quality (low pollution). The **fourth** is community involvement, measured by involvement of local residents in mining activities. The **fifth is** improving infrastructure, measured by improvements and facilities in supporting economic activities. The **sixth** is the impact of other industries, measured by the growth of other industry sectors, and **the last** the is increasing welfare and greater employment opportunities for the community.

Before collect the data, surveyors team educated by researcher to guide how data could be collected and why survey conducted. Each Regencies / Cities respondence was not similar, it was depended on the number of mining corporation in its area. The final participant of this study consisted 78 participants.

RESULT

The mean of the respondent's answer to this research questionnaire shows a reasonable value. The mean value for each study variable, respectively, is: (1) the Mining Acceptance = 3.52; (2) Living cost= 4,26; (3) Environmental Quality = 3.15; (4) Community Involvement = 3.36; (5) Infrastructure Improving = 3.38; (6) Impact of Others Industry = 3.09; and (7) Public Welfare = 3.48. The whole has a relatively similar value. Except for Living Cost which has a mean value that tends to be highest. Table 1 explains each correlation test result between variables. In addition, the mean and standard deviations are explained in the table. Furthermore, a discussion about the acceptance of mining companies using consideration of living costs.

The community will reject the existence of mining when the necessities of life are getting higher. Statistics on the correlation between mining receipts and living costs show a negative relationship (R = -0,531**). This finding also demonstrates that mining companies need to pay attention to the elements of community needs around mining activities carried out, such as the presence of clean water and ease as well as relatively low prices to obtain basic needs, and so forth.

Low environmental quality (indicated by poor air quality, high noise, garbage, declining soil fertility, damage to post-mining ecosystems, etc.), will result in more public acceptance of mining companies. Statistics shows a positive correlation value (R = 0.858 **). Other analysis shows that environmental quality has a negative impact on people's living costs (R = -0.607 **). This means that the lower the quality of the environment, the higher the cost of living that will be paid by the community.

Table 1 Relationship between variables

Note: 1. Mining acceptance; 2. Living cost; 3. Environmental quality; 4. Community involvement; 5. Infrastructure Improving; 6. Impact of others industry; 7. Public welfare.
** Significant level <0,01

The relationship between community involvement and mining company revenue is positive (R = 0.874 *). This figure indicates that the higher the community involvement in mining companies, the higher their acceptance of the company. Community involvement in mining company activities will increase community income. That way, the community will be able and easier to meet the cost of living. The cost of living feels lower when the ability to pay is higher. Finally, with the low cost of living, community income to mining companies is higher (R = -0.569 **). The involvement of the community in mining must be considered by the company. The involvement of the community in mining companies can be as mining workers, or as providers of supporting activities for mining companies (such as transportation, food or food providers, business partners, etc.).

Road improvements around the company will result in a smooth production process. In addition, the community benefits from the infrastructure built in the company environment. In accordance with the concept of CSR, the company's concern for infrastructure will gain the sympathy of the surrounding community, so that it will gain legitimacy. The results of this study are in line with what the legitimacy theory predicts, where the relationship of infrastructure development is positively related (R = 0, 875 **) to the acceptance of mining companies.

Communities around mining companies also need infrastructure improvements, such as the availability of electricity and good main roads. As with conditions in the village area, the availability of electricity is still relatively limited. If the availability of electricity is

mostly absorbed by mining activities, it can be ascertained that the community will often experience a long duration of blackouts. Infrastructure that is not well developed will have a high cost of living. The quality of the main road to community settlements must be maintained quality. Damaged roads will cause economic movements to require a relatively long time, and ultimately increase the cost of goods. The study found that the worse the infrastructure, the lower the acceptance of mining (R = -0,521 **).

The correlation test results between industrial growth and mining company revenues were found to be positive (R = 0.922 **). These results indicate that the more industries grow around mining companies (especially if the mining company triggers the growth of the new industry), the higher the community's acceptance of the mining company. This result is in line with the legitimacy theory and stakeholder theory. Both theories predict that in its operational activities, the company must pay attention to the interests of its stakeholders. If it is in line with stakeholder interests, the company concerned will obtain legitimacy in the community.

This study also found empirical evidence that industrial growth reduced living costs (R = -0.604 **). The growth of other industries around mining companies was also a concern in this study. The presence of mining activities followed by the growth of other business activities in the surrounding areas indicates that mining activities can drive economic growth in the region. Economic growth will encourage the ability of the community to fulfill their needs.

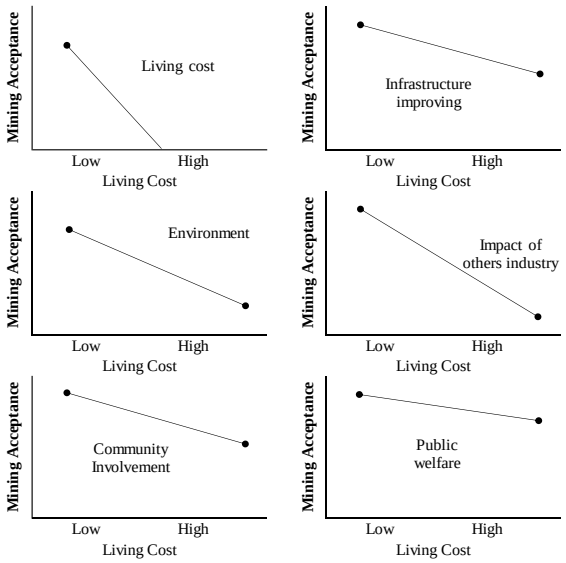

Fig. 2. Illustration of relationship between variables when living cost as situational factor.

Finally, this study found that community welfare was positively related to the acceptance of mining companies around them (R = 0.759 **). In general, the concept of community welfare is indeed the main measure of economic success. The results of this study also found a negative correlation between the welfare of the community and the acceptance of mining companies in their area (R = 0.455 **). Low people's welfare will encourage the difficulty of the community in fulfilling their needs. On the other hand, the cost of living will be increasingly heavy. The higher the cost of living, the lower the community's acceptance of mining. Figure 2 show the illustration of relation between variables and living cost as a situational factor. Living costs are a consideration in discussing the main variable relationship because this variable is very relevant and important in developing country society. Results generated discussion becomes more interesting.

CONCLUSIONS

The study found empirical evidence that public acceptance of mining companies is influenced by several factors, including the cost of living, quality of the environment, community involvement, improved infrastructure, the impact of other industries, and public welfare. These results are increasingly interesting when considering the cost of living in interacting between variables. These results are increasingly interesting when considering the cost of living in interacting between variables. Where it was found that the cost of living statistically was negatively related to the variable.

An important implication of this research is the need for attention from the company to maximize the interests of the community around the company. Because, community acceptance is absolutely needed by the company to ensure the sustainability of the company's operations.

Several limitations of the study were encountered, especially when the surveyor team went to the field to get respondents. The difficulty in reaching the location of the mining company and the research schedule that coincided with the days of Ramadan (when Muslims fasted for a full month) caused the low number of respondents to this study. However, the conduct of surveys is still carried out with a high level of caution, to obtain quality research results.

ACKNOWLEDGMENTS

This research was funded through the Professor Grant at the University of Lampung, 2019. Collaboration with the district/city/provincial government contributed greatly to maximizing secondary and primary data collection. Interesting discussion with a peer group of environmental science courses to strengthen practical argument, which resulted in this paper more attractive. For these reasons, we thank you for the involvement of all the parties we mentioned above. Hopefully this paper can contribute, especially to the Lampung Province.

VALIDATING CREATIVE THINKING PROCESS EFFECT IN THE 2011 TOHOKU DISASTER AREA: DESIGNING LANDSCAPE RESILIENCE

Misato Uehara[1], Rob Roggema[2] and Makoto Fuiji[3]
[1] Shinshu University, Japan; [2]Hanze University of Applied Sciences, Netherlands,[3] Tonich Engineering Consultant, Japan

ABSTRACT

In order to treat which is suitable for climate change and natural disasters beyond forecasting, drafting a flexible plan and consensus among the residents are important issues. However, empirical verification of successful creative discussion and planning processes are limited, because experimental verification of the effect of such planning theory and communication is extremely difficult. Our purpose was to prove benefits of the Swarm Planning's Centre for Development of Creative Thinking (COCD) tool which is one of creative planning processes. To make the member construction for each four design groups (General process, Swarm process), we questioned 41 universities' students about their opinions and interests in the 2011 Tohoku disaster area and its reconstruction conflict. These score allowed us to make the same allocation of people who were agree or disagree with current relocation housing and sea wall development plan, gender, interest of disaster area. We required all eight groups to plan relocation housing site for tsunami disaster victims, required to plan destroyed sea wall reconstruction of the Tohoku disaster area. Four groups used the general planning approach, while the other four groups use the COCD box tool. After this, every group presented their design proposals, and audiences scored them. After this, each student scored their proposal too. The research concluded that evaluation of proposals by Swarm Planning got higher evaluation than regular planning proposals on three criteria, habitability, appropriateness and originality in statistically.
Keywords: Participatory planning, Post-disaster, Design Charrette, Future Design

1. INTRODUCTION

At the 2011 Japan Earthquake Tsunami disaster, many Tohoku cities which had been built through proper processes were damaged: Dead or missing 18,430 people, destroyed 404,890 buildings. In addition, despite strong opposition by few residents and ecologists, a huge seawall was re- constructed, and relocation houses on the hill were developed in the disaster area. As a result, these developments used 4 billion yen, but about 100,000 victims did not choice to return to the reconstructed town, for residents on the hill were not convenient, and huge sea wall hid beautiful coastal line view. Alternative new planning process is required rather than past general planning process for adaptation to climate change and natural disaster recovering. This is our question.

Previous studies reported that digital technologies (GIS, 3Dmapping) in workshops can help to stimulate understanding and discussion of issues by the interview survey [1,2] and participatory observations [3-7]. Warden R et al [8] indicated the demerits of using digital tools. Zhang H et al and Valencia-Sandoval C et al [9,10] showed the importance of a simple discussion tool in disaster areas and rural areas where digital data resources are not available. Höppner C et al, Knox MW et al, Rohrbach B et al [11-13] verified the merits of the whole workshop program. Thus, there are very few quantitative empirical studies of the effects of workshops with citizen's participation. Therefore, the purpose of this paper is compare the final qualities the plans by two different workshop discussion process of reconstruction plans from 2011 Tsunami disaster by quantitative analysis.

2. STUDY MATERIALS AND METHODS

This article focused on setting up a process of comparative design, which should make it possible to identify the potential benefits of Swarm Planning over regular planning.

General planning process and design aims to provide limited solutions for relatively straight forward, 'tame' problems [14], while climate adaptation is seen as a 'wicked' problem [15]. General planning processes' main stakeholders are 'consulted', which means they are approached with some design proposals which have been already well thought through and proven. The role left for the stakeholders is in general to accept or reject such proposals. Real influence or a contribution in the form of suggestions is often not possible, nor welcomed. Though different opinions are introduced here, they are chosen in the final majority and the minority's opinion is ignored.

On the other hand, Swarm Planning approach's

key factor is to deal with complex issues [16]: it is the most important advantage of working in a design charrettes; the method that is possible to make complex issues, such as climate adaptation which is concrete and conceivable. Roggema developed workshop process using tool by the COCD-box methodology [17].

In this article, the benefits of the Swarm Planning's COCD-box thinking process are investigated. We required six students' groups to plan relocation housing site for Tsunami disaster victims, required them to consider destroyed sea wall reconstruction of the Tohuku Disaster area. Four groups used the general planning approach, while the other four groups used the COCD box tool. After group discussion and workshop, every group presented their design proposals, and the audience scored each proposals and own group's proposal too. To evaluate each proposal, a Semantic Differential Method questioner was used.

2.1 Defining the design teams

This study investigated the effect on quality of proposals by two different discussion process for reconstruction of the 2011 Tohoku earthquake and tsunami disaster. In order to make each group have students who had different opinion equally, we questioned the 41 university students about their opinions and interests in the 2011 Tohoku disaster area.

The score of answers to this questionnaire showed the difference of their premise knowledge and opinion of 2011 disaster area. This data was used to make member construction for each eight design groups. Additionally, in forming the group members, we considered the gender balance too. We allocated each eight groups had approximately five students under above process. As a result of this adjustment, each group had same allocation of people who had favor and against opinion for housing-relocation on the high land, and sea wall re-construction. In order to evaluate the usability of swarming planning statistically, Swarm Planning four groups used COCD-box tool, while the other general planning four groups did not used COCD-box tool. This design setting made it possible to compare proposal qualities by two different thinking process.

2.2 Planning theme and target issue

All eight groups were required to plan a new a sea wall development and relocation housing site planning for destroyed residential community by tsunami disaster. This subject is a very important issue. In the actual disaster area, 40 trillion yen of reconstruction budget was used, and the new sea wall and the new town were rebuilt [18]. However, planned population has not recovered because many of these new-residential sites and rebuilt apartments' rooms are left empty.

Our each workshop group had similar members, used same work time (One and a half hours), same design task, materials such as colored plasticine to proposed plan of sea wall (yellow cray), new housing site (red cray) and another land-use proposal (green cray) ,according to design charrettes setting [16]. All groups were given the same advance information; Disaster area's favor or against opinions for relocating houses to higher ground and reconstructing seawalls.

Fig.1 The COCD-box sheet with favor or against opinions for relocating houses to higher ground and reconstructing seawalls

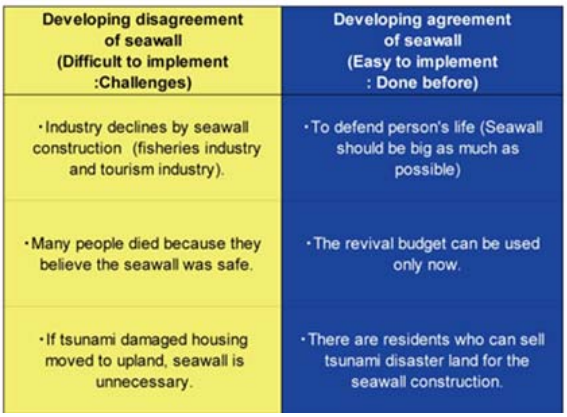

Fig.2 The simple tow column sheet with favor or against opinions for relocating houses to higher ground and reconstructing seawalls

The four groups of Swarm Planning were used the COCD-box tool, which was developed by COCD (Centre for development of Creative Thinking) (Fig.1). The COCD-box has 2 axes: 1. Difficulty or ease of implementation, 2. Agree or oppose to existing proposals, (Generality or uniqueness of planning idea). Therefore, compared to the column sheet, even if the discussion is based on the same positive and negative opinions, new discussion direction with the conflict of two opinions was assumed to be stimulated. Swarm Planning process groups (SG) discussed the matter with COCD box to focus on the new direction (red column of Fig.3); the ease of implementation normal idea and creative idea which is not (yet) feasible (SG1,2,3,4).

The control groups used simple tow column sheet (Fig.2). Every group was allocated the students by the result of questionnaire survey, so each group's favor and against opinion for current development (relocation and sea wall renovation) were same percentage. General planning process groups (GG) had discussion which is based on the original ideas. This is the ease of implementation and creative idea which is not (yet) feasible in parallel (Fig.2). Then, we assumed they tend to decide by majority rule, and tend to ignored minority's opinion (GG1,2,3,4).

2.3 Evaluation of proposal quality difference by two planning process using a Semantic Differential Method

After the workshop, all students scored each proposal using employing Semantic Differential Method including own team's plan, which took One and a half hours. In order to abandon potentially biases, the SG and the GG presented their proposals alternately. The respondents evaluated using Semantic Differential Method scale; A point value is assigned for each of the spaces on a seven-point scale so that a set of seven spaces or a continuous line between the opposing adjectives could be constructed. When the positive adjective is on the right side, assign the values 1 to7 from left to right; for example, 1 = uninhabitable, 4 = no opinion, 7 = habitable. After evaluation, the authors analyzed the evaluation score's difference between the four proposals by Swarm Planning and the four proposals by the General planning. This analysis used Welch's t test. This analysis showed the relationship between the type of planning process (Swarm planning way or General planning way) and these evaluation score's average of difference.

3.RESULTS

In this paper, we compared the quality of proposals by two different process, for we revealed the validity of the use of the Swarm Planning approach. First, we compared the design proposals' quality by the two different processes. Next, we compared the evaluation scores statistically.

3.1 Design proposals differences

Figure 3 showed the results of the proposals by general planning process. As a whole, all the groups made proposals to rebuild the sea wall for tsunami breakwaters (yellow clay) (Fig.3). This decision seemed to be same in actual disaster area.

The GG3 group also proposed to rebuild the residential area in the affected area of the tsunami again, and GG1 and GG2 proposed high land relocation. The remaining GG 4 group could not propose relocation sites. Especially GG3 plan did not seem to have considered on the cost aspect: the sea wall at twice the height as before (10 m), making a 100 m tower. In addition, the reason of the relocation housing site did not seem to be logical (Fig.3).

Although many seawalls could not save the coastal residents at 2011 disaster, from the GG's discussions and proposals, we can see that it is difficult to break away from the conventional and general decision. Furthermore, using the conventional discussion process, there were some cases when the proposal became childish, and cases when answers to the requested task could not be made.

Figure 4 showed the results of the proposals by Swarm Planning process. As a whole, all the groups' plan had no seawall construction, for all group also proposed to relocation site on the hill.

The SG1,2,3 plans seemed to be consideration on the both coastal site and hill site with road networking. They set the seawall cost to road networking construction cost.

Especially, we were interested in the SG1's housing resettlement site which was located in the highest altitude tsunami affected land ; they explained 'The reason for this choice was that it will achieved both minimum tsunami disaster risk and land cost was cheap than that of the area which was not affected inland.'

Unlike the regular planning process group, half of the group had additional proposal of seaside tide forest and network roads using green cray(Fig.4).

On the other hand, the regular planning groups were also given the same consultation option as green clay which proposes land use other than seawalls and relocation housing, their additional proposal such as seaside tide forest and roads were few(Fig.3).

3.2 Evaluation scores and its comparison

In order to conduct a Semantic Differential Method test, a total of eight design proposals were introduced with a brief presentation.

The students evaluated each proposal using the method of semantic differential scale. The proposed plans in each of the methods of GG and SG had alternating announcements, to reduce the impact of order on evaluation; It was to avoid the possibility that the first half of the proposals are highly appreciated than the second half of the proposals.

In this test, preferences of each plans were scored along a seven-point scale. A score of seven points means that the subject has a strong positive

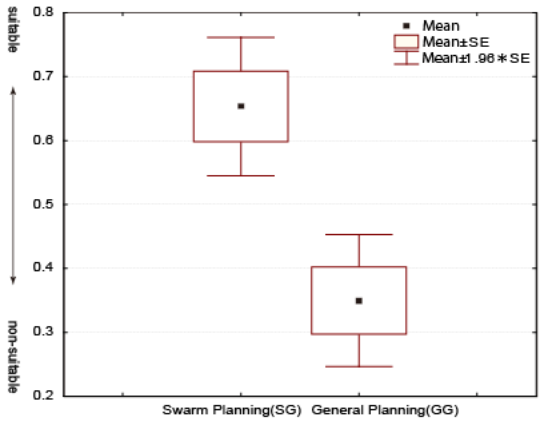

Fig.5 The comparison evaluation score of Swarm Groups and General Groups plan's suitability

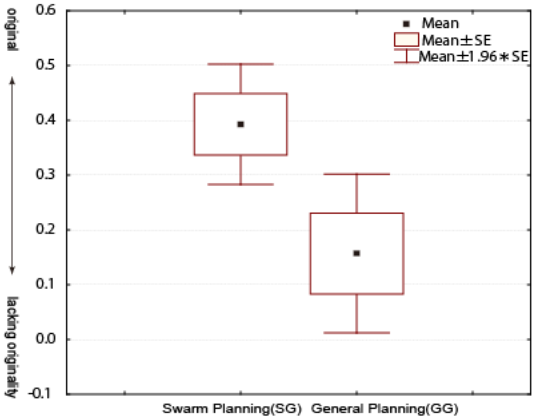

Fig.6 The comparison evaluation score of Swarm Groups and General Groups plan's originality

impression of the sample, while a score of one point denotes a strong negative impression: Each land use plan's appropriateness, habitability and originality. This result of the analysis showed the effect of Swarm Planning, as interpreted through the Welch's t test (Fig.5,6,7). Overall, the evaluated scores were significantly higher in Swarm Planning groups plans than general planning groups' ones. In other words, the majority of the 41students evaluated the Swarm Planning groups land use plans higher than the control general groups in statically (Fig.5,6,7).

The evaluation scores of suitable(2) to non-suitable(-2) was significantly higher in Swarm Groups (mean 0.65) than General Groups (mean 0.35) , with t=4.00 p<0.001 (two-tailed), df=489.2 (Fig.5). The evaluation scores of habitable (2) to non-habitable (-2) was significantly higher in Swarm Groups (mean 0.34) than General Groups (mean -0.04) , with t=4.59, p<0.001 (two-tailed), df=489.4(Fig.6). Similarly, the evaluation scores of Originality (2) to lacking-originality(-2) was significantly higher in Swarm Groups (mean 0.39) than General Groups (mean 0.16) , with t=2.56, p=0.011(two-tailed), df=454.1 (Fig.7).

The results suggested that Swarm Planning process using the COCD-box will lead to more favorable outcomes of planning than general planning process without the COCD-box. This analysis revealed that the relationship between the type of planning process and the quality of proposals in terms of resilience. And it proved that the Swarm Planning approach's result is as good as quantitative empirical studies.

CONCLUSIONS

In this paper, we investigated the relationship of planning processes and its proposal qualities, to reveal the validity of the use of the Swarm Planning process. First, we compared the design proposals' quality by planning process type. Second, we also compared each plan's evaluation scores by planning process type in statistically. Empirical verification of

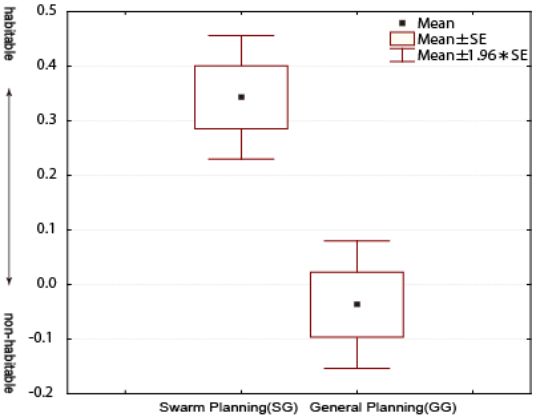

Fig.7 The comparison evaluation score of Swarm

successful and creative discussion and planning processes is limited, because experimental verification of the effect of such planning theory and communication is extremely difficult. Though this is based on qualitative interviews, Cheng P. et al. **[2]** points out the importance of using a matrix for thinking and forcing new ideas with different options. Kojima et al **[19]** also revealed that when members of an imaginary future generation are present during negotiations, groups tend to select more sustainable options. The results of this study support**ed** it quantitatively. In this article, we accomplished to analyze the suitability and usability of the Swarm Planning approach with COCD- box tool.

Additionally, this study reveal**ed** novel results in aspect of difference of planning effect's empirical verification. All groups had the same disagreement, because we assigned members with diverse opinions to each group. Despite above design setting, it can be concluded that the Swarm Planning approach performs better quality of proposal than regular planning approaches.

Each group also included students who opposed to the standard relocation housing and sea wall development idea of the 2011 disaster areas. After that, the same study time and the same materials

were given. Thus, although the group condition and design work task were unified, the proposal contents by two different processes appeared to be distinctly different. Also, in the individual evaluation of 41 students for the proposal, the proposals with COCD-box were statistically evaluated higher than the proposals by the conventional method of planning. This result seem**ed** to be one evidence that will overcome the general planning problem; Although different opinions were introduced on the table, they were chosen in the final majority and the minority opinion was ignored.

In fact, despite strong opposition, a huge seawall was constructed, and the relocation houses on the hill were developed in the affected area. As a result, the seawall and the relocation of houses were completed at a cost of 4 billion yen, but about 100,000 victims did not return to the reconstructed town. This fact indicates an inconsistency in the existing planning process. In that context, we could point out the possibility of flexible planning process using Swarming planning and COCD-Box. It is recommended to use the Swarm Planning approach in areas that suffer or potentially suffer after a climatic event. In these cases, the planning approach could help to minimize the damage after a disaster and/or to anticipate a disaster by designing a more resilient urban environment.

[2] Faculty of System Engineering, Wakayama University, Wakayama, Japan

ABSTRACT

The responses of diatom communities distributed on the surface of substrates in stream beds were investigated at 17 study sites in three areas with different geological characteristics: closed-mine, serpentine and limestone areas. Our aims were to describe how diatom communities in different geological areas respond to and are affected by water chemistry. High Mg^{2+} and Ni concentrations characterized stream water chemistry in the serpentine area. The limestone area was characterized by high pH , Ca^{2+} and $HCO3^-$ concentrations. Samples collected at 17 study sites were clustered into 5 groups, depending on diatom species similarities. Results from nonmetric multidimensional scaling(nMDS) and canonical correspondence analysis (CCA), showed chemical variables in running water were strongly related to diatom communities. Only four diatom communities belonging to cluster 3 (2 sites in closed-mine area and 2 sites in serpentine area) had positive correlations with three chemical variables (F^-, Zn and NH_4^+). Moreover, those communities at two sites in limestone area were affected by pH values. It is clear that species compositions of diatom communities were different for the three areas with different geological characteristics, and that those compositions were greatly affected by water chemistry.

Keywords: diatom, serpentine, limestone, water chemistry, geology

INTRODUCTION

Diatoms, green algae, and cyanobacteria typically comprise the majority of species in benthic algae communities. These occur within virtually all rivers, typically in intimate association with heterotrophic microbes and the extracellular matrix, known by the all-inclusive terms periphyton or biofilms [1]. Sheath and Cole [2] recorded 259 taxa of algae, of which 35% were green algae, 24% were cyanobacteria, 21% were diatoms and other chrysophytes, and 20% were red algae. Recently, water pollution has become a very important social problem, and benthic algae, including diatoms and other algae, have been used as tools to assess the degree of water pollution. Because of their ability to concentrate metals from aqueous solutions, marine and fresh water algae have great potential as biological monitors for anthropogenic waste [3]. As in Europe and the United States, many studies concerned with bio assessment have been conducted in Japan. Diatoms and other benthic algae play important roles as primary producers in aquatic food webs. Many benthic invertebrates, such as trichoptera, ephemeroptera and plecoptera, feed diatoms and other algae, and seetfish (*Plecoglossusaltivelis*) called Ayu in Japan is well known as one of the main diatom feeders [4]. However, studies concerning the response of diatom communities to bed rock geology, such as serpentine and limestone, have rarely been conducted in Japan. Therefore, the aim of this study was to make clear how diatom communities in streams respond to the bed rock geology.

STUDY SITES AND METHODS

STUDY SITES

Samples were collected at 17 study sites in streams running in areas with different characteristics. Seven sites from st.1 to st.7 were located around the Ikuno mine, in the central part of Hyogo Prefecture (Fig 1). That mine was closed in late March 1973, after operating for about 1200 years. The elevations of sites in this area ranged from 343m to 513m. Five sites (st.8–st.12) in the area of serpentine geology were located in Yabu City, in the northern part of Hyogo Prefecture, and were set in Oecho, Fukuchiyama City, Kyoto Prefecture (Fig.1). All of the streambeds of the five sites in those areas were composed of serpentine rocks, and the land aroundthe sites was largely covered by serpentine soils produced after weathering of the rocks. The serpentine rocks in Japan were described by Suzuki [5], and were found

along two south-northeast-trending belts in Kyushu, Shikoku, central and southern Honshu. The serpentine areas in Yabu City and Oecho are two wide spreading areas in Honshu. Two other sites (st.13 and st.14) in the limestone area were located inTaishaku valley, Tojocho, in the northern part of Hiroshima Prefecture (Fig.1). Those sites were selected in the Mito river and the Taishaku river respectively. The streambeds of the two rivers have substrates of limestone walls around the rivers. In addition to those sites, we have
three reference sites for comparison with results from serpentine, limestone and closed-mine areas, in the Yada River system in the northern part of Hyogo Prefecture. Three sites (st.15–st.17) were located in the Yamada river, Kumanami river, and Kyonyo river, respectively (Fig.1). These sites were chosen due to their geological characteristics (Yamada river: sedimentary rocks; Kumanami river: quartz porphyry, and Kyonyo river: basalt).

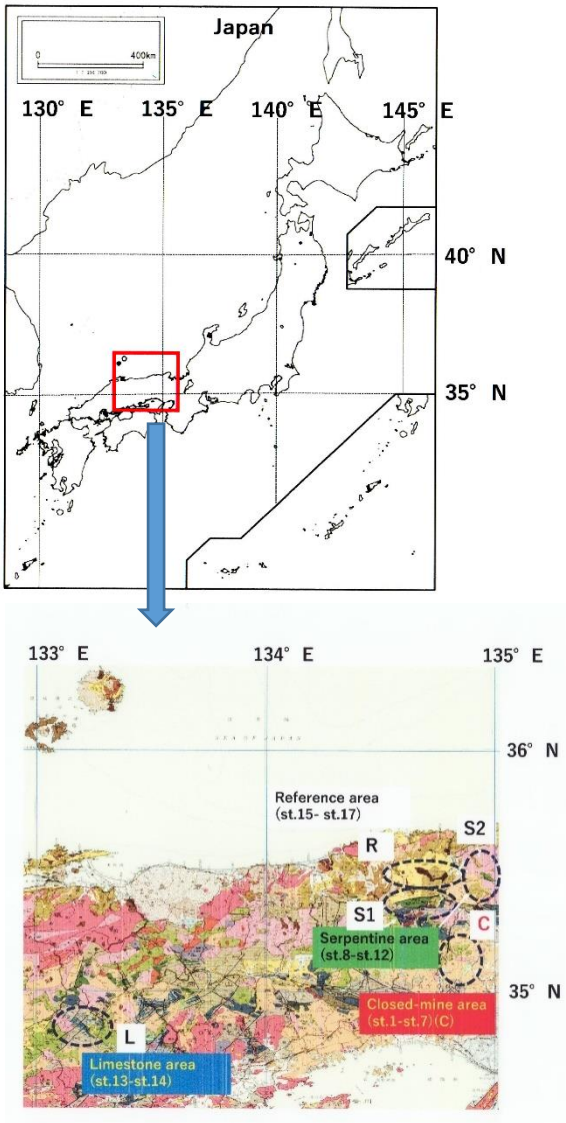

Fig. 1 Seventeen study sites: st.1–st.7 in closed-mine area; st.8–st.12 in serpentine area; st.13and st.14 in limestone area, and st.15–st.17 in reference area with sedimentary and igneous rocks.

SAMPLING AND ANALYTICAL METHODS

Benthic diatoms were collected from at least 5 stones from the lotic parts of the sampling sites. The upper surface of stones were scratched with a toothbrush in an area of 5cmX5cm and rinsed with river water on site. Collected materials were placed in 50ml plastic bottles, and then the samples were fixed in 5% formaldehyde. Diatom specimens for microscopy were mounted using Naphrax [3]. Diatom counts and identification were performed atx1000 magnification using a light microscope (Zeiss, Germany). Water samples were collected in spring and autumn from 2010 to 2012. Water temperatures, pH, and conductivity (EC), dissolved oxygen (DO) and total dissolved solids (TDS) were measured at each site by using a sensor probe (W-23XD, Horiba). Water samples were collected in two polyethylene bottles (100mL), with one bottle being acidified with nitric acid (HNO3) before transportation to the laboratory. The water samples were analyzed by ICP-AES (Inductivity Coupled Plasma Atomic Emission Spectroscopy) (SPS1700HVR) for measurements of heavy metal concentrations. The other samples were used for ion chromatographic analysis (DIONEX ICS-1500) for other nonmetallic ions, including Ca^{2+} and Mg^{2+}. Water samples were stored in a refrigerator running at about 10℃ until chemical analysis.

DATA ANALYSIS

Multivariate Analyses and Ordination

First, diatom communities were clustered into several groups by K-medoids [6,7]. The number of clusters was decided by maximizing the average silhouette width [6, 7]. Indicator species of each cluster were detected by using the indicator values (IndVal) [6,7]. For each site, we estimated exponential Shanon diversity {expH' = exp[-$\sum p_i \log_e(p_i)$], where pi is the proportion of abundance for species I }, and Shimpson's inverse diversity. Second, we performed nonmetric multidimensional scaling(nMDS) to investigate the similarities among 17 diatom communities. After that, canonical correspondence analysis (CCA)was performed to get more information with respect to the relationship between diatom communities and chemical variables. Species diversity, clustering, nMDS and CCA analyses were carried out using packages of cluster (pam) [8], labdsv (indval) [9] and vegan [10] in R 3.3.2 software.

RESULTS

Diatom Communities and Diversity

Seventeen diatom communities were clustered into 5 groups as follows (Fig.2); cluster 1 (st.1, st.7, st.3, st.8, st.15 and st.16), cluster 2 (st.2), cluster 3 (st.12, st.4, st.5 and st.9), cluster 4 (st.11, st.13, st.14. st.6 and st.10), and cluster 5 (st.17). Two clusters (cluster 3 and cluster 4) revealed higher values than the average

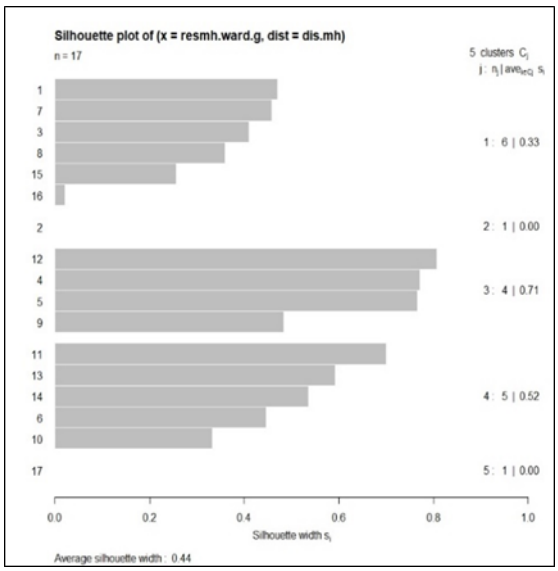

Fig.2 Silhouette plots of 17 study sites: average silhouette width = 0.44. The numerical number expresses study sites

value (0.44), and those values indicated that those communities closely

Table 1 Indicator species of each cluster. The number of (;) shows IndVal values and p-values of permutations.

Cluster	Number of sites	Average silhouette width	Indicator species (IndVal; permutation p<0.10)
Cluster1	6	0.33	
Cluster2	1	0.00	
Cluster3	4	0.71	*Cymbellade licatula*(0.842;. p<0.082)
Cluster4	5	0.52	*Naviculatri punctata*(1.000; p<0.058) *Navicularhynchocephala* (0.792; p<0.034) *Achnanthidiumsubhudsonis*(0.574; p<0.034)
Cluster5	1	0.00	*Gomphonemaangustatum*(0.739; p<0.078)
Total	17	0.44	

Table 2 Dominant species in each cluster.

Number of cluster	Dominant species
luster 1	*Achnanthidiumconvergens*(st.1, st.3, st.7,st.8,st.15,st.16) *Planothidiumlanceolatum*(st.1, st.16)
Cluster 2	*Gomphonema*spp.*(st.17)*
Cluster 3	*Achnanthidiumminutissimum*(st.4,st.5,st.9,st.12) *Achnanthidiumconvergens*(st.9) *Cymbelladelicatula* (st.9,st.12)
Cluster 4	*Achnanthidiumsubhudsonis*(st.6,st.10,st.11,st.13,st.14) *Sellaphorapupula*(st.10,st.11) *Vavicularadiosav.tenella*(st.10,st.11,st.14) *Gomphonema*spp.(st.14)
Cluster 5	*Cocconeislineata* (st.2) *Achnanthidiumconvergens*(st.2)

resembled each other within the same cluster. One cluster (cluster 1) showed a lower value than the average value (Fig.2), and revealed that that cluster had a great variety of species compositions. Indicator species of each cluster were designated by IndVal. However, species of two clusters (cluster 1 and cluster 2) were not detected by that method (Table.1). Dominant species observed at each site are listed above (Table 2). Exponential Shanon-Wiener diversity index (ESI) was estimated at each site (Fig.3 [A] [B] [C]). In the closed-mine area, the values of ESI at st.4 and st.5 revealed 1.357 and 1.124, representing quite low diversities with comparison to those of the reference area. The values of ESI at st.1 and st.3 were 12.415 and 13.486. In the serpentine area, ESI at st.9 showed a lower value of 2.542 rather than another site in the serpentine area. However, the value of ESI at st.10 was 11.295. In the limestone area, values of ESI at two sites (st.13–st.14) were 5.351 and 8.937. In the reference area, ESI value at st.15 was 16.829, which was the highest value among diatom communities collected at the 17 sites.

Water chemistry

The concentrations of zinc (Zn) at st.4 and st.5 were 1.273 (mgL^{-1}) and 1.457 (mgL^{-1}) respectively. These values were remarkably high compared with the values at sites in other areas (Table 1). In addition to that, iron (Fe) concentration at st.7 was 1.320 (mgL^{-1}), being the highest value in all sites. Nickel (Ni) concentrations showed higher values at five sites (st.8–st.12) in the serpentine area rather than other sites. Results of paired-tests, revealed that the concentrations of magnesium ion (Mg^{2+})were closely related to that of nickel (Ni)(paired test: p=0.731), and correlations among some chemical variables were observed. For instance, the concentrations of manganese (Mn) correlated with Pb (p=0.881), and the relationship between zinc (Zn) and fluoride ion(F^-) was strong (p=0.957). Moreover, we could see a high value (p=0.828) in the relationship between nickel (Ni) and phosphorus ion (PO_4^{3-}). We performed paired-tests among chemical variables, which are listed in Table 3.

Ordinations

Firstly, we analyzed the data of diatoms and chemical variables by using nonmetric multidimensional

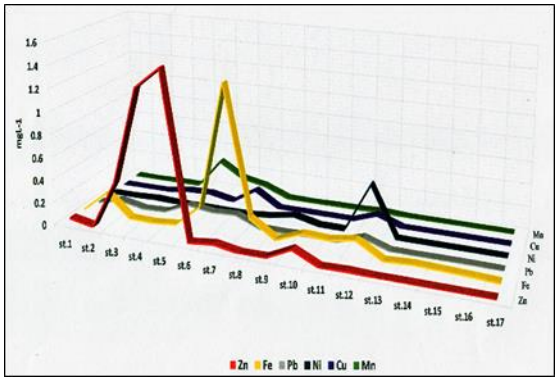

Fig.5 Concentrations of six chemical variables (Zn, Fe, Pb, Ni, Cu and Mn).

scaling (nMDS) (Fig. 6). The final stress value showed 10.421, representing a fair result. From the result of nMDS, five clusters located separately escape from two clusters (cluster 1 and cluster 4), which are very widespread. After that analysis, we carried out canonical correspondence analysis (CCA) with constructing some models. In this model from CCA with eight chemical variables, the constrained inertia (sum of squared distance) was 2.048 (51.5% of the total inertia). Eigenvalues ofthe first and second axes were 0.715 and 0.441, respectively. Permutation test of this model by ANOVA indicated significant results (F=1.364, Pr(>F)=0.033). Diatom communities belonging to cluster 3 (st.4, st.4, st.9 and st.12) had remarkably strong relations to Zn and F^- (Fig.6). In addition to this, the communities belonging to cluster 4 (st.6, st.10, st.11, st.13, and st.14) and cluster 2 (st.17) were affected by phosphorus ion (PO_4^{3-}). However, we could not see clear relations among the communities, belonging to cluster 1 (st.1, st.3, st.7, st.8, st.15 and st.17) and cluster 5 (st.2). Figure 7 indicates that st.13 and st.14 in limestone area are affected by pH values in comparison with Ca^{2+} concentration, and shows that six sites in cluster 1 and 5 tend to have negative relations to chemical variables.

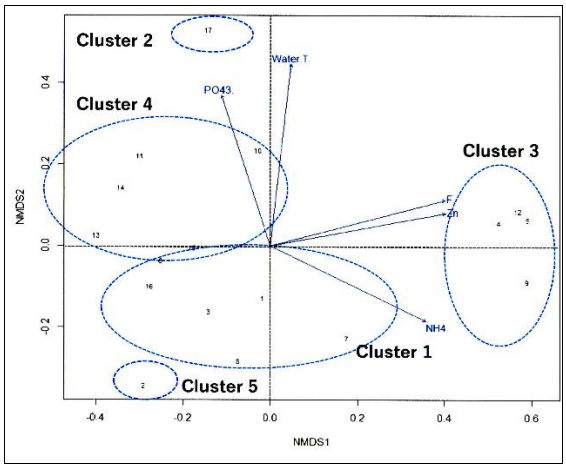

Fig.6 Ordination by nMDS of diatom communities sampled at 17 sites. Sites were classified into 5 clusters. Moreover, five significant chemical variables were plotted as vectors: water temperature (water T.)(r^2=0.384, Pr(>r)=0.032), F- (r^2=0.329, Pr(>r)=0.071), PO_4^{3-} (r^2=0.284, Pr(>r)=0.085), NH_4^+(r^2=0.307, Pr(>r)=0.078), and Zn (r^2 =0.320, Pr(>r)=0.071)

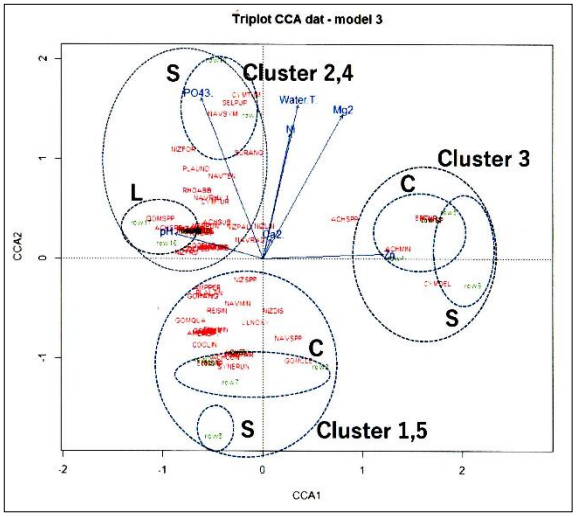

Fig. 7 Ordination by CCA based on triplot projections of the seven variables. Eigenvalues of CCA1 and CCA2 are 0.715 and 0.441, respectively. Study sites and area are expressed by numeric numbers (1–17) andfour capital letters: C = closed-mine area, S = serpentine area, L = limestone area, and R = reference area.Significant chemical variables were plotted as five vectors. Diatom species are expressed by CODE with four capital letters as followes;

CODE:ACHMIN=*Achnanthidium minutissimum*, ACHCON = *Achnanthidium convergens*, COCLIN= *Cocconeis lineata*, CYMDEL= *Cymbella delicatula*, SELPUP= *Sellaphora pupula.*

DISCUSSION

The values of exponential Shanon-Wiener diversity indices at four sites (st.4, st.5, st.9 and st.12) were significantly low, representing the effectiveness of three chemical variables (Zn, F^- and NH_4^+). The result of CCA also indicates the influence of those chemical variables on diatom communities (Fig.7). Those sites belonging to cluster 3 locate separately from other clusters (Figs.6, 7). In particular, diatom communities at st.4, st.5 and st.9 are mainly composed of *Achnanthidum minutissimum*, well known as a pollution-tolerant species [11]. In addition to that, from the result of CCA, we can see some influence of pH value on the communities at st.13 and st.14. It might be said that the influence of pH may be greater than the influence of the calcium ion (Ca^{2+}) . Diatom communities belonging to cluster 1 and 5 locate on the opposite side of chemical variables, and this location indicates that those communities are mainly composed of pollution-sensitive species such as *Cocconeis lineata*. It is possible to say that two chemical variables (Mg^{2+} and Ni) greatly affect the communities in the serpentine area, and that the pH value remarkably influences those in limestone areas. However, we need to consider many more factors, such as light, suspended solid invertebrates and so on, to control the diatom community composition.

CONCLUSION

It is clear that diatom communities are composed of very different species in areas with different geological characteristics of serpentine, limestone and closed-mine. In particular, zinc (Zn) partly affects the species composition in closed-mine and serpentine areas. However, it might be said that species composition in those communities is controlled by many factors such as substratum instability, light, suspended solid, invertebrates and fish. Geological characteristics of diatom habitats may be one of the important factors controlling their composition.

ACKNOWLEDGEMENTS

We gratefully thank Dr. Tomoko Shimodoi for the identification of diatom species and for providing us with much useful advice. We also thank Dr. Yoshinari (Idea Co.) and Dr. Taniguchi (Wakayama University) for help with analyzing the concentrations of chemical ions in stream waters and biostatistical analysis. Finally, we thank Dr. Noboru Nishimura (President of Hyogo Freshwater Biological society) for promoting our study in advance.

ANALYSIS OF WATER QUALITY OF RIVERS AND RESERVOIRS IN CHELYABINSK REGION, SOUTH URAL

Anastasiya M. Kostryukova, Irina V. Mashkova and Elena E. Shchelkanova
Chemistry Department, South Ural State University, Russia

ABSTRACT

Overland water resources of the Chelyabinsk region are presented by the basins of the Tobol, Ural, Volga (Kama) rivers. The total number or rivers exceeds 3.5 thousand, many of them are headwaters. This work assesses a ten-year change of water quality in 3 rivers and 3 reservoirs of the Tobol basin that are as well the source of drinking water for the residential area of the Chelyabinsk region. There are many ferrous, non-ferrous, power and machine building industry facilities in the region. As a result, most of the rivers in South Ural are affected by industrial and household wastewaters. Any significant improvement of the water quality in the studied rivers has not been monitored for 10 years. The water can be characterized as "polluted" - "very polluted". The Miass river has the most anthropogenic impact in the Chelyabinsk region. It used to be "extremely polluted". The given work aims to reveal interrelations between the water quality and the state of the studied water-bodies by means of principal component analysis. Principal component analysis allowed to distinguish 2 - 3 periods that are characterized by similar pollution. The environment of rivers under a human-made impact changes adversely and transforms into another ecological state for a couple of years.

Keywords: Rivers, Reservoirs, Pollution, Principal Component Analysis

INTRODUCTION

The pollution of natural waters, both sea and fresh, is a crucial issue all over the world [1]-[3]. Countries have various regulations that are aimed at assessing the environment of water-bodies and designing improvement strategies. The EU Water Framework Directive aims at improving the environment of all underground and overland waters in Europe [4], [5]. The Clean Water Act governs water pollution in the USA [6]. The Water Code of the Russian Federation addresses the issue in Russia [7]-[9].

Russia, as well as other countries, pays special attention to freshwater rivers and artificial reservoirs. The function of the national observation network in Russia is to control the pollution of overland waters, to monitor their environment and to analyze the overland water quality [10]. All the regions of the country including the Chelyabinsk region (South Ural) monitor chemical pollution of water-bodies [11]. According to the national report on environmental protection of 2017 [10] the Chelyabinsk region leads in the amount of wastewater discharge (691.3 million / $m^{3)}$ in the Ural Federal District.

More than 3.6 thousand rivers with a total length of about 18 thousand km run on the territory of the Chelyabinsk region. They belong to the basins of such large rivers of Russia as the Kama, the Tobol, the Ural. Most of the rivers are under an intensive man-made impact [11], [12].

Annual comprehensive reports on the environment in the Chelyabinsk region present information about chemical pollution of the large rivers of South Ural [11], [12]. It also refers to the rivers of the Tobol basin. Besides, separate studies of their environment and biota are being conducted [13], [14]. But these studies are scattered and do not usually consider one exact water-body and do not provide the long-term dynamics of water pollution.

The aim of the paper is to assess the change of water quality in the rivers of the Tobol basin as a source of drinking water in 2007-2016.

METHODOLOGY

Study Area

Three large rivers of more than 200 km, the Uy, the Uvelka, the Miass (Table 1), many smaller rivers such as the Syntashpy, the Ayat, the Kartaly-Ayat, the Kidysh, the Toguzak, the Sak-Alga, the Atkus, the Sinara, and three reservoirs Troitskoye, Argazinskoye, Shershnevskoye belong to the Tobol basin [15]. The head-rivers of the basin are mountain rivers (the Uy, the Miass) as they start in the Urals and then flow into the plain. The Tobol basin is 55 thousand km^2 [15].

The Uy river water in its chemical composition belongs to the hydrocarbonate class of the calcium group. Four towns, including Troitsk, are located in the Uy basin, as well as some villages where the river is the main water source. Troitskoye reservoir

with the volume of 45.1 million m^3 is built on the river [15], which flows mainly on farmland being polluted by effluents from cattle farms and fertilizers. The river is heavily affected by human activity within the limits of Troitsk where industrial and sewage facilities discharge effluents. Much of the pollution is then found in Troitskoye reservoir. The reservoir water in its chemical composition belongs to the hydrocarbonate class of the calcium group. Residential sewage comes into the river from all the catchment area.

Table 1 General characteristics of the Uy, Uvelka, Miass rivers

River	Total length, m	Maximum depth, m	Basin, km^2
Uy	462	15	34 400
Uvelka	234	4	5 820
Miass	658	7	21 800

The Uy river water in its chemical composition belongs to the hydrocarbonate class of the calcium group. Four towns, including Troitsk, are located in the Uy basin, as well as some villages where the river is the main water source. Troitskoye reservoir with the volume of 45.1 million m^3 is built on the river, which flows mainly on farmland being polluted by effluents from cattle farms and fertilizers. The river is heavily affected by human activity within the limits of Troitsk where industrial and sewage facilities discharge effluents [12]. Much of the pollution is then found in Troitskoye reservoir. The reservoir water in its chemical composition belongs to the hydrocarbonate class of the calcium group. Residential sewage comes into the river from all the catchment area [15].

The Uvelka is a left tributary, the largest one. Its water in its chemical composition belongs to the hydrocarbonate class of the calcium group. Like the Uy river, the Uvelka is polluted by farms, villages and industrial facilities of Yuzhnouralsk (a town in the Chelyabinsk region) [15].

The Miass river starts at the eastern slopes of the Ural [15]. It crosses all the forest-steppe zone of the Chelyabinsk region and then joins the Iset river. The Miass river water is widely used as a water supply for some cities including Chelyabinsk. Two reservoirs are built on the river: Argazinskoye and Shershnevskoye. Argazinskoye reservoir, the largest one, with the volume of 980 million m^3 [15], is the main source of water for the Chelyabinsk industrial hub. Shershnevskoye reservoir, with the volume of 176 million m^3 [15], is used as a water supply for Chelyabinsk [14]. The river water in its ion composition belongs to the hydrocarbonate class of the calcium group.

Effluents are discharged into the Miass river along its whole length. The river headwaters are the cleanest. Industrial and household effluents of Miass city come into the river water and then go into Argazinskoye reservoir. Along the way from Argazinskoye reservoir to Chelyabinsk sewage from farming and household activities of some villages are put into the Miass river. The river water then goes into Shershnevskoye reservoir where it is slightly cleaned. But the city industrial facilities and treatment plants of Chelyabinsk also discharge their effluents into the Miass river [12], [15].

Data of Monitoring of Chemical Pollution of the Studied Rivers and Reservoirs

To analyze the dynamics of how water quality in the Uy, Uvelka and Miass rivers, Troitskoye. Argazinskoye and Shershnevskoye reservoirs is changing, the data of monitoring chemical pollution of water-bodies in the Chelyabinsk region given in comprehensive reports on the environment of the Chelyabinsk region were taken. The reports are at an open access on the site of the Ministry of Ecology in the Chelyabinsk region [11], [12]. Monitoring sections are represented in Fig. 1.

Specific Combinatorial Water Pollution Index (SCWPI)

Specific combinatorial water pollution index (SCWPI) is used to assess water quality in Russia. RD 52.24.643-2002 [16] gives the methods of calculating the index.

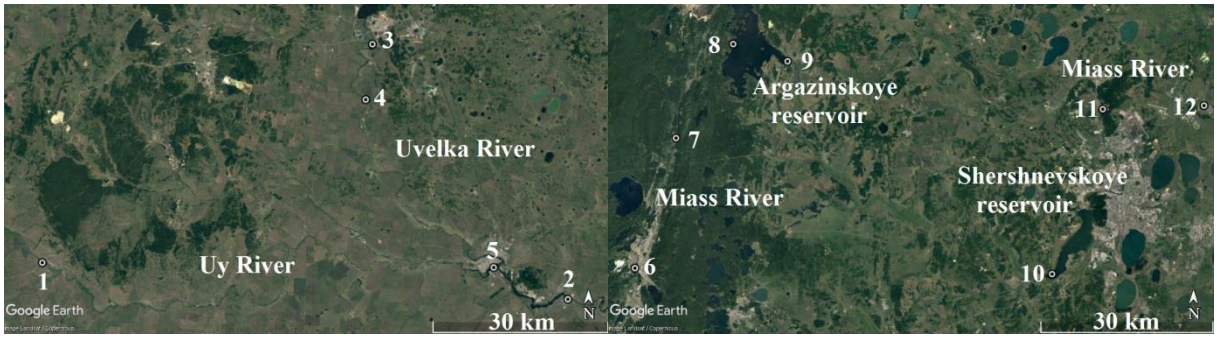

Fig. 1 Quick map of rivers and reservoirs of the Tobol basin (Chelyabinsk region).

It is calculated in 2 stages: first, each separate ingredient and pollution index is measured, and then all the pollutants are considered in complex, and the final assessment is given (Table 2). Maximum permissible concentration (MPC) of hazardous substance for fishery waters is taken for the standard.

Table 2 Effluent quality classification according to SCWPI [11]

Class	Category	Water pollution characteristics
1		conditionally clean
2		slightly polluted
3	a	polluted
	b	very polluted
4	a	dirty
	b	dirty
	c	very dirty
	d	very dirty
5		extremely dirty

RESULTS AND DISCUSSION

Monitoring of the Studied Water-bodies and Rivers Chemical Pollution

According to the Comprehensive reports on the environment in the Chelyabinsk region in 2007, 2008, 2012-2016 [11], average annual maximum permissible concentrations are exceeded for the following substances (Tables 3, 4).

Table 3 Intervals of pollutant concentration (C_i), C_i / MPC_i

Index	Uy river		Uvelka river		Troits-koye reservoir
	s. 1	s. 2	s. 3	s. 4	s. 5
Cu	2.0-4.0	1.6-3.5	1.8-4.2	2.2-4.2	1.9-4.1
Zn	2.9-12.0	2.7-9.6	2.7-3.6	3.0-3.7	2.8-13.7
Mn	11.9-45.6	5.7-9.5	4.0-7.5	12.0-26.2	6.2-13.9
Fe	2.3-4.0	-	-	1.1-1.8	-
PO_4^{3-}	-	1.1-1.5	-	1.1-3.5	-
SO_4^{2-}	1.4-2.4	1.5-2.0	1.2	1.1-6.8	1.3-2.8

Tables 3 and 4 show that such metals as Cu, Zn, Mn pollute the studied rivers and water-bodies constantly. Higher standard values for COD and petroleum products are registered in all the sampling sites. Phenols, Ni, sulfates and fluorides are rare, but that kind of pollution can't be called an isolated discharge, as the standard values for phenols, Ni, sulfates and fluorides are exceeded throughout the year.

Mn, Zn and Cu are registered as the main pollutants in all the sampling sites, except for 11 and 12.

Figure 2 shows the analysis of Mn content with the help of principal component analysis (PCA) for all monitoring period [17]. Most of the sampling sites are grouped in one locality and characterized by similar pollution. Sites 1, 4, 6 and 8 differ from the rest.

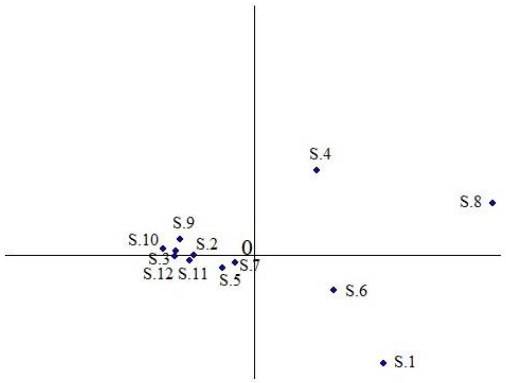

Fig. 2 Resulting diagram Mn content of PCA.

Exceeding of average annual Mn content over MPC in sampling sites 1 (the Uy river) and 8 (Argazinskoye reservoir) in some years was 45.6 - 47. Mining and ore-processing effluents come into the water of sampling site 1. Sampling site 2 is under an adverse impact of the Miass river tributary that is polluted by copper mining and processing facilities. Sewage, industrial and storm waters of Yuzhnouralsk are discharged into sampling site 4, site 6 is the head of the Miass river.

Figures 3 and 4 show the PCA of Cu and Zn content for all monitoring period. Unlike Mn, the situation with Cu and Zn is slightly different. Sampling site 8 is singled out of the rest with an average annual Zn content 2-5 and Cu 2.5-6 times higher than in the other sampling sites where these metals content in water is almost identical irrespective of the year.

Sampling sites 11 and 12 can also be marked. They are the furthest down the stream of the Miass river and take effluents from the city sewage systems, ferrous, non-ferrous, power and machine building facilities. The list of the main pollutants varies in sites 11 and 12. Mn is still leading with nitrites joining it in both sampling sites and petroleum products and phosphates being found in site 11.

Table 4 Intervals of pollutant concentration (C_i), C_i / MPC_i

Index	Miass river		Argazinskoye reservoir		Shershnevskoye reservoir	Miass river	
	s. 6	s. 7	s. 8	s. 9	s. 10	s. 11	s. 12
Cu	1.7-3.0	2.3-3.7	10.8-24.5	2.0-4.1	1.4-2.8	2.3-3.4	1.7-2.6
Zn	2.8-3.7	2.0-4.3	7.8-19.0	3.2-3.7	2.7-3.8	2.9-4.2	3.1-3.7

Water Quality Assessment of the Studied Rivers and Water-Bodies

Pollutant content ordination with the help of PCA for the sampling points in the Uy river, Troitskoye reservoir and its tributary (Fig. 5, a) and the Miass river and its reservoirs (Fig. 5, b) allows to distinguish 2-3 periods that are characterized by similar pollution.

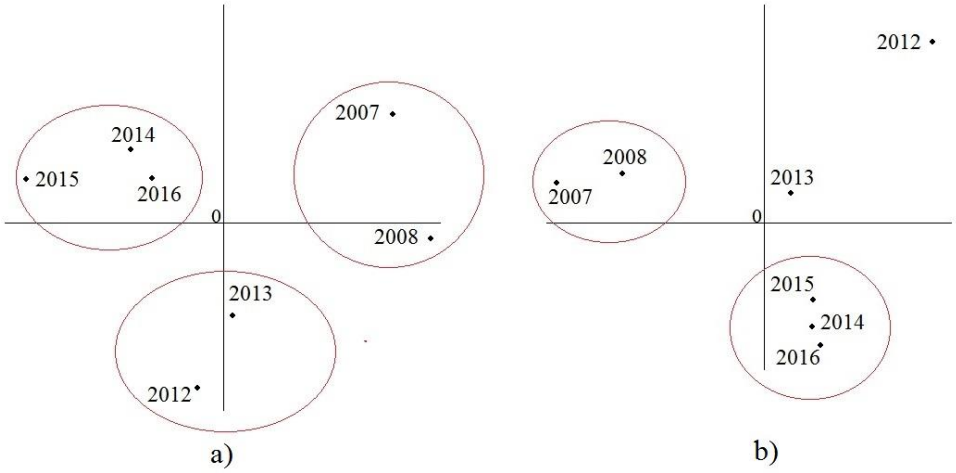

Fig. 5 Resulting diagram of PCA ordination of pollutants content in the Uy, Uvelka rivers, Troitskoye reservoir, the Miass river, Argazinskoye and Shershnevskoye reservoirs.

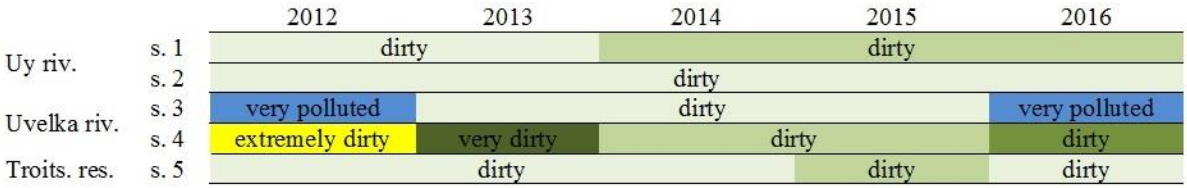

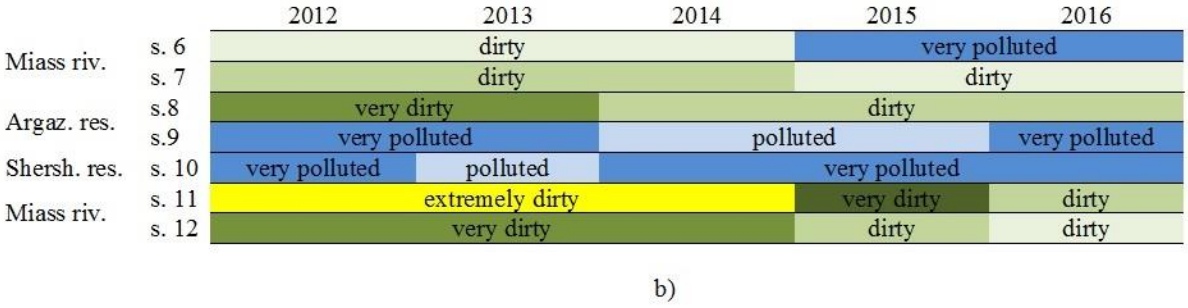

Fig. 6 Water pollution class of the studied rivers and reservoirs. Class 3 is blue, 4 - green, 5 - yellow. Colour density shows the category deterioration.

Thus, it can be noted that the environment of rivers under a human-made impact changes adversely and transforms into another category for a couple of years.

Figure 6 shows water pollution class of the studied rivers and reservoirs on the basis of specific combinatorial water pollution index (SCWPI) for 2012-2016. As the figure shows the water can't be called conditionally clean or slightly polluted. As these water-bodies are used as the main source of drinking water, there is a serious problem concerning the water quality and its influence on the population. Water quality is deteriorating downstream the rivers. The worst situation is in Chelyabinsk. Although, water quality in most of the sampling points is stated to become better since 2014-2015, the water is still not clean.

The situation is similar in many regions of Russia. Thus, the federal project "Clean Water" is designed within the limits of the national project [18]. The aim of the project is to improve drinking water quality by means of modern water supply and treatment systems with the help of innovative technologies. Its realization will provide 95.5 % of the city population with clean quality water.

CONCLUSIONS

Adverse environment of drinking water sources is one of the crucial issues of the Chelyabinsk region. Rivers and reservoirs of the Tobol basin have been

continuously polluted by the city sewage treatment facilities, industrial plants, agribusinesses, and spate flow. Higher concentrations of Cu, Zn, Mn, Fe, Ni, phosphates, sulfates, nitrites, ammonium ions, fluorides, COD, BOD_5, petroleum products and phenols were registered during the monitoring. Cu, Zn, Mn, COD and petroleum products are chronically exceeding the standard values. Unfortunately, water of the studied water-bodies in the Chelyabinsk region can't be qualified as satisfactory. In spite of some improvement the water is not clean enough. That is the matter of national concern, so the federal project "Clean Water" has been designed to tackle it.

EFFECT OF SALINE SOIL ON GROWTH AND YIELD OF BLACK SESAME

Darika Bunphan[1*]

[1]Faculty of Technology, Mahasarakham University, Thailand

*Corresponding Author

ABSTRACT

Saline-soil is a major problem in northeast of Thailand. Several crops are sensitive with saline-soil, however some are moderate sensitive i.e. peanut, soybean and sesame. Sesame is moderate sensitive with saline-soil and drought tolerant, it is oil crop with short life cycle and attractive for being second crop, however, previous reports did not study on effect of saline-soil on growth and yield in black sesame clearly. Therefore, the objective was to study on effect of saline-soil on growth and yield in black sesame. The research was carried out in factorial in RCBD with three replications. The level of salinity was used as factor A, non-saline and saline soil (3 dS/m^{-2}) and six sesame cultivars were used as factor B. All black sesame was planted in pot with 9 kg soil contain. The results showed that all trait was not significant in 15 DAT except plant height. At 30 and 45 DAT, plant height, number of branches $plant^{-1}$, total chlorophyll content, number of capsules $plant^{-1}$ had significantly different whereas SCMR and chlorophyll fluorescence had response on level of saline-soil, however, these two traits of 6 cultivars were not significance. Total dry matter, capsule dry weight and harvest index at harvest day were significantly different. An interaction between salinity level and cultivar was found in all trait except plant height at 3 and 45 DAT, SCMR, total chlorophyll content and chlorophyll fluorescence.

Keywords: Salt tolerant, Saline soil, Black sesame, Agronomic traits

INTRODUCTION

Sesame (*Sesanum indicum* L.) is one of the oldest known oilseeds, with its origin being Central Africa is oilseed [1], it ranged the nine position among the most cultivated oilseed crops in the world and world production estimated at 3.5 M tons of grains [2]. It is widely used in food and in the nutraceutical, and pharmaceutical industry in many countries due to its high oil content, antioxidant and protein contents [3] and [4].

Sesame is cultivated in dry and semi-dry regions of the world where soil and/ or water salinization is common [5]. Sesame is an important oilseed crop rated moderately salt tolerance and capable of producing profitable crops in saline condition [6]. At seedling stage found that salinity reduced sesame growth [7]. Mahmood et al. [12] reported that salinity reduced growth, yield, yield components and oil content, but increased protein content of sesame cultivars. However, Ramirez et al. [8] evaluated sesame genotypes for their salt tolerance at germination, vegetative and maturity stages. Germination parameters, growth and yield of the genotypes increased under low salinity level, but decreased under high salinity level, they also detected high variability in tolerance to salinity among the genotypes. Gaballah et al. [9] also reported that low salinity level increased while high salinity level reduced growth parameters of sesame cultivars. The previous reports reviewed that sesame cultivars were subject to salinity stress using sandy soil [9] and [4].

In Thailand, sesame is second crop and it was planted after harvesting main crops because it is drought tolerance, short life cycle, it can be grown in marginal land and moderate sensitive with salt tolerance. In some area of northeast Thailand occupies with saline soil with low fertility and some crop cannot be grown. Therefore, sesame is one of the alternative crops for production in these area, however the study on sesame in saline soil is lacking especially in black sesame. The objective was to study on effect of saline-soil on growth and yield in black sesame.

MATERIALS AND METHODS

Plant Material

Six black sesame cultivars namely KU18, CM07, Kanchanaburi, Buriram, UBonratchathani3 and KKU2 were used. KU18 and CM07 were kindly donated from Kasetsart University, Kanchanaburi and UBonratchathani3 were donated from Ubon Ratchathani Farm Crops Research Center, KKU2 was kindly donated from Khon Kaen University.

Experimental Design

The experiment was conducted in Buriram province in plastic pots. It was randomized complete blocks in 2 × 6 factorial scheme (12 treatments), with three replications, a total of 72 experimental units. Factor A was two levels of soil salinity (A0 = no salt solution was added to soil in the pots and A1 = 27.45 g NaCl was added to soil and salinity was found 3 dS m^{-2}), Factor B was 6 cultivars of black sesame namely KU18 and CM07 were donated from Kasetsart University, KKU2 from Khon Kaen University, UB3 and Kanchanaburi from Ubonrachathani Field Crops Research Center and Buriram was donated from farmer. The pot was 20 cm diameter and 28 cm height, each pot contained 9 kg of soil. The soil properties with pH 7.25, EC 0.0067 dS m^{-2}, organic matter is 0.615%, exchangeable N is 21.09 mg kg^{-1} and soil texture is sand.

Agricultural Practice

After 15 days after planting (DAP), all of sesame was transplanted to 72 pots and 2 plants were transplanted in each pot, 27.45 g NaCl was mixed with soil and contained in 36 pots and other 36 pots had 0 g NaCl. Chemical fertilizer (NPK) at rate 156.25 kg ha^{-1} was applied as basal fertilizer and applied the same rate at 30 days after transplanting.

Data Collection

The following data were recorded at 15 30 and 45 days after transplanting and harvesting day. Plant height measurement: it was considered from the soil surface to the tip of sesame, no. of branches/plant; was recorded primary branch of sesame. The SCMR was measured using by SPAD-502 meter (Minolta SPAD-502 meter, Tokyo, Japan). The chlorophyll content in leaves was measured by the method described by Moran [10] Briefly, the leaf was cut one small leaf disc with the area 1 cm^2 using cork border, the leaf disc was placed in a vial containing 5 ml DMF (N, N-dimethyl formamide) and incubated in 4 °C for 24 h in dark. The chlorophyll extract was measured at 647 and 664 nm by a spectrophotometer. The equations to calculate for total chlorophyll, chlorophyll a (Chl a) and b (Chl b) were as follows: Chl a = 12.64 A664-2.99 A647, Chl b= -5.6 A664+23.24 A647, expressed in µg cm^{-2}. The CF was measured two positions in the middle of leaf and midrib was avoided, Fv/Fm was used and averaged as a single value, the CF was measured using chlorophyll fluorescence meter (PAM-2000, Heinz Walz GmbH, Germany). The measured leaf was dark-adapted for 30 min using leaf clips (FL-DC, Opti-Science) before fluorescence measurements. The chlorophyll fluorescence was determined following the procedures of Maxwell and Johnson [11]. Number of capsules $plant^{-1}$, total dry matter $plant^{-1}$, pod dry weight $plant^{-1}$, harvest index (HI) was recorded at physiological maturity.

Statistical Data Analysis

Analysis of variance (ANOVA) was conducted on the collected data using STATISTICS 9 and treatment means were separated using LSD at 5 % probability level.

RESULTS

Analysis of variance

At 15 DAT, SCMR, Total chlorophyll content and chlorophyll fluorescence were not significantly different and we did not found interaction between salinity level and sesame cultivars, plant height at 15 DAT was not significant when compared between non-saline and saline soil, however we found significantly plant height among six sesame cultivars and interaction between salinity level and sesame cultivar.

At 30 DAT, number of branches per plant, number of pods per plant were significantly different and we found interaction between salinity level and sesame cultivar. However, plant height showed significantly different both in salinity level and sesame cultivar but we did not found interaction in salinity and cultivar. SCMR and chlorophyll fluorescent were significantly in salinity level but they had no significant among cultivar and we did not found interaction between salinity level and cultivar. Total chlorophyll content was significant among sesame cultivar but it was not significant in salinity level and it had no interaction between salinity level and sesame cultivar.

At 45 DAT, number of pods per plant was significantly different and we found interaction in salinity level and sesame cultivar. We did not found

interaction in plant height but we found in number of branches per plant.

We found interaction between salinity level and sesame cultivar in total dry weight, pods dry weight and harvest index. Moreover, salinity level and sesame cultivar had significantly different of these traits but HI was not different when compared in salinity level.

Effect of salinity level on six sesame cultivars

Plant height at 15 DAT, CM07, UB3, Kanchanaburi and Buriram had higher than KKU2 and KU18. We found interaction in plant height at 15 DAT but did not find in 30 and 45 DAT. At 15 DAT when considered salinity level and sesame cultivar we found that Kanchanaburi in non-saline soil showed the highest plant height (31. cm) following Buriram, UB3 and CM07 (29.8, 28.2 and 28.0 cm respectively) when planting in saline soil.

KKU2 with non-saline soil had the highest number of branches plant^{-1} following UB3 and Kanchanaburi. At 45 DAT, CM07 with non-saline soil had the highest number of branches but it was not different to UB3 in saline soil (3.5 and 3.0 branches respectively). At 30 and 45 DAT, KKU2, UB3 and Kanchanaburi had the higher plant height.

We found interaction in number of branches per plant at 30 and 45 DAT. At 45 DAT, CM07 with non-saline soil had the highest number of branches but it was not different to UB3 in saline soil (3.5 and 3.0 branches respectively).

We did not find interaction between salinity level and cultivar in SCMR, total chlorophyll content and chlorophyll fluorescence at 15 and 30 DAT. However, at 30 DAT we found the difference of SCMR between salinity level. Total chlorophyll content at 30 DAT among six cultivars were significantly different and KKU2 had the highest chlorophyll content when compared to other five cultivars.

Number of capsules per plant at 30 and 45 DAT were significantly different and it had interaction between salinity level and cultivar. Number of capsules per plant in non-saline soil had higher than planting in saline soil both at 30 (10.7 and 5.4 capsules respectively) and 45 (9.6 and 5.1 capsules respectively) DAT. KKU2 had the highest capsules per plant both in 30 and 45 DAT (16.1 and 11.9 capsules). KKU2 in non-saline soil showed the highest number of capsules both at 30 and 45 DAT (21.3 and 17.3 capsules respectively) and higher than cultivars planting in saline soil, however at 30 DAT KKU2 planting in saline soil had higher capsules than other five cultivars that planting in saline soil. In the other hand, at 45 DAT Kanchanaburi planting in saline soil showed higher capsules than other five cultivars.

Total dry weight per plant in non-saline soil was higher than planting in saline soil (2.59 and 1.07 g respectively), KKU2, UB3, Kanchanaburi and Buriram had higher total dry weight that CM07 and KU18. Moreover, KKU2 planting in non-saline soil showed higher total dry weight that other cultivars. In saline soil, Kanchanaburi had higher total dry weight than other cultivars.

Capsules dry weight per plant in non-saline soil was higher than in saline soil (1.10 and 0.44 g respectively) and Buriram had higher capsules dry weight than other five cultivars. Moreover, Buriram in non-saline soil had higher capsules weight than other cultivars, however Kanchanaburi planting in saline soil had higher capsules dry weight than other cultivars.

HI was not different between salinity level, Buriram had highest HI that other cultivars. When planting in non-saline soil Buriram had highest HI, following KU18 planting in saline soil, UB3 planting in non-saline soil, UB3 and Kanchanaburi planting in saline soil

DISCUSSION

Many previous researches studied on effect of salinity to sesame, however they did not study on black sesame, some study used $CaCl_2$ and they found that salinity level had effect to dry matter and leaf area on sesame [12], it similar to our study that salinity affected to total dry matter. Suassuna et al. (2017) [13] and Bahrami et al. [14] reported that saline stress affected to reducing of plant height and number of capsules and theirs result were accordance to present study, in contrast to Gaballah et al. [9] reported that low salinity level increased while high salinity level reduced sesame height and there were significant differences between the cultivars for this trait. Their results were different with ours perhaps due to differences between salinity level, plant genotypes and environmental conditions. Reduction in the plant height could be due to drought stress caused by salt on water adjustment in plant tissues and cell enlargement as well as increase in leaf senescence and abscission [15].

Many previous studies varied salinity level but present study has set only 2 level of salinity (non-saline soil and slightly saline soil) because sesame is moderated sensitive salt tolerance. Moreover, our study used black sesame as a treatment and previous study did not clearly reported. Bahrami et al. [14] reported that plant height was negatively affected by salinity level, as salinity level increased number of

capsules per plant decreased, root dry weight, seed yield, 1000 seeds weight and oil content, some result was similar to our study however, our study did not focus on root dry weight. Present study also focused on SCMR, total chlorophyll content and chlorophyll fluorescence but previous study did not report. Reduction in the number of capsule per plant was perhaps due to reduction in the plant height and roots and shoots growth [14]. Not only capsules in sesame decreased as increased salinity level, but also canola [16].

In present study only study effect of saline soil in black sesame and root traits were not focused, in further study we would focus on white and red sesame and more traits would be studied.

CONCLUSIONS

Sesame is moderate sensitive with saline soil. Saline soil has effect to growth and yield of black sesame. All trait of black sesame when planting in saline soil decreased except at 15 DAT. At 30 and 45 DAT, plant height, number of branches plant^{-1}, total chlorophyll content, number of capsules plant^{-1} had significantly different whereas SCMR and chlorophyll fluorescence had response on level of saline-soil, however, these two traits of 6 cultivars were not significance. Total dry matter, capsule dry weight and harvest index at harvest day were significantly different. An interaction between salinity level and cultivar was found in all trait except plant height at 3 and 45 DAT, SCMR, total chlorophyll content and chlorophyll fluorescence.

ACKNOWLEDGMENTS

This research was supported by a grant from the National Research Council of Thailand. I am thankful the Department of Agricultural Technology, Faculty of Technology Mahasarakham University. The author would like to thank Kasetsart University, Kalasin University, Ubonrachathani University for kindly donated sesame seeds for our research.

Table 1 Effect of salinity level on plant height, number of braches per plant, SCMR, total chlorophyll content and chlorophyll fluorescence of black sesame

	Plant height (cm)			Number of branches per plant		SCMR (SPAD unit)		Total chlorophyll content (µg cm^{-2})		Chlorophyll fluorescence

QUANTITATIVE EVALUATION OF BUCKLING STRENGTH OF DAMAGED COLUMNS

Yazid Alkhatib, Hani Doummar and Yoshitaka Suetake
Graduated School of Engineering, Ashikaga University, Japan

ABSTRACT

The objective of the present investigation is to find an approach for evaluating buckling strength of damaged columns. Because of wars, natural disasters, explosion, or overloading, a lot of structures has been damaged in different levels. Some of these damaged structures can be repaired and reused by specifying their damaged levels. In order to do that, we focus on damaged levels of structural members through the buckling strength of column members. In the present investigation, the damage columns is represented by partial loss of their sections, which is modeled by step-formed changing cross sections. In addition, a damage index, which indicates damage levels, is defined by using the critical loads of damaged and non-damaged columns. Several numerical calculations are performed in order to study the efficiency of the present damage index. Especially, influences of the boundary conditions and the section parameters to the damage index are discussed through the numerical results.

Keywords: Buckling, Columns, Damaged index, Variable cross section

INTRODUCTION

Damaged members or damaged structures are found in natural disaster areas or war damaged areas. If the damage is not serious, however, we can repair the members or the structures and reuse them sometimes. In order to do that, we have to evaluate the level of the damage appropriately. Especially, we have to know the remaining strength of the members or the structures.

For columns, members are subjected to axial force, the buckling strength is one of the most important points of view. Therefore, in damaged members, it is also important to understand buckling behavior of damaged columns and to estimate critical loads. Investigation of the critical loads of columns has become the center of attention and got more and more systematic during the second half of the 20th century.

The problem is how to represent the damage columns. In the present investigation, it is represented by partial loss of their sections, which is modeled by step-formed changing cross sections. Therefore, we have to calculate the critical loads of columns with non-uniform sections. The determination of critical loads of columns with non-uniform cross-section can be a complex task that depends on several parameters and boundary conditions.

In the present investigation, the classical energy method is employed for determining the critical loads of the damaged columns. Since the energy method is approximate approach, we have to make sure the accuracy of the solutions. In this paper, a part of the numerical results is compared with the result obtained by the exact approach.

On the other hand, damage level of the columns also have to be evaluate appropriately. Damage levels of the structure and their corresponding displacements could be presented both qualitatively and quantitatively (based on the performance-based design method). For quantitative evaluation of damage level in structures, a damage index is used. Researchers have proposed several functions based on the nonlinear dynamic and cyclic behavior of the structural members for quantitative evaluation of damage. On the other hand, for evaluation of the damage index, various uncertain parameters such as load and resistance exist [1]. In this paper, we will focus on the definition based on the reduced stiffness [2] formulated with the following expression:

$$DI = 1 - \left[\frac{K_{final}}{K_{initial}} \right] \tag{1}$$

Where DI is the damage index, $K_{initial}$ is the initial stiffness or the initial tangent before the damaged impact and K_{final} is the tangent of the curve after the damaged impact. The amount of DI ranges from zero to one; zero represents no damages and one represents incipient collapse of the structure. Calibration of damage indices performed as [3] are presented in Table 1, as well as the degree of observed damage in the structures.

Table 1 Interpretation of the Damage Indices [4]

Degree of Damage	Damage Index, DI	State
Collapse	> 1.0	Loss of building
Severe	0.4 - 1.0	Beyond repair
Moderate	< 0.4	Repairable
Minor/Slight	< 0.2	

In this paper, we adopt Eq. (1) as the definition of the damage index. Then, we use the critical loads for columns with a uniform section as $K_{initial}$ and the one for columns with non-uniform sections as K_{final}.

Several numerical examples are performed in this paper. Especially, influences of the boundary conditions and the section parameters are discussed through the numerical results. It follows from the numerical results that the present damage index is effective to evaluate the buckling strength of the damaged columns.

METHODOLOGY OF ANALYTICAL MODEL

In this paper, damaged columns are modeled by using columns with step-formed changing cross sections. In order to calculate critical loads of the step-formed columns, two classical approaches are employed here; one is the eigenvalue analysis of the governing equations and the other is the energy method.

As an example, a two-steps column is used here. In the analyses, we assume that the line that goes through the centroids of all cross-sections is straight. In addition, the following assumptions are made: the column is assumed to be made of homogeneous material that obeys Hooke's law, the load P is concentrated and the deformations of the column are small.

Eigenvalue Analysis

In this section, we explain the eigenvalue analysis of the column buckling [5]. As an example, we treat with a two-steps cantilever type column as shown in Fig. 1. The compression load P acts at the top of the column, the point B.

As well-known, the governing equations of this column buckling are given by

$$\frac{d^2 y_1}{dx^2} + k_1^2 = k_1^2 \delta \quad ; \quad k_1^2 \equiv \frac{P}{EI_1} \ (i = 1, 2) \qquad (2)$$

where y is the deflection of the column, δ the deflection of the free end, E Young's modulus, and I the moment inertia of area. The subscript i represents a region of the column. The general solutions are

$$y_1(x) = D_{2i-1} \sin k_i x + D_{2i} \cos k_i x + \delta \qquad (3)$$

where D_i $(i = 1 \sim 4)$ are arbitrary constants.

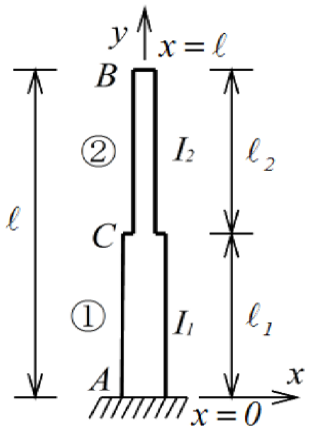

Fig. 1 Cantilever type two-steps column

The boundary conditions and the continuity conditions at the intermediate point C are as follows:

$$y_1(0) = 0 \quad , y_1'(0) = 0 \ , \ y_2(\ell) = \delta \qquad (4)$$

$$y_1(\ell_1) = y_2(\ell_1) \quad , \ y_1'(\ell_1) = y_2'(\ell_1) \qquad (5)$$

Applying these conditions to the general solu tions, we have the following matrix notation f or determining the arbitrary constants: (6)

$$\begin{bmatrix} \sin k_2\ell & \cos k_2\ell & 0 \\ \sin k_2\ell_1 & \cos k_2\ell_1 & \cos k_1\ell_1 \\ -k_2\cos k_2\ell_1 & k_2\sin k_2\ell_1 & k_1\sin k_1\ell_1 \end{bmatrix} \begin{Bmatrix} D_3 \\ D_4 \\ \delta \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \\ 0 \end{Bmatrix}$$

A necessary and sufficient condition such that this equation has a non-trivial solution is that the determinant of the coefficient matrix of Eq. (6) becomes zero. Thus we have

$$(k_1 / k_2) \tan k_1\ell_1 \tan k_2\ell_2 = 1 \qquad (7)$$

The solutions of Eq. (7) are the eigenvalues of the coefficient matrix of Eq. (6) and the minimum eigenvalue corresponds to the critical load of the column.

For given values of I_2/I_1 and ℓ_1/ℓ, the critical load parameter $k_1\ell$ can be calculated by using the Newton Method as shown in Table 2.

The values in Table 2 are regarded as standard values in this paper.

Table 2 Critical load parameter (standard)

I_2/I_1 \ ℓ_1/ℓ	0.2	0.4	0.6	0.8
0.1	0.606	0.775	1.060	1.465
0.2	0.836	1.027	1.294	1.527
0.4	1.128	1.292	1.459	1.555
0.6	1.321	1.430	1.520	1.564
0.8	1.462	1.515	1.552	1.568

The same approach can be also used when number of steps in cross sections is greater than the above example. Naturally, with an increase in the number of steps, it is difficult to apply the eigenvalue analysis to calculations of critical load of columns. Therefore, it is desirable to use alternative approximate methods.

Energy Method

As an alternative approximate method, the energy method [5] is adopted in this investigation.

The internal energy of columns ΔU is given by

$$\Delta U = \int_0^\ell \frac{M^2}{2EI} dx = \frac{1}{2E} \int_0^\ell \frac{M^2}{I} dx \tag{8}$$

On the other hand, the external energy ΔT is given by the multiplication of the compression load P and the axial displacement, $\Delta\ell$, that is,

$$\Delta T = P\Delta\ell = \frac{P}{2} \int_0^\ell (\frac{dy}{dx})^2 dx \tag{9}$$

Since $\Delta U = \Delta T$ when the compression load P is equal to the critical one, we can obtain the following formula for determining the critical load:

$$\frac{1}{EP} = \int_0^\ell \frac{M^2}{I} dx = \int_0^\ell (\frac{dy}{dx})^2 dx \tag{10}$$

One end free and the other end fixed

We deal with the cantilever type column as shown in Fig. 1 in this subsection. First, we assume a buckling shape as

$$y(x) = \delta(1 - \cos\frac{\pi}{2\ell} x) \tag{11}$$

Substituting Eq. (11) into Eq. (10), in view of $M = P(y - \delta)$ for the cantilever type column, we can obtain the critical load parameter $k_1\ell$ as

$$K_1\ell = \sqrt{\frac{p_{cr}}{EI}}\ell = \frac{\pi}{2\sqrt{\alpha}} \tag{12}$$

$$;\alpha \equiv \frac{\hat{\ell}_1}{\hat{I}_1} + \frac{\hat{\ell}_2}{\hat{I}_2} + \frac{1}{\pi}(\frac{1}{\hat{I}_1} - \frac{1}{\hat{I}_2}) \sin \pi \hat{\ell}_1$$

where $\hat{I}_i \equiv I_i / I$ is a non-dimensional moment inertia, $\hat{\ell}_i \equiv \ell_i / \ell$ a non-dimensional length, and I a standard moment of inertia. The results calculated by Eq. (12) is shown in Table 3.

Table 3 Critical load parameter (cantilever)

I_2/I_1 \ ℓ_1/ℓ	0.2	0.4	0.6	0.8
0.1	0.615	0.819	1.147	1.489
0.2	0.845	1.061	1.333	1.532
0.4	1.133	1.306	1.467	1.556
0.6	1.323	1.434	1.522	1.564
0.8	1.462	1.515	1.551	1.568

Comparison of the results of Table 3 with those of Table 2 shows that the maximum error is 8.67%. Therefore, the approximation by using the energy method gives us satisfactory results. In this paper, we employ the energy method for the analyses of columns under the other boundary conditions.

Both ends fixed

We deal with columns with both ends fixed as shown in Fig. 2 in this subsection. We assume a buckling shape as

$$y = -\frac{M_0}{P}(1 - \cos\frac{2\pi x}{\ell}) \tag{13}$$

Substituting Eq. (13) into Eq. (10), in view of

$$M = -M_0 \cos\frac{2\pi x}{\ell} \tag{14}$$

we can obtain the critical load parameter $k_1\ell$ as

$$K_1\ell = \sqrt{\frac{p_{cr}}{EI}}\ell = \frac{2\pi}{\sqrt{\beta}} \tag{15}$$

$$;\beta \equiv (\frac{1}{\hat{I}_1} - \frac{1}{\hat{I}_2})(\hat{\ell}_1 + \frac{1}{4\pi} \sin 4\pi \hat{\ell}_1) + \frac{1}{\hat{I}_2}$$

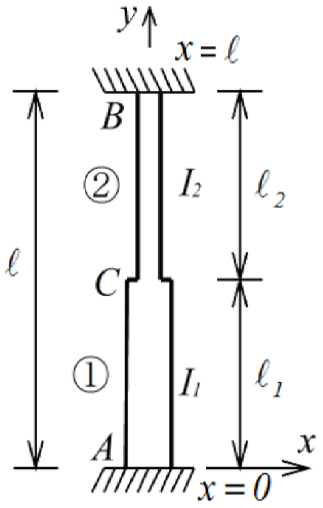

Fig. 2 Two-steps column with both ends fixed

The results calculated by Eq. (15) is shown in Table 4.

Table 4 Critical load parameter (fixed ends)

I_2/I_1 \ ℓ_1/ℓ	0.2	0.4	0.6	0.8
0.1	2.253	2.361	3.174	3.501
0.2	3.137	3.265	4.145	4.457
0.4	4.305	4.428	5.153	5.368
0.6	5.127	5.217	5.697	5.822
0.8	5.764	5.811	6.043	6.098

One end hinged and the other end fixed

We deal with columns with one end hinged and the other end fixed as shown in Fig. 3 in this subsection. We assume a buckling shape as

$$y(x) = -\frac{M_A}{P}\{\frac{\sin k_0(\ell - x)}{\sin k_0 \ell} - \frac{(\ell - x)}{\ell}\} \tag{16}$$

Substituting Eq. (16) into Eq. (10), in view of

$$M = \frac{M_A}{\sin k_0 \ell}\sin k_0(x - \ell) \tag{17}$$

we can obtain the critical load parameter $k_1\ell$ as

$$k_1 l^2 = \sin k_0 \ell \sqrt{\frac{2k_0{}^3\ell^3}{\gamma}}$$

$$;\gamma \equiv (\frac{1}{\hat{I}_1} - \frac{1}{\hat{I}_2})(\hat{\ell}_1 + \frac{1}{4\pi}\sin 4\pi\hat{\ell}_1) + \frac{1}{\hat{I}_2} \tag{18}$$

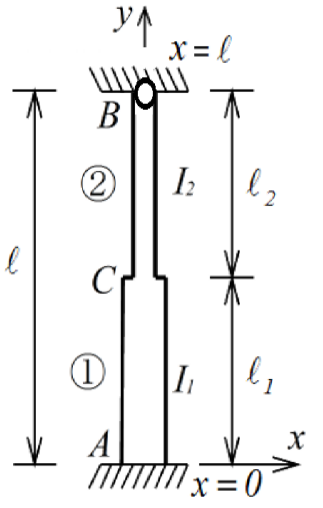

Fig. 3 Two-steps column with hinged-fixed ends

The results calculated by Eq. (18) is shown in Table 5.

Table 5 Critical load parameter (hinged-fixed ends)

I_2/I_1 \ ℓ_1/ℓ	0.2	0.4	0.6	0.8
0.1	1.616	1.642	1.963	3.290
0.2	2.249	2.280	2.646	3.819
0.4	3.084	3.115	3.439	4.200
0.6	3.670	3.693	3.920	4.356
0.8	4.124	4.136	4.250	4.440

DAMAGE INDEX

After war or Earthquake excitations often cause damage to structures, the extent of which can be quantitatively described by an advanced tool called damage index (DI). Many proposals are currently available to calibrate DI based on a number of parameters such as deformation, stiffness, energy absorption etc. To date, there is no universally accepted range for the magnitude of DI, although a scale varying between 0 (no damage) to 1 (total collapse) would be rational for this indicator [6]. Damage analysis has increasingly attracted many researchers to come up with both empirical and theoretical approaches in order to propose appropriate DIs. Last 30 years we have seen many concepts for DI proposed in order to calibrate the observed levels of damage. In recent years the damaged index has been introduced by some researchers which takes the stiffness before and after the damaged into account in order to determine damage index. Reference [2] defined a new relation between performance level and damage level for structures, based on the reduced stiffness.

They concluded [7] that the maximum drift

depends on the primary characteristics of the structure and independent of the stiffness of the structure at the beginning. Therefore, drifts cannot be merely considered for the assessment of damages index.

In this paper we will defined DI based on the reduced stiffness as Eq. (1). Damage index represents the degree of damage that may occur at each performance level. Damage extent to the structure also has a direct relationship with the structural stiffness variations. In the study of damaged columns, buckling loads of them plays a key role to evaluate the stiffness variations. In this paper, we regard the variation of the buckling loads as the stiffness variations. Therefore, we use the critical loads for columns with a uniform section as $K_{initial}$ and the ones for columns with non-uniform sections as K_{final} in Eq. (1).

NUMERICAL RESULTS

Numerical results are shown in Fig.4 to Fig.6 the damaged index in each case that depend on different boundary conditions.

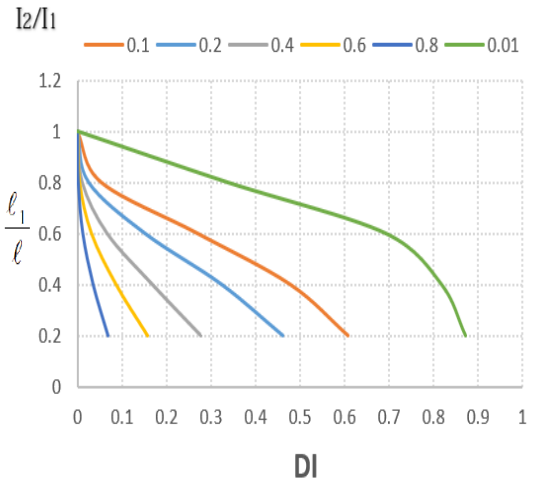

Fig.4 DI for column with one end fixed and the other end free

Figure 4 shows 6 curves for different moments of inertia (I2/I1) for columns with the fixed end and the free end boundary conditions.

The DI values increase in accordance with the decrease of the length ratio L1/L without regard to the moment inertia ratio I2/I1. The increase of I2/I1 leads to the decrease of DI.

When the range of L1/L is between 0.8 and 0.1, the 5 corves except I2/I1=0.01 are approaching from each other. In other words, the change of DI in this range is quite small depending on the moment inertia ratio I2/I1.

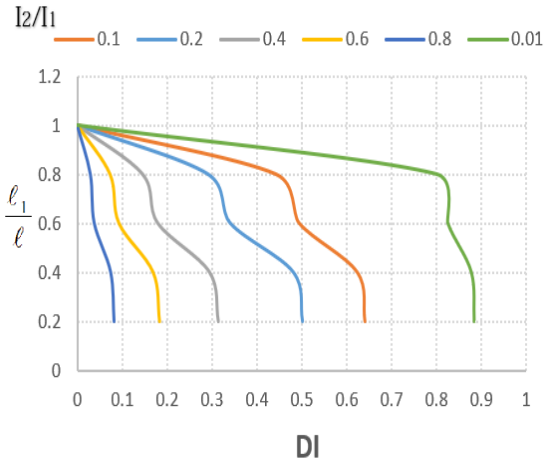

Fig.5 DI for column with both fixed ends supported

Figure 5 shows 6 curves for different moments of inertia (I2/I1) for columns with the fixed ends.

The DI's increase in accordance with the decrease of L1/L without regard to I2/I1, again. The increase of I2/I1 also leads to the decrease of DI. However, all curves are diverging from each other near to L1/L=1 unlike Fig. 4.

When we notice the range between L1/L =0.4 to L1/L=0.8, we can observe the sudden changes in curves, especially in the case of I2/I1=0.01. It is possible that the constraint of both ends deeply affect the buckling behavior.

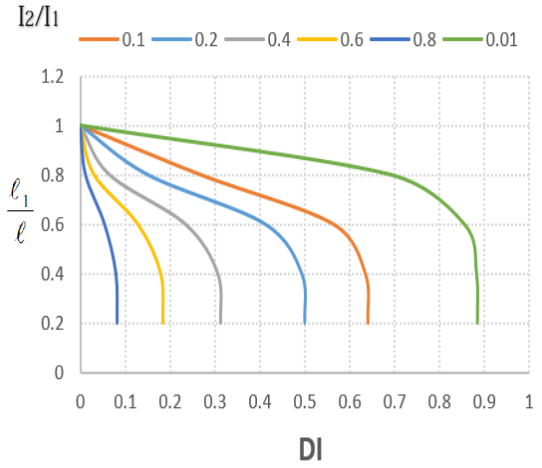

Fig.6 DI for column with fixed-pinned ends supported

Figure 6 shows DI-length parameter curves for columns with fixed-pinned ends.

In Fig. 6, we can observe intermediate tendency between Fig. 4 and Fig. 5. From I2/I1=0.1 to 0.4, the three curves are approaching from each other near to L1/L=1. On the other hand, in the case of I2/I1>0.4, the curves are diverging from each other near to L1/L=1.

When the length parameter L1/L decreases, DI

approaches a constant in all curves. The sudden changes are not observed in all curves.

It can be seen from these three figures that when the constraint at both ends intensifies, there exist stagnation parts of DI changes.

INTERPRETATION OF THE DAMAGE INDEX

The damage index DI has been recognized as an effective tool of quantitatively expressing the extent of damage. The Structure damage is described quantitatively according to the range of DI. To estimate the degree of the damage, we use Table 1 and adopt a column with one end fixed and the other end free as an example. The result is shown in Fig.7.

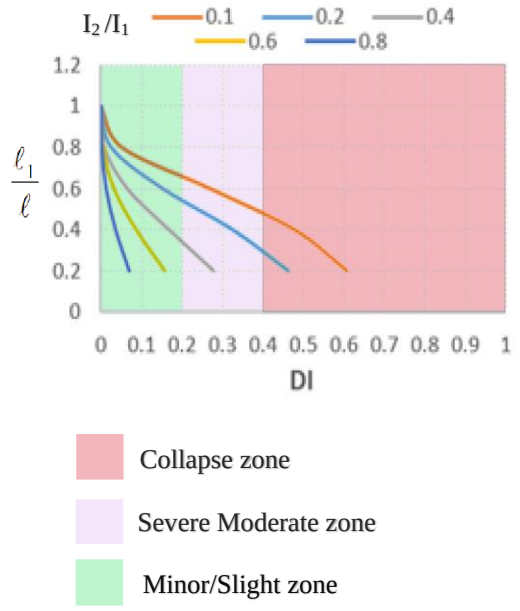

Fig.7 Degree of Damage for column with one end fixed and the other end free

Figure 7 shows the state of column depending on DI. When the parameter I2/I1 is over 0.2, the damage of the column does not reach the collapse zone even in the range of small L1/L. We can obtain the same results for the other boundary conditions.

CONCLUSIONS

In this paper we determine the buckling loads for columns with changing in the cross section with different end conditions. From the present investigation, the following conclusions may be drawn.

1- A damage index, DI, is redefined by using buckling loads of damaged and non-damaged columns.
2- The damage index, DI, increases in accordance with the decrease of the length and the moment inertia parameters. Namely, large loss of the sections leads to the increase of DI.
3- When the constraint at both ends of the columns intensifies, stagnation parts of DI occur.

ABSTRACT

Issues of improving energy performance of any nation borders on increasing energy supply to meet up energy demand; and also reducing energy consumption through efficiency practices to attain sustainable energy utilization. Nigeria as a nation is bedeviled with the problems of inadequate energy supply as well as inefficient utilization of the low-supplied energy. In spite of the enormous and abundant energy resources across the country (renewable and non-renewable alike), the question of sustainable energy development in Nigeria remains a farce. All spheres of energy development (generation, transmission and distribution) together with consumption is occasioned by irregularities that have plunged the nation into a protracted energy crisis for decades due to its inability to harness adequately the abundant energy resources, and sustainably utilize the low-supplied energy. This study therefore attempts to review the state of energy development in Nigeria with its attendant limitations in terms of energy supply and its utilization in a bid to attaining a sustainable national energy development. Thus, a framework of strategies towards attaining sustainable energy development through the deployment of renewable energy resources and energy efficiency practices is therefore proffered.

Keywords: Sustainable energy development, Energy efficiency, Renewable energy resources, Nigeria

INTRODUCTION

Energy development involves all activities of policies and operations that bring about obtaining energy primarily from natural resources through conventional or non-conventional applications to power the national economy. A sustainable energy development has today become a global concern that requires the development and implementation of technologies as well as policies that can improve the energy situation of a country without exhausting resources for all generations; in a manner that the society is not adversely affected socially, economically and environmentally. However, this development mainly focuses on effective and efficient electrical energy supply essential for modern life and economy. It is generated from either renewable sources or non-renewable sources which are mainly fossil fuels, hydroelectricity, nuclear power and other sources like solar, wind, biomass, etc. Sources other than renewables are prone to depletion, and cause environmental degradation and pollution, climate change, etc. Thus, the need for a sustainable energy development which produces energy sources that meet today's demand and thereby eliminating the feared danger of depletion, environmental degradation and climate change; and can be used over and over again. Exploration of sustainable energy is harmless to the environment and equally cost-effective.

Electric energy is on the top grade in energy hierarchy and it is fundamental and inevitable to our daily lives. It is used in homes, industry, agriculture, education, defence and transportation. In fact, the economic growth of any nation depends heavily on the electrical power supply. The per capita consumption of electricity is an index of the standard of living of the people of the country; and to maintain a steady growth and development, the electricity

industry is always engaged in a continuous planning process which now calls for a sustainable dimension. Thus, sustainable generation, transmission and distribution planning becomes very crucial in the expansion planning of the utility alongside population growth [1].

Nigerian society has for many years being experiencing a critical problem of energy poverty occasioned by extreme electricity shortage. The power sector is characterized by low generating capacity in spite of the nation's abundant reserves of hydro-energy, petroleum, coal and gas. This has resulted in unsatisfactory electricity power supply that has left many of the citizens without access to steady power supply for decades unabated. Socio-political, financial and structural factors which are mutually exclusive are known to be responsible for this deficiency [2, 3]. Nigeria as a nation is endowed with enormous energy resources more than many countries combined that are exclusively out of energy poverty; yet, Nigeria presents a persistent and complex scenario of unresolved energy issues in the face of massive reserve of energy resources. In addition to the mentioned adverse factors, the menace of corruption in the Nigerian public service which has ravaged every sector of the economy, including energy, has drawn the country backward among community of nations [4].

Nigeria is the most populous black nation of the world with a population of about 180 million people with an annual growth rate of about 6%. It is heavily endowed with an abundance of natural resources which are grossly unharnessed. Nigeria is among the major oil producing and exporting countries in Africa with average of 2.5 million barrels per day. As an entity, it is among the countries with the largest natural gas reserves in the world, with an estimated 182 trillion cubic feet of established reserves. It is also endowed with extensive coal reserve of between 1.5 billion to 2.5 billion metric tonnes. In addition, there is the much availability of renewable resources like water, wind and sun energy, from which appreciable power can be generated as shown in table 1 [2, 4, 6].

The national grid is essentially hydro and thermal powered, in which less than 40% of the population is connected to the grid; and this meagre proportion is short of power for over 60% of the time [3]. In the face of the acute deficit in power supply, the energy sector operates at very high cost (over 8 billion Naira/53 million US dollars) and with more than 80% of this cost going into staff salaries and welfare. It is characterized with high energy losses in generation, transmission and distribution in both technical and non-technical dimensions; and with inadequate expertise [5]. With a lot of funds expended on the sector (over 40 billion US dollars) over the past decade, the country remains barely over 7,500 MW of installed generating capacity in a country of approximately 180 million people [6]. Regimes upon regimes; and energy programmes upon programmes, the story of energy poverty remains persistent. The scenario remains bleak for decades which require a strategic approach to address the constraints in all spheres of energy development in order to support national growth and economic development. Thus, the framework of sustainable energy development in a bereft power supply economy of Nigeria becomes essential.

THE CHALLENGES OF THE POWER SECTOR

As a nation, the power supply is expected to grow in line with power demand. But, according to David-

West [21], the Nigeria peak load demand in 2010 is 12, 800 MW compared to its maximum generation of 3, 400 MW; creating a supply/demand gap of 73%. However, the reported peak load is a misnomer of the actual demand for electricity. In fact, access to electricity at the national level is 51% in favour of the urban areas, while rural access to electricity is under 20%. This has actually put Nigeria among other nations in a very bleak economic situation in terms of power generation per capita as indicated in figures 1 and 2.

Nigeria has gone through successive power reforms from the earlier time as a British Protectorate to now as a Democratic Nation. But, the electricity supply crisis ensued with a decline in generating capacity of the power sector coupled with the population explosion without a corresponding improvement/maintenance of power supply/transmission/distribution facilities. This is occasioned by such challenges as slow growth in generation capacity, market deregulation process delay, power lines and power distribution vandalism, poor maintenance of existing power system, lack of adequate funding and corruption among others [20]. The generating capacity as at 1993 was just about 1,669 MW, which up to this moment (2019) has sparingly reached 7,000 MW [2] in spite of earlier intervening reforms. Consequent upon slow growth and inadequate supply of the needed power on demand, the Federal Government began a gradual process of power revitalization by setting up the Electric Power Sector Implementation Committee. This committee facilitated the passage of the Electric Power Sector Reform Act of 2005. The sole aim of this act was to ensure and promote efficiency of the power sector through privatization. The privatization exercise later took effect to unbundle the prime utility company (Power Holding Company of Nigeria) into several successor companies likely to be more efficient in services provision to undo the ugly power situation of the country.

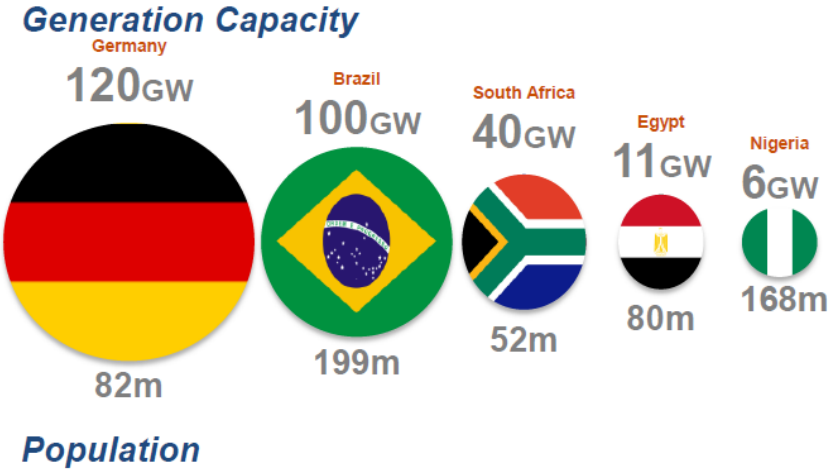

Figure 1: Putting Nigeria in Perspective of Population to Generation Capacity Ratio
Source: KPMG [8]

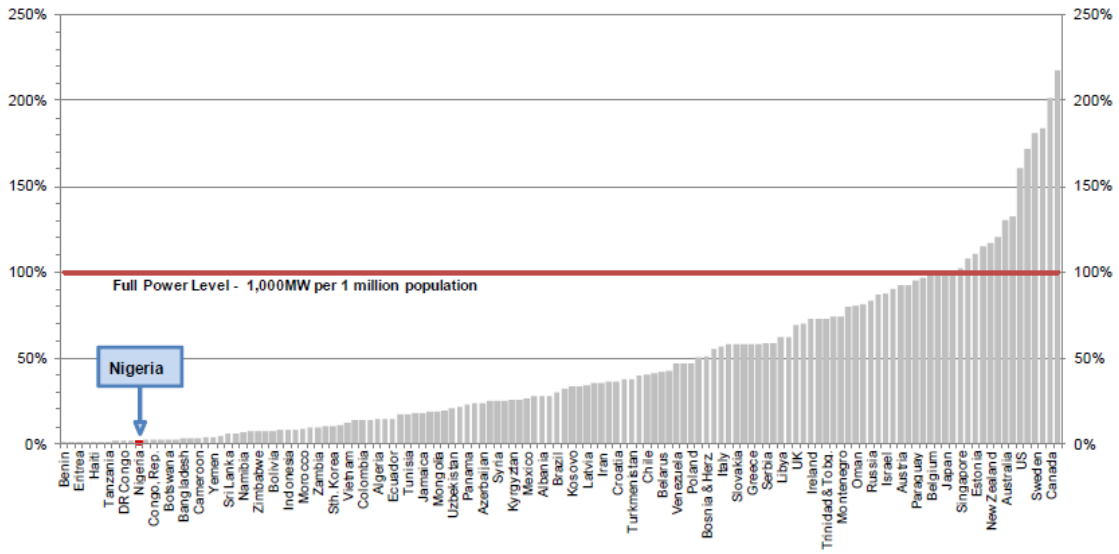

Figure 2: Generation Capacity per Capita (2010)
Source: US Energy Information Administration, CSL Research in David-West [20]

In fact, the challenges of the power sector are multifaceted and are witnessed at all levels of operation; - generation, transmission, distribution and consumption. The major root cause of these challenges is the preponderance of corruption resulting in lack of transparency and uncertified credibility of the government officials. In summary, the power sector of Nigeria is highly engrossed in inadequate power generation; inefficient technologies/equipment deployed for generation, transmission and distribution; and inefficient consumption in the industries and housing units due to inefficient behaviours.

To confront the surmounting challenges of the power sector, there is the need for further reforms focusing on sustainably increasing generation capacity to adequately meet the demand, in line with the expansion of both the transmission and distribution lines collectively with the deployment of sustainable and efficient technologies. Establishing public awareness and information programmes on energy efficiency and conservation equally becomes crucial. Sambo [7] has however, argued that the persistent energy poverty in Nigerian society is due largely to the lack of infrastructural development of the energy sector for decades

Adequate energy supply is the power drive of all nations as it promotes economic growth and global competitiveness. Therefore, the current gloomy state of the Nigerian power sector deserves to undergo further reform for a successful development outcome among nations. According to KPMG [8], "The Nigerian power sector remains adequately positioned as the next destination for massive power investments." To attain this, the identified challenges/obstacles must be adequately addressed. However, the current global trend in energy reforms include the unbundling of the sector into manageable sub-sectors, the privatization of ownership and the introduction of competition into the power generation sector. As part of the reform, the government has successfully embarked on the approach of unbundling. This, according to Washington Consensus, is being promoted by the World Bank and

IMF [2]. This reform pattern is necessary because of the need to rationalize the power sector development through liberalization that requires optimal resource allocation.

All the drive issues of reform are to be regulated by adequate and appropriate guidelines of operation for a successful and sustainable power industry. The guidelines include market issues, electricity transmission license, power purchase agreements, multi-year tariff order, grid code, metering code, market procedure and interim market rules [5]. To accomplish a successful mission of reform, the evolved frameworks must be in consideration of a sustainable outlook; and with the deployment of renewables in the energy-mix for grid production.

A SUSTAINABLE OUTLOOK APPROACH

The study focuses on attaining sustainable energy development for the Nigerian economy through formidable framework of energy resources utilization. To accomplish this goal, a textual analysis of the current state of energy development in conjunction with energy resources potentials of the country is undertaken. However, the current global energy development trend has a great and enhanced consideration for a sustainable outlook. This is consequent upon the fact of persistent depletion of the non-renewable sources; the environmental degradation and pollution due to resources exploitation; the associated climate change and loss of biodiversity etc.; and the fear of energy scarcity. The dimension of a sustainable outlook is mainly focused on the deployment of the renewables in the energy-mix in power generation. The Nigerian government has recognized this potential and has established renewable energy research and development centres across the country (at Usman Danfodio University Sokoto, University of Nigeria Nsukka, etc.) as subsidiaries of the Energy Commission of Nigeria (ECN). Unfortunately, the activities of these centres have been limited to solar photovoltaic development, and solar energy products and devices like solar cookers, water heaters, dryers, etc. on a very minimal level. Solar power generation has not actually been introduced into the power grid; and other renewables like wind, biomass, etc. have outrightly been ignored.

On a global scene, many countries are turning towards renewable energy sources in their power mix on a very significant level. Examples are; Germany already generates about 13% of its electricity from renewable sources; in the United Kingdom (UK), there is already a rule that any new building must reduce its carbon emission by 10% through use of renewables; member states of the European Union (EU) are required to generate one-fifth ($1/5^{th}$) of their power from renewable sources by the year 2020; and the United States of America (USA) has legislated that all publicly traded utility power companies should generate 15% of their power from clean sources like windmills, solar panels, etc. by the year 2020 [3], [4]. It is therefore necessary for the government of Nigeria to imbibe a sustainable outlook in recognition of global trends through a framework of sustainable energy development as presented in this study. The changing energy mix trend should include non-hydro renewables and natural gas. The hydropower generation as it is presently could be doubled to increase its contribution in the mix since much of the hydropower potential is grossly unexplored.

There is also the need to introduce a decentralized renewable energy capacity in the form

of off-grid solutions in all the six (6) regions of the country based on the local renewable sources potential to serve the regions including the remote and rural communities that have being deprived of access to electricity for decades [9] .

THE OPPORTUNITIES IN THE POWER SECTOR

Based on the geographical and socio-economic landscape of Nigeria, several opportunities abound in the bid to overturn the current scenario into a plausible and more sustainably efficient venture. Some of these opportunities as observed, and in line with Deloitte Global [9] presentations are as follows;

i. Renewable energy opportunities

There are ample opportunities to explore in renewable energy sources in all regions of the country. Principal among these are, solar, wind, tidal wave and biomass. These opportunities will become evident for firms in this sector in the form of research and development, project management, consulting, as well as capacity building and skills training.

ii. Restructuring utilities

This opportunity would tend to encourage greater private participation in the electricity market in which private sector players will emerge, with a particular focus on sources for project funding.

iii. New technologies and systems

There is the need to consider new innovations and adopting new technologies in order to modernize the national utilities. This can be achieved by the introduction of smart metering and process automation systems so as to ensure the sustainability of the power industry. Application of DSM (demand-side-management) in most utilities is essential.

iv. New-build and project supply opportunities

Within the traditional thermal and hydropower sectors, there are opportunities within the new build and civil construction and supply of inputs environment for power generation projects. There are also the noted renewable energy opportunities, spanning solar, wind, geothermal and biofuel related technologies.

v. Skills development

Presently, there is a substantial level of skills deficit in the power sector and sectors that support it that creates an opportunity for foreign investors to partner with the national government in order to develop technical training schools and fund more students enrolling in science and engineering programmes on long-term plans. But for immediate requirements of professionals in the sector, it is necessary for the government to import skills and facilitate skills transfer through tailor-made programmes.

vi. Technologies and systems for rural electrification

There is need for a rigorous focus on rural electrification and use of renewable energy technologies (RETs) in stand-alone off-grid or mini-grid systems to reach out to large sections of the rural communities. This will unlock opportunities for investors, financiers, technology owners, builders, project managers and entrepreneurs in rural electrification projects.

vii. Scenario planning

For the onward success or sustainability of the power industry, the government and the utility agencies will need to engage in scenario planning in order to get a

view of what is really required for successful operations.

viii. Improved stakeholder engagement

It is required and very important to develop clear stakeholder engagement strategies for new entrants, vis-à-vis policymakers, regulators, utilities and operators.

ix. Others are diversified investment attraction and portfolio optimization.

FRAMEWORK OF SUSTAINABLE ENERGY DEVELOPMENT

The proposed framework is intended to provide working plan/strategies for the operation of the power sector in terms of generation, transmission and distribution; and energy consumption efficiency in consideration of the overall energy resources potential of the country based on sustainability principles, and in recognition of the observed opportunities.

Nigeria as a country is divided into six (6) geopolitical regions, and each of the regions is endowed with enormous renewable (see tables 1) and non-renewable energy resources. They are; the North central, North west, North east, South west, South east and South south regions. The abound resources in these regions include; large and small water bodies for hydropower, sunshine for solar power, strong winds for wind power, ocean tides and biomass from the enormous waste disposal across the country.

Table 1: Renewable energy potential in Nigeria

Energy Resources	**Estimated Reserve**
Large Hydropower	11,250 MW
Small Hydropower (<30 MW)	3500 MW
Fuel Wood	11 million hectares of forest and woodland
Municipal Waste	30 million tonnes/year
Animal Wastes	245 million assorted animals in 2001
Energy Crops and Agricultural Residue	72 million hectares of agricultural land
Solar Radiation	3.5-7.0 kW h/m2/day
Wind	2-4 m/s at 10 m height Wind speeds in Nigeria range from a low 1.4 to 3.0m/s in the Southern areas, except for coastal line and 4.0 to 5.1m/s in the North. The Plateau area particularly interesting.

Source: Energy Commission of Nigeria (ECN), "Draft National Energy Master Plan [2014]"
Adapted from Energypedia at https://energypedia.info/wiki/Nigeria_Energy_Situation [22]

A. Framework of Sustainable Power Generation

This is undertaken in consideration of mostly, the renewable energy resources in the various regions of the country;

i. Hydropower source

The nation has a very high hydropower potential of large and small rivers; and some few water falls. According to Idris, Kura, Ahmed & Abba [2] the total technically exploitable large scale hydropower potential is estimated at over 10,000 MW capable of producing 36,000 GWh of electricity annually. Only about one-fifth of this potential has been developed as at 2001, and since then, there has not been any significant improvement. The small hydropower potential is estimated at over 734 MW. The current hydropower infrastructures are in dire need of rehabilitation; and their actual energy output is far below their operation capacity. The hydropower source cuts across all the regions of the country; as such, the maximal exploitation should be the prerogative of all regions.

ii. Solar Power Source

There is a great solar power generation potential in Nigeria which has been undermined and utilized on a very meagre scale (less than 5% of total generation). In fact, the entire geography of Nigeria has fairly well distributed solar radiation across all regions. This is because; Nigeria is located in a high sunshine belt of the equatorial region of the globe. The annual average of total solar radiation varies from about 12.6 MJ/m^2/day in the south-coastal areas to about 25.2 MJ/m^2/day in the far north. The solar radiation intensities range from 3.5 – 7.0 kWh/m^2/day; and sunshine duration ranges from 4.0 – 9.0 hours/day [2].

Solar power generation is also suitable for all regions of the country but most suitable for the northern regions. It is a very promising renewable energy sources because of its limitless potential and capacity to be installed at the very point of load or load centre making it suitable for remote and local communities not connected to national grid [10].

iii. Wind Power Source

The wind power source distribution in Nigeria varies greatly based on the regional climate variation. There is a very good wind power potential in the north which constitutes a great resource for power generation for the northern regions, particularly to communities not connected to the grid.

It is estimated that Nigeria has annual average wind speed of 10m heights, varying from 3m/s in the coastal areas and above 5- 7m/s in the far north where vegetation is less [2].

iv. Biomass

There is much biodegradable waste disposal in both the rural communities and the urban centres across the country. This situation presents biomass which is a plant derived matter a great renewable resource for power generation. This requires the deployment of biomass technologies such as “digesters” to generate biogas as a sustainable by-product for power generation. Biomass resources of Nigeria are in the form of wood, forage grasses and shrubs, animal waste, agricultural and forestry residue, municipal and industrial activities as well as aquatic biomass. Plant biomass can be utilized as fuel for small-scale industries [11, 12].

v. Tidal waves

Nigeria is a coastal country along the Atlantic Ocean making it a good potential for tidal energy from the

waves of the Atlantic. Tidal wave can be a very efficient and sustainable source of power if the difference between the high and low tide is great [13]. Therefore, the appropriate technology can be deployed to take advantage of the tidal waves for power generation for the coastal regions of the country.

B. Framework of Sustainable Power Transmission

Transporting electricity over long distances is technologically and economically challenging that the proponents of electricity market have tended to support regional markets as a more sustainable option. As such, there are fundamental changes away from traditional ways in the manner that grids are designed, built and managed today. The traditional grid transmission originates from the era of industrialization which never took cognizance of the challenges of the 21st century sustainable development. Therefore, an intelligent/smart grid system of transmission of renewable resources that would optimize a balance between demand and supply of electricity would be essential. This system should ensure transmission without loss of power even over long distances as exemplified today in China and some European countries using high-voltage direct current (HVDC) option of electric power transmission. However, the first sustainable approach is the 'unbundling' system in which production and transportation of electricity is separated to create room for competition and an open and transparent market. This should be supported by adequate grid planning to ensure technological developments and advancements in the aspect of energy transportation across long distances. This shall be based on specifications and objectives related to regional planning policy, environmental and nature protection targets and economic criteria in terms of efficient, considerate and timely infrastructure investments [14].

C. Framework of Sustainable Power Distribution

It is a fact that the power distribution system is the lifeline infrastructure that determines the level of development of any nation and it plays a significant role in its industrialization and the general economic development. As such, it becomes necessary that both the transmission and distribution systems should be reliable, efficient and sustainable. A reliable power distribution system ensures safety of energy end-users, and promises reliable and quality electricity at affordable prices. The advancement of the power distribution system is known to have direct impact on the development potential of economic growth particularly in the urban centres. Promoting efficient power distribution infrastructure according to the 'International Copper Association Asia' [15] has enormous benefits among which are;

i. The environment-link economic sizing of cables campaign in Japan, Korea and China creates annual energy saving potential of 51 Billion kWh which is enough to power 27% of total residential lighting in United States.

ii. Energy efficient distribution transformer programmes in India and China helps to reduce 192 Billion kWh or a net savings of USD 138 Billion.

Therefore, all nations of the world aspiring to attain a sustainable power supply to its citizenry must drive towards achieving reliability in power distribution infrastructure. This can be accomplished by the following;

i. Power loss reduction with the use of energy efficient transformers and power cables (high conductivity cables).

ii. Power reliability enhancement by use of underground cabling systems to prevent power theft and mitigate challenges caused by visual pollution.

iii. Mitigating power quality issues by creating awareness and deploying solutions to ensure reliability and quality in the energy supply.

D. Framework of Sustainable Power Consumption

The power consumption unit is the terminal (end) point of energy supply chain. It deals with the energy end-users and their pattern and manner of consumption. It is therefore necessary to establish a framework of sustainable consumption so that many of the benefits of greater technological efficiency attained may not be lost to irrational behaviour [16].

Sustainable power consumption typically targets energy efficiency which is the application of efficient appliances/equipment/installations; and energy conservation which concerns human behaviour in energy use. It is about shaping the behaviour of power consumers in the direction of energy efficiency and conservation. The framework focuses on the human dimension of energy use which according to Abdul Majid and Hussaini [17] can foster significant boost in the efficient use of all energy resources if well understood and implemented. The human dimension according to Lutzenhiser [18] can amplify or reduce the effects of technology-based efficiency improvements in energy consumption. Therefore, the prime agenda of the framework of sustainable power consumption is to attain energy efficiency and conservation which has countless benefits in environmental and socio-economic sense. This could be in the form of reduced running costs, reduced environmental impact, improved ambient conditions and increased productivity/equipment life [17]. Sustainable power consumption can be achieved through government policies and regulations on energy utilization; and by providing public awareness/information programmes on energy efficiency and conservation. On this note, Grady [19] has presented the proposal of the Garrison Institute which stipulates the 'TIME model' on attaining energy efficiency on the public or consumer domain as follows;

T – Targeting: to recognize consumption pattern so as to regulate it towards efficiency through targeting and auditing programmes, etc.

I – Informing/engaging: helping people to develop capacity to be mindful of their energy use through 'people-centered-initiative.'

M – Motivating: use financial and non-financial mechanisms to turn intentions into behaviour in efficient use of energy.

E – Empowering/enabling: use concerted effort to remove financial and structural barriers to power consumption; and to provide better choice sets through policies and legislation, etc.

CONCLUSION

The Nigerian Power Sector has been in operation for decades and has witnessed several transformative/initiative reforms in policy and pattern of operation; yet the energy poverty of the nation remains unabated. This is because a 'sustainable outlook' has not been deployed in the successive

reforms; and the policies evolved have not been sustainably strategic. As such, available opportunities could not be adequately tapped or harnessed for growth and posterity of the sector and the general society. The sustainable outlook calls for adequate maintenance of all infrastructures of electricity production and transportation, with an increase in generation capacity of existing facilities which are grossly under-utilized far below their installed capacities; and to be accompanied with broad introduction of renewable resources into the energy-mix. The enormous potentials of the renewable resources across all regions of the country have been subsequently ignored in past reforms. Therefore, efficient and sustainable utilization of the abundant renewable and non-renewable energy resources of Nigeria on the platform of effective and good governance is the panacea to the relentless energy/power problem of the nation.

In addition, the power sector has being subjected to several daunting challenges in power generation, transmission and distribution responsible for losses and failures over the years. In short, the power infrastructure in place is in a state of apathy, very unreliable, inefficient and unsustainable. As such, it needs to be strategically revitalized through a sustainable approach. The prelude to the approach is the 'unbundling' system in which production and transportation of electricity is separated to create room for competition and an open and transparent market. This is has been carried out by the government, and this study further recommends adequate grid planning to ensure technological developments and advancements in all the facets of operation so as to liberate the power industry out of the present state of impasse.

ABSTRACT

Adsorption is one of cost-effective method to treat heavy metals in wastewater and the use of locally-available materials as adsorbents is receiving much attention especially in developing countries. This research was done to examine the potential use of laterite brick (from Vietnam) as a locally-available adsorbent to remove Chromium (Cr) and Arsenic (As) from wastewater. For comparison, commercially available zeolite and autoclaved aerated concrete (AAC) from Japan were used. Effect of initial metal concentration, pH and solid to liquid ratio (S:L) was examined for the fraction of 0.105-2 mm grains. The change in pH and electrical conductivity (EC) before and after the adsorption was measured. For laterite, both Langmuir and Freundlich models were fitted well for Cr and As adsorption isotherms and the maximum adsorption capacities (Q_m) became 1.3 mg/g for Cr and 8.2 mg/g for As. The measured Q_m for laterite became lower than zeolite but higher or equal to tested AAC. The change in pH became opposite between Cr and As adsorption, i.e., ΔpH (equilibrium pH–initial pH) increased with increase in Cr adsorption but ΔpH decreased with increase in As adsorption. Results revealed, for both As and Cr adsorption were dependent of initial pH and S:L ratio and desorption isotherms shown irreversibility of adsorbed metal ions onto laterite. Laterite has a possibility in treating Cr and As contaminated wastewater as commercially available zeolite. Further studies on the effects of competitive metal ions and ionic strength on adsorption process are highly recommended.

Keywords: Adsorption, Heavy metals, Laterite, Wastewater

INTRODUCTION

Adverse effects on the environment and human health is highly influence by heavy metal contamination in water is a global significance problem. Human population and environment are under severe dangers as treat to human by cancers, organ mutilation and death in serious cases through bioaccumulation of heavy metals [1]. Among them chromium (Cr) and arsenic (As) have become more hazardous pollutants. About 200 million people in worldwide are suffered due to arsenic contaminated drinking water [2]. The carcinogenic influence of Cr is also strong by making harm to the human [3]. Hence effective and efficient treatment technologies are essential to evade this issue.

Chemical precipitation, coagulation, membrane filtration, reverse osmosis, electrocoagulation and ion exchange can be identified as improved efforts among wastewater treatment methods [4]. High initial, maintenance and operation costs, expensive in large scale, severe pollution occurs due to regeneration of chemical reagents, chemical consumption and high sludge volume generation are drawbacks of them [5]. Positive image has received for adsorption process as an effective and economic technique for heavy metal removal because of low cost, high efficiency with easy operation conditions [6] and sometimes adsorbents can be regenerated [5].

There are various adsorbent materials as industrial products, natural and industrial geomaterials and biosorbents. Promoting the low cost adsorbents in adsorption process is needed to improve the economic feasibility and user-friendliness.

Therefore, laterite was used in this study as a locally-available and low cost adsorbent to examine the suitability for the removal of chromium and arsenic from wastewater.

MATERIALS AND METODS

Adsorbents Preparation and Physicochemical Characterization

In this study, laterite bricks from Vietnam was chosen to analyze adsorption characteristics expecting to be a better locally available material for Cr and As removal. Commercially available zeolite and autoclaved aerated concrete (AAC) in Japan were used as reference materials. All the materials were crushed by hand and sieved, and 0.105-2 mm particles were prepared and stored under natural moisture conditions. Determination of basic physical and chemical properties such as pH, electrical conductivity (EC), gravimetric water content of air-dried particles, specific gravity and loss of ignition (LOI) were done for all the tested materials, and are exemplified in Table 1.

The Batch Experiments for Adsorption Studies

Adsorption experiments under full contact conditions were followed according to the standard batch method proposed by the Organization of Economic Cooperation and Development (OECD) [7]. H_3AsO_4 and K_2CrO_4 reagents (Wako Pure Chemical Industries, Ltd., Japan) were used to preparation of adsorbates. Triplicate samples of adsorbents and adsorbates as 1:10 solid:liquid ratio (S:L) in 50 mL Violamo Centrifuge tubes (AO1350002, Sigma-Aldrich, USA) were shaken for 24 hours at 100 rpm at 20 ˚C in a reciprocating shaker. Subsequently 15 min centrifuge at 8000 rpm, membrane filtration (Millipore 0.22 µm) of supernatants and dilution with pure water to predetermined dilutions were conducted towards measurements of heavy metal concentrations by atomic adsorption spectrophotometry (AAS-AA-6200, Shimadzu, Japan). Both pH and EC values before and after the adsorption process were monitored.

The Effect of Initial Metal Concentration on Adsorption

Batch experiments for Cr and As adsorption at natural pH onto tested adsorbents by varying initial metal concentrations of 0-2,000 mg/L was accomplished to estimate the maximum metal adsorption capacity. Observed experimental data were fitted into Langmuir model [Eq. (1)] [8] and Freundlich model [Eq. (2)] [9] to examine the adsorption behaviors. Removal efficiency of metal contaminant was calculated using Eq. (3).

$$\frac{C_e}{Q_e} = \frac{1}{bQ_m} + \frac{C_e}{Q_m} \quad (1)$$

Where C_e=equilibrium aqueous metal ion concentration (mg/L), Q_e=amount adsorbed per adsorbent at equilibrium (mg/g), b=Langmuir constant related to binding strength (L/g), and Q_m= maximum adsorption capacity (mg/g).

$$\mathrm{Log}Q_e = \mathrm{Log}K_f + \frac{1}{n}\mathrm{Log}C_e \quad (2)$$

Where K_f =Freundlich adsorption capacity (L/g), and 1/n = adsorption intensity.

$$R = \frac{C_i - C_e}{C_i} x100 \quad (3)$$

Where R=Removal efficiency (%), and C_i=initial metal ion concentration (mg/L).

The Effect of Initial pH on Adsorption

Initial pH can be identified as one of a controlling factor for adsorption process [10]. Batch adsorption experiments were done in the pH ranges from 1 to 10, adjusted by adding either 1N HCl or 1N NaOH. S:L ratio was 1:10 and C_i was 500 mg/L for each solution.

The Effect of Solid:Liquid Ratio on Adsorption

Effect of S:L ratio on the adsorption was performed by using three different ratios as 1:5, 1:10 and 1:30, for 500 mg/L initial metal ion concentration at natural pH condition.

Desorption Experiments

Leaching of adsorbed metals from the adsorbent materials was examined by desorption experiments according to the sequential decant-refill technique [11]. Initially, the batch adsorption experiment under natural pH was performed. After centrifugation, 10 mL of the supernatant was removed, and the suspension was filled up with 10 mL of Millipore water (pure water). Then, samples were equilibrated under the same conditions as adsorption test. Consecutive desorption process was repeated at least three more times to achieve a well-fitting desorption isotherm. The hysteresis index (ω) [Eq. (4)] was valued according to the different between adsorption and desorption isotherms modeled by the Freundlich model [Eq. (2)]. Difficulty in detachment of the adsorbed metals to the adsorbent shows by higher ω value [12].

$$\omega = \left[\left(\frac{n_a}{n_d}\right) - 1\right] x100 \quad (4)$$

Where n_a=adsorption intensity and n_d=desorption intensity according to the Freundlich model [Eq. (2)]. Reversible metal adsorption indicated by $n_a=n_d$ or $n_a<n_d$, while $n_a>n_d$ shows irreversibility [11].

RESULTS AND DISCUSSION

Physical and Chemical Properties

Metal adsorption of liquid to solid phase is governed by adsorbent's characteristics [12]. Japanese AAC showed the high pH indicating capability of release OH^- in aqueous solution (Table 1). Narayanan [13] shows crystalline, semi-crystalline and near amorphous tobermorite group of calcium silicate hydrates (C-S-H) may cause to release OH^- . Hematite and Goethite are ion rich compounds in laterite which improve the positive charge governs to low pH in aqueous solution.

Table 1: Basic physical and chemical properties of tested materials.

Properties	Laterite	Zeolite	AAC
Water content (%)	0.7	0.04	10.2
Natural pH	4.2	8.4	10
EC (mS/cm)	0.02	5.6	1.8
LOI (%)	24	1.1	10.8
Specific gravity	3	2.7	2.5

The Effect of Initial Metal Concentration on Adsorption

Measured Cr and As adsorption isotherms fitted well in Langmuir model for entire range of C_i with high regression co-efficient (r^2>0.9) for laterite. Fitted with Langmuir model shows homogeneous and monolayer type adsorption [14]. Measured isotherms and fitted Langmuir models [Eq. (1)] data are shown in Fig. 1a and Fig. 1c for Cr and As respectively. The measured Q_m values became 1.3 mg/g for Cr and 8.2 mg/g for As, for laterite, lower than zeolite but higher or equal to tested AAC. Comparison of Q_m values with previous studies are summarized in the Table 2 and fitted Freundlich model [Eq. (2)] parameters are shown in Table 3.

Table 2: Comparison of Q_m (mg/g) values for Cr and As adsorption with previous studies.

Adsorbent	Cr	As	Reference
Laterite	1.3	8.2	This Study
Zeolite	5.4	14.6	This Study
AAC	-	4	This Study
Coir pith	11.6	-	[15]
Sepiolites	14.1	-	[16]
Chitosan	55.8	-	[17]
Cement	-	1.9	[18]
Brick	-	0.04	[18]

The ΔpH (difference between equilibrium pH and initial solution pH) relationship with equilibrium adsorption (Q_e) of Cr and As for laterite is shown in Fig. 1b and Fig. 1d. It indicated opposite behavior in Cr and As adsorption as decreasing ΔpH with increase in Q_e for As while positive ΔpH with increasing Q_e for Cr. This outcomes may due to the presence of Ca^{+2}, Mg^{+2}, Fe^{+2} and Cl^- like ions, which adsorption onto materials got affected.

Further studies are needed to interpret the results of metal adsorption process with relating to pH change and Ca^{+2} elusion before and after the adsorption process.

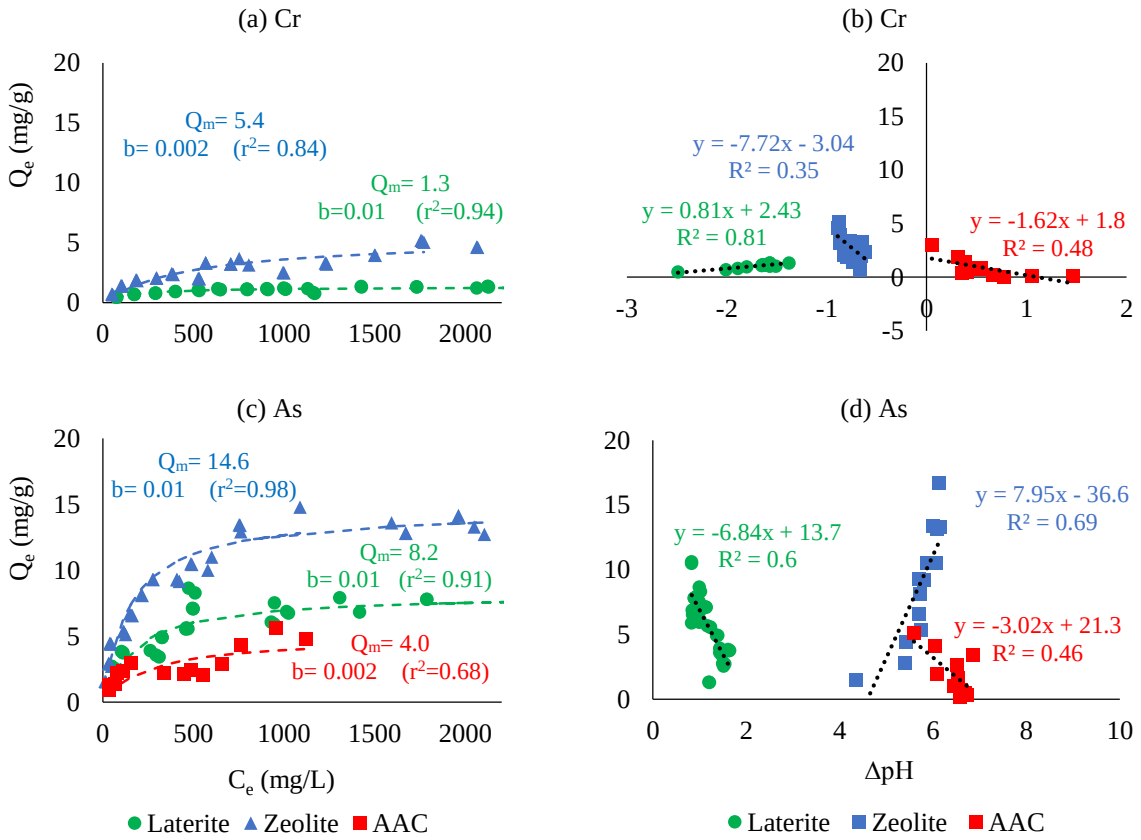

Fig. 1: Measured adsorption isotherms and fitted Langmuir models of (a) Cr and (c) As and the ΔpH relationship with equilibrium adsorption (Q_e) of Cr (b) and As (d) for all the tested materials.

The Effect of Initial pH on Adsorption

As the pH rises from 2 to 10 it was found to slight decrease in removal rate of Cr for all the materials as illustrated by Fig. 2a. In contrast, As removal shown in Fig. 2b increased from pH 1 to 2 in all the tested adsorbents and then decreased with pH increase in the solution. This results revealed that there is an effect on As and Cr adsorption with related to initial pH in the solution. Arsenic exists as neutral species in the pH range of 4-8.5 cause to slight reduction in adsorption [19]. Surface property of the adsorbent and adsorbate ionization degree may be changed with solution pH and it shows a significant impact on the heavy metal uptake [20].

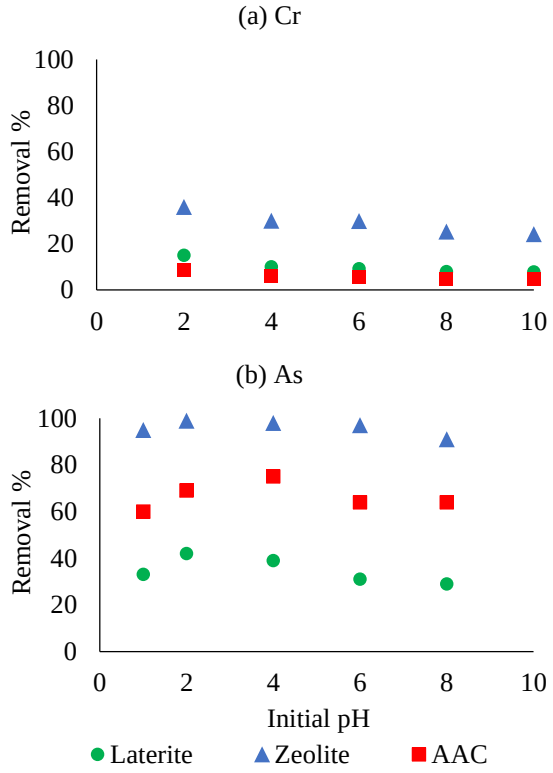

Fig. 2: Effect of initial pH of the solution for removal of (a) Cr and (b) As for tested materials.

The Effect of Adsorbent: Adsorbate (S:L) Ratio on Adsorption

As in the Fig. 3, higher solid content showed higher removal efficiency since increased in active adsorption sites. Removal efficiencies for laterite became lower than zeolite but higher or equal to tested AAC. S:L ratio of 1:10 can be suggested as a good ratio for laterite to remove both metals since it showed 7.8% and 42% of removal efficiency for Cr and As respectively at the natural pH conditions.

Reducing the pH condition of solution, removal efficiency of laterite was improved up to 15% for Cr as showed in the Fig. 2a. Therefore, there may be a possibility of improving the adsorption efficiency by doing some modifications to the materials, so; future studies are greatly recommended to improve the adsorption characteristics.

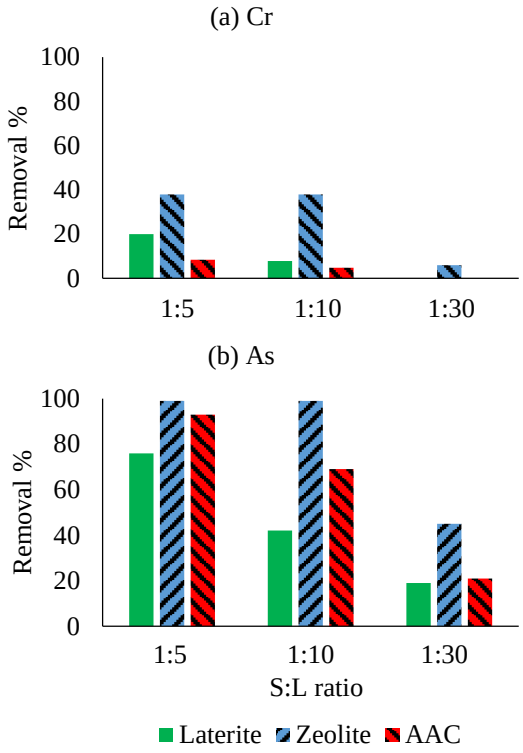

Fig. 3: Effect of S:L ratio for removal of (a) Cr and (b) As.

Desorption Experiments

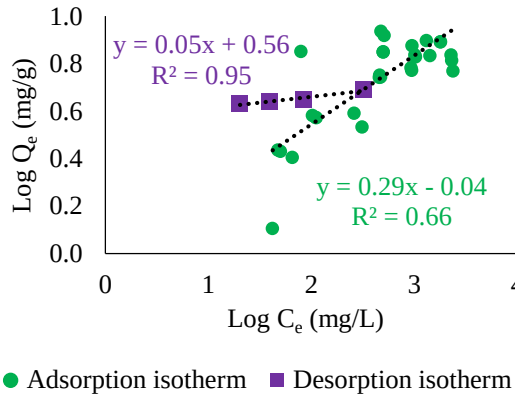

Fig. 4: Measured adsorption and desorption isotherms and fitted Freundlich models for As onto laterite.

Table 3: Fitted parameters for adsorption and desorption isotherm models (K_f, n, r^2) and hysteresis index (ω) for tested adsorbents.

Metals	Adsorbents	Adsorption			Desorption			ω
		K_{fa}	n_a	r^2	K_{fd}	n_d	r^2	
Cr	Laterite	0.24	0.24	0.69	2.16	0.07	0.28	242
	AAC	$1.5*10^{-4}$	1.38	0.78	2.8	0.03	0.06	4500
	Zeolite	0.22	0.4	0.74	0.84	0.17	0.67	135
As	Laterite	0.92	0.29	0.65	3.65	0.05	0.95	480
	AAC	0.37	0.69	0.69	0.87	0.25	0.81	176
	Zeolite	0.8	0.41	0.87	2.86	0.18	0.98	128

Reversibility and irreversibility behavior of the metal adsorption can be identified by consecutive desorption tests. For both adsorption and desorption data fitted with Freundlich model [Eq. (2)] are shown in the Table 3 with the estimated hysteresis index (ω) [Eq. (4)] (only adsorption and desorption isotherms were shown for the laterite fines in Fig. 4). All the tested materials showed higher regression coefficients (r^2) for As desorption higher than 0.8, while it is quite questionable for Cr desorption for both laterite and AAC compared to zeolite. Hence repeated experiments are essential to be followed for further studies.

Laterite has higher hysteresis index (ω) indicating irreversibility of adsorption process for As than other two adsorbents (Fig. 4). For all the materials, n_d values were lower than the n_a values, revealing strong bonds of adsorbed metal ions to adsorbents in water extraction conditions. Further studies are needed to examine the effect of pH onto the immobilization of sorbed ions.

CONCLUSIONS

Applicability of laterite bricks for As and Cr removal from wastewater was examined by a series of batch adsorption and desorption experiments. For laterite, both Langmuir and Freundlich models were fitted to the measured data. Arsenic adsorption showed higher Q_m value than chromium adsorption onto tested laterite, became 8.2 mg/g for As and 1.3 mg/g for Cr. It revealed higher adsorption capacity than AAC for both metal ions. For all the tested adsorbents, higher solid fraction affected in increasing the removal efficiency due to increase in active adsorption sites. Removal of Cr and As were high at pH 1 and 2 respectively, revealing pH dependency on adsorption. Lower leaching of adsorbed As was observed onto laterite with comparatively higher hysteresis index than other tested adsorbents. Based on the overall tested results, it suggested that laterite used in this study had a reasonable potential as an adsorbent to treat Cr and As contaminated wastewater.

Further studies on the effects of competitive metal ions in binary and multi-metals systems and ionic strength together with pH effect on adsorption process are essential to understand the adsorption mechanism in the typical wastewater conditions.

CHARACTERIZATION OF TEMPERATURE ENVIRONMENT ON MIKURA-JIMA ISLAND, JAPAN WITH CONSIDEARATION OF VEGETATION RECOVERY

Teruo Arase[1], Tetsuo Okano[1], Masayuki Hino[2] and Taizo Uchida[3]
[1]Faculty of Agriculture, Shinshu University, Japan; [2] Botanist in Mikura-jima Island, Japan;
[3] Faculty of Engineering, Kyushu Sangyo University, Japan

ABSTRACT

Vegetation recovery following landslides caused by typhoons has been monitored on Mikura-jima Island. Despite having a temperature profile of a warm temperate zone, Mikura-jima has many plant species representative of a cool temperature zone. Temperature environment is an essential parameter for determining the development of vegetation and flora, but little data are available for the island. In the present study, we measured atmospheric temperature by thermographs at seven different elevations (130, 300, 400, 500, 600, 700 and 800 m) over a period of 5 years (from 2013 to 2017), and we determined the warm index, cool index and rate of decline with elevation. The lapse rate along elevation gradient was 0.98 ˚C per 100 m for elevations 500 m and below, and 0.66 ˚C per 100 m for elevations 500 m and above. Warm index (W.I.) was estimated to fall below 85 at elevations over about 800 m, which allows the existence of a cool temperature zone. The re-examination of temperature environment in the present study will facilitate planning of goals and evaluation or estimation of vegetational succession on Mikura-jima Island.

Keywords: Atmospheric Temperature, Warm index, Lapse rate, Vegetation, Mikura-jima Island

INTRODUCTION

Vegetation recovery projects require planning of remediation activities based on monitoring data and evaluation of success at the species level. The course of remediation efforts may differ greatly from project to project and will reflect the purpose of the project. In the case of urgently needing to stabilize the base of a slope to prevent landslides near populated areas, rapid establishment of ground cover may be achieved by using exotic pasture grasses owing to their superior germination and growth compared to native plant species. However, when restoration in a natural ecosystem is not so urgently required, it is desirable to focus on establishing native plant species. The importance of native species becomes greater in isolated natural ecosystems such as solitary islands due to its vulnerability to disturbance by non-native species [1].

What determines the distribution of native species? Humidity and temperature environment, which can be measured by precipitation and atmospheric temperature, have been demonstrated to influence the distribution of vegetation in various studies [2], [3]. In the 'Sino-Japanese Region' including China, the Korean peninsula and Japan, differences in atmospheric temperature are generally more critical than precipitation in determining the distribution of vegetation and flora because precipitation is abundant across this region [4]. Temperature environment is essential for determining the development of vegetation and flora [2]-[5] and, accordingly, it is an essential parameter for setting goals and evaluating or estimating the succession of vegetation.

The range of each plant species is determined by biomass production (i.e., photosynthesis, respiration, growth and storage), ability of survival in unfavorable seasons, as well as reproduction and competition [5]. From these points of view, several temperature indices such as the warm index (W.I.) and cool index (C.I.) [3] have often been used to characterize the habitat environment. For example, Kira [3] showed that the boundary between the cool temperature zone (deciduous broad-leaved tree forest) and a warm temperature zone (evergreen broad-leaved tree forest) is around 85 for the W.I. and -10 for the C.I. in Japan.

On Mikura-jima Island (Fig. 1), one of the solitary islands of the Izu Islands of Japan in the Pacific Ocean, vegetation recovery following landslides caused by typhoons has been monitored [6], [7]. Mikura-jima Island naturally has an 'irregular' vegetation distribution, having many plant species that are representative of a cool temperature zone but that are inconsistent with the previous placement of the entire island into a warm temperature zone. This inconsistency in classification poses challenges for setting goals for vegetation recovery and evaluating the succession of vegetation.

However, little data is available on the temperature environment of Mikura-jima Island. The only temperature dataset on Mikura-jima Island was recorded for 5 years from 1960 to 1964 at the village school located at an elevation of 130 m reported by Kawamoto [8]. Mikura-jima Island is encircled by a shoreline of uninhabitable sheer sea cliffs and has a highest peak (Mt. Oyama) with an elevation of 850.9 m [9]. Since clouds and fog usually cover the high elevation area of the island (Fig. 2), it is reasonable to consider that the atmospheric temperature shows a lapse rate along the elevation gradient in humid conditions: taking a lapse rate of 0.6 ˚C per 100 m produces an estimated difference of about 4.3 ˚C in temperature and 51.6 (= 4.3 × 12) in W.I. between at the village school and the mountaintop. This empirical estimation provides an W.I. of more than 100 at the top of Mt. Oyama, which exceeds the criteria of a cool temperature zone, which is W.I. of less than 85 [10].

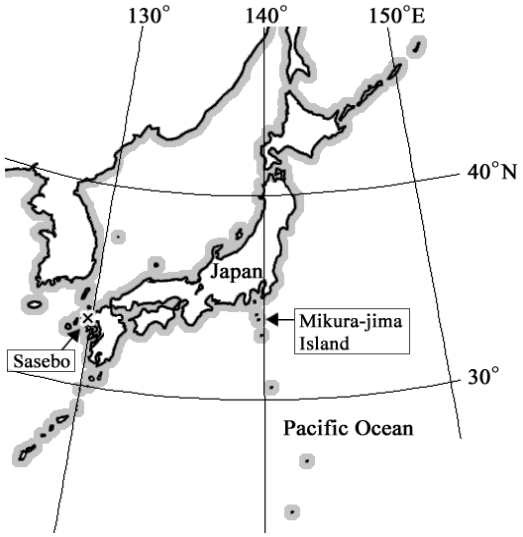

Fig. 1 Location of Mikura-jima Island, Japan with Sasebo, a city with nearly the same latitude, shown for reference.

Fig. 1 Photo of Mikura-jima Island. The shoreline is made up of sea cliffs, and the high-elevation area of the island is usually covered by clouds and fog.

In the present study, atmospheric temperature is measured continuously at several points with various elevations on Mikura-jima Island. We characterize the temperature environment of Mikura-jima Island and furthermore, re-examine the relationship between the distribution of vegetation and the temperature environment.

METHODS

Measurement of Atmospheric Temperature

Seven points at different elevations (130, 300, 400, 500, 600, 700 and 800 m) were established for the measurement of atmospheric temperature. Among them, six points were at an elevation of 300 m or higher and are located along a path leading to the top of Mt. Oyama. The observation point at 130 m is at a village school (elementary school along with a junior high school) in a residential area.

Atmospheric temperature at each observation point was measured using a waterproof self-registering thermograph (TR-51, T AND D Corporation). The thermographs were placed at the six points along a path leading to the top of Mt. Oyama in August 2012. Each was placed at a height of 1.5 to 2.0 m shaded from direct sunlight by placement under tree crowns along the path and in an instrument shelter at the village school.

Measurements were taken every hour on the hour, and the thermographs were exchanged every summer in order to collect registered data.

Measurements were continuously taken starting in August 2012 and are continually being taken as of publication of this report. In the present study, we analyzed the results of 5 years with entire-year data from 2013 to 2017.

Data Analysis

Based on the atmospheric temperature dataset, average monthly temperature and average annual temperature were calculated in each of the 5 years. From the viewpoint of the ‘irregular’ distribution of plant species in cool temperature zone, we also counted the number of days with freezing temperatures (i.e., the minimum temperature was below 0 ˚C) occurring each year.

The warm index (W.I.) at each point was calculated as follows,

$$W.I. = \Sigma (T - 5) \quad \text{(if T is higher than 5 ˚C)} \qquad (1)$$

where T is the average monthly temperature and the value of W.I. works out a positive number.

The cool index (C.I) at each point was calculated

by the similar formula to W.I.,

C.I. = Σ (T - 5) (if T is lower than 5 ˚C) (2)

and the value of C.I. gives a negative number. Equations (1) and (2) were proposed based on a general rule that plants can grow at temperatures above 5 ˚C [3].

The lapse rate along the elevation gradient was estimated by the relationship between elevation and each temperature index (average annual temperature, W.I, C.I and the number of days with freezing temperature). A simple regression model was employed to estimate the relationship, and the significance of fitness of the model was determined by an F-test based on the value of R^2.

RESULTS

Atmospheric Temperature

Table 1 Average monthly temperature and temperature indices by elevation on Mikura-jima Island over the period from 2013 to 2017.

Month	Elevation (m)						
	130	300	400	500	600	700	800

C.I.	-	-	-	-	-0.2	-2.4	-3.4
DF	-	0.4	1.0	2.0	10.0	18.8	24.7

An.ave.: the average annual temperature, W.I: warm index, C.I.: cool index, and DF: days with freezing temperature (below 0 °C).

Table 1 shows the average monthly temperature, average annual temperature and temperature indices (W.I, C.I, and days with freezing temperature) by elevation over the 5-year period from 2013 to 2017. The seasonal changes in atmospheric temperature on Mikura-jima Island presented as profiles of average monthly temperature at elevations of 130, 600 and 800 m (Fig. 3) show that the coldest month was January and the warmest month was August at all elevations. All temperature parameters showed that temperatures decrease with higher elevation throughout the year. C.I. was determined to be '0' at the points at elevation lower than 600 m because the average temperature did not fall below 5 ˚C in any month.

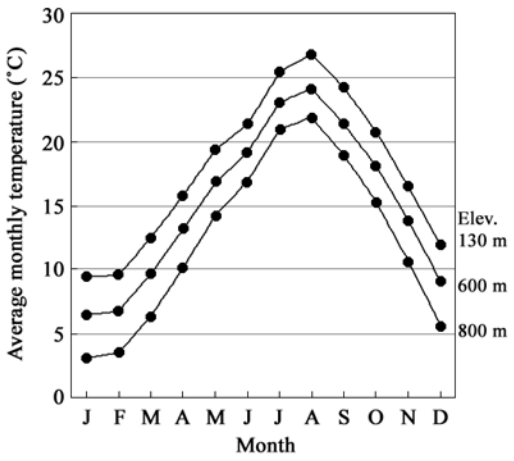

Fig. 3 Average monthly temperature in Mikura-jima Island, from 2013 to 2017.

Lapse Rate along Elevation Gradient

The lapse rate along the elevation gradient is shown for average annual temperature (Fig. 4), W.I. (Fig. 5) and days with freezing temperature (Fig. 6). We excluded C.I. from this analysis because only three observation points at high elevation had observations that could be used to calculate C.I.

For average annual temperature (Fig. 4), fluctuation among years seemed small (standard error (se) = 0.42 ˚C) at each elevation point. A statistically significant regression line using all data points (R^2 =0.951, p <0.0001, F-test) was obtained:

$y = 18.5 - 0.0080\ x$

where x is elevation and y is the average annual temperature. The slope (-0.0080) indicates a lapse rate in atmospheric temperature over the elevation gradient of approximately 0.80 ˚C per 100 m.

Regression lines fitted to data for lower and upper elevations separately (dashed lines in Fig. 4) showed a significant difference in slope (p<0.005, F-test by analysis of covariance). Lapse rate for elevations 500 m and below was 0.98 ˚C per 100 m, while the lapse rate for elevations 500 m and above was 0.66 ˚C per 100 m (R^2 = 0.954 and 0.742, respectively; p <0.0001, F-test).

For W.I. (Fig. 5), variation among years was also small (se = 5.1) at each elevation. A statistically significant regression line (R^2 =0.944, p <0.0001, F-test) was obtained as follows:

$y = 160.6 - 0.091\ x$,

where x is elevation and y is W.I. The slope (-0.091) indicates a lapse rate in W.I. over the elevation

gradient of approximately 9.1 per 100 m.

Breaking down the observation points by lower and upper elevation (dashed lines in Fig. 5) shows a significant difference in the slope of the regression line (p<0.0002, F-test by analysis of covariance) between lower elevations and upper elevations with a lapse rate of 11.7 per 100 m for elevations at 500 m and below and 6.5 per 100 m for elevations at 500 m and above (R^2 = 0.953 and 0.718, respectively; p <0.0001, F-test).

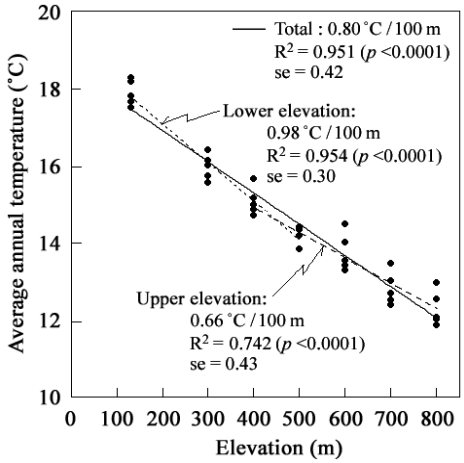

Fig. 4 Lapse rate for average annual temperature.

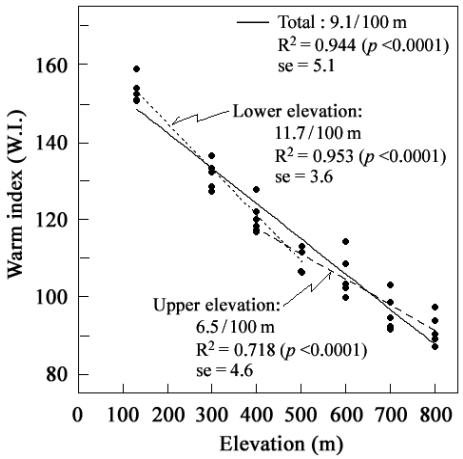

Fig. 5 Lapse rate for warm index (W.I.).

On the other hand, days with freezing temperature, or DF, showed large variation among years, especially at the points at higher elevations (Fig. 6). DF was zero or small up to elevations of 400 or 500 m and tended to increase with increasing elevation above 400 m. A statistically significant regression line was obtained for data over the elevations from 400 to 800 m (R^2 =0.717, p <0.0001, F-test):

$y = 25.9 + 0.062\ x$,

where x is elevation and y is days with freezing temperature. The slope (0.062) indicates that for elevations above 400 m, there is a rate of increase of approximately 6.2 days of freezing temperature per 100 m.

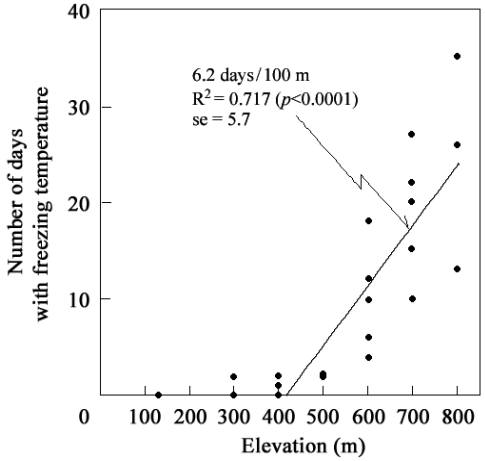

Fig. 6 Lapse rate for days with freezing temperature.

DISCUSSION

Temperature environment in Mikura-jima Island

Over the 5 years from 2013 to 2017, the average annual temperature was 17.8 ˚C and W.I. was 153 at an observation point in the residential area of Mikura-jima Island at an elevation of 130 m.

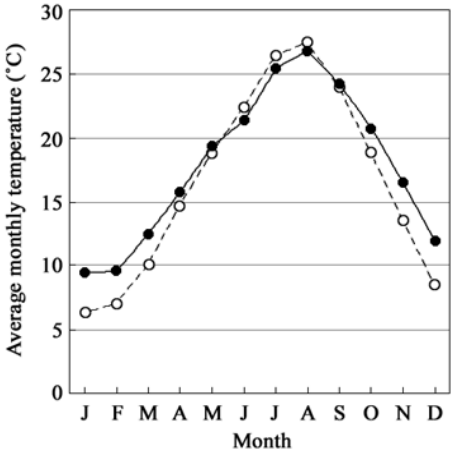

Fig. 7 Comparison of average monthly temperature between Mikura-jima Island at elevation 130 m (closed circles and solid line) measured in this study and Sasebo City (open circles and broken line) [11]. Data are averages over 5 years (2013 to 2017).

Kawamoto (2006) reported that the annual temperature range on Mikura-jima Island was smaller (i.e., cooler in summer and warmer in winter) than in Sasebo [3], a city at nearly the same

latitude (Fig. 1). From a plot of average monthly temperature on Mikura-jima Island using data collected in this study and in Sasebo city using data obtained by the Japan Meteorological Agency [11] over the same 5-year period from 2013 to 2017 (Fig. 7), we see a range in annual temperature on Mikura-jima Island of 17.4 ˚C, which is smaller than that in Sasebo City (21.0 ˚C). Further, the average monthly temperature was higher from October to April and lower from June to August on Mikura-jima Island than in Sasebo City. These data show that the temperature environment conditions on the island reported by Kawamoto [3] are as applicable in recent years as previously.

The lapse rate against elevation gradients differed between lower and higher elevations (Fig. 4 and Fig. 5). The patterns are classified as different patterns as for average annual temperature with the rate for elevations of 500 m and below of 0.98 ˚C per 100 m considered as a dry adiabatic lapse process, while the rate at elevations of 500 m and above of 0.66 ˚C per 100 m considered as a moist adiabatic lapse process [12]. These classifications are fitting with the clouds and fog that usually cover the high-elevation area of the island (Fig. 2). Other studies have also reported changes in lapse rate along the elevation gradient for other islands in Japan [13], [14], but the change in the lapse rate was relatively mild on Mikura-jima Island: the moist adiabatic lapse rate at higher elevations was larger than that on Mimami-Iwo-To Island (-0.47 ˚C [13] and 0.56 ˚C [14] per 100 m). We consider that this less distinct difference in lapse rate is due to the landform of Mikura-jima Island, or the strong winds that almost steadily blow up from the sea.

The regression equation on lapse rate enables us to estimate W.I. at any elevation and, conversely, to determine elevation from any W.I.. Using the regression equations in Fig. 5, we estimated the elevation corresponding to W.I. over the entire Mikura-jima Island. As W.I. is related to vegetation, the elevations with W.I. = 120 and W.I. = 85 were estimated to be at 409 ± 36 m and 895 ± 92 m, respectively (estimated elevation ± se). The lower confidence interval of W.I. = 85 involves the upper part of Mt. Oyama with elevations over 803 m, which implies that the temperature environment in Mikura-jima Island would support a cool temperature zone: W.I. can fall below 85 at elevations over about 800 m, where the days with freezing temperatures total up to about a month (Fig. 6).

Re-examination of Distribution of Vegetation

Fig. 8 shows the distribution of classes of vegetation on Mikura-jima Island by elevation with notation of W.I. The vegetation classes are as defined following Sanada [15] with the following examples:

(a) Forest vegetation:
A: Daphniphyllo - Trochodendretum aralioidis,
B: Carci - Castanopsietum sieboldii,
C: *Castanopsis* coppice forest,
D: Hydrangeo - Alnetum sieboldianae,
E: *Alnus sieboldiana* secondary forest,
F: Euonymo - Pittosporetum tobira,
(b) Harbaceous vegetation:
G: Patrinio - Calamagrostietum insularis,
H: Sasa community,
I: Chrysanthemo - Miscanthetum condensatus,
(c) Artificial vegetation:
J: *Buxus microphylla* plantation,
K: *Cryptomeria japonica*, *Chamaecyparis obtusa* plantation.

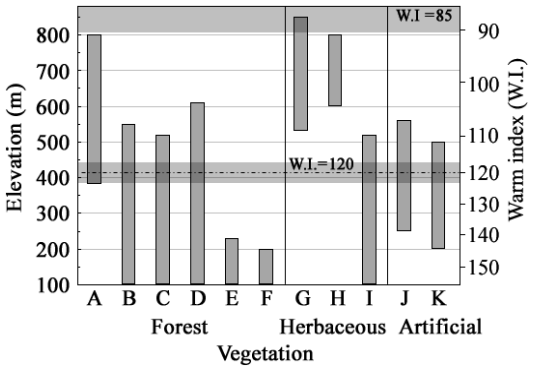

Fig. 8 Distribution of vegetation in Mikura-jima Island by elevation and estimated W.I.. A to K are the patterns of vegetation described in the text. Horizontal shading indicates confidence intervals (elevation ± se estimated by W.I.).

Compared to empirical estimations obtained by setting the lapse rate at 0.6 ˚C per 100 m, the temperature environment on Mikura-jima Island proved to be overall cooler. In particular, the distributions of Daphniphyllo - Trochodendretum aralioidis (A), Patrinio - Calamagrostietum insularis (G) and Sasa community (H) on the coastal wind-blown slopes are reasonably explained by the estimated W.I. in the present study (Fig. 8). These distributions of vegetation corresponding to W.I. were not inconsistent with those of previous reports [16], [17]. In addition to the lapse rate phenomenon, shading by clouds and fog and the occurrence of freezing temperature days likely contribute to cooling the environment in the high elevation area, which appears to enable plant species representative of a cool temperature zone to grow naturally on Mikura-jima Island.

CONCLUSIONS

We measured the atmospheric temperature on Mikura-jima Island over a period of 5 years using

thermographs placed at seven different elevations (from 130 to 800 m). Analyses of the temperature environment produced the following conclusions:
(1) Along elevation gradients, the average annual temperature ranged from 17.8 to 12.3 ˚C, and the warm index (W.I.) ranged from153 to 91.3 on the island.
(2) The lapse rate differed between lower and upper elevations with rates of 0.98 ˚C per 100 m for elevations of 500 m and below and 0.66 ˚C per 100 m for elevations of 500 m and above.
(3) W.I. was estimated to fall below 85 at elevations over about 800 m, which would produce a cool temperature zone, which reasonably explains the distribution of vegetation patterns.

These solved the inconsistency in the distribution of plant species and vegetation. Temperature environment re-examined in the present study will facilitate the planning of the goal and the evaluation or estimation of vegetational succession on Mikura-jima Island.

It should be noted that temperature observations were not taken at elevations over 800 m (e.g., the top of Mt. Oyama), and the lapse rate above 800 m can not be confirmed to maintain the 0.66 ˚C per 100 m at elevations over 800 m. It is desirable to achieve a more precise characterization of the temperature environment in Mikura-jima Island.

EXPERIMENTAL STUDY OF TWO-STAGE FORCED CONVECTION FURNACE FOR RIBBED RUBBER SMOKED SHEET (RSS) PRODUCTION

Machimontorn Promtong*
* Department of Mechanical Engineering, Faculty of Engineering, Mahidol University, Bangkok, 73170, Thailand

ABSTRACT

Due to improper design of the original rubber smoking-room, the Ribbed Smoked Sheets (RSS) productions at Thai Rubber Smoking Cooperatives (RSCs) are undergoing. In this research, a prototype of the two-stage forced convection system has been proposed to renovate the traditional smoking process. Generally speaking, to enhance the efficiency of fuel consumption and to increase the number of qualitative RSS, the new hot-gas supplying system was carefully designed and constructed. Eight small ventilating lids were specifically used at the smoking-room ceiling to improve the velocity and temperature distributions. To obtain the optimal temperature (60°C) for natural rubber smoking, the feeding rates of firewood and the supplying rates of hot gas while operating this new forced convection system were optimized. According to the RSS production (1458 sheets), the drying time and the fuel consumption were found at 90 hrs, and 1.04 ton per a ton of the dried sheets, respectively. Surprisingly, 92% (822 kg) of the dried RSS were found to be above the selling grades; nevertheless, the remaining was in the cutting-grade due to having the unacceptable thickness (> 3mm). Overall, the new two-stage forced convection system could save 25% of production time and 35% of fuel consumption compared with the original natural convection system. Because the harmful aerosol particles could be trapped, so this new forced convection system may be friendly to the environment as well. In future work, a Computational Fluid Dynamics (CFD) technique will be used to enhance the efficiency of this new smoking room system for RSS production.

Keywords: Forced convection flow, Ribbed Smoked Sheets (RSS), Natural rubber smoking, Temperature distribution, Energy efficiency

INTRODUCTION

Thailand has become one of the largest natural rubber (NR) producing and exporting country in the world. In 2018, 3.84 million tons ($1,000 million) of natural rubbers were produced and exported into four forms including Concentrated Latex (36%), Ribbed Smoked Sheet (RSS) (16%), Block Rubber (~1%), and miscellaneous other forms (47%). Due to the price decline of natural rubber, the production of RSS at the community's level has gained more attractive ($2.87 per kg in 2012 to $1.33 US in 2018). Nevertheless, the RSS producing time has taken up to 6 days and the consumed firewood has found as high as 1.5 tons per ton of dried RSS. Over 40 percent of the produced RSS has been also represented at low quality. According to this situation, more than half (over 300 groups) of the Rubber Smoking Cooperatives (RSCs) in Thailand cannot be operating. According to the literature reviews, the non-uniformity of the hot gas during the smoking-process has been mentioned and this is because of the improper design of the original smoking-room [1], [2] and [3].

Over a few decades, many researchers have studied the curing parameters for natural rubber drying. For instance, the effects of temperature, velocity, and moisture of inlet air were particularly demonstrated [4], [5], [6] and [7]. In order to lower the RSS production cost, the free and friendly environment energy like a solar house was designed. Basically, the solar heat could be used to preliminarily remove the moisture from the wetted rubber sheets prior to the smoking process [8], [9], [10], and [11]. Furthermore, a recently developed technology like the multiple hot-air jets was particularly suggested for curing the RSS and reducing the production time [12]. As well as, a Computational Fluid Dynamics (CFD) technique was introduced by Promtong and Tekasakul for improving the uniformity of hot gas flow inside the smoking-room. Regarding the recommendations, the original rubber smoking-room was suggested to modify further, then the smoking-time and RSS quality could be significantly improved [1] and [13].

As known, during the burning of the firewood for each RSS production, the harmful wood particles are usually released out to the environment. To protect the worker's health, many researchers have investigated the environmental pollutions at the RSCs. For example, the concentration of the aerosol particles inside the factory area was observed [14], [15], [16], and [17]. Electro Static Precipitator (ESP) was designed to trap a number of particles before

entering the smoking-room [18]. As explained, this way could improve not only the RSS quality but also reduce the number of detrimental chemicals released into the atmosphere [19], [20], and [21]. Similarly, the wastewater issue was found to be another critical problem as well [22] and [23]. Therefore, to renovate the current smoking process at the RSCs, the environmental effects should be seriously brought into consideration.

The main objectives of this research are i) to experimentally study the capability of the new forced convection smoking room system under various operating conditions, ii) to investigate temperature distribution inside the modified smoking-room while operates using two proposed functions and iii) to evaluate the performance of the new smoking-room system under real RSS production, especially in term of fuel consumption, production time, and the percent of the RSS satisfied the marketing grades.

THE RUBBER SMOKING-ROOM AND ITS MODIFICATIONS

The Original Smoking Room

The dimensions of the original rubber smoking room are 2.6-wide×6.2-depth×3.7 height-m (Fig. 1). On the room floor, twelve 10-cm diameter inlet gas supply ducts are used for hot-air introduction during the smoking period. At the ceiling, two 0.6×0.6-m ventilating lids are installed for the air outlets. Also, there is an 8-m chimney with a 200-mm-diameter used for hot air exhaust and temperature control inside the smoking-room.

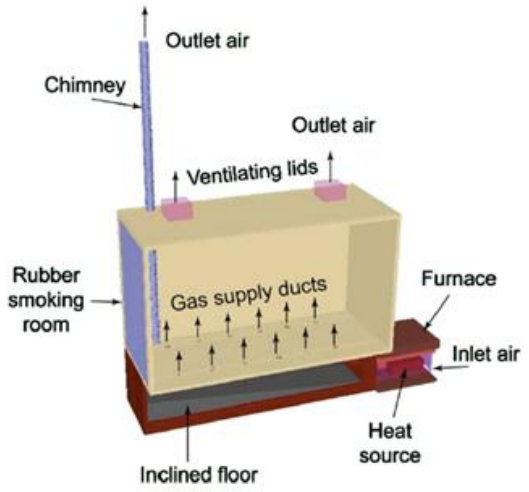

Fig. 1 The model of original rubber smoking-room used at Thai Rubber Smoked Cooperative [13]

Details of the New Smoking-Room System

Due to having a high-temperature variation inside the traditional rubber smoking room (~15°C), about 40% of the produced RSS were represented at low quality [6]. As a consequence, the parts of the rubber smoking-room were suggested to be modified. For instance, since it was found that a chimney is the cause of the loss of energy, thus the draft tube was disconnected from the heat supply system [5]. However, in this work, the size of the rubber smoking room was not modified because its capacity is suitable for daily RSS production at the community's level.

Modifications of the room inlet and outlet

The adjustment of sizes and positions of the inlets and the outlets of the rubber smoking-room could improve the uniformity of the flow [4]. At the room inlets, 12 round ducts remained the same diameter and positions for the hot gas introduction. However, they are directly connected to the new furnace via the main supply duct (Fig. 3). At the outlets, two original ventilating lids (0.6×0.6 m) at the ceiling were replaced by the eight lids of 0.25×0.25 m and their locations are identical with the simulation. Further details can be found in our previous simulation study [1].

Details of the new two-stage forced convection smoking room system

As shown in Fig. 3, the new forced convection system consisting of the heat exchanger unit, a 1-HP-motor with a fan set, and a piping loop, is mainly used for hot gas supplement and circulation. A Variable-Frequency Drive (VFD) is installed to control the fan speed and torque by varying motor input frequency and voltage. Adjustments of the firewood fed and the motor speed via the VFD, hence the velocity and temperature inside the smoking-room can be controlled within the desired range for RSS production [8].

In practical, this new forced convection system can supply the hot gas to either one or two rubber smoking-rooms. By using two rooms, about 3,150 wetted rubber sheets can be smoked at the same time. For a safety reason, a pressure relief valve is installed at the top of the furnace. Likewise, three dust-trap boxes are installed along the main pipes between the furnace and the smoking-room for blocking and collecting the fly ash (however they are not detailed).

Functions of the new forced convection system

The one-way flowing and the waste gas recirculation are two functions of the new forced convection system that are designed for RSS production. Basically, this first function is proposed to efficiently remove the moisture of the wetted rubber sheets. As shown in Fig. 3 the flow path of this one-way supplying mode is started from 1→2→3→4 respectively. Ideally, the desired length of the flow path of hot gas in the smoking-room should be a strength line (as short as possible) from the floor to the ceiling during this function operation. In this first stage, the ventilating lids should be fully opened to allow the moisture flowing out without any blockages.

The waste gas recirculation function is designed to enhance energy efficiency by utilizing the wasted gas. Briefly, the direction of the flow path is started from 5→6→2→3→5, respectively (Fig. 3). It should be noted that during this second stage the ventilating lids should be closed so that the wasted gas can be circulated and reused. Therefore, the circulation of the waste gas during this lateral function may reduce the number of soot particles released into the environments.

EXPERIMENTAL DETAILS

The experiments were carried out using two modified rubber smoking-rooms at Ban-Nong-Deang Samaggi Rubber Cooperative, Nakhon Si Thammarat province, Thailand. Details of tools, measuring positions, research methodology, and performance indicators are described as follows:

Measurement Tools

Type-K thermocouples were used for the temperature measurement, and a data logger (Data-Taker, DT 500) was used to record the temperatures at 5-min intervals to ensure a continuous reading. A hot-wire anemometer (Airflow, TA400T, 3% full display scale) was used for the velocity measurement. The firewood of known mass was fed to the burner to supply heat to the rubber smoking-room and its moisture content was determined on a dry basis. Drying the wood samples in a laboratory oven at 105°C until its mass did not change, then the moisture content and its heating value can then be examined [24].

Positions of Measurements

Three positions at the burner inlet were used to measure air velocities. The outlet gas velocities at eight ventilating lids of the rubber smoking-room were also measured for comparison purposes. These measurements were recorded every hour during the experimental period and their locations are presented in Fig. 4.

Moreover, the temperatures of fifteen positions in the modified rubber smoking-room were also investigated (Fig. 4). As well, the temperatures of two positions (T_{rear} and Tf_{ront}) at the ceiling were

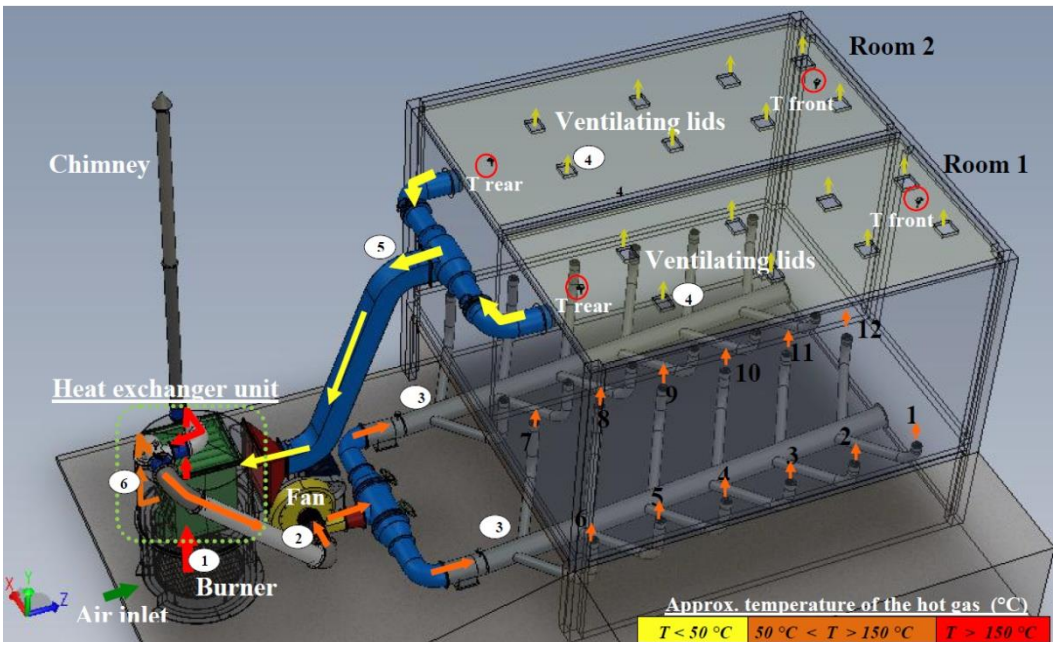

Fig. 3 Details of the new smoking room system and approximate hot gas temperature entering and leaving the smoking room

particularly monitored during the suitable rates of the firewood and the motor speeds were examined (Fig. 3). Their probe ends are situated at 0.40 m below the ceiling inside the rubber smoking-room. Ambient temperature was also measured, and this measurement was close to the air inlet of the burner.

optimize together with monitors of the temperature occurred inside the rubber smoking-room. To prevent the deterioration of the natural rubber sheet, the smoking temperature is specifically controlled to be around 60°C.

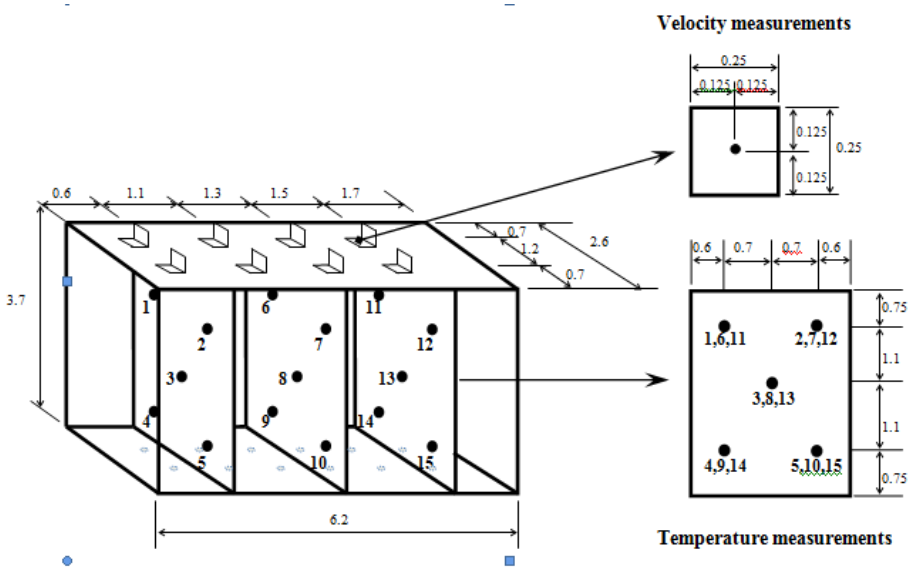

Fig. 4 Positions of temperature (side view), and velocity measurements (top view) at the smoking room (units in meters)

Research Methodology

In order to conduct the experiments for evaluating the capability of the new forced convection smoking room system, this research work is thus divided into four main steps as illustrated in Fig. 5. In brief, the fan speeds and the feeding rates of firewood are firstly focused to

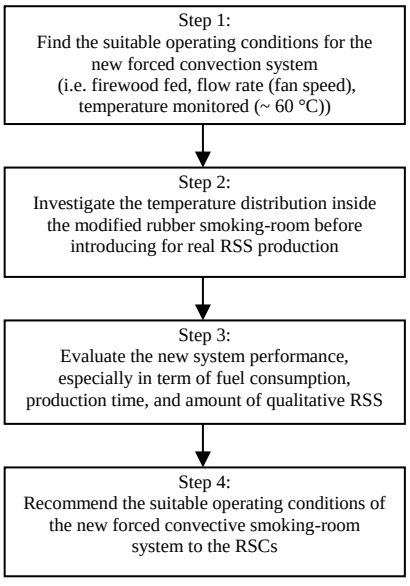

Fig. 5 A flow chart representing the main research methodology

A lower temperature is also acceptable; however, a longer time for RSS production may be required. Temperatures of fifteen positions in the modified rubber smoking-room are secondly investigated under the use of suitable operating conditions. During the experiment, the temperatures were monitored every 5 minutes for continuous reading. The interesting results from this investigation are presented and discussed in the following section.

Thirdly, the new forced convection smoking-room system is used for real RSS production. During the experimental investigations, the fuel consumption, the production time and the percent of qualitative RSS for the one-room operation are discussed. The performance of this new smoking room system is then evaluated and reported in this paper. Lastly but most importantly, the instructions regarding how to operate this new forced convection smoking-room system for RSS production are recommended to the RSCs.

Performance Indicators

Thermal efficiency and specific firewood consumption are normally used for estimating the performance of the new forced convection rubber-smoking system. However, in the section of results, only the specific firewood consumption is discussed.

Thermal efficiency ($\eta_{thermal}$) is calculated as shown as follows [25]:

$$\eta_{thermal} = \frac{m_L \times L}{(HV)_{firewood} \times m_{firewood}} \quad (1)$$

where $m_L, m_{firewood}$ are the evaporation mass of water (kg) and the firewood mass (kg), L is the latent heat of vaporization (kJ/kg), $(HV)_{firewood}$ is the heating value of the firewood (kJ/kg).

The specific firewood consumption per ton of dried rubber sheet while using the new smoking room system can be calculated by using the following equation:

$$Firewood-consumption = \frac{m_{firewood}}{m_{dried-RSS}} \quad (2)$$

As mentioned in [26], $m_{dried-RSS}$ is the total mass of dried RSS.

RESULTS AND DISCUSSION

The important results including the ambient temperature, inlet and outlet velocities (volumetric flow rate), firewood feeding rate as well as temperature variation are firstly presented in this section. To investigate the temperature variation, the experiments were conducted using the empty modified smoking-room, thus the moisture effects can then be ignored. Other interesting results including the ambient temperature, the firewood moisture are additionally given.

After the temperature investigation, this new forced convection smoking-room system was reintroduced for RSS production. So, in the second part of this section, the results regarding the performance indicators of the new smoking-room system, i.e. temperature variation, firewood consumption and percent of satisfied RSS are presented and discussed.

Case 1: Investigating temperature variations in the empty modified smoking room

Because the configurations of the two modified smoking-room are identical, thus only one room was used to conduct the experiment. The appropriate operating conditions from preliminary observations were adopted for this temperature distribution investigation. Generally speaking, the maximum difference of the temperature among fifteen locations for both available functions (one-way flowing and waste gas recirculation) was specifically observed and also compared with the original rubber smoking room.

Feeding rates of firewood and inlet/outlet velocities (volumetric flow rates)

To accelerate the temperature inside the modified smoking-room for the first 2 hrs, 60 kg of the firewood was fed at the furnace and the fan speed was specified by setting VFD at 60 Hz (Table 1). From the measurements, the average air velocity at the burner inlet was found about 2.68 m/s and the average hot gas velocity at the ventilating lid outlets was about 1.02 m/s. After calculations, the volumetric flow rates of inlet air and outlet gas were found to be 0.282 m^3/s and 0.421 m^3/s, respectively.

After the heating-up period, 40 kg of the firewood was fed at the burner in every 3 hrs during 2-14 hrs and the VFD frequency was reduced to 50 Hz. Average velocities of air entering the burner and the gas flowing out the ventilating lids were found at 2.17 m/s and 0.88 m/s, respectively. According to the values, the volumetric flow rates were 0.227 m^3/s and 0.365 m^3/s, respectively.

Table 1 The velocities measuring at furnace inlet and ventilating lids and their volumetric flow rate.

Operating function (Time/VFD frequency/Feeding rate)	INLET	OUTLET
	Average velocity (m/s)	Average velocity (m/s)
	The flow rate of inlet air (m^3/s)	The flow rate of outlet waste gas (m^3/s)
One-way flowing (0-2 hrs /60Hz /60 kg every 2 hrs)	2.68	1.02
	0.282	0.421
One-way flowing (2-14 hrs/ 50Hz/ 40 kg every 3 hrs)	2.16	0.88
	0.227	0.365
One-way flowing (14-32 hrs/ 50Hz / 35 kg every 3 hrs)	2.11	0.85
	0.222	0.349
Waste gas recirculation (32-64 hrs/ 40Hz/ 30 kg every 3 hrs)	-	-

The reductions of the firewood fed and the fan speed were due to a requirement of the temperature control around 60 °C. Lower feeding rate of the firewood (35 kg every 3 hrs) at the burner was attempted for the third period (14-32 hrs). As a result, the volumetric flow rates of inlet air and outlet exhaust gas were found slightly lower than the second period (0.222 m^3/s and 0.349 m^3/s).

For the last period (32-64 hrs), the waste gas recirculation function was introduced instead of the one-way flowing. During the operation, the ventilating lids were shut down and the waste gas temperature was circulated and reheated using the heat exchanger. Also, to maintain temperature around 60 °C, the feeding rate of the firewood required was found at only 30 kg every 3 hrs.

Temperature distribution and other interesting parameters

Fig. 6 shows the temperature results measured in the modified smoking-room. Clearly, the temperatures are quickly climbed up and reached 70°C within the first hour. With the selected firewood fed and the fan speed, the room temperature can be raised efficiently. During these two hours, the maximum variation of the temperature was found as high as 6.3°C.

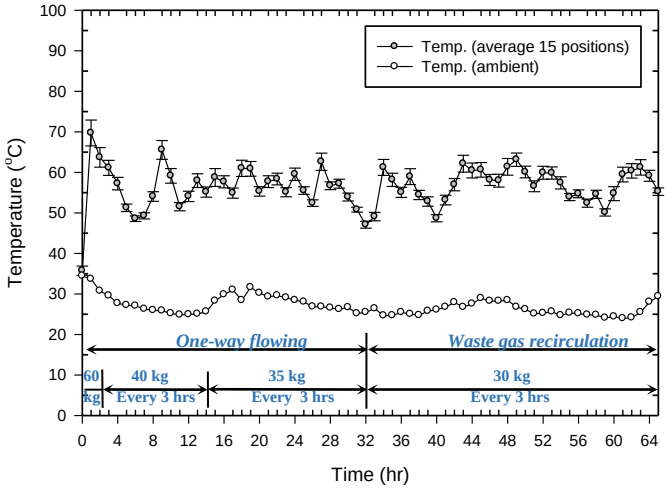

Fig. 6 The average temperature of fifteen positions measuring in the smoking-room and the ambient temperature

During the employment of one-way flowing function, all the ventilation lids were fully opened. For the second and third periods (2-32 hrs), the average temperature from the fifteen positions was 56.3°C and the maximum variation remained at 4.6 °C, occurred at a ninth of the experiment.

While the waste gas recirculation (32-64 hrs), the average temperature among the measuring positions was 57.3°C and the maximum variation was reduced to 3.8 °C. According to these results, with a lower feeding rate of the firewood (5 kg every 3 hrs), in general, the average temperature was higher than using the one-way flowing mode.

Using the waste gas recirculation for the last period, the average temperature from fifteen positions was found at 57.3°C, and the maximum variation remained only 3.8°C (Fig. 6). The firewood consumption fed in this period was less than that used in the one-way flowing mode about 5 kg every 3 hrs. Nevertheless, it still gave a higher average temperature in the rubber smoking-room.

Because the ambient temperature is usually high and the air humidity is also low during daytimes, hence heating up the room temperature and removing the rubber sheet moisture on this time may be easier and more efficient. According to this reason, the one-way flowing function is suggested to be first introduced during daytimes for RSS production.

Case 2: Evaluating the performance of the modified smoking-room system for RSS production

As aforementioned, the performance of the new smoking-room system used for RSS production is another focus to be observed in this work. Prior to the smoking process, the preparations of the wetted ribbed rubber sheets at the RSCs can be reviewed from the work of Dejchanchaiwong [26]. The number of wetted rubber sheets filled up the smoking room for the case of one-room smoking was 1458 sheets. The experiments were begun at 11.00 a.m.; hence the ambient temperature at the beginning was found near the highest on that date.

Feeding rates of firewood and inlet/outlet velocities (volumetric flow rates)

In this experiment, the operating conditions used during the RSS production (0-78 hrs) are similar to the previous study that the temperature variation was investigated. For instance, 60 kg of the firewood feeding rate was fed at the burner for raising the smoking temperature for the first 2hrs (Table 2). Due to an attempt to reduce fuel consumption in the low-moisture period (78-92 hrs), the feeding rate was reduced to 25 kg every 3 hrs.

Table 2 The inlet air velocities, outlet hot gas velocities and their volumetric flow rates

Operating function (Time/VFD frequency/Feeding rate)	INLET	OUTLET
	Average velocity (m/s)	Average Velocity (m/s)
	The flow rate of inlet air (m^3/s)	The flow rate of outlet waste gas (m^3/s)
One-way flowing (0-2 hrs /60Hz /60 kg every 2 hrs)	2.42	0.644
	0.254	0.266
One-way flowing (2-14 hrs/ 50Hz/ 40 kg every 3 hrs)	2.29	0.590
	0.240	0.244
One-way flowing (14-32 hrs/ 50Hz / 35 kg every 3 hrs)	2.28	0.619
	0.239	0.255
Waste gas recirculation (32-92 hrs/ 40Hz/ 30 kg every 3 hrs)	-	-

As shown in Table 2, the velocities of inlet air are between 2.28-2.42 m/s and the average velocities of outlet gas at the ventilating lids are between 0.590-0.644 m/s. The volumetric flow rates of inlet air and outlet gases were at 0.239-0.254 m^3/s and 0.255-0.266 m^3/s, respectively.

Also, the velocities and the flow rates measured at the outlets in this RSS production were lower than the previous study about 35%. This may be because the gas had a lower temperature and the rubber sheets also caused the pressure drop.

Temperature distribution and other interesting parameters

The temperatures of fifteen locations measured during the smoking process are presented in Fig. 7. As can be seen, for the first 2 hours the temperatures climbed up slowly and reached a maximum of about 55.2°C. During using the one-way flowing function (0–32 hrs), the average temperature was about 52.5 °C and the maximum variation of the temperature was 10 °C.

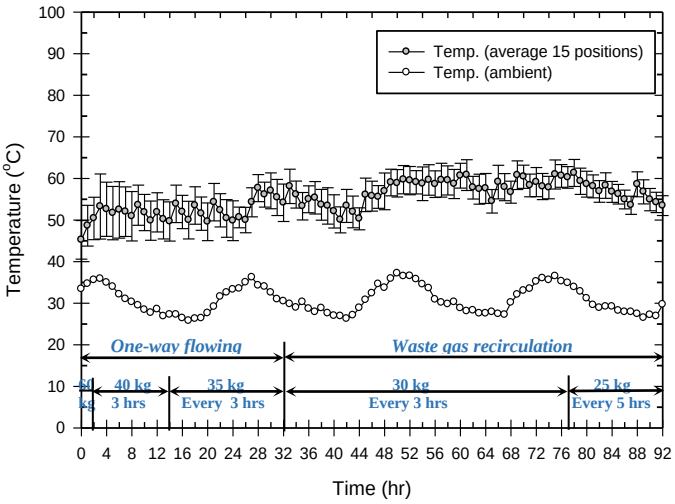

Fig. 7 The average temperature of fifteen positions measuring during the smoking process and ambient temperature

The reduction of the average smoking temperature (~8 °C) may be caused by the moisture removal process. During the drying process, the flowing heats were absorbed by the wetted rubber sheets and caused the moisture (mass) transferring to the surface. Afterward, the moisture was swept away by the carrier gas, as a consequence, the temperature of the hot gas was reduced. Anyways, with a higher rate of firewood fed, the smoking temperature could be increased.

During the waste gas circulation period (32-92 hrs), with the mentioned firewood fed (25-30 kg for every 3 hrs) the average temperature was about 57.1 °C. The maximum variation was found around 8.0 °C, which occurred at the 40th of the experiment. This high variation may be because having a low ambient temperature and high moisture in the smoking room.

CONCLUSIONS

The new two-stage forced convection smoking room system has been proposed to renovate the traditional natural convection smoking-process. To maintain the temperature around the optimal for natural rubber smoking (60 °C), the highest consumption rate was found at 30 kg every 3 hrs. Surprisingly, this consumption rate was less than the average feeding rate used at the RSCs around 35%.

According to the temperature investigation, the maximum difference (4.6 °C) inside the modified smoking-room was found less than approximately three times compared with the original smoking-room. Comparing between the one-way flowing and the waste gas recirculation functions, the maximum temperature variation of the recirculation was found at a lower value (3.8 °C). Also, this temperature result can confirm the previous simulation study.

From the RSS production (1458 sheets), the drying time and the consumption were required at 90 hrs and 1.04 ton per a ton of dried sheets, respectively. After the cutting process, around 822 kg (92%) of the produced RSS represented above the marketing grades. Therefore, it can be anticipated that this new forced convection system could save about 25% of the production time and 35% of the fuel consumption.

ACKNOWLEDGEMENTS

ABSTRACT

Every year, earthquakes cause injuries, deaths, severe structural damage to buildings and destruction of property in many countries. In developing countries, economic growth depends on industrial development. Therefore, if an earthquake occurs, it may cause severe damage to large industrial factories. This present study aims to examine the structural behavior of industrial buildings under the earthquake force which is a reinforced concrete building. The structure of an industrial building is different from a general building. In this study, the factory is a four-story building with the dimensions of 34.4 meter in width, 59.2 meters in length and 15.6 meters in height. In the analysis, the nonlinear dynamic procedure is applied to analyze the building behaviors. The 20 seismic waves are selected and adjusted with the ASCE41-13. LMSR wave are considered in x-direction and y-direction. From the results, the responses and damage of the industrial structure are analyzed. The building has performed the soft story irregularity. The performance level for the acceptance criteria, according to ASCE41-13 and FEMA365 is life safety performance level. Therefore, the industrial factory building is needed to enhance the seismic capacity for damage prevention.

Keywords: Seismic behavior, Reinforced concrete, Industrial factory building, Nonlinear time history procedure

INTRODUCTION

The industrial sector has had an important role in the economic growth in developing countries. Pricing instruments with technological innovation are installed in factories. Therefore, if an earthquake occurs, it may cause severe damage to industrial instruments and building structures. To prevent and reduce this potential damage, an industrial factory is analyzed under seismic loading in this present study. A four-story reinforced concrete building located in the Northeastern region of Thailand is analyzed. The building model comprises a linear elastic element, a fiber element and a rigid joint. The fiber element is located at both ends of structural members to represent the nonlinear behavior of them. This analysis applies a nonlinear time history procedure subjected to 20 seismic waves using PERFORM3D program [1]. A three-dimensional fiber model is used to model plastic hinges for columns and beams. The seismic waves are appropriately scaled with a design response spectrum of the Northeastern region according to the Earthquake Resistant Design code 1303 [2] of Thailand. The analysis results are reported in terms of maximum inter-story drift and rotation of fiber elements, which are used to specify the damage level related to the acceptance criteria of ASCE41-13 [3] and FEMA356 [4].

ANALYZED BUILDING

The analyzed industrial factory is a 4-story reinforced concrete building which is used as a cooling tower. The structural type is a moment-resisting frame with beams and columns. The first-floor plan with beam section is shown in Fig. 1. The dimensions of this factory building are 22.4 meters in width, 59.2 meters in length and 16.2 meters in height. There are eight spans of columns in length and four spans of columns in width with a span of 7.4 meters and 5.6 meters, respectively. As illustrated in Fig. 2, the height of each story from the first floor to the fourth floor is 1.80 meters, 7.45 meters, 3.82 meters and 3.11 meters, respectively. This building has a symmetrical appearance in the plan, but the structural configuration is an irregularity in the vertical. There are two rectangular column sections in the building as shown in Table 1. The 650x650 mm column section consists of 20-DB32mm longitudinal reinforcement bars and 5-DB12@200mm crossties stirrup. The 700x700 cm column section includes of 24-DB32mm longitudinal reinforcement bars and 7-DB12@200mm crossties stirrup. There are seventeen rectangular beam sections in the building. The section and reinforcement of beams are demonstrated in Table 2. Rotors and gearboxes are placed at the roof level, with the weights of 1,843

kilograms and 1,937 kilograms, respectively. In the construction drawing, the compressive strength of concrete is 23.54 MPa and the specified yield strength of reinforcement is 490.33 MPa.

SEISMIC HAZARD

Seismic behaviors under the seismic hazard of the factory building in the Northeast region of Thailand is analyzed by using the nonlinear time history procedure. The seismic waves are appropriately scaled with the design response spectrum constructed from the seismic hazard. The new seismic hazard for this area was proposed by Janpila [5]. which is approximately twice as high as the Earthquake Resistant Design code 1303 of Thailand [2]. The highest seismic hazard location is selected, which is in Nongkai province. According to the Earthquake Resistant Design code 1303 [2], the seismic hazard with the probability of exceedance of 10% in 50 years is used to evaluate the seismic behavior of an existing building structure. The seismic hazard map in the term of spectral acceleration (SA) at the structural periods of 0.2 and 1.0 second at base rock level with 5% critical damping ratio for reference return periods of 10% POE in 50 years are shown in Fig. 3 and 4, respectively. The spectral acceleration at the structural periods of 0.2 and 1.0 second at Nongkai province are 0.567 m/s^2 and 0.204 m/s^2, respectively. The target design response spectrum used to analyze the factory building is shown in Fig. 5.

BUILDING MODEL

Model calibration

The building model is analyzed with the nonlinear time-history procedure under 20 seismic waves by using PERFORM3D [1] program. The nonlinear behaviors of the structure are represented by fiber elements located at both ends of structural members. The fiber element is separately modelled by considering the behavior of each material, which primarily consists of unconfined concrete models, confined concrete models and longitudinal reinforcement models. The stress-strain relationships of unconfined concrete are modeled using the equation proposed by Kent and park [6]. The confined concrete behavior is modeled using the equation proposed by Hoshikuma et al. [7]. The longitudinal reinforcement is modeled using the equation proposed by Menegotto and Pinto [8]. When conducting a structural model validation, the results of RC columns experiment obtained from the study by Wehbe et al. [9] and RC frames experiment results received from Anil and Altin [10] are compared to analytical results. The plastic hinge lengths of beams and columns are evaluated by using the equation proposed by Paulay and Priestley [11] as shown in Eq. 1.

$$L_p = 0.08L + 0.022d_b f_y \quad (1)$$

where L is the distance from a critical section to the point of contraflexure (meters), d_b is the diameter of longitudinal reinforcement (meters) and f_y is the yield stress of longitudinal reinforcement (MPa).

RC columns experiment conducted by Wehbe et al. [9] yielded results of a rectangular column section with the dimensions of 610mm x 380mm and 2.050 m in height. The longitudinal reinforcements were 18-DB19mm. The transverse reinforcements were 2-RB6mm crossties and 2-RB10mm crossties with an equal space of 110mm interval along with the column height. The RC column was tested under cyclic loading with an axial force of 615 kN. The compressive strength of concrete was 27.2 MPa. The yield strengths of reinforcements were 445 MPa, 428 MPa and 448 MPa for DB19, RB10 and RB6, respectively. The column model consists of the fiber element and elastic element is shown in Fig 6. The plastic hinge is 0.352 m in length. The comparison of force and deformation obtained from the analytical results versus the experimental results is shown in Fig 7. The analytical results can also capture experimental behaviors. The analytical results give a slightly lesser amount of the maximum load and slightly greater estimates of the initial stiffness than the experimental results.

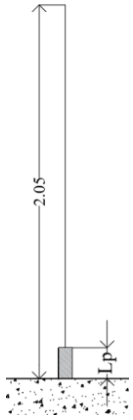

Fig. 6 Model of RC columns experiment results conducted by Wehbe et al. (1999).

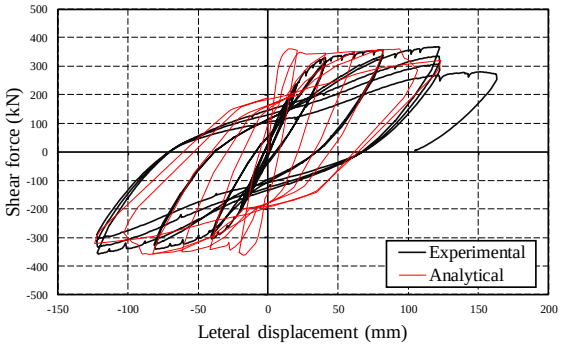

Fig. 7 The Comparison of analytical results versus experimental results by Wehbe et al. (1999).

For RC bare frame experiment results of the study by Anil and Altin [10], the rectangular columns were the 100x150mm section with 4-DB10mm for the longitudinal reinforcement and RB6 crossties with an equal space of 40mm interval along with the column height. The rectangular beam was 150x300mm section with 4-DB8mm for both top and bottom reinforcement and RB4 crossties with an equal space of 40mm interval along the beam length. The compressive strength of concrete was 21.8 MPa. The yield strengths of reinforcements

for DB10, DB8, RB6 and RB4 were 475 MPa, 592 MPa, 427 MPa and 326 MPa, respectively. The bare frame model which comprises the fiber element, elastic element and rigid joint connection is shown in Fig. 8. The plastic hinge lengths of beam and column are 0.174 m and 0.150 m, respectively. The comparison of the analytical results versus the experimental results is presented in Fig. 9. Experimental behaviors can be captured by analytical results.

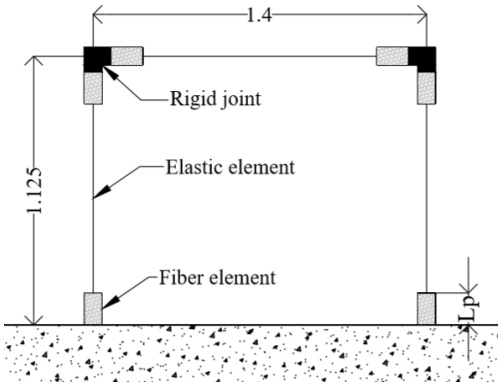

Fig. 8 Model of RC frame experiment results of the study by Anil and Altin (2007).

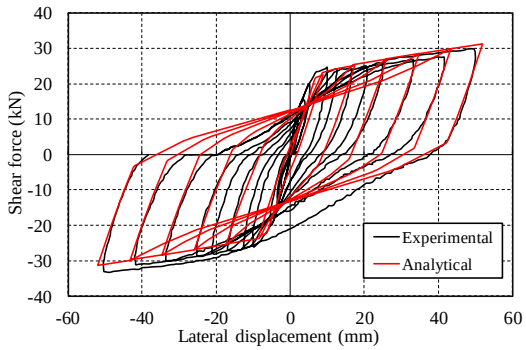

Fig. 9 The Comparison of analytical results vs. experimental results of the study by Anil and Altin (2007).

Analyzed model

An analysis of seismic behavior under seismic hazard of the factory building located in Northeastern Thailand applies the nonlinear time history procedure. The building model consists of the elastic elements in the middle of members, the fiber elements at both ends of members and the beam-column connection which is assumed to be rigid. The foundations are modelled as fixed support. RC slab in each floor is considered as a rigid floor. The fiber element is modelled by dividing the cross-section into the properties of each material, which are confined concrete, unconfined concrete and longitudinal reinforcement. Fig. 10 describes the fiber section of columns C1 and C2. For column C1, the fiber section is divided into 18 sub-elements for unconfined concrete, 8 sub-elements for confined concrete and 20 sub-elements for longitudinal reinforcement. For column C2, the fiber section is divided into 18 sub-elements for unconfined concrete, 8 sub-elements for confined concrete and 20 sub-elements for longitudinal reinforcement. The 3D building model is shown in Fig. 11. The Preliminary analysis of the building model is performed by determining the natural period in X and Y directions, which are used to scale the seismic waves. The natural periods of building model are 0.758 sec for X direction and 0.733 sec for Y direction.

SEISMIC WAVE

The seismic waves, collected by the Pacific Earthquake Engineering Research Center (PEER) [12] database, are selected to analyze the building model. As mentioned before, although the Northeast region of Thailand is classified as a low seismic hazard region, there are two active faults. Therefore, the large-magnitude small distance (LMSR) seismic wave type is considered in this analysis. The wave selection criteria are as follows:

1 Distance from the earthquake epicenter to the considering site is in the range of 30 km to 50 km.
2 Earthquake magnitudes are in the range of 6.5 Mw to 6.9 Mw, which is the possibility maximum magnitude of the faults in this area.
3 The fault of earthquake events is a crustal fault and the epicenter is shallow.
4 The soil type in Northeastern Thailand is soil type D with the shear wave velocity (V_s30) of about 180-360 m/s.

Twenty seismic waves that are considered to be appropriate for the Northeast region are shown in Table 3. According to the Earthquake Resistance Design Code.1302 of Thailand, the response

spectrums of seismic waves are analyzed and compare with the target design response spectrum (Fig. 5). All seismic wave response spectrums have to be higher than the target design spectrum for the natural period in the range of 0.2T to 1.5T, where T is the natural period of the analyzed building model. The response spectrums of seismic wave are scaled at least 1.17 times. The scale factors of each seismic wave in X-direction and Y-direction are demonstrated in Table 3. The scaled response spectrum of twenty seismic waves as compared with the target design spectrum for X-direction and Y-direction are shown in Fig. 12 and Fig. 13, respectively.

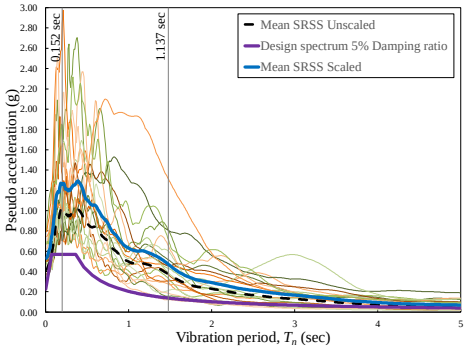

Fig. 12 Response spectrum and scaled SRSS spectrum LMSR for X- direction

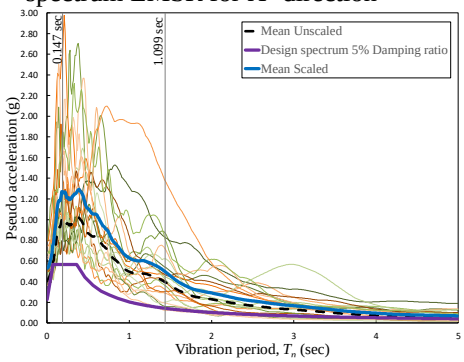

Fig. 13 Response spectrum and scaled SRSS spectrum LMSR for Y- direction

ANALYSIS AND RESULTS

The building model is analyzed under twenty seismic waves in both X-direction and Y-direction. According to the Earthquake Resistance Design Code 1303 of Thailand [2], the analyzed load combinations for the 3-dimensional model are defined into two case.

1) $$E = 1.00X + 0.30Y \quad (2)$$

2) $$E = 0.30X + 1.00Y \quad (3)$$

where E is the earthquake load, X is the load in X-direction and Y is the load in Y-direction. For conservative, the seismic waves in X-direction and Y-direction are switched to evaluate the maximum building responses. Therefore, four cases are considered in the analysis. From [3] and [4] , the acceptance criteria performance level for the plastic hinge rotation angle and the maximum inter-story drift are shown in Table 4 and Table 5, respectively. The acceptance criteria performance level is classified into 3 levels, which are immediate occupancy (IO), life safety (LS) and collapse prevention (CP).

Table 4 Acceptance criteria for the plastic rotation (ASCE41-13).

Performance Level	IO	LS	CP
Rotation Angle (radians)	0.005	0.045	0.060

Table 5 Acceptance criteria for the maximum inter-story drift (FEMA356).

Performance Level	IO	LS	CP
Maximum Inter Story Drift	<1%	<2%	<4%

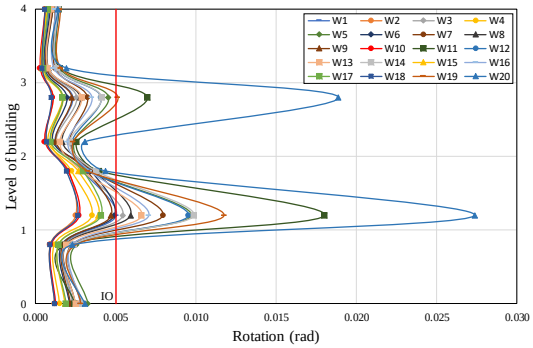

Fig. 14 Plastic rotation angle of the column

From the analysis result, the maximum plastic rotation of columns at all levels under each seismic wave are shown in Fig. 14. The top of columns under the second floor at an elevation of 9.25m has the highest rotation angle due to the long column. The maximum rotation angle is 0.0274 rad due to the W20 Northridge-01 seismic waveform which

occurs the immediate occupancy performance level and is reached about 61% of life safety performance level. The building model has performed the immediate occupancy performance level under eleven seismic waveforms.

The maximum inter-story drift has occurred int the weak direction of the structure as shown in Fig. 15. The maximum inter-story drift of column is on the second floor that has the highest column. The column height of this level is 7.45 meters. The performance level of the structure is life safety, which has the maximum inter-story drift more than two percentage, under the seismic wave number W12, W14, W5, W19, W11, and W20. The maximum inter-story drift under the seismic waveform W20 is closely reached the collapse prevention performance level.

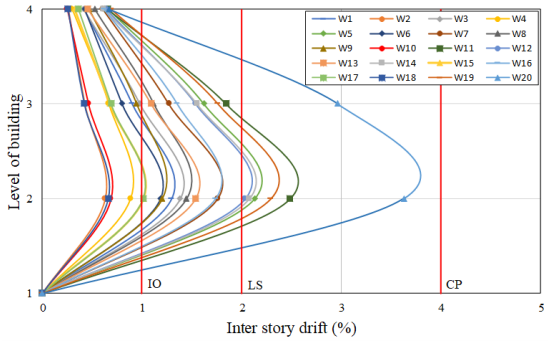

Fig. 15 Maximum inter-story drift

CONCLUSIONS

The industrial factory building is analyzed the seismic behavior under seismic hazard in Northeastern Thailand according to the Earthquake Resistant Design code 1303 [2]. Twenty seismic waveforms are selected and scaled for this area. The nonlinear time history procedure is applied to capture the building responses. The building model consists of the elastic elements in the middle of members, the fiber elements at both ends of members and the beam-column connection, which is assumed to be rigid. From the results, the maximum damage has occurred in the second-floor column with a height of 7.45 m. The columns in this floor perform the soft story irregularity. The building is severe damage due to the W20 Northridge-01 seismic waveform. The performance level for the acceptance criteria for the plastic rotation is immediate occupancy with the rotation angle of 0.0274 rad, and for the maximum inter-story drift is life safety with the inter-story drift of 3.63 percentage. Therefore, the industrial factory building is needed to enhance the seismic capacity for damage prevention.

ABSTRACT

This study developed a disaster prevention education program for children who continued to live in the Aso area after the Kumamoto earthquake with the aim to enhance their disaster prevention capabilities and to help them take active roles in the reconstruction of the region. This study clarified the objectives, teaching materials, learning methods of the disaster risk prevention education program after the disaster, and clarified the educational effects of the program. The study set the evaluation criteria based on the ministry's curriculum guideline called "Zest for Living". It has become evident that, the knowledge based on the local historical experiences can be a good starting point for the reconstruction immediately after the Kumamoto Earthquake. One of the educational effects of the program was, as it became clear that the local children are deeply interested in the wisdom and customs of reading and understanding nature. The program successfully raised children's level of awareness from the classroom education of disaster prevention to regional disaster prevention in the three years it has been implemented. Furthermore, with the passage of time after the disaster, it has become apparent that the programs called 'Prediction of Danger and Taking Independent Action', which aims at recognizing dangers associated with various disasters and 'Contributing to Society and Basics for Disaster Service Workers' can also be implemented.

Keywords: Kumamoto Earthquake, Disaster Prevention Educational Program, Aso

1. INTRODUCTION

Disaster Risk Education plays an important role in overcoming the memory of the disaster and in providing preparation for future disasters. The objectives and programs of disaster risk prevention education differ according to the periods prior to the disaster, at the time of the disaster and in the periods of recovery and reconstruction.

Most of the disaster prevention programs deal with the pre-disaster phase. Many of these programs use simulation models [1] and hazard maps [2] [3]. The contents of learning include evacuation training to ensure safety and the understanding and prediction of the hazards associated with disasters [4].

On the other hand, there are not many disaster prevention education programs for recovery and reconstruction. In particular, there is a lack of disaster prevention training programs that would foster attitudes which promote participation, cooperation and contribution to the safety of the area during times of recovery and reconstruction [5].

It is important to provide such education to those children who will continue to live in disaster-stricken areas that fosters their attachment to the community and promotes attitudes which contribute to the recovery and reconstruction [6]. Two months after the Great East Japan Earthquake, Iwate Prefecture designed an education program called: "Iwate's Reconstruction Education" with the goal of "nurturing people who love their hometown and are involved in the reconstruction and development" [7].

As a response to the 2011 Great East Japan Earthquake, the Ministry of Education, Culture, Sports, Science and Technology (MEXT) set up an expert committee for reviewing disaster prevention education and management. MEXT published a revised material in 2013 titled Zest for Living. It includes not only evacuation procedures during disasters, but also educational programs from the viewpoint of local life and customs[8].

The Aso area suffered from recent natural disasters such as the Kumamoto earthquake (April 2016). From the viewpoint of reconstruction following the Kumamoto earthquake, promotion of disaster prevention education is required based on traditional lifestyle and knowledge that have helped local people to coexist with the volcano and overcome natural disasters, such as eruptions and landslides. Especially during times of disasters, the traditional lifestyle, knowledge and feelings of local patriotism are considered to have helped the children psychologically [9].On the other hand, education psychology studies reported that children who had experienced disasters have to deal with the effects of serious psychological stress in daily life [10].

Therefore, it is important to clarify the objectives of the educational program, the teaching material and learning methods that are to be considered during the post-disaster recovery and reconstruction period.

This study aimed to develop a disaster risk educational program, which promotes place attachment for reconstruction from disasters and fosters awareness for disaster prevention. This study carried out the disaster prevention education program in the three years immediately after the 2016 Kumamoto earthquake. It also clarified the objectives of the teaching materials, the learning methods of the disaster risk prevention education in the time after the disaster, and clarified the educational effects of the program.

2. DEVELOPMENT OF THE DISASTER PREVENTION EDUCATIONAL PROGRAM FOR RECONSTRUCTION AFTER KUMAMOTO EARTHQUAKE

The study set the evaluation criteria based on "Zest for Living", the Ministry's curriculum guideline. In "Developing disaster prevention education that fosters "Zest for Living"set the following three aims for disaster prevention education [11].

The following articles from the Education Ministry guidelines are incorporated into the elementary school curriculum: "to help pupils become aware of the close relationship between the national land, people's lives and livelihoods" - from the objectives of Social Studies; "to help pupils develop interest in the relationships between themselves, the people around them, the various local places, public facilities; to enable them to appreciate their locality and to develop a feeling of attachment to it; at the same time, to enable them to think about their roles and actions as members of their groups or society and to act safely and appropriately" - from the objectives of Life Environment Studies.

The education programs, based on the disaster situation, were planned in cooperation with the locals and the elementary teachers. The education programs were carried out in two Minami-Aso Elementary Schools, and Aso Elementary School a Minami-Aso Junior High School,Aso Elementary School,by scientist, locals and NPO, teachers.

The study looked at the effects of the program based on the selected keywords from children's oral comments and the interview survey results by children.

Table 1 Disaster prevention education of "Zest for Living"

The evaluation criteria of "Zest for Living"	The objective
Knowledge, Consideration, Judgment	To understand disasters that are likely to occur in the area, to learn from the past disasters of the area, and to use them in making decisions for taking safe actions
Danger Prediction, Independent Action	To recognize danger at the time of disaster and to be able to secure one's own safety using daily training etc.
The Foundation of Social Contribution	To respects one's own life and those of others, to be able to help the safety of other individuals, To be able to take useful action to help groups and areas during and after disasters that occur in the area.

3.1 The Disaster Prevention Educational Program 6 months after the Kumamoto Earthquake

The education programs were planned in cooperation with local elementary school teachers and NPOs from May 2016, two months after the Kumamoto earthquake. The conclusion of the advance meeting with local teachers was that the educational program aimed at helping children deal with the damage and trauma of the earthquake was too early. Therefore, this study established three disaster education programs. The first was a program to leverage the local historical experiences, such as the grassland management techniques（controlled burning, fire belt, seven plants in season）. The aim of the second program was to learn about the attractiveness of living together with volcanoes and grasslands through national parks and geoparks. The third program introduced the interaction between the inside and the outside of the area through the case of Kumamoto's reconstruction efforts in Tokyo. The teaching materials used numerous photos of grassland landscapes and local agricultural activities such as controlled burning, mowing and pasturage in the Aso area. In addition, this program featured a 3D terrain model to enhance the sensory perception of the volcanic terrain of the Aso area.

The program was carried out on September 24, 2016 with the participation of 30 children in total from 3rd grade and 4th grade of two elementary schools in Minami-Aso.The instruction method included the presentation of a 3D topography model of Aso with the purpose to enhance the understanding of the volcanic topography and caldera topography of

Aso. The 3D terrain model is 29 cm long, 25 cm wide, has a maximum of 3 cm in height, and was created at the scale of 1 to 100,000. In order to help children grasp the size of the secondary grassland areas of Aso we compared it to the Yahoo! Dome of Fukuoka which the local children are familiar with. In addition, when explaining the total distance of the secondary cut in the grassland, the idea was to make it easy for children to imagine the total area of the open area and the cut, so it was compared to the distance between Aso and Nagoya.

The second program explained about the purposes of National Parks, Globally Important Agricultural Heritage Systems, and Global Geoparks. In addition, the program explained that the reasons for recognitions as Global Agricultural Heritage Systems and Global Geopark are the livelihood of the people in the grasslands and the volcano of Aso.

The third program introduced a sales promotion event held in Tokyo in order to support the reconstruction after the Kumamoto earthquake.

The educational effect includes the appearance frequency of controlled burning, and the deepened understanding of the maintenance and management of the grassland and its relationship with people's activities. The educational effect was frequent in case of national parks (11 times). Therefore, it became clear that incorporating national parks and world geoparks into the educational materials would enhance understanding and interest in the area.

3.2 The Disaster Prevention Educational Program 1 year after the Kumamoto Earthquake

A year has passed since the Kumamoto earthquake, and following meetings with teachers, we planned an educational program that placed stronger emphasis on the perspective of disaster prevention education than the one in 2016.

The objective of the program continued to highlight the attractiveness of Aso through the activities of grassland management such as the fire controlled burning, and through the recognition as national park and geopark, in order to enhance the appeal of the hometown and to promote place attachment. In addition, learning points from a disaster prevention point of view about the wisdom of Aso that overcame natural disasters and the bond between the community were further included along with traditional land use techniques based on the caldera's topography [12]

The program was carried out for 60 5th grade students of Aso City's Aso Elementary School on December 11, 2017.

The educational methods of the continued program was the same as the previous one.

The program featured wisdom gained from overcoming natural disasters, reflected on the bond within the community, incorporated methods for passing on past disasters within the community and introduced traditions related to the natural disasters and the natural phenomena of the Aso region. For example, "Han"(the wooden plate is called) used to alert the neighborhood of impending disasters. It is not used anymore, of course, but it is kept there to remained people of the importance to help each other at times of disasters.

Concerning the local customs, the contents of the program did not investigate the question of scientific validity, but merely aimed at understanding the fact that local ancestors have faced nature by closely observing it.The program explained about the traditional land use from the walls of the caldera to the floor of the caldera, with the aim to learn about traditional land use.

As for the educational effect, from the high frequency of the appearance of words that refer to the management of the area (e.g. controlled burning), it was possible to confirm the educational effect that children possess an understanding of the management of the grassland and have a raised level of interest toward it.Furthermore, the frequency of appearance of the phrases 'National Park' (25 times) and 'Knowing' (26 times) was high. There were many children who did not know that Aso was designated as a National Park, Globally Important Agricultural Heritage System, or Global Geopark. The largest number of comments were about the natural disasters of Aso and its natural phenomena. It became apparent that children are interested in the area's traditional customs and wisdom. Furthermore, it was also confirmed that the wisdom gained from overcoming natural disasters and the bond within the community helps form a place attachment to the Aso area.

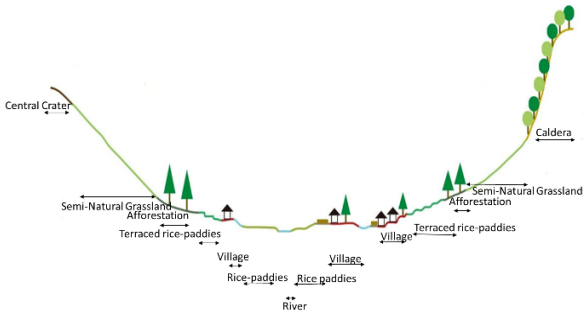

Fig. 1 The land use of Aso area

3.3 The Disaster Prevention Educational Program of Program 2 years after the Kumamoto Earthquake

As one of the educational effects of the program implemented so far, it turned out that the children have a strong interest in the wisdom and customs of reading and understanding nature. Therefore, in the educational program two years after the Kumamoto earthquake, sixty 6th grade students who participated in the educational program of the previous year were interviewed about the wisdom and customs they acquired from their families and neighbors related to understanding natural disasters in the Aso area. The range of the survey period is from July to December 2018.

The result is that 'tradition and wisdom about rain' was the most frequent with 43 mentions (36.4%).

There were as many as 18 stories (15.2%) of 'lore and wisdom related to earthquakes'.It was observed from comments that many of the surveyed have heard from family and neighbors about the experiences of the Kumamoto earthquake, such as: "I was helping (being helped by) neighbors or other local people at the time of the Kumamoto earthquake.". Furthermore, there were comments such as "My great grandmother had fled to the rice fields when there was an earthquake in the old days, because there were not many open places." which show that experiences related to past earthquakes are still kept alive.

There were 11 cases (9.3%) of 'lore and wisdom about snow'. "When there was a lot of snow, we shoveled the snow together with the people of the area to clear the road." These comments clearly indicate that children heard tales about living through the severe winters of the Aso area and providing mutual assistance.

There were 4 cases (3.4%) of 'lore and wisdom about frost'. Aso area is an area where early frost and late frost are likely to occur in May and in early autumn around October. As a result, we were able to confirm practices related to frost and agriculture.

There were two cases (1.7%) of 'lore and wisdom on grassland management', which were about the timing of the controlled burning and the necessity of grassland management.

There were two cases (1.7%) of `traditions and wisdom concerning firefighting`, and those referred to the prevention of fire spreads and related prediction techniques.

The learning points summarized by the children were compiled into a booklet which contain the wisdom of coexisting with nature and Aso, and were shared with families, multigenerational groups, and local communities. Therefore, the program was able to raise awareness of disaster prevention education from school education to regional disaster prevention.

In addition, a public workshop was conducted on September 8, 2018. The topics included the risk characteristics of Aso's natural disasters, forecasting, preparedness and fostering social contribution after disasters. Eleven students ranging from the 5th grade of elementary school to the 1st grade of junior high schools have participated from the local schools of the Aso area.

As part of the learning method, in order to learn about the risk characteristics of Aso, children were explained about the types of landslides (slump, topple, debris flow, rockfall), the differences between landslides that occurred as a result of the Kumamoto earthquake and the landslides that were the results of rain. Subsequently, children enhanced their learning by using confectioneries to simulate the differences of rock topples and slumps.

During the emergency food preparation session, participants used familiar natural resources, eco ovens and bamboo in order to learn the skills to survive natural disasters.

Finally, using elevation maps and 3D topographic models, the children deepened their understanding of the relationship between the topographical characteristics of the Aso area and the disasters. Then, imagining that a disaster occurred while the participants were at home, disaster prevention maps and evacuation action plans were created for each child simulating scenarios of volcanic eruption, landslide disasters and earthquake disasters.

There were several comments made by the participating students regarding the educational program's learning points: "I want to tell about the landslide disaster and the evacuation sites of Aso that I learned about today to my friends and family ", "I want to take advantage in my daily life of the many things I learned about, such as the nature of Aso, or making emergency food and disaster prevention plans.As a result of the educational program various learning points have been confirmed from understanding the blessings of nature, the understanding of the characteristics of disasters that are likely to occur in the area, to the 'knowledge' and 'social contribution' needed to take safe action.

3.4 Readjustment and future proposals for the educational materials of the Disaster Prevention Education Program for the recovery and reconstruction periods

This study developed a disaster prevention education program for children who continued to live in the Aso area after the Kumamoto earthquake with the aim to enhance their disaster prevention capabilities and to help them take active roles in the reconstruction of the region.

Immediately after the Kumamoto earthquake, the program incorporated 'knowledge' about natural environments, national parks, geoparks, and other local attractions into the educational programs. It became apparent that it is useful to raise children's interest and attachment to the Aso area. Furthermore, it has also become evident that, the knowledge based on the local historical experiences can be a good starting point for the reconstruction after the Kumamoto earthquake.

One year after the Kumamoto earthquake, and local traditions and disasters have been incorporated into the educational programs from the perspective of disaster prevention education. Consequently, 'knowledge' and 'decision' that are necessary for understanding disasters which are likely to occur and past disasters of the area were obtained as a result. Furthermore, valuable educational effects became evident as the result of deepening interest and awareness by linking past traditional wisdom and modern disaster management approaches.

In the second year after the Kumamoto earthquake, children have become proactive in learning about past regional disasters and their community and love of our homelands. Further, this study clarified that, immediately after the disasters, such educational curriculum, involving the learning of local historical experience, helps nurturing the sense of place attachment to local community. This study suggests that, with the passage of time after the disaster, the disaster prevent programs aspect of place attachments help 'Prediction of Danger and Taking Independent Action', which aims at recognizing dangers associated with various disasters and 'Contributing to Society and Basics for Disaster Service Workers' can also be implemented.

Table 2 Disaster Prevention Educational Program for Reconstruction after Kumamoto Earthquake

ABSTRACT

A fragility curve is a primary component in the risk assessment, which is useful for evacuation planning, estimation of potential losses, and estimation of the damage to residential buildings caused by natural hazards. In general, a fragility curve represents the relationship between the probability of exceeding a specific damage state of a structure and natural hazard intensity. For determining such a curve, two parameters: the median and standard deviation are estimated. A fragility curve can be constructed using empirical data and analytical data. Numerical fitting data is used to develop the fragility curve. Various methods have been proposed using numerical fitting data to approximate the fragility curves. However, the most widely used methods for developing fragility curves are the least-squares method and the maximum likelihood method. In this present study, these two different numerical fitting data methods for fragility curve development are analyzed and compared. Basic assumptions and limitations of each method are also discussed. The building damage data used in all methods to derive the fragility curve is generated from hypothetical damage data assuming a lognormal distribution. Finally, the maximum likelihood method is proven to be optimal for developing fragility curve based on structural damage data.

Keywords: Optimal method, Fragility curve, Building damage, Risk assessment

INTRODUCTION

Each year, several countries are affected by a variety of natural hazards, including hurricanes, tropical storms, strong winds, floods, earthquakes, and tsunamis. Therefore, risk assessment is the key to provide a way to prevent and mitigate damages or losses resulting from natural disasters in the future. The risk assessment process includes natural hazard identification, building inventory, and fragility curve. The Natural hazard is identified at any given site to determine the likely impacts in the form of a hazard map. The building inventory is a classification procedure in which buildings are grouped based on similar damageability/loss characteristics into a set of predefined building classes. Model building types are further constructed by developing the damage and loss prediction models to represent the average building population characteristics within each class. A fragility curve is utilized to estimate a vulnerability, which expresses a relationship between the probability of being in or exceeding building damage state and the intensity of natural hazard. Therefore, a fragility curve is the key parameters in risk assessment for evaluating the damage probability at a specific damage level under the hazard. Statistical methodology is applied to establish a fragility curve. The building damage data, which is assumed to follow the lognormal distribution [1], is used in exploring the relationship of damage probability and hazard intensity. In general, methods most commonly used to develop the fragility curve are the least squares estimation (LSE) [2]-[3] and maximum likelihood estimation (MLE) [4]-[10]. Thus, in this study, the two most commonly used methods of estimation are compared, and the optimal method of fragility curve development is demonstrated based on statistical principles.

FRAGILITY CURVE

In this section, the concept and the key parameters of a fragility curve are described here to provide a basic understanding of analysis in fragility curve development for obtaining the appropriate method. A fragility curve describes a relationship between the level of damage probability and hazard. The probabilities defined in fragility curve are conditional probabilities as shown in Eq. (1):

$$F_d = \boldsymbol{P}\left[D \geq d \mid X = x\right] \quad d \in \{1, 2, \ldots N_D\} \tag{1}$$

where F_d represents the fragility function for damaged state d evaluated at the hazard level of x $P[A|B]$ is the probability that event A occurs given that event B has taken place. D is a damaged state of a particular component, which takes on a value of $\{0,1,\ldots,n_D\}$, and d is a damaged state. X is an uncertain excitation which is called demand parameter (DP) and x is a particular value of X.

The structural failure data follows a lognormal distribution as shown in Fig.1. The probability density function (PDF) as defined in Eq. (2) represents the probability of structural damage. The dispersion or width of distribution indicates the uncertainty of each damage state. Then the probability of the structural failure can be obtained by cumulative distribution function of the lognormal distribution with intensity measure on the horizontal axis The probability of structural failure is obtained through the cumulative standard log-normal distribution function in which the horizontal axis represents the intensity measure. The log-normal cumulative distribution function expresses the fragility curve as defined in Eq. (3).

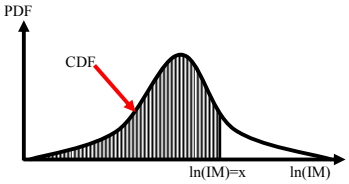

Fig. 1 Cumulative distribution function with intensity measure equal to x

$$f_d = \frac{1}{x\beta\sqrt{2\pi}} e^{(-1/2)\left[(\ln x-\alpha)/\beta\right]^2} \tag{2}$$

$$F_d = \int_{-\infty}^{\ln x} \frac{1}{x\beta\sqrt{2\pi}} e^{(-1/2)\left[(\ln x-\alpha)/\beta\right]^2} dx = \Phi\left(\frac{\ln(x/\alpha)}{\beta}\right) \tag{3}$$

where Φ[.] represents the standard normal cumulative distribution function, α and β are parameters which controls the shape of the fragility curve. Thus, α is the median which controls the location of the fragility curve and β is the log-normal standard deviation which represents the dispersion of the fragility curve.

ESTIMATION METHOD FOR FRAGILITY CURVE

In this paper, we compare the results of two different estimation methods, LSE and MLE, for establishing the fragility curve. The optimal method is statistically proven based on the assumptions and properties inherent to each method.

Least Squares Estimation

Least squares estimation is the method which gives the minimum sum of squared errors in finding the optimal parameter values. The error term expresses the difference between the sample values, Y_i, and the estimated values, $\hat{Y}_i$. The estimated values $\hat{Y}_i$ can be written as $E[Y_i|X_i]$. The least squares estimation is used for a simple linear regression. Given X is an independent variable, Y is a dependent variable, and β is a constant. Then, a linear relationship between Y and X can be set up as shown in Eq. (4):

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 \tag{4}$$

Considering the population regression model with p parameters and n observations written as follows:

$$\begin{aligned}
\hat{Y}_1 &= E(Y_1|X_1) = \beta_0 + \beta_1 x_{1,1} + \beta_2 x_{2,1} + \ldots + \beta_{p-1} x_{p-1,1} \\
\hat{Y}_2 &= E(Y_2|X_2) = \beta_0 + \beta_1 x_{1,2} + \beta_2 x_{2,2} + \ldots + \beta_{p-1} x_{p-1,2} \\
&\vdots \quad \vdots \quad \vdots \quad \vdots \\
\hat{Y}_n &= E(Y_n|X_n) = \beta_0 + \beta_1 x_{1,n} + \beta_2 x_{2,n} + \ldots + \beta_{p-1} x_{p-1,n}
\end{aligned} \tag{5}$$

Then, the matrix form is cast in the following form:

$$\hat{\boldsymbol{Y}} = E(\boldsymbol{Y}|\boldsymbol{X}) = \boldsymbol{X}\boldsymbol{\beta} \tag{6}$$

$$\hat{\boldsymbol{Y}} = \begin{bmatrix} \hat{Y}_1 \\ \hat{Y}_2 \\ \vdots \\ \hat{Y}_n \end{bmatrix}; \boldsymbol{X} = \begin{bmatrix} 1 & x_{1,1} & x_{2,1} & \cdots & x_{p-1,1} \\ 1 & x_{1,2} & x_{2,2} & \cdots & x_{p-1,2} \\ \vdots & \vdots & \vdots & & \vdots \\ 1 & x_{1,n} & x_{2,n} & \cdots & x_{p-1,n} \end{bmatrix}; \boldsymbol{\beta} = \begin{bmatrix} \beta_1 \\ \beta_2 \\ \vdots \\ \beta_{p-1} \end{bmatrix}$$

Estimates of the error terms refers to the differences between the observed value of the dependent variable and its predicted value in the model:

$$Y_i - \hat{Y}_i = \varepsilon_i \tag{7}$$

$$\varepsilon_i = Y_i - \hat{Y}_i = Y_i - E\left[Y_i|X_i\right] \tag{8}$$

$$S = \sum_{i=1}^{n} \varepsilon_i^2 = \sum_{i=1}^{n} \left(Y_i - E\left[Y_i|X_i\right]\right)^2 = \sum_{i=1}^{n} \left(Y_i - \beta_0 - \beta_1 X_i\right)^2 \tag{9}$$

Eq. (9) can be expressed in matrix form as follows:

$$\begin{aligned}
\boldsymbol{S} &= \boldsymbol{\varepsilon}'\boldsymbol{\varepsilon} = (\boldsymbol{Y} - \boldsymbol{X}\boldsymbol{\beta})'(\boldsymbol{Y} - \boldsymbol{X}\boldsymbol{\beta}) \\
&= \boldsymbol{Y}'\boldsymbol{Y} - \boldsymbol{\beta}'\boldsymbol{X}'\boldsymbol{Y} - \boldsymbol{Y}'\boldsymbol{X}\boldsymbol{\beta} + \boldsymbol{\beta}'\boldsymbol{X}'\boldsymbol{X}\boldsymbol{\beta} = \boldsymbol{Y}'\boldsymbol{Y} - 2\boldsymbol{\beta}'\boldsymbol{X}'\boldsymbol{Y} + \boldsymbol{\beta}'\boldsymbol{X}'\boldsymbol{X}\boldsymbol{\beta}
\end{aligned} \tag{10}$$

It should be noted that $\boldsymbol{\beta}'\boldsymbol{X}'\boldsymbol{Y}$ and $\boldsymbol{Y}'\boldsymbol{X}\boldsymbol{\beta}$ are the same scalar. Then, the least squares estimation of β is shown in Eq. (11) and Eq. (12)

$$\frac{\partial \boldsymbol{S}}{\partial \hat{\boldsymbol{\beta}}} = \frac{\partial \boldsymbol{\varepsilon}'\boldsymbol{\varepsilon}}{\partial \hat{\boldsymbol{\beta}}} = -2\boldsymbol{X}'\boldsymbol{Y} + 2\boldsymbol{X}'\boldsymbol{X}\hat{\boldsymbol{\beta}} = 0 \tag{11}$$

$$\hat{\boldsymbol{\beta}}_{OLS} = \left(\boldsymbol{X}'\boldsymbol{X}\right)^{-1}\boldsymbol{X}'\boldsymbol{Y} \tag{12}$$

where $\hat{\boldsymbol{\beta}}_{OLS}$ is the least squares estimator of β.

Assumptions of LSE

1. The dependent variable, $\boldsymbol{Y}$, is continuous.
2. The relationship between the dependent variable, $\boldsymbol{Y}$, and the independent variable, $\boldsymbol{X}$, is linear.
3. Observations are independently and randomly drawn.
4. The error term has the expected value equal to zero and the variation equal to σ^2.
   $E\left[\varepsilon_i\right] = 0$; $Var\left[\varepsilon_i\right] = \sigma^2\mathbf{I}$
5. The error term is not auto correlated.
   $COV\left[\varepsilon_i, \varepsilon_j\right] = 0$; if $i \neq j$
6. The error term, ε, is independent of $\boldsymbol{X}$.
   $COV\left[X_i, \varepsilon_j\right] = 0$; for all i and j

7. The error term is approximately normally distributed.

$\varepsilon_i \approx N(0,\sigma^2)$; for i = 1, 2, …, n

We can write this in matrix form as $\boldsymbol{\varepsilon} \approx N(0,\sigma^2\mathbf{I})$ where $\mathbf{I}$ is identity matrix. From this assumption, the distribution of the dependent variable, $\boldsymbol{Y}$, is written as: $\boldsymbol{Y} \approx N(\boldsymbol{X\beta},\sigma^2\mathbf{I})$

The properties of LSE

1. The estimator of least squares method is unbiased estimator. The estimator is unbiased if and only if the expected value of an estimator, $E[\hat{\beta}]$ equals parameter β, that is,

$$E[\hat{\beta}] = \beta \tag{13}$$

From Eq. (12), we derive the following equation:

$$\begin{aligned}\hat{\boldsymbol{\beta}}_{OLS} &= (\boldsymbol{X'X})^{-1}\boldsymbol{X'Y} = (\boldsymbol{X'X})^{-1}\boldsymbol{X'}(\boldsymbol{X\beta}+\boldsymbol{\varepsilon}) \\ &= (\boldsymbol{X'X})^{-1}(\boldsymbol{X'X})\boldsymbol{\beta} + (\boldsymbol{X'X})^{-1}\boldsymbol{X'\varepsilon} \\ &= \boldsymbol{\beta} + (\boldsymbol{X'X})^{-1}\boldsymbol{X'\varepsilon} \end{aligned} \tag{14}$$

$$E[\hat{\boldsymbol{\beta}}_{OLS}] = E[\boldsymbol{\beta}] + E[\boldsymbol{X}^{-1}\boldsymbol{\varepsilon}] = \boldsymbol{\beta} + \boldsymbol{X}^{-1}E[\boldsymbol{\varepsilon}]$$

According to Assumption 4, if $E[\varepsilon_i]=0$ then $E[\hat{\boldsymbol{\beta}}_{OLS}] = \boldsymbol{\beta}$

Therefore, $\hat{\boldsymbol{\beta}}_{OLS}$ is an unbiased estimator of β.

2. The least squares estimator is an efficient estimator. The estimator is efficient if and only if the variance of estimator, $V[\hat{\beta}]$ is minimum

$$Var[\hat{\boldsymbol{\beta}}_{OLS}] = E\left[(\hat{\boldsymbol{\beta}}_{OLS}-\boldsymbol{\beta})(\hat{\boldsymbol{\beta}}_{OLS}-\boldsymbol{\beta})'\right] \tag{15}$$

From Eq. (14), we now obtain:

$$\hat{\boldsymbol{\beta}}_{OLS} - \boldsymbol{\beta} = (\boldsymbol{X'X})^{-1}\boldsymbol{X'\varepsilon}$$

$$\begin{aligned} Var[\hat{\boldsymbol{\beta}}_{OLS}] &= E\left[((\boldsymbol{X'X})^{-1}\boldsymbol{X'\varepsilon})((\boldsymbol{X'X})^{-1}\boldsymbol{X'\varepsilon})'\right] \\ &= (\boldsymbol{X'X})^{-1}\boldsymbol{X'}E[\boldsymbol{\varepsilon\varepsilon'}]\boldsymbol{X}(\boldsymbol{X'X})^{-1} \end{aligned}$$

According to Assumption 4, given

$Var[\varepsilon_i] = \sigma^2\mathbf{I} = E[(\varepsilon - E[\varepsilon])^2] = E[\varepsilon^2]$ then

$$\begin{aligned} Var[\hat{\boldsymbol{\beta}}_{OLS}] &= (\boldsymbol{X'X})^{-1}\boldsymbol{X'}\sigma^2\mathbf{I}\boldsymbol{X}(\boldsymbol{X'X})^{-1} \\ &= \sigma^2(\boldsymbol{X'X})^{-1} \end{aligned} \tag{16}$$

3. The estimator of least square method is the best unbiased estimator.

Given $\hat{\boldsymbol{\beta}}^* = [(\boldsymbol{X'X})^{-1}\boldsymbol{X'} + \boldsymbol{A}]\boldsymbol{Y}$, where $\boldsymbol{A}$ is a matrix which treats $\hat{\boldsymbol{\beta}}^*$ as the unbiased parameter.

$$E[\hat{\boldsymbol{\beta}}^*] = \boldsymbol{\beta}$$

$$\begin{aligned}\boldsymbol{\beta} &= [(\boldsymbol{X'X})^{-1}\boldsymbol{X'} + \boldsymbol{A}]E[\boldsymbol{Y}] \\ &= \boldsymbol{\beta} + \boldsymbol{AX\beta}\end{aligned}$$

Thus, if $\boldsymbol{AX} = 0$ then $\hat{\boldsymbol{\beta}}^* = (\boldsymbol{X'X})^{-1}\boldsymbol{X'Y} = \hat{\boldsymbol{\beta}}_{OLS}$

$$Var[\hat{\boldsymbol{\beta}}^*] = E\left[(\hat{\boldsymbol{\beta}}^*-\boldsymbol{\beta})(\hat{\boldsymbol{\beta}}^*-\boldsymbol{\beta})'\right]$$

$$= E\left[((\boldsymbol{X'X})^{-1}\boldsymbol{X'Y} + \boldsymbol{AY} - \boldsymbol{\beta})((\boldsymbol{X'X})^{-1}\boldsymbol{X'Y} + \boldsymbol{AY} - \boldsymbol{\beta})'\right]; \boldsymbol{Y} = \boldsymbol{X\beta} + \boldsymbol{\varepsilon}$$

$$= E\left[((\boldsymbol{X'X})^{-1}\boldsymbol{X'\varepsilon} + \boldsymbol{AX\beta} + \boldsymbol{A\varepsilon})((\boldsymbol{X'X})^{-1}\boldsymbol{X'\varepsilon} + \boldsymbol{AX\beta} + \boldsymbol{A\varepsilon})'\right]; \boldsymbol{AX} = 0$$

$$= E\left[((\boldsymbol{X'X})^{-1}\boldsymbol{X'\varepsilon} + \boldsymbol{A\varepsilon})((\boldsymbol{X'X})^{-1}\boldsymbol{X'\varepsilon} + \boldsymbol{A\varepsilon})'\right]$$

$$= \left[((\boldsymbol{X'X})^{-1}\boldsymbol{X'X}(\boldsymbol{X'X})^{-1}) + \boldsymbol{AA'} + (\boldsymbol{X'X})^{-1}(\boldsymbol{AX})' + (\boldsymbol{AX})(\boldsymbol{X'X})^{-1}\right]\sigma^2; \boldsymbol{AX} = 0$$

$$= \left[(\boldsymbol{X'X})^{-1} + \boldsymbol{AA'}\right]\sigma^2$$

Given $\boldsymbol{AA'} = \boldsymbol{B} = (b_{ij})$, where is $b_{ij} > 0$. Then, $Var[\hat{\boldsymbol{\beta}}^*]$ is minimum if and only if $b_{ij} = 0$ for all i=1, 2,…,p.

Given $\boldsymbol{A} = (a_{ij})$, $b_{ii} = \sum_{j=1}^{n} a_{ij}^2 = 0$ Therefore,

$a_{ij} = 0$ for i =1, 2, …, p and j = 1, 2, …, p

That is, when $\boldsymbol{A} = 0$, $\hat{\boldsymbol{\beta}}^* = (\boldsymbol{X'X})^{-1}\boldsymbol{X'Y} = \hat{\boldsymbol{\beta}}_{OLS}$ is the minimum variance parameter of β.

The least squares estimation has many assumptions. This estimation method is considered to be improper to develop the fragility curve using structural damage data due to some invalid assumptions. For instance, Assumption 4, $Var[\varepsilon_i]=\sigma^2\mathbf{I}$, which assumes the error term has a constant variance and Assumption 6, $COV[X_i,\varepsilon_j]=0$, which implies that the error is uncorrelated with all independent variables. The variance of the errors of structure damage is small when the IM (intensity measure) is small (most structures are not damaged). That is, the variance increases when the structure starts to damage and then the variance decreases again when IM is large because most structures are damaged. As a result, the variance of the errors is not constant and depends on IM. Thus, Assumption 7, $\varepsilon_i = N(0,\sigma^2)$ becomes invalid. In addition, review of the literature indicates that the data of structural component failure appear to fit the log-normal distribution well. Although the log-normal distribution can be transformed to linear logarithm, properties of the error term are changed.

The Method of Maximum Likelihood

Maximum likelihood estimation is a method for parameter estimation by maximizing the likelihood function. Given X is a random variable with probability distribution function $f(X\ \theta)$, where θ is a single unknown parameter. Let $x_1, x_2, ..., x_n$ be the observed values in a random sample of size n. Then, the likelihood function of a sample is defined as:

$$\begin{aligned} L(\theta|X) &= L(\theta|x_1,x_2,...,x_n) = \prod_i^n f(x_i|\theta) \\ &= f(x_1,\theta)\cdot f(x_2,\theta)\cdots f(x_n,\theta) \end{aligned} \tag{17}$$

The likelihood function depends on the unknown parameter θ only. Essentially, the maximum likelihood estimator is the value of θ that

maximizes the probability of occurrence of the sample by differentiating $L(\theta|X)$ with respect to θ and setting that derivative equal to zero:

$$\frac{\partial L(\theta|X)}{\partial \theta}=0 \tag{18}$$

Then, with the second derivative value being less than zero we have a maximum:

$$\frac{\partial^2 L(\theta|X)}{\partial \theta^2}<0 \tag{19}$$

The assumptions of MLE

1) The observations are independently and randomly drawn.
2) The parameter $\hat{\theta}$ maximizes the likelihood of the sample, i.e., it represents the maximum likelihood estimator of θ in which $L(\hat{\theta}|X)\geq L(\theta|X)$.

Properties of MLE

1. The maximum likelihood estimator does not need to be unbiased since it can be corrected. The estimator is unbiased if and only if the expected value of an estimator, $E[\hat{\theta}]$ equals parameter θ.

We consider the random sample $x_1, x_2, ..., x_n$, where n is the random sample size. The random sampling distribution is assumed to be normal which comprises two unknown parameters, μ and σ^2. The probability density function of normal distribution can be expressed as:

$$f(x)=\frac{1}{\sqrt{2\pi\sigma^2}}e^{-(1/2)[(x-\mu)/\sigma]^2} \tag{20}$$

$$L(\mu,\sigma^2|X)=L(\mu,\sigma^2|x_1,x_2,...,x_n)=\prod_{i=1}^{n}\left(\frac{1}{\sqrt{2\pi\sigma^2}}e^{-(1/2)[(x_i-\mu)/\sigma]^2}\right)$$

$$=\frac{1}{\left(2\pi\sigma^2\right)^{n/2}}e^{-(1/2\sigma^2)\sum_{i=1}^{n}(x_i-\mu)^2} \tag{21}$$

Simplifying Eq. (21) by taking the log of both sides yields:

$$\ln L(\mu,\sigma^2|X)=-\frac{n}{2}\ln\left(2\pi\sigma^2\right)-\frac{1}{2\sigma^2}\sum_{i=1}^{n}(x_i-\mu)^2 \tag{22}$$

Then, the estimator of μ and σ^2 is

$$\frac{\partial \ln L(\mu,\sigma^2|X)}{\partial \hat{\mu}}=\frac{\partial\left(-\frac{n}{2}\ln\left(2\pi\sigma^2\right)-\frac{1}{2\sigma^2}\sum_{i=1}^{n}(x_i-\hat{\mu})^2\right)}{\partial\hat{\mu}}=-\frac{1}{\sigma^2}\sum_{i=1}^{n}(x_i-\hat{\mu})=0$$

$$\hat{\mu}=\frac{1}{n}\sum_{i=1}^{n}x_i=\bar{x} \tag{23}$$

Next, we check that the estimator $\hat{\mu}$ gives maximum L:

$$\frac{\partial^2 \ln L(\mu,\sigma^2|X)}{\partial\hat{\mu}^2}=\frac{\partial\left(-\frac{1}{\sigma^2}\sum_{i=1}^{n}(x_i-\hat{\mu})\right)}{\partial\hat{\mu}}=-\frac{1}{\sigma^2}\frac{\partial\left(\sum_{i=1}^{n}x_i-\sum_{i=1}^{n}\hat{\mu}\right)}{\partial\hat{\mu}}=-\frac{n}{\sigma^2}<0$$

$$\frac{\partial \ln L(\mu,\sigma^2|X)}{\partial\hat{\sigma}^2}=\frac{\partial\left(-\frac{n}{2}\ln\left(2\pi\hat{\sigma}^2\right)-\frac{1}{2\hat{\sigma}^2}\sum_{i=1}^{n}(x_i-\mu)^2\right)}{\partial\hat{\sigma}^2}=\frac{-n}{2\hat{\sigma}^2}+\frac{1}{2\hat{\sigma}^4}\sum_{i=1}^{n}(x_i-\mu)^2=0$$

$$\hat{\sigma}^2=\frac{1}{n}\sum_{i=1}^{n}(x_i-\bar{x})^2 \tag{24}$$

And if the estimator $\hat{\sigma}^2$ treats maximum L then

$$\frac{\partial^2 \ln L(\mu,\sigma^2|X)}{\partial\left(\hat{\sigma}^2\right)^2}=\frac{\partial\left(\frac{-n}{2\hat{\sigma}^2}+\frac{1}{2\hat{\sigma}^4}\sum_{i=1}^{n}(x_i-\mu)^2\right)}{\partial\hat{\sigma}^2}=\frac{n}{2\hat{\sigma}^4}-\frac{1}{\hat{\sigma}^6}\sum_{i=1}^{n}(x_i-\mu)^2$$

$$=\frac{n}{2\hat{\sigma}^4}-\frac{1}{\hat{\sigma}^6}\left(n\hat{\sigma}^2\right)=\frac{n}{2\hat{\sigma}^4}-\frac{n}{\hat{\sigma}^4}=-\frac{n}{2\hat{\sigma}^4}<0 \quad \text{OK.}$$

According to Eq. (19), we obtain:

$$E[\hat{\mu}]=E[\bar{x}]=\frac{1}{n}E[x_1+x_2+x_3+\ldots+x_n]=\frac{1}{n}\sum_{i=1}^{n}E[x_i]=\frac{1}{n}(n\mu)=\mu \tag{25}$$

Thus, $\hat{\mu}$ denotes an unbiased estimator of μ. From Eq. (24), we now derive the following form:

$$\hat{\sigma}^2=\frac{1}{n}\sum_{i=1}^{n}(x_i-\bar{x})^2=\frac{1}{n}\sum_{i=1}^{n}(x_i-\mu+\mu-\bar{x})^2=\frac{1}{n}\sum_{i=1}^{n}\left((x_i-\mu)-(\bar{x}-\mu)\right)^2$$

$$=\frac{1}{n}\left(\sum_{i=1}^{n}(x_i-\mu)^2-2n(\bar{x}-\mu)^2+\sum_{i=1}^{n}(\bar{x}-\mu)^2\right)$$

$$E\left[\hat{\sigma}^2\right]=\frac{1}{n}E\left[\sum_{i=1}^{n}(x_i-\mu)^2-2n(\bar{x}-\mu)^2+\sum_{i=1}^{n}(\bar{x}-\mu)^2\right]$$

$$=\frac{1}{n}\left(\sum_{i=1}^{n}V[x_i]-nV[\bar{x}]\right)$$

Based on the properties of normal distribution in which $V[x_i]=\sigma^2$ and $V[\bar{x}]=\frac{\sigma^2}{n}$, we obtain

$$E\left[\hat{\sigma}^2\right]=\frac{1}{n}\left(\sum_{i=1}^{n}\sigma^2-n\frac{\sigma^2}{n}\right)$$

$$=\frac{1}{n}\left(n\sigma^2-n\frac{\sigma^2}{n}\right)$$

$$=\frac{(n-1)\sigma^2}{n}\neq\sigma^2 \tag{26}$$

$\hat{\sigma}^2$ is the biased parameter of σ^2. Then, $\hat{\sigma}^2$ is corrected to be unbiased as follows

$$\hat{\sigma}^2=\frac{1}{n}\left(\frac{n}{n-1}\right)\sum_{i=1}^{n}(x_i-\bar{x})^2=\frac{1}{n-1}\sum_{i=1}^{n}(x_i-\bar{x})^2 \tag{27}$$

2. The maximum likelihood estimator is efficient. The estimator is efficient if and only if the variance of an estimator, $V[\hat{\theta}]$ is minimal and unbiased:

$$V[\hat{\mu}]=Var\left[\frac{x_1+x_2+x_3\ldots x_n}{n}\right]$$

$$=\frac{1}{n^2}\left(E[x_1]+E[x_2]+E[x_3]+\ldots+E[x_n]\right)$$

$$=\frac{n\sigma^2}{n^2}=\frac{\sigma^2}{n} \tag{28}$$

To determine the variance of $\hat{\sigma}^2$, Chi-square distribution is utilized. Chi-square distribution is the distribution of the sum of squared standard normal deviates. Given the random variable for a Chi-square distribution with *k* degrees of freedom; that is,

$$Q=Z_1^2+Z_2^2+Z_3^2+\ldots+Z_k^2\sim\chi^2_{(k)} \tag{29}$$

where Z_i is a standard normal distribution which is independently and identically distributed, that is, $Z_i \sim N(0,1)$. The expected value and variance of Q are written as:

$$E(Q) = k$$
$$Var(Q) = 2k \quad (30)$$

According to Eq. (20), given $z = \frac{x-\mu}{\sigma}$ which can be written as $\frac{x-\mu}{\sigma} \sim N(0,1)$, it can be shown that

$$\sum_{i=1}^{n}\left(\frac{x_i-\mu}{\sigma}\right)^2 \sim \chi^2_{(n)}$$

$$\sum_{i=1}^{n}\left(\frac{x_i-\mu}{\sigma}\right)^2 = \sum_{i=1}^{n}\left(\frac{x_i-\mu-\bar{x}+\bar{x}}{\sigma}\right)^2 = \sum_{i=1}^{n}\left(\frac{x_i-\bar{x}}{\sigma}+\frac{\bar{x}-\mu}{\sigma}\right)^2$$

$$= \sum_{i=1}^{n}\left(\frac{x_i-\bar{x}}{\sigma}\right)^2 + \left(\frac{\bar{x}-\mu}{\sigma/\sqrt{n}}\right)^2$$

$$= \chi^2_{(n-1)} + \chi^2_{(1)} \quad (31)$$

Considering Eq. (28), the second term on the right-hand side of the equation is the normal distribution of $\bar{X}$ which gives a Chi-square distribution with 1 degree of freedom. Then, the formula becomes

$$\sum_{i=1}^{n}\left(\frac{x_i-\bar{x}}{\sigma}\right)^2 = \chi^2_{(n-1)} \quad (32)$$

From Eq. (27), the unbiased estimator of parameter σ^2, denoted as $\hat{\sigma}^2 = \frac{1}{n-1}\sum_{i=1}^{n}(x_i-\bar{x})^2$ or alternatively written as $\sum_{i=1}^{n}(x_i-\bar{x})^2 = (n-1)\hat{\sigma}^2$, is substituted into Eq. (32):

$$\frac{(n-1)\hat{\sigma}^2}{\sigma^2} = \chi^2_{(n-1)}$$

Now, from Eq. (30) we have

$$V\left[\frac{(n-1)\hat{\sigma}^2}{\sigma^2}\right] = 2(n-1)$$

$$V\left[\hat{\sigma}^2\right] = \frac{2\sigma^4}{(n-1)} \quad (33)$$

3. The maximum likelihood estimation method appears to be the best possible or optimal estimator because its variance of estimator equals the Cramér -Rao Lower Bound which yields a minimum variance estimator. Let $f(x|\ \theta)$ be the probability density function of the population and $\hat{\theta}$ denotes an unbiased estimator of parameter θ. The Cramér -Rao Lower Bound can be expressed as:

$$V(\hat{\theta}) \geq \frac{1}{n\mathrm{E}\left[\left(\frac{\partial \ln f(x|\theta)}{\partial\theta}\right)^2\right]} \quad (34)$$

Assuming normal distribution, it follows that

$$f\left(x|\mu,\sigma^2\right) = \frac{1}{\sqrt{2\pi\sigma^2}}e^{-(1/2)\left[(x-\mu)/\sigma\right]^2}, -\infty < x < \infty$$

$$\ln f\left(x|\mu,\sigma^2\right) = -\frac{1}{2}\ln\left(2\pi\sigma^2\right) - \frac{1}{2\sigma^2}(x-\mu)^2$$

$$\frac{\partial \ln f\left(x|\mu,\sigma^2\right)}{\partial\mu} = \frac{1}{\sigma^2}(x-\mu)$$

$$E\left[\left(\frac{\partial \ln f\left(x|\mu,\sigma^2\right)}{\partial\mu}\right)^2\right] = \frac{1}{\sigma^4}\mathrm{E}(x-\mu)^2 = \frac{V[x]}{\sigma^4} = \frac{\sigma^2}{\sigma^4} = \frac{1}{\sigma^2}$$

Taking into account Eq. (28), substituting the above equation into Eq. (34) yields

$$\frac{1}{n\mathrm{E}\left[\left(\frac{\partial \ln f\left(x|\mu,\sigma^2\right)}{\partial\mu}\right)^2\right]} = \frac{1}{n\left(\frac{1}{\sigma^2}\right)} = \frac{\sigma^2}{n} = V[\hat{\mu}] \quad (35)$$

$$\frac{\partial \ln f\left(x|\mu,\sigma^2\right)}{\partial\sigma^2} = -\frac{1}{2\sigma^2} + \frac{1}{2\sigma^4}(x-\mu)^2$$

$$E\left[\left(\frac{\partial \ln f\left(x|\mu,\sigma^2\right)}{\partial\sigma^2}\right)^2\right] = \frac{1}{4\sigma^4} + \frac{1}{4\sigma^4}\left[V\left[\left(\frac{x-\mu}{\sigma}\right)^2\right] + \left(E\left[\left(\frac{x-\mu}{\sigma}\right)^2\right]\right)^2\right] - \frac{1}{2\sigma^6}V[x]$$

From Eq. (30), since $V\left[\left(\frac{x-\mu}{\sigma}\right)^2\right] = 2$, $E\left[\left(\frac{x-\mu}{\sigma}\right)^2\right] = 1$

then,

$$E\left[\left(\frac{\partial \ln f\left(x|\mu,\sigma^2\right)}{\partial\sigma^2}\right)^2\right] = \frac{1}{4\sigma^4} + \frac{1}{4\sigma^4}(2+1) - \frac{1}{2\sigma^4} = \frac{1}{2\sigma^4}$$

Now, the above equation is substituted into Eq. (34) and Eq. (33) is taken into consideration:

$$\frac{1}{n\mathrm{E}\left[\left(\frac{\partial \ln f\left(x|\mu,\sigma^2\right)}{\partial\sigma^2}\right)^2\right]} = \frac{1}{n\left(\frac{1}{2\sigma^4}\right)} = \frac{2\sigma^4}{n} < V\left[\hat{\sigma}^2\right] = \frac{2\sigma^4}{(n-1)} \quad (36)$$

4. The maximum likelihood estimator is consistent because it converges to the true value of parameter being estimated.

From Eq. (26), despite having $E\left[\hat{\sigma}^2\right] = \frac{(n-1)\sigma^2}{n} \neq \sigma^2$, but $E\left[\hat{\sigma}^2\right]$ converges to σ^2 for a large sample size (n-1 $\approx$ n). In the same way, $2\sigma^4/n$ converges to $V\left[\hat{\sigma}^2\right] = \frac{2\sigma^4}{(n-1)}$ as shown in Eq. (36).

The development of fragility curve using the maximum likelihood method have been adopted in many previous studies [1], [4]-[10]. The review of literature shows that the structural component failure data fits with the lognormal distribution well. A log-normal distribution appears to set robust precedent in risk analysis and assessment. Furthermore, theoretically, applying a lognormal distribution yields zero probability density at and below zero intensity measure (IM).

TESTING ESTIMATION METHOD FOR FRAGILITY CURVE

As a first step of the method for the fragility curve development, the parameter values of μ and σ^2 assuming a lognormal distribution is chosen. Next, 100 groups of 50 data is randomly generated from these parameters. Finally, estimated values of the parameter mean and variance ($\hat{\mu}$ and $\hat{\sigma}^2$) are

obtained from using the MLE and LSE methods for each group of data. Precisely, $\hat{\mu}$ is not equal to μ for all groups of data, as well as the estimated value of $\hat{\sigma}^2$. A summary of findings is presented in Table 1. The distribution of estimated parameter value is shown in Fig.2. The estimated probability density function, which is inherent in Eq. (2), appears to have a bell-shaped curve. The maximum likelihood estimation gives μ = -0.80 and σ^2 = 0.40 which has a smaller variance than the variance of the least square estimation. The results show that the MLE method based on the lognormal approach yields better estimates than the LSE method.

Table 1 The estimated parameters by LSE and MLE

Methods in numerical fitting	Estimated parameter		Error (%)	
	μ	σ^2	μ	σ^2
Least Squares	-0.8116	0.3994	0.0065	0.0016
Maximum Likelihood	-0.7985	0.4003	0.0063	0.0016

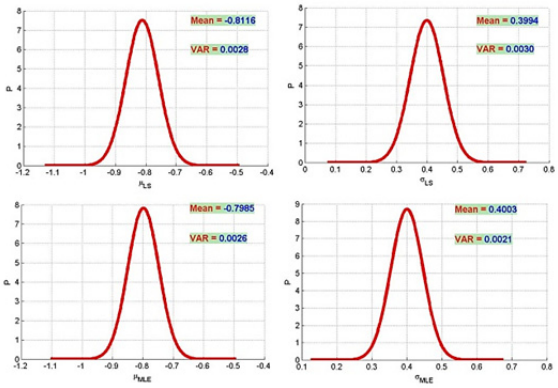

Fig. 2 The distribution of estimated value.

CONCLUSIONS

In this paper, the estimated parameter of mean (μ) and variance (σ^2) of a lognormal distribution are determined either by the maximum likelihood estimation (MLE) or by the least squares estimation (LSE). Then, the estimated results obtained from these two methods are compared with each other. To develop a fragility curve, the method starts by choosing the parameter values of μ and σ^2, assuming a lognormal distribution. The results indicate that the size of variance obtained with MLE is smaller than the variance obtained with LSE. In summary, the MLE method based on the lognormal approach gives better outcomes of the estimated parameter of mean (μ) and variance (σ^2) of lognormal distribution. In other words, fragility curves developed by the MLE method appears to be more consistent and efficient than those developed by the LSE method.

HEAVY METAL CONCENTRATION CHANGE IN OYSTER AFTER CHANGING LIVING PLACES WITH VARIOUS HEAVY METAL CONDITION IN OSAKA BAY, JAPAN

Tetsuya Fukano[1] and Hiroyuki Ii[2]
[1]Graduate School of Systems Engineering, Wakayama University, Japan
[2]Faculty of Systems Engineering, Wakayama University, Japan

ABSTRACT

Heavy metal concentration of oysters in the Osaka Bay were measured. As the result, high Zn and Cu concentration oyster was found in Takaishi fishing port in the Osaka Bay. In 2018, Cu concentration of oyster sampled at Takaishi fishing port was extremely high, 7.8 ‰ dry weight. On the other hand, Zn and Cu concentrations of these oysters gradually increased after these oysters living place changed from natural beach area of Takashinohama to the boat maintenance sloops of Takaishi fishing port. Similarly after changing living place from Takaishi fishing port to Izumiotsu port, heavy metal concentration of oyster at Takaishi fishing port gradually changed to heavy metal concentration of oyster at Izumiotsu port with 7 weeks. Cu, Mn, Fe, Ni, Pb and Zn concentrations of oyster sampled at Takaishi fishing port are high, but As concentration was low. Cu, Mn, Fe, Ni, Pb and Zn concentrations of oyster sampled at Izumiotsu port were low, but As concentration was high, 0.023~ 0.029 ‰ dry weight. The goal of the changing living place was concentration of naturally lived oyster at Izumiotu port. It means oyster do not keep accumulating the heavy metals. As the result heavy metal concentration of oyster was clarified to change with time. Each heavy metal concentration for various internal organs was measured. Cu, Fe, Pb and Zn concentrations in all internal organs decreased in direct ratio. Mn concentrations in mantle, gill showed various change. Ni concentration in gill showed various change. Concentrations of As in all internal organs increased in direct ratio. The speed of decrease, Pb was fastest in all heavy metal. Every metal concentrations of oyster changed gradually in Hepatic gland even the oyster was small one. And the speed of change was almost same to other tissues. Hepatic gland has blown or green color, so easy to find and separate. From this study, Hepatic gland has most high potential as an environmental index in oyster.

Keywords: Oyster, changing living place, heavy metal accumulation, internal organs, hepatic gland

INTRODUCTION

The absorption and accumulation of heavy metals in sea water by aquatic organisms was reported by Ikuta [1]. Concentration and distribution of toxic and essential metals in biological samples collected in Okayama prefecture were reported by Morita and Ogata [2]. Metal contamination of sea water was evaluated by seaweed [3] and in particular, metal concentration of seaweed along the Kii Peninsula was measured and high Cu, Fe and Zn concentrations were found around metal mines [4]. Use of seaweed is useful for sea contamination. The use of bivalves as possible sentinel marine organisms to monitor metal pollution in coastal water was reported by Takayanagi and Sakami [5].

"*Ostrea gigas*," a very popular coastal oyster, lives in the same location for several years, thus has high potential as a heavy metals index. The relation of Pb, Cd and Cr between sea water, sea sediment and oyster (*Crassostrea virginica*) was clarified and influence of metal contamination caused by the runoff of household and industrial discharge on oyster was evaluated in Mexico [6]. Then, this study is to clarify how to change heavy metal concentration of oyster with time and location condition, and determine the potential of oysters as an environmental index for heavy metal. Heavy metal concentration of oysters is measured with time after changing living place of oyster. Moved oyster was sampled every week for 7 weeks, and each heavy metal concentrations for various internal organ, mantle, gill, muscle, hepatic grand, others, and whole oyster were measured. The heavy metals measured were Cu, Mn, Fe, Ni, Pb, Zn and As. Cu concentrations of each oyster parts were analyzed at Oman Sea [7] and those of tissue were higher than those of shell although Pb concentrations of tissue were lower than those of shell.

METHOD

Shells of sampled oysters were opened carefully with a stainless-steel knife. The soft tissues of the oysters were cut into small pieces and put into pre-weighted laboratory dishes. The soft tissues were

dried at 60 degrees for a week. Each dried sample was ground manually into fine powder form by mortar and a pestle. Each dried ground sample was stored separately in airtight polypropylene bags.

0.020g of dried ground sample was mixed with 5.0 mL of concentric nitric acid in a glass vessel and then kept for a week at room temperature. After ground samples were dissolved by nitric acid completely, added 10mL water. And the solution was filtered with a 0.45μm filter and then dry weight concentrations of heavy metal were measured by Inductively Coupled Plasma (ICP).

RESULT

Oysters were changed living place from Takaishi fishing port to izumiotu port. At Takaishi, Oysters were lived on boat maintenance slope. On the slope, many small red paint flakes were peeled off from bottom of boats. The paint was anti-fouling paint, ingredient of the paint were Cu_2O and ZnO [8]. After changing place, oysters in polyethylene mesh net bags were hanged about 2m depth from surface at Izumiotsu port. At Izumiotsu port, anti-fouling paint flakes were not seen.

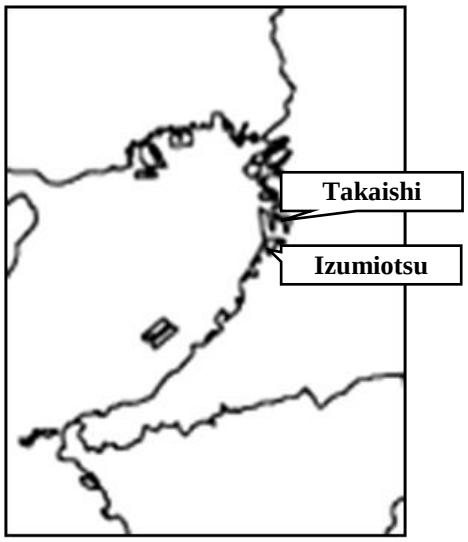

Fig.1 Sampling points
(Located at east side of Osaka Bay)

Oysters were sampled from Takaishi fishing port and moved to Izumiotu port at 5-Mar. 2019. Moved oyster was sampled every week for 7 weeks. And concentration of Cu, Mn, Fe, Ni, Pb, Zn and As for Mantle, Gill, Adductor muscle, hepatic gland, and whole oyster were measured. Samples were choose big oyster over 10g wet weight without shells. Concentrations of heavy metals in small oyster contained many irregular data. Last results of May in each figures showed heavy metal concentration in oyster naturally lived at Izumiotu port.

Cu concentration in oyster

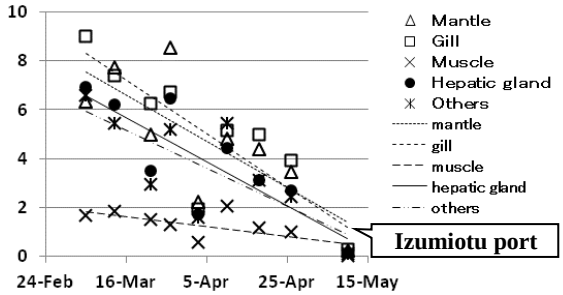

Fig. 1 Cu ‰ [dry wt.] in each internal organ

Fig.1 showed concentration of Cu in each internal organ decreased in direct ratio. Especially gill and hepatic gland were showed smooth decrease, R^2 were 0.72 and 0.68.

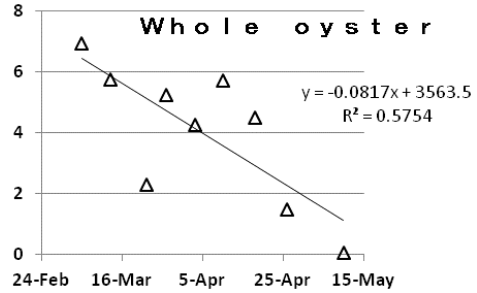

Fig. 2 Cu ‰ [dry wt.] in whole oyster

Fig.2 showed concentration of Cu in whole oyster decreased in almost direct ratio.

Mn concentration in oyster

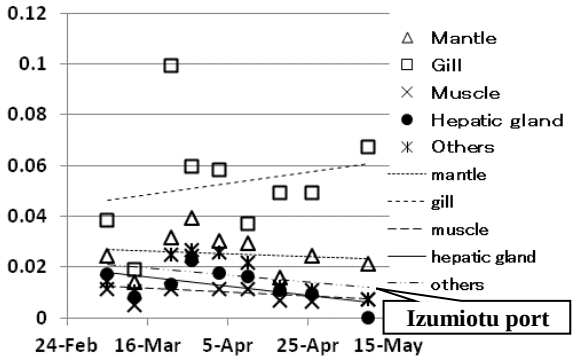

Fig. 3 Mn ‰ [dry wt.] in each internal organ

From Fig.3, Mn concentrations in mantle and gill showed various change.

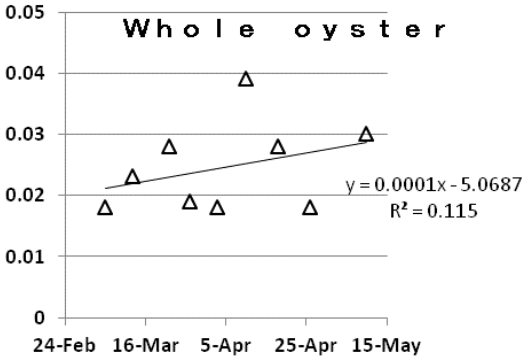

Fig. 4 Mn ‰ [dry wt.] in whole oyster

Fig.4 showed concentration of Mn in whole oyster gleatly changed. But concentration of Mn in hepatic gland decreased in almost direct ratio.

Fe concentration in oyster

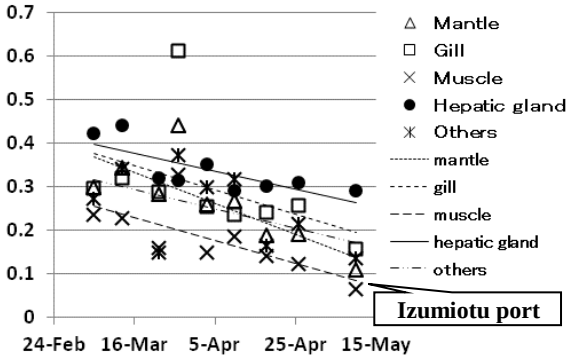

Fig. 5 Fe ‰ [dry wt.] in each internal organ

Fig. 5 showed concentration of Fe in each internal organ decreased in direct ratio roughly. Especially mantle and hepatic gland were showed smooth decrease, R^2 were 0.61 and 0.61.

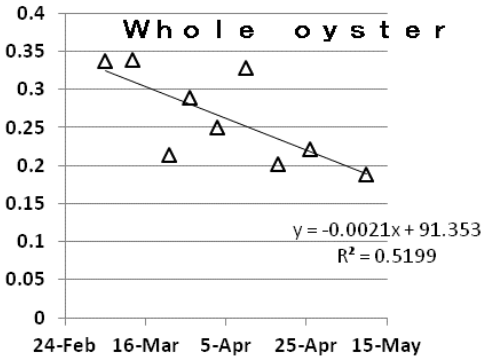

Fig. 6 Fe ‰ [dry wt.] in whole oyster

Fig. 6 showed concentration of Fe in whole oyster, decreased in almost direct ratio.

Ni concentration in oyster

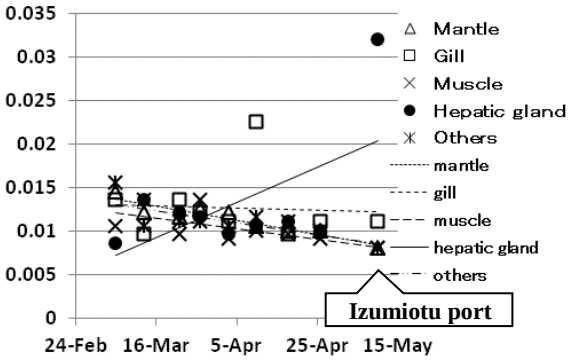

Fig. 7 Ni ‰ [dry wt.] in each internal organ

Fig. 7 showed concentration of Ni in each internal organ decreased in almost direct ratio except some errors. Especially mantle showed smooth decrease, R^2 was 0.86.

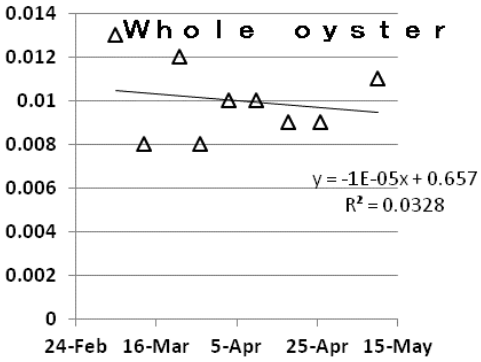

Fig. 8 Ni ‰ [dry wt.] in whole oyster

Fig. 8 showed concentration of Ni in whole oyster decreased in direct ratio roughly, R^2 were low 0.032.

Pb concentration in oyster

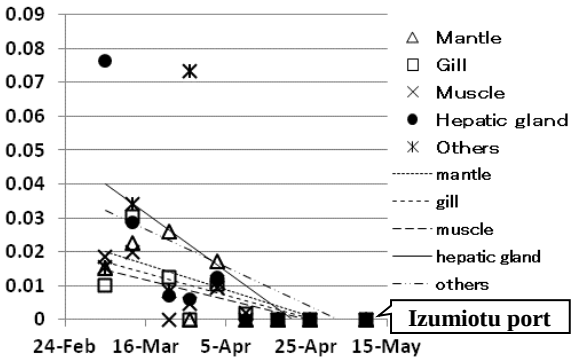

Fig. 9 Pb ‰ [dry wt.] in each internal organ

Fig. 9 showed concentration of Pb decreased in direct ratio. And the speed of decrease was fast.

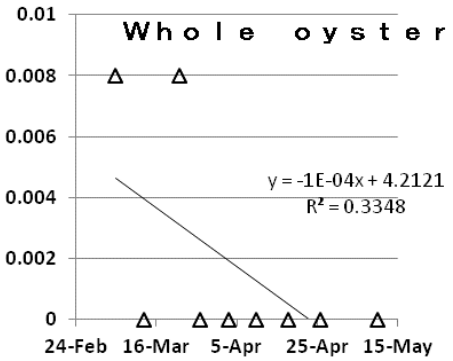

Fig. 10 Pb ‰ [dry wt.] in whole oyster

Fig. 9 and Fig. 10 showed concentration of Pb decreased in direct ratio. The speed of decrease, Pb was faster than other heavy metal.

Zn concentration in oyster

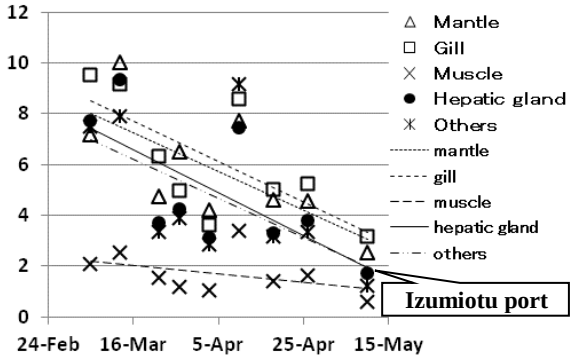

Fig. 11 Zn ‰ [dry wt.] in each internal organ

Fig. 11 showed concentration of Zn in each internal organ decreased in almost direct ratio.

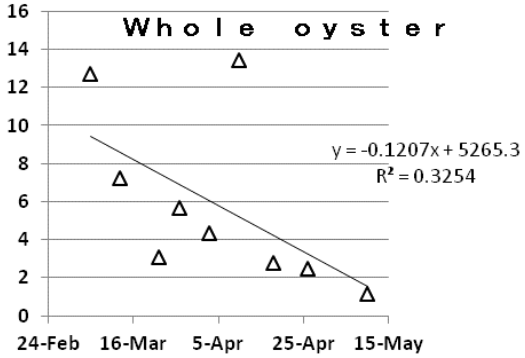

Fig. 12 Zn ‰ [dry wt.] in whole oyster

Fig. 12 showed concentration of Zn in whole oyster decreased in almost direct ratio except some errors.

As concentration in oyster

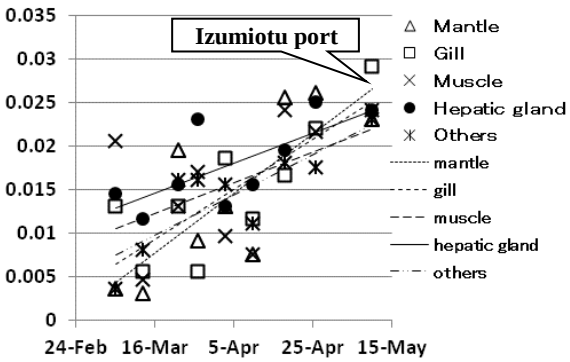

Fig. 13 As ‰ [dry wt.] in each internal organ

Fig. 13 showed concentration of AS in each internal organ increased in almost direct ratio.

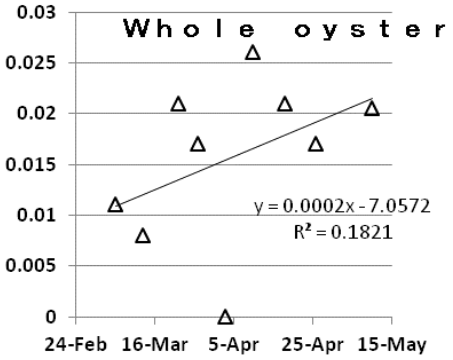

Fig. 14 As ‰ [dry wt.] in whole oyster

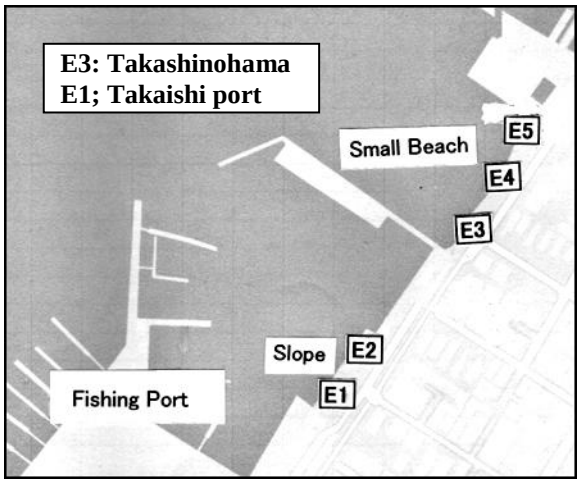
Fig. 14 showed concentration of As in whole oyster increased in direct ratio roughly.

From fig.1to14, results sometimes contained irregular data. But heavy metal concentrations of oyster changed gradually with relocation, and goal of the change was concentration of naturally lived oyster at Izumiotu port. Concentration of Cu, Fe, Ni in Mantle approach to goal in about 6 weeks, and bigger oyster showed smooth change. The change of Pb was fast, reached to goal in about 5 weeks. Concentration of As in oyster at izumiotu was higher than Takaishi, then concentration of As in moved oyster increased quickly.

Concentrations of Cu and Zn in changed living places oysters at Takashinohama port

Oysters were sampled from 10th January 2016 to 28th February 2016 at sampling point E1 and E3 to check for changes of Cu and Zn concentrations after changed living places.



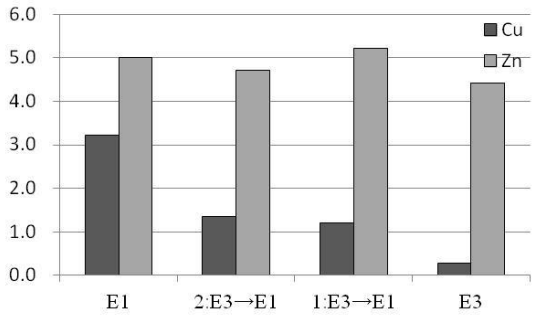


Fig.15 Concentrations of Cu and Zn in changed living places oysters. (‰ [dry wt.])

Oyster changing living places was done in the following way; "1:E3→E1" indicates that oysters were sampled 10th January 2016 at sampling point E3 and released at sampling point E1. Sampling point E3 was a beach area of Takashinohama, and sampling point E1 was an area of the boat maintenance sloops of Takaishi fishing port. Oysters changed living places were sampled again at sampling point E1, 23rd January 2016. Therefore, the "living time" at sampling point E1 was 13 days.

"2:E3→E1" indicates that oysters were sampled 11th February 2016 at sampling point E3 and released to sampling point E1. Oysters changed living places were sampled again at sampling point E1, 28th February 2016. Therefore, the "living time" at sampling point E1 was 17 days.

Fig.15 showed the relation between Cu and Zn concentrations of the oysters and living time at sampling point E1. Cu concentration increased with living time 0.3, 1.2, 1.7 and over 3.0 ‰ for living time from 0, 13, 17 days to long term. But Zn concentrations in oysters did not increased with location and living time at sampling point E1 and values were uniform. Therefore, sampling point E1 increased Cu concentration in the oysters but did not increase Zn concentration.

CONCLUSIONS

Cu, Fe, Ni, Pb, Zn, As concentrations of oyster changed gradually with relocation and goal of the change was concentration of naturally lived oyster at Izumiotu port. It means oyster do not keep accumulating the heavy metals. When changed living place 6~7 weeks, heavy metals concentrations of oyster approached to goal. And big oyster showed smooth change.

But concentration of Mn showed various change in Mantle and Gill. Mantle and Gill are outside tissues of oyster, so easy to be contaminated with fine particle size of mad or sand.

Every metal concentrations of oyster changed gradually in Hepatic gland even the oyster was small one. And the speed of change was almost same to other tissues. Hepatic gland has blown or green color, so easy to find and separate.

From this study, Hepatic gland has most high potential as an environmental index in oyster.

ABSTRACT

Recent disasters highlighted that water distribution systems (WDS) suffered greatly during seismic events. But people cannot afford to have extended water service interruption as it is essential for drinking, sanitation, and medical services. Thus, it is imperative that WDS provides adequate resistance to extreme events. And in the event of failure, it must recover functionality within short period. Resilience-based engineering ensures that infrastructures be robust to adequately resist seismic events and recover from failure fast. It also requires to have resources and redundant systems. This implies that WDS must satisfy resiliency requirements for it to function satisfactorily during and after seismic events. This study quantifies the resiliency of La Trinidad Water District (LTWD) through measuring the impacts of restoration sequences to recovery duration and knowing which sequence satisfies resiliency. LTWD, in Benguet, Philippines, is at risk to earthquake due to geologic and geographic setting, thus, it must be "resilient". In this study, restoration strategies were conducted using constrained spanning trees to determine the most efficient network connectivity. Horn's algorithm was applied for repair sequence. Results showed that restoration sequence is directly related to rapidity of resiliency. The shortest restoration resulted to a faster recovery to return back to its pre-event system functionality.

Keywords: Resilience, Horn's algorithm, Restoration curve, Earthquake, Water distribution network

INTRODUCTION

The Philippine Institute of Volcanology and Seismology (PHIVOLCS) [1] considered the province of Benguet to be, among the provinces in the Philippines, the third at risks to earthquakes considering its geologic and geographic setting. According to Mines and Geosciences Bureau (MGB) [2], La Trinidad - a municipality in Benguet is highly vulnerable to geologic hazards because of several active fault lines in the area. This makes the water infrastructure vulnerable to earthquake hazards.

The case study area is La Trinidad Water District (LTWD), located in La Trinidad in the province of Benguet (Fig. 1). La Trinidad is where Baguio City is located. Baguio city is considered to be the summer capital of the Philippines due to its cold weather and has become one of the country's top tourist destinations. LTWD is a local water district that serves 16 barangays with drinking water. It has been in operation for more than 30 years but has not received any technology-based upgrade yet. Its only upgrade is the continuous expansion of water pipe networks to serve a rapidly increasing demand. It has also increased its water source, from four to seventeen comprised of mixed spring and deep well sources. La Trinidad was devastated by a magnitude 7.8 earthquake in 1990 where casualties and damage to structure is considered to be among the deadliest earthquake that hits the country [3].

The area is surrounded by five (5) active major faults: (1) Philippine fault, (2) Digdig fault, (3) San Manuel fault, (4) Tebbo fault, and (5) Tubao fault. LTWD was lucky to have not suffered any major damage during the 1990 earthquake though there were reports of few pipe breakages due to joint pullout from the main transmission line, but was repaired immediately.

Because of great risks that earthquake hazard poses to the area of La Trinidad, it is important to for LTWD to satisfy water distribution network resiliency as it is of utmost importance that water supply remains functional during earthquake events for life safety, rescue, and healthcare operations. Hence, this study conducted the following: (1) assessment of the possible impact of earthquake hazard to LTWD, (2) evaluation of post-earthquake restoration strategy to ensure that functionality of LTWD can return back to its pre-event functionality at the soonest possible time.

THEORETICAL BACKGROUND

Graph theory [4] was employed to simplify the water distribution network, where pipelines are treated as "branches" or links of each "tree" joined by demand nodes. Here, $G = (V, E)$ represents the network configuration of a water pipeline system,

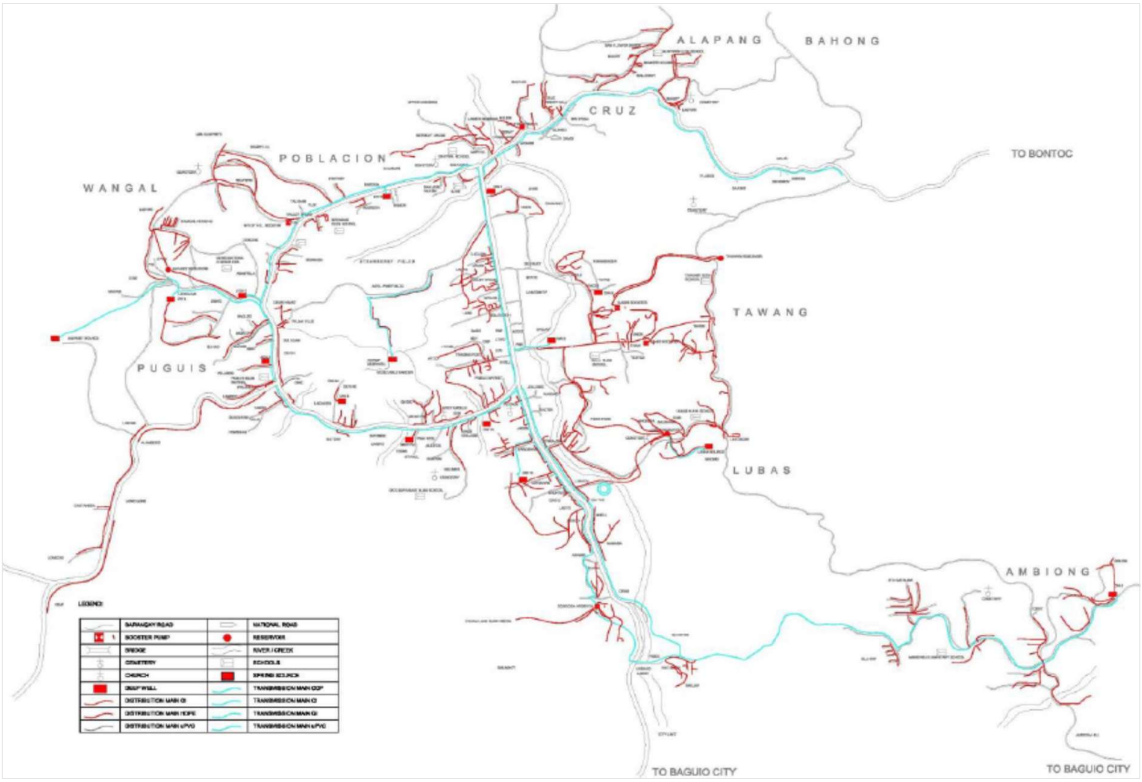

Figure 1. Digitized schematic diagram of LTWD (green lines – transmission; red lines – distribution)

where V and E are nodes and links, respectively. A series of single rooted tree, which is a finite directed network with a distinguished node root (i.e. supply node of the network) directed towards demand nodes along a single line with no closed loops, represents the system.

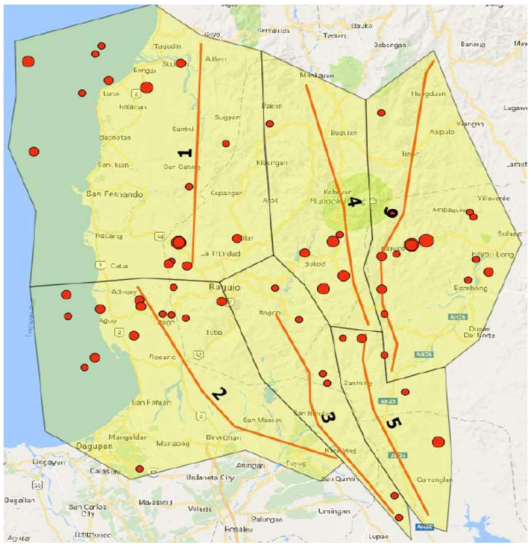

Figure 2. Faults considered in conducting PSHA

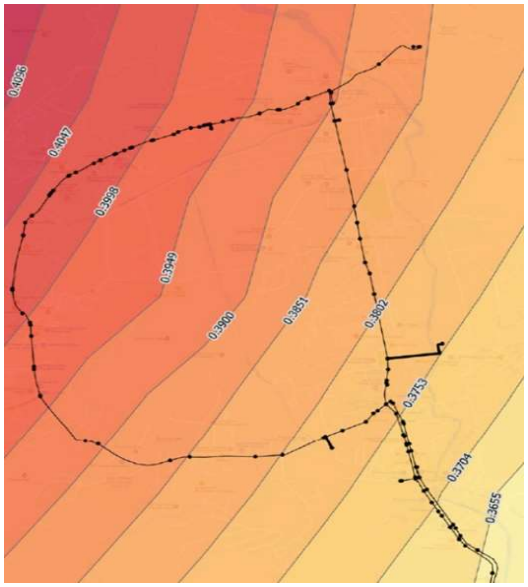

Figure 3. PGA contour map (as fractions of g)

In optimizing the restoration process, the study utilized restoration curve which is time-dependent function that represents the degree of restoration with respect to time. The restoration curve $R(Tj)$ is a stepwise function defined by the following equation:

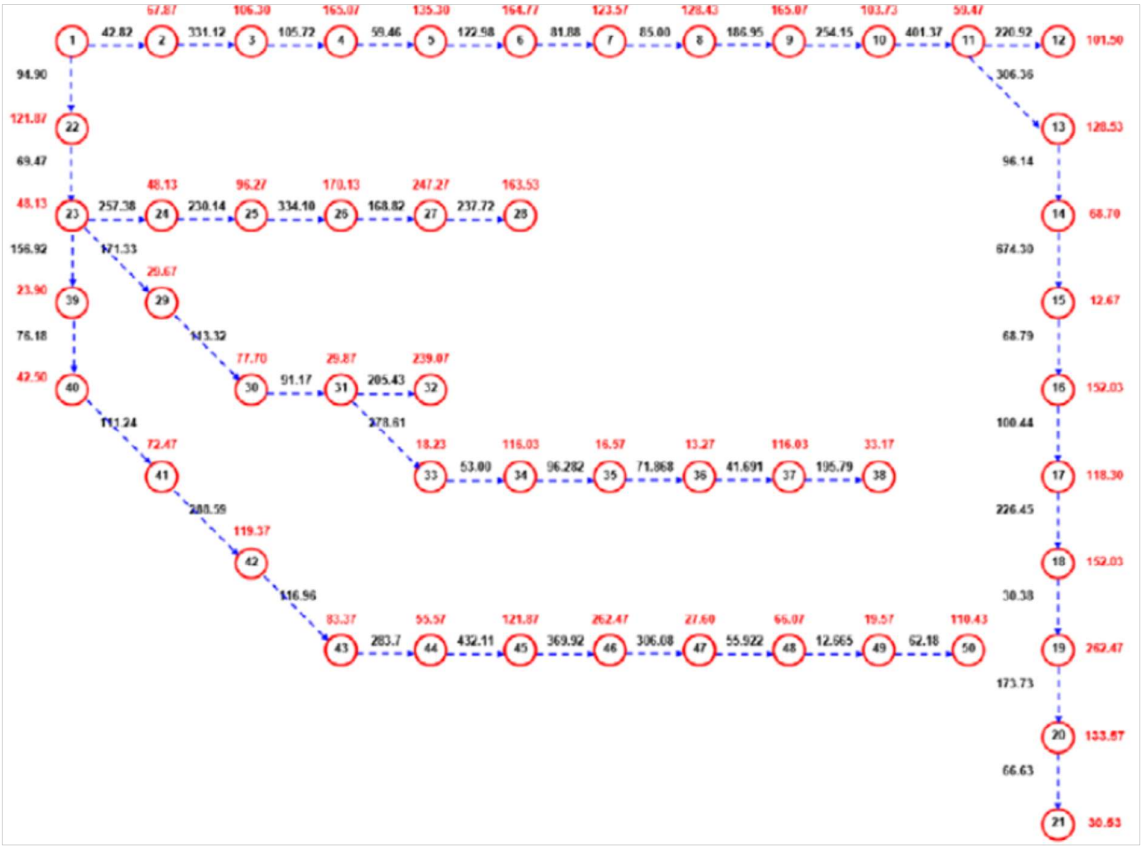

Figure 4. LTWD schematic scheme model (red – repair time, blue – node capacity)

$$R(Tj) = \sum_{\sigma(k)\leq\sigma(j)} h_k / \sum_{i=1}^{n} h_i \quad (1)$$

where $\sigma(j)$ = position number assigned to each node v_j in the recovery sequencing; t_j = net time required to repair each damaged component j. Also, h_i represents users that are linked to demand node (v_j) restored at time T_j after an earthquake event.

$$T_j = \sum_{\sigma(k)\leq\sigma(j)} t_k \quad (2)$$

Using Horn's algorithm [5], an optimized restoration sequence for damaged LTWD during a seismic event is achieved. In sequencing the repair of nodes, priority is given to demand nodes with higher efficiency. This is to restore service first to nodes that will supply water to more consumers in the shortest time possible.

Global optimization, through Horn's algorithm, is done by minimizing the area above the restoration curve. This is achieved using the improved efficiency parameter, γ_j*, and is computed by:

$$\gamma_j^* = \sum_{i\in U(j)} h_i / \sum_{i\in U(j)} t_i \quad (3)$$

where $U(j)$ is a subset of a set of nodes reachable from node v_j. It is determined so that γ_j* takes on the greatest value. The improved efficiency is taken along a directed path from supply nodes on a single line. Obviously, there are no directed cycles. The area above the restoration curve, called the linear delay penalty, is computed as follows:

$$t_A = \sum_{i=1}^{n} h_i T_i / \sum_{i=1}^{n} h_i \quad (4)$$

t_A represents the average time for restoration and can be regarded as the measure of the overall impact of lifeline malfunction.

Table 1. Horn's algorithm sequencing and efficiency parameter

Sequence	Node	γ*	Sequence	Node	γ*	Sequence	Node	γ*

METHODS, ANALYSIS, AND RESULTS

In conducting the probabilistic seismic hazard analysis (PSHA), seismic sources that will significantly influence the study area are the ones considered. Hence, foreshocks and aftershocks are not considered, earthquakes with magnitude less than 5.0 were removed, and only earthquake events within 100-kilometer radius are evaluated. Moreover, only six (6) seismic sources are considered (Fig. 2). These faults were divided into 100-meter segments and distances are measured from a point on the fault to a point on the grid. This is necessary to determine the probability of radius for each seismic zone.

Gutenberg-Richter equation [6] was used to generate the magnitude and frequency of the earthquakes from the six seismic sources mentioned. To translate PSHA output into a peak ground acceleration (PGA) map, the LTWD seismic map was subdivided into grids and points. For ground motion prediction, Youngs, Chiou, Humphrey, and Silva [7] ground motion prediction equation was used. The resulting PGA contour map was shown in Figure 3. It can be observed that PGA only ranged from a maximum of 0.409g to a minimum of 0.365g. Hence, this range is very narrow which validates the assumption that all pipes can fail during a seismic event.

The study's delimitation considered only the main transmissions that were laid out along the highway. This also caused many of the other water sources of LTWD to be excluded because they do not contribute to the transmission main. Hence, in the development of the schematic network model, for the optimization of repair sequencing, only a single supply source is applicable. The schematic diagram of the simplified network model is shown in Figure 4.

The rate of repair for the damaged pipes was taken as 1 kilometer of pipe-length per day. The schematic diagram (Fig. 4) shows six (6) trees, all rooted at node 1. Among these trees, the node in the tree with higher total efficiency is repaired first, followed by the next higher efficiency. This repair sequence goes on until all nodes are restored.

The result of repair sequence is shown in Table 1. It is derived after imposing Horn's algorithm. In this table, nodes were arranged based on repair sequence. The improved efficiency parameter is also shown. The total time of restoration is 8.62 days (Fig. 5). So, an all-pipe failure scenario will only take approximately 9 days to repair and bring back the water distribution network to its original pre-event functionality.

CONCLUSION

The six (6) identified seismic sources can each potentially damage and disrupt water supply service provided by La Trinidad Water District (LTWD). Based on PSHA, the north-western part of the municipality will experience the highest PGA implying that pipes located in that area will be highly

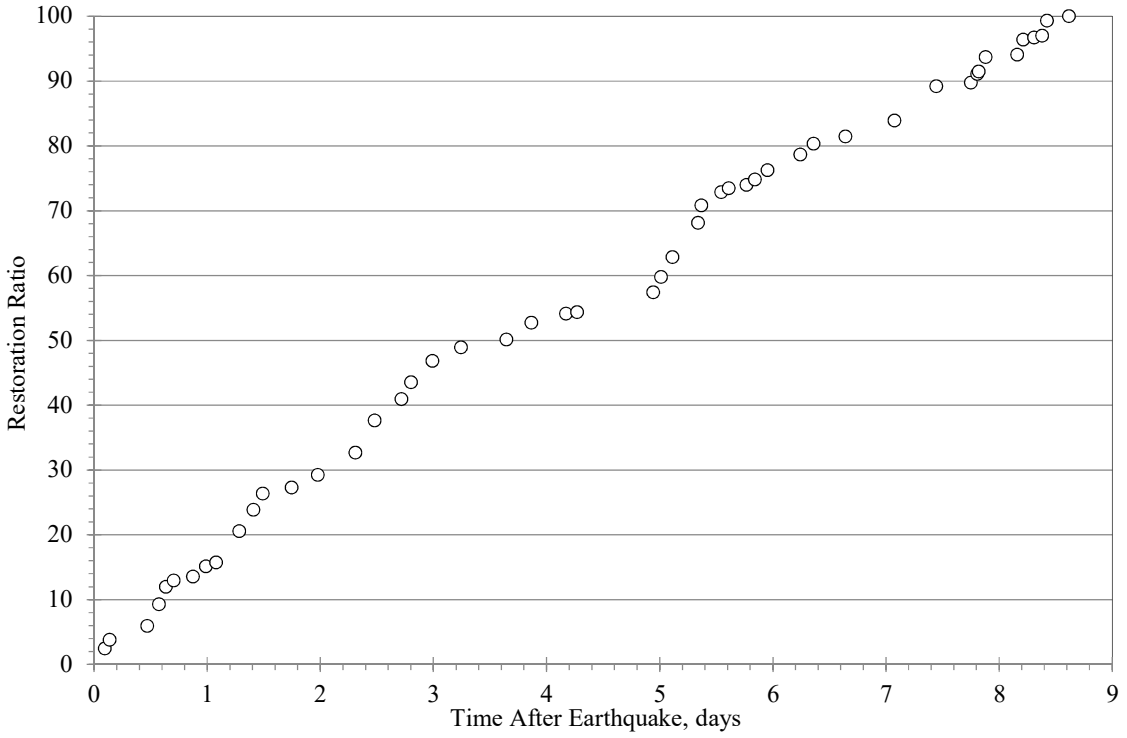

Figure 5. Restoration curve for LTWD during a seismic event using Horn's algorithm

vulnerable to damage due to earthquake. Moreover, about 3 kilometers (37.5%), serving about 39% of total demand, of the pipe network is projected to be damaged based on PGA derived from PSHA. Utilizing the average time for restoration (t_A) based from Horn's algorithm resulted to a t_A value of 3.95 days with a total restoration time of 8.62 days. In an event where earthquake causes an all-pipe-failure, following the repair sequence as derived from Horn's algorithm, it can be guaranteed that water demand can be met sooner at areas where demand is highest. This implies that more consumers get to have their water supply back faster.

ABSTRACT

Clustering algorithms in data mining is the method for extracting useful information for a given data. It can precisely analyze the volume of data produced by modern applications. The main goal of clustering is to categorize data into clusters according to similarities, traits and behavior. This study aims to describe regional cluster pattern of rainfall based on maximum daily rainfall in Johor, Malaysia. K-Means algorithm is used to obtain optimal rainfall clusters. This clustering is expected to serve as an analysis tool for a decision making to assist hydrologist in the water research problem.

Keywords: Clustering, Data mining, K-Means, Rainfall

INTRODUCTION

Malaysia is located in Southeast Asia and near the equator where it receives higher concentration of solar energy since the sun rays strikes almost on all year round. It is also surrounded by the sea and the air is moist and is usually covered with clouds.

Every year, Malaysian experiences two types of monsoon, the Northeast Monsoon (wet) and Southwest Monsoon (dry). The Northeast Monsoon started from early November to March, originating from China and the north Pacific, brings heavy rainfall to the east coast states of the Peninsular Malaysia. The Southwest Monsoon from late of May and ends in September, and is dried period for the whole country. However, there is also a period that happens in between of both monsoon (April – October) and is known as the inter-monsoon.

Above are statements that usually heard by reader. Thus in this paper we evaluated all real rainfall data and classified all of them to differentiate the rainfall according to the period of time stated before. K-Means cluster analysis is used to obtain optimal month of rainfall clusters. This clustering is expected to give better rainfall forecasting result and rain caught.

Literature review is given in second part of this paper, continued by methodology as the third part. Next results and discussions are given followed by conclusion and references.

LITERATURE REVIEW

K-means clustering is a clustering algorithm that aims to partition n observations into k clusters. There are 3 steps which are initialisation (K initial centroids are generated at random), assignment (K clusters are created by associating each observation with the nearest centroid) and update (the centroid of the clusters becomes the new mean).

Many contries have done on rainfall data reserch via K-means clustering. Baeriswyl et. al in [1] has conducted clustering analysis of Australia using Principal Component Analysis and K-means cluster analysis. Results have shown that the regions identified by both analyses are largely same. While in [2], the entire region of Bangladesh is grouped into certain homogeneous regions based on temperature and rainfall by using K mean clustering method.

Munoz in [3] used Principal Component Analysis to divide Spain in to a number of climatically homogeneous zones. Ward's method is used for clustering. Then, optimum number of clusters is determined by plotting distance between merged clusters as a function of the stage analysis.

K-means all used in [4] to get a good regionalization in determining how many clusters are required according to the type of data or objective and how good is the clustering itself. To answer these questions, hierarchical and non-hierarchical algorithms were applied to six experiments based on the data sets for precipitation and temperature available from traditional weather stations.

A paper by Shirin & Thomas in [5] grouped the entire region of Kerala into an optimum number of clusters using Ward's method of clustering. The purpose of Clustering Analysis is to place objects into groups suggested by the data, so that objects which are similar to each other in some sense are grouped into one cluster, and dissimilar objects in different clusters.

In 67], an effective framework for landslide susceptibility mapping (LSM) is presented by integrating information theory, K-means cluster analysis and statistical models.

The RMSE value can be minimized by including seasonal elements in the model, both in BPS and K-Means clustering. In addition, the K-Means clustering done in [7] may also reduce the RMSE value of model, both on non-seasonal and seasonal models.

The best model for this case is GSTARK-Seasional ie Seasonal GSTAR model on K-Means clustering.

K-means are very useful as stated before. In this study, rainfall data from 8 stations in Johor are used and clustered by using K-means clustering.

METHODOLOGY

In this section, study area and method used are given.

Study Area and Data Description

Johor Bahru, capital of the Malaysian state of Johor, sits at the southern tip of the Malay Peninsula. With a causeway across the Straits of Johor connecting it to Singapore. For this study, the entire state of Johor Bahru which occupies the southernmost part of peninsular Malaysia, is selected that located at 1.4927° N, 103.7414° E. The total area of the state accounts to around 220 sq.km.

The main parameter required is the monthly rainfall of all the gauging stations in Johor Bahru. The monthly rainfall data are collected for a period of 31 years (1981-2012). Rainfall data each year for 9 stations are obtained from Department of Hydrology Malaysia.

Determination of Optimum Number of Clusters

In order to use the k-Means method we have to find the optimal number k of clusters for the given dataset. In some cases, the called elbow method can be used to determine a nearly-optimal number k of clusters. The elbow method consists in plotting in a graph the WCSS(x) value on y-axis according to the number x of clusters considered on the x-axis, the WCSS(x) value being the sum for all data points of the squared distance between one data point x_i of a cluster j and the centroid of this cluster j (as written in the formula below), after having partionned the dataset in x clusters with the k-means method.

$$\mathrm{WCSS}(k) = \sum_{i=1}^{k} \sum_{x_i \in \text{cluster } j} \left\| x_i - \bar{x}_j \right\|^2 .$$

RESULTS & DISCUSSION

In this section we state the optimal number for cluster and proceed with clustering the dataset. Results are discussed after that.

Number of Clusters

The optimal number of clusters is given by the points located on the curved WCSS curve that look like "elbows". We can visually search or we can use formal tricks consisting of finding the optimum point of the WCSS curve. In the following, we arbitrarily set the maximum number of clusters to the square root of the dataset size. This means that if the data is uniformly distributed and the partition is built with this maximum number of clusters, then the number of data points in each cluster will be equal to the number of clusters, which is considered to be quite large here.

Given the dataset, the function generates the WCSS curve data as given in Fig. 1.

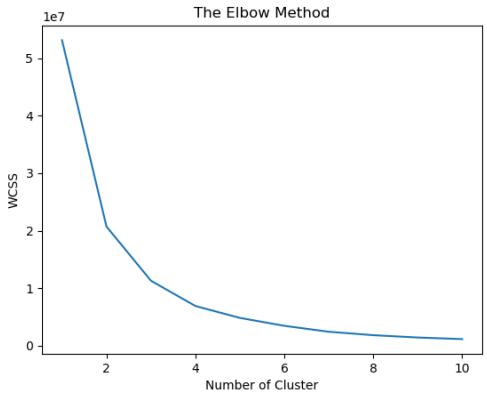

Fig. 1 The Elbow Method.

Here the x= 4, which leads to an optimal number of clusters. Once we found the optimal number of clusters we can launch k-means with this number and get the resulting y_kmeans classification of the given X data points.

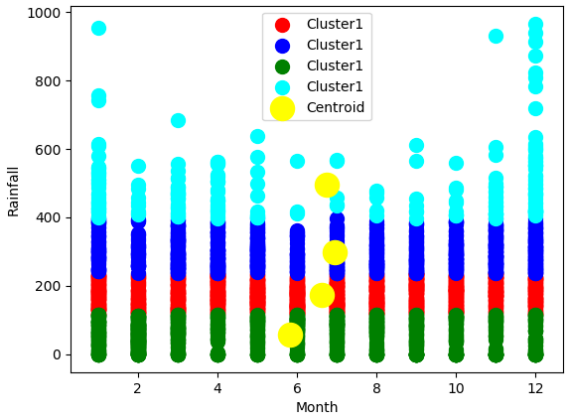

Fig. 2 Cluster of Rainfall

The number of groups in the K-means clustering in this study were four, which are region 1 (Cluster 1) in green, region 2 (Cluster 2) in red, region 3 (Cluster

3) in blue, and region 4 (Cluster 4) in cyan. This refers to the 4 clusters by Elbow Method.

We can see from that figure; each month has 4 groups. Only the fourth group distinguishes the monthly rainfall distribution. This proves that Malaysia has a humid climate throughout the year. More rainfall in December and January where plots abound in the fourth group. In June, on average, there is less rainfall compare to other months.

CONCLUSIONS

Johor Bahru is the selected area to study and monthly rainfall from 9 stations in Johor Bahru are used. The monthly rainfall data are collected for a period of 31 years (1981-2012). The optimal number of clusters is given by the points located on the curved WCSS is 4 which leads to an optimal number of clusters. There are four clusters in all and three clusters exist in all months except for the fourth cluster that is mostly large of data (most are December and January) and some less of data (June).

ACKNOWLEDGMENTS

The authors would like to thank the Department of Irrigation and Drainage Malaysia for providing the data of this research work. The authors also would like to acknowledge the Universiti Malaysia Pahang (UMP) for providing the internal research grant RDU1703265.

ABSTRACT

The goal of this study is to analyze the impact of climate change on the hydrological regime changes in Cimanuk Watershed, West Java, Indonesia, analyzes the existing problems and contributes to the management of water resources in monsoon climate region in Indonesia. The results have shown that climate change is shown by the increasing temperature, meanwhile the air humidity, wind speed, sunshine duration, and evaporation are decrease. Changes of the hydrological regime have been known by the analysis of the main components of the hydrological cycle specifically discharge (Q) and precipitation (P). Precipitation and discharge had shown an increasing trend from 1987 to 2012, but with high variability in annual and monthly period. The critical condition of water availability for four months (June to September), while the excess water condition occurs during eight months (October to May). The Model of input-output correlation between precipitation and discharge have shown a positive correlation 0.9564 for the monthly average, and 0.5417 for the annual. The coefficient of annual water availability is high, shows that the region is monsoon with great potential for flooding. Therefore, need for optimal management of surplus water in the rainy season so not wasted.

Keywords: Climate Change, Hydrology Regime, Monsoon Area, Water Availability, Water Resources

INTRODUCTION

Water Resources states that water as a source of community life is dynamic existence naturally flow to a lower place without knowing the administrative boundaries. According to Arwin [1], Source of water is a natural resource that can be updated through the hydrologic cycle depending on the climate and weather be affected by cosmic factors, regional and local (watershed) form the hydrological regime. Where is the main component of the hydrological cycle of rainfall is input in the watershed system and the output is the discharge and the quality of surface water (river water) and groundwater reserves. The second component is characterized by random variables and stochastic as well as water drainage to the sea is a deterministic phenomenon. Uncertainties of climate and weather triggered by global warming from greenhouse gas emissions in the atmosphere result in temperature increases the earth [1,2]. The presence of water follows the hydrological cycle is closely related to the weather conditions in an area that causes uneven water availability in every time and every region. Changes in surface water availability extreme would be a serious problem in terms of the sustainability of water management [3,4,5]

In the monsoon area, water resource availability is a serious problem in terms of the sustainability of water management. Monsoon patterns are characterized by monthly V-shaped rainfall distribution with low seasonal rainfall in June, July or August. In normal conditions, when the west monsoon will get abundant rainfall (rainy season) while in the eastern monsoon the amount of rainfall is very little (dry season). In monsoonal rain patterns the region has a clear distinction between the period of the rainy season and the dry season. Numerous studies have been conducted, some of them are about the availability of water during the rainy season and the dry has a very high degree of variability about scenario development for watershed management [1,6,7,2,8].

Therefore, this research specifically examines: a) climate change and hydrological regime changes in Cimanuk Watershed and b) the impact on the water resources sustainability in monsoon regions. Conditions impact of climate change and land conversion may have occurred in the Cimanuk Watershed, as the main water source rivers Jatigede Reservoir.

MATERIAL AND METHOD

The quantitative approach has been done to analyze the impacts of climate change on the hydrological regime change. Series precipitation data are used daily and monthly throughout the 26 years (1987 to 2012) from 9 (nine) precipitation stations around the Cimanuk watershed. Data climate elements derived from Cimanuk Climatology and Wado Discharge Station, while the series of monthly discharge data for 32 years (1980 to 2013). Figure 1 shows the study area of Cimanuk Watershed, the discharge station namely Q Wado, and for the rainy station from P1 Pamegatan, P2 Pangauban, P3 Kepakan, P4 Tarogong, P5 Leuwigoong, P6 Darmaraja, P7 Pamulihan, P8 Cilimun, P9 Majalengka.

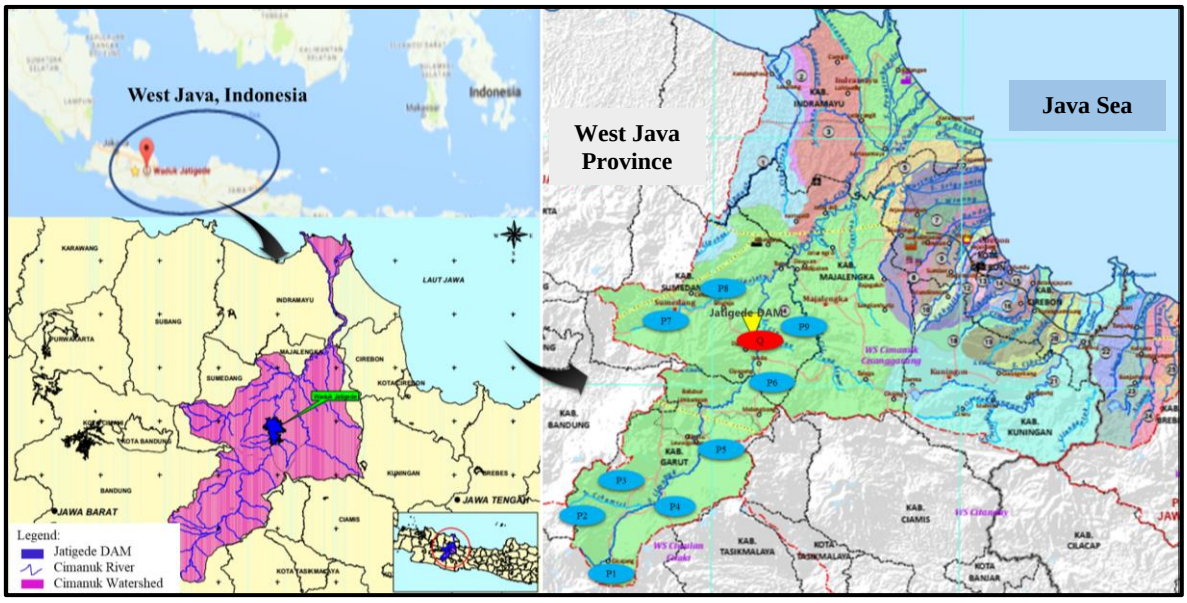

Fig.1 Study Area

The analysis of climate parameters, precipitation and discharge trends revealed by the data using the moving average method, the range of values and the average values were compared at different periods. In addition to the analysis of changes in precipitation are also using the IDF Curve method. The significance level between precipitation and discharge, using the Spearman Correlation Test model of a two-way with a significance level of 5%.

RESULTS AND DISCUSSION

Climate Change

Climate parameters which have been analyzed were: air temperature, wind speed, air humidity, sunshine duration, and evaporation. Results of the analysis showed that the average air temperature of 28,44°C, the lowest in March at 22,27 C and highs in October amounted to 31,35°C. Relative humidity average is 68,29% with the highest data in January by 98,01% and the lowest in September at 8,9%. For evaporation, the average is 60 mm/day, the highest evaporation occurs in August 88,70 mm and the lowest in October amounted to 43,01 mm. Average wind speed of 1325,66 km/day, the biggest in September amounted to 7861,87 km/day and the lowest in March at 33,8 km/day.

Figure 2 shows the trend of climate change parameters on average time series from 2000 to 2013 (14 years) as follows: temperature has shown an upward trend with changes in average temperature was 0.1037°C per-year, while the trend of global temperature changes 0.7°C every 100 years. IPCC [9] reported that the distribution of increase in the global temperature anomaly is uneven and varies between land and sea, between the northern hemisphere and southern hemisphere, and between regions and between types of land cover are different.

Other climate parameters results have shown a downward trend for the 14 year observation period, namely: humidity -1,3968 % per-year; wind speed 266,58 km/day per-year; and evaporation -0.6908 mm per-year. Result analysis shows the changes in temperature and evaporation are the same climate change theory that rising temperatures will lead to increased evaporation.

The temperature's rise is not evenly distributed around the earth cause low pressure and new high pressure. The pattern of wind is shifting and the precipitation patterns are changing either. Indonesia's geographic position greatly affects the extreme climate events, in this case is flooding and drought. The phenomenon that affects the climate in Indonesia is called ENSO because Indonesia is located between two oceans, the Pacific and Indian oceans. El Niño events will cause drought in

Indonesia, especially in areas that have a pattern of monsoonal precipitation. While La Niña phenomenon will lead to increased precipitation in Indonesia during the dry season and the rainy season led the advance [2]. The research of Jayanti et al [10] showed that in 2005 the last year, there was a wet-dry phenomenon happening throughout the year so that the rainy season. This is one example of the extreme climate that occurs as a result of climate change.

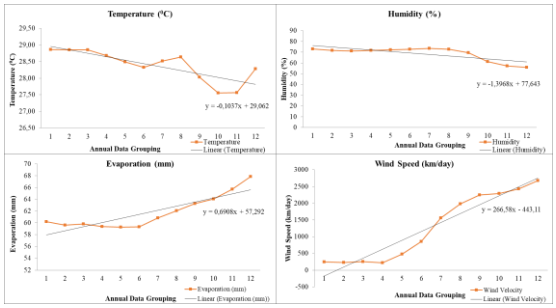

Fig.2 Trend of Climate Parameters Changes

The changes in climate parameters that occurred can result in a change of the magnitude and distribution of water, and the long-term sustainability of water resources being threatened and requires serious attention.

Hydrological Regime Changes

Changes in climate parameters will impact directly or indirectly on the hydrological response of the region further define the availability of water for various needs. Changes in the hydrological regime in this study were observed through changes in the main components of the hydrological cycle that is precipitation and discharge.

Changes of Precipitation Intensity

Changes of the hydrological regime (precipitation), observed among others by changes in precipitation intensity with curve IDF method (Intensity Duration Frequency). Precipitation intensity data over different time periods (1987 to 1999 and 2000 to 2012). Analysis of the results for the period of 2 years and 10 years as shown in Figures 3 and 4.

On the return period (RP) 2nd annual, overall precipitation stations have a higher intensity of precipitation for the current period (1987 to 1999) compared to the previous period (2000 to 2012). Pamegatan station has a value greater margin between the two periods of rain showers in the appeal of other stations and also has the highest intensity for a short period of rain (5 minutes).

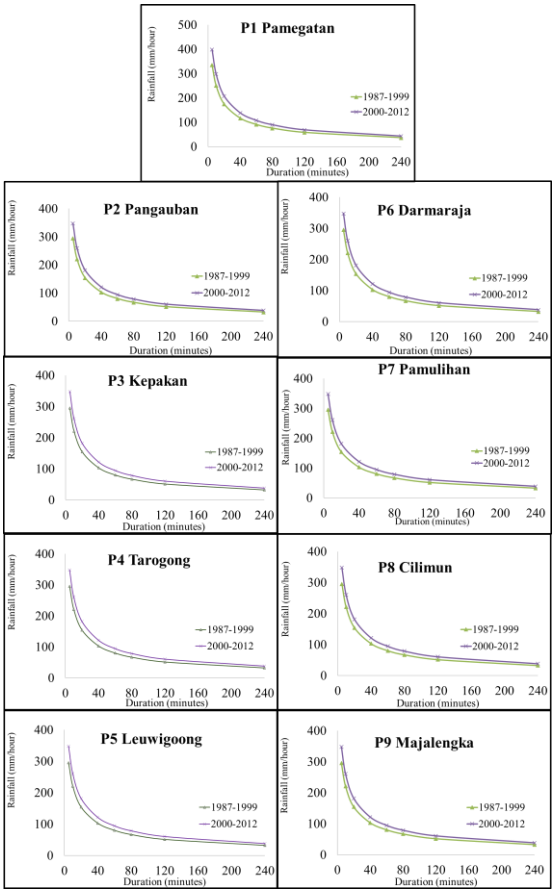

Fig.3 IDF Curve for 2nd Annual Return Period (1987-1999 and 2000-2012)

For the 10th annual return period (figure 4) the highest precipitation intensity occurred in urban areas (Darmaraja and Tarogong). The results of this analysis showed that differences in land use affect the value of the hydrological regime. Condition is consistent with that presented in the IPCC report (2007), that differences in the distribution of land use will result in the increase of global temperature anomalies uneven and different.At 10th annual return period, a trend increasingly little difference in intensity between the 2 periods of the calculation (the curves coincide).

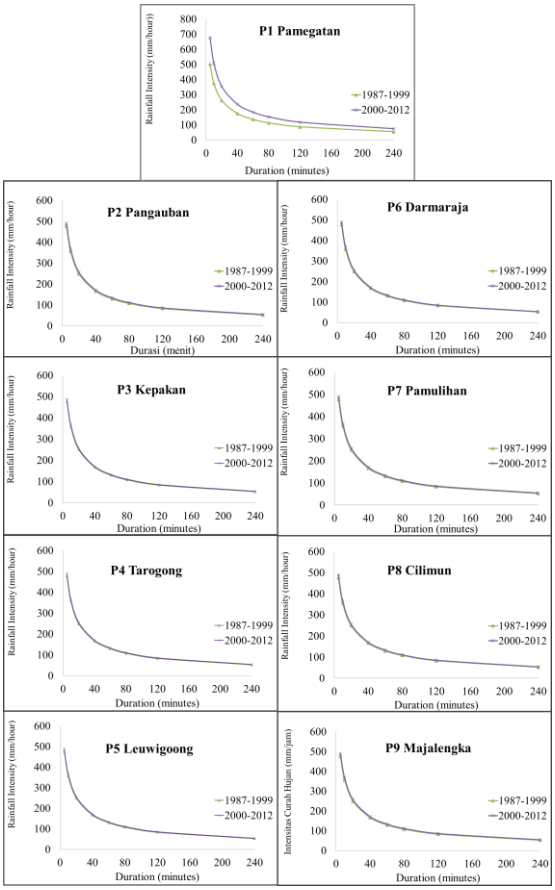

Fig.4 IDF Curve for 10th Annual Return Period (1987-1999 and 2000-2012)

The intensity of rain between the 2nd calculation period (1987 to 1999 and 2000 to 2012) is also getting random between stations because there are stations with the intensity of the period 1987-1999 is higher than the period 2000 to 2012 and on the contrary. From the analysis of the return period 25th, 50th and 100th annual also shows that the greater the return period, the smaller the value of the different intensity precipitation or curve formed by the overlaps.

Precipitation changes

The analysis results of precipitation changes show increases trend (Figure 5a) [10]. Distribution of precipitation monthly averages in Figure 5b shows the wet season occurs during the eight months (October to May), while the other four months (Juni to September) is a dry month, which means that the dominant dry season occurs in the study area. Monthly precipitation pattern that occurs is monsoon type [10].

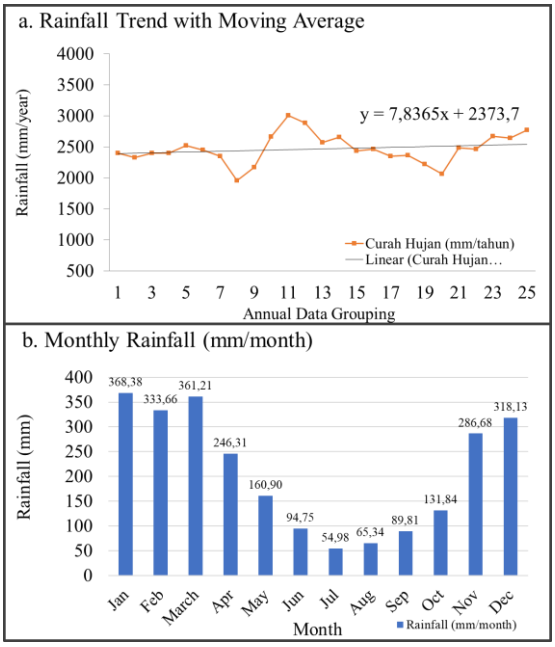

Fig.5 Trend and Distribution of Precipitation at Cimanuk Watershed, Indonesia (1987-2013)

Precipitation variability is also different in the wettest month (rainy season) and dry months (dry season). In the wet months, the more extreme precipitation in the dry season wet while getting extreme precipitation dried (figure 6).

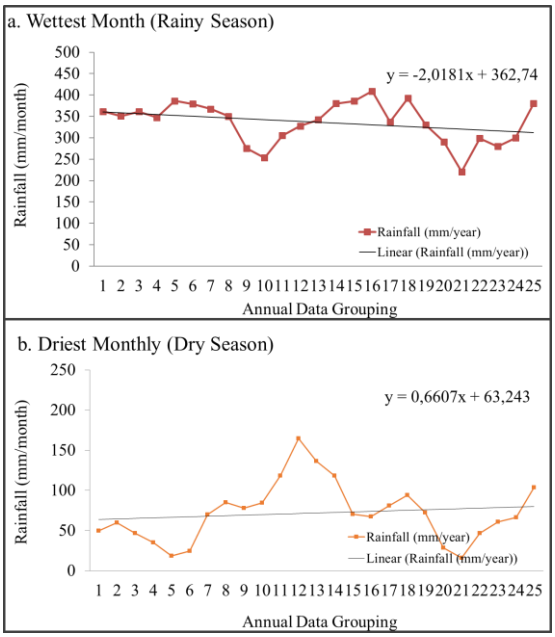

Fig.6 Trend of Average Precipitation in Rainy Season and Dry Season with 3rd Annual Moving Average Method

This means that climate change may lead to a shift of the season, which will last a long dry season, causing drought. The rainy season will take place with the trend of precipitation intensity is higher than normal precipitation, the impact of floods.

Precipitation data were grouped in two different periods shows the more extreme precipitation in the period 2000-2013 where the average precipitation of 2502,82 mm/year, while in the previous period (1987 to 1999) only amounted to 2386,28 mm/year. Which means that the change increased by 8.10%. If the precipitation data grouped by wet months (October to May) and dry months (June to September). The data also shows that the more extreme the current period in the previous period in the wet in the rain (2209,72 mm versus 2044,06 mm) and in dried drier (293,1 mm versus 342,22 mm).

Discharge Changes

Trend analysis shows an increase in annual discharge changes (Figure 7a). Changes occurring discharge is 96,48 m^3 per-32 years or 0,9648 m3/year. Monthly average discharge showed different distributions of per-month (Figure 7b).

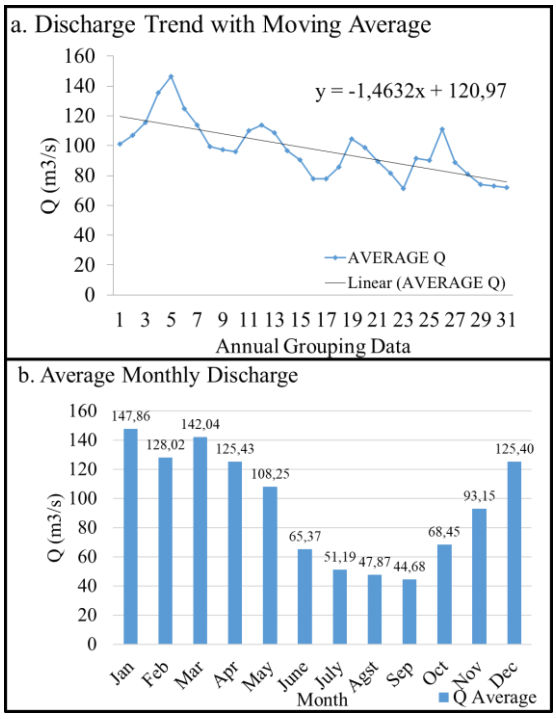

Fig.7 Trend and Pattern of Annual Discharge (1980-2013)

The amount of discharge change between wet months (October to May) is 117,34 m^3/s and dry (June to September) is 52,28 m^3/s. The monthly maximum discharge occurred in January amounted to 147,86 m3/second, and the smallest was 44,68 m3/second occurred in September with an average discharge of 95,64 m3/second /months. The Month from October to May is a condition in which the discharge that occurs above the average discharge, and the month from June to September is a condition in which the discharge occurred under average discharge. This differs from the pattern seen in the precipitation which occurred a shift in the months from October to May (for precipitation) to the month of June to September (for discharge). This happens because of the precipitation that occurred the previous month (October) used to fill the pores of the soil that had vacancies during the dry season. If the soil pores are fully charged (saturated) then becomes surface water (river flow).

Discharge changes also differ in the wettest and driest months. In the wettest month (January) shows the trend of increasing discharge (147,86 m^3/second per-year), as well as the driest month (October), increased 44,68 m^3/second per-year (Figure 8).

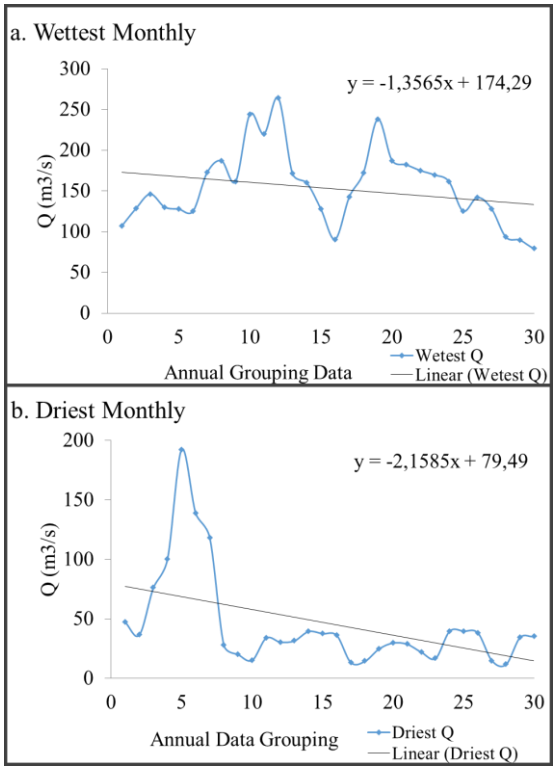

Fig.8 Trend of Discharge in The Wettest Month and Driest Month

Conditions of discharge increase during the driest season, although the value is not significant, in monsoon area that indicates improvements in the condition of the watershed water use planning.

Correlation between Precipitation and Discharge

Correlation between precipitation and discharge in this study is that the greater the precipitation intensity, the greater the discharge occurs. Spearman correlation test at a significance level of 0.05% two-way test, for a monthly average data shows a correlation value 0,9564 which means that the increase in discharge can be explained 95,64 % due to an increase in precipitation, while the

remaining 4.36% is explained by the variables others, such as in wet or dry conditions during the rains, the amount of base flow (baseflow), and other factors. On annual average data, the relationship between precipitation and discharge correlated at 0.5417. The results of this analysis showed that precipitation is the biggest input on discharge of Cimanuk watershed, West Java, Indonesia.

Hydrology in Monsoon Region

The study area is monsoon regions indicated by the following indicators: (a) the average precipitation 2422,09 mm/year, (b) the number of rainy days with an average of 240 days/year, (c) evaporation 747,14 mm/years, (d) potential evapotranspiration (ETo) 2600 mm/year, and (e) the annual water availability coefficient of 1,468, the water deficit as much as 1338,6 mm/year which results in a high risk of drought.

The critical condition of water availability for four months (June to September), while the excess water condition occurs during eight months (October to May) For the foreseeable future water needs of irrigation and drinking water will increase, especially in the dry season, because it's raw water supply challenges will be even greater.

CONCLUSION

Global climate change that also has occurred in the study area that will affect the hydrological response ie, the observed changes in the hydrological regime through the major components of the hydrological cycle that is precipitation and discharge. This change will determine the availability of water for various needs. Increased precipitation and discharge, though with little value, the observation period 1987 to 2012 is a favorable condition for the availability of water in the study area. But with the higher variability between dry season and rainy season that resulted in the need for optimal management of surplus water in the rainy season can be accommodated to be used in the dry season.

[3] Associate Professor of Agricultural Engineering, Faculty of Engineering, Khon Kaen University, Thailand

ABSTRACT

Rainfed rice cultivation is the key agricultural practice in the Northeast of Thailand. Climate variability is the main cause affecting the rice production. Climatic water balance index namely standardized precipitation evapotranspiration index (SPEI) indicates variation of climate conditions, whether the area is wet (positive) or dry (negative). Our study concerned the effect of climate variability on the production and yield of rice cultivations in five provincial stations in the northwestern of the Northeast which has one of the most extreme climatic conditions in Thailand. El Nino Southern Oscillation (ENSO) is also related to SPEI and related to rice production and yield.

For the study rainfall and meteorological data between 2005 to 2016 were used for analyses. Changes of monthly SPEI over all stations were abrupt compared to ENSO changes which were gradual. During the rice cultivation period, May to September, 1-month SPEI fluctuated from month to month. The summation SPEI values within that 5 months were compared to rice production and yield from each station. All of rice productions increased with SPEI values but only three stations had yields agreeing with SPEI. This shows that amount of production always relates to wetness but not the yield which depends on other factors such as soil fertility and good management. In marginal paddy fields, cultivation is limited to positive wet conditions. Production may increase depend on the area cultivate, but yields will reduce.

Keywords: climate variability, standardized precipitation evapotranspiration index, rice production and yield

INTRODUCTION

Rice is the main staple food of Southeast Asia and some other parts of the world. It has been believed that rice was originated from Southeast Asia region then spreading throughout the world [1]. Rice is a special crop that needs much more water than any other cereal crops it can survive even in standing water as long as the whole plant does not inundated [2]. The benefit of the standing water is that it controls weed growth. The climate of Southeast Asian countries is one of the best regions for cultivating rice crop since it has large amount of rain during wet season. The Northeast of Thailand is such a place that has plenty of rain during May to October each year [3]. It receives rain from two sources the southwest monsoon from Indian Ocean and the tropical cyclone from the Pacific Ocean [4]. The northwestern part of the Northeast is quite a special place because it has an orographic effect from the Phetchabun, Dong Phaya Yen, and Sankambeng mountain ranges to retard the flow of Southwest monsoon into the region. In case of the tropical cyclone from the Pacific, before reaching the region, the cyclone has to travel passing Vietnam, Laos, Cambodia, the eastern part of the Northeast before reaching the northwestern region. The region normally receives less rainfall than the other parts of Thailand even worse when the southwest monsoon is weak, and no tropical cyclone occurred. However, the area can be flooded during a year of strong summer monsoon and coupling with a large number of tropical cyclones. These dry and wet years are the result of atmospheric and Pacific Ocean interaction indicated by El Nino Southern Oscillation (ENSO) [5]. The majority type of rice growing in the region is glutinous (*Oriza Sativa var. Glutinosa*) [6]. Rice culture in the northwestern part of the Northeast, Thailand, mainly is planted in a paddy lot of irregular size, rectangular shape, and surrounding with small earth bunds to confine water in the paddy. These lowland rainfed paddy fields receive water from rainfall and runoff and loss water through evapotranspiration, the combination of evaporation and crop transpiration. The indicator of water availability for rice crop is the difference between rainfall and evapotranspiration, namely standardized precipitation evapotranspiration index (SPEI) [7], [8]. The SPEI index is superior to other indices that it can detect both extremes, flood and drought. Our objectives are to compare and correlate the rice productions and yields of the five northwestern provincials of the Northeast, Thailand, to their SPEI's then to ENSO.

STUDY AREA AND DATA COLLECTION

Our study area is in the northwestern part of Northeast, Thailand, between 15 31 -18 21 N and 100 83 -103 66 W. It covers 5 provincial areas namely Chaiyaphum, Nongbualamphu, Khonkaen, Udonthani, and Loei. The whole Northeast is one of the large sub-basin on the right bank of the Mekong River called the Khorat Plateau. The plateau is separated into two basins by Phu Phan mountain range lying in west to east direction. The upper (northern) basin is Sakol Nakhon Basin and the lower (southern) one is Khorat Basin. Interestingly, our study area involves both basins, the Khorat Basin comprises Chaiyaphum, and Khonkaen; whereas Udonthani and Loei are in the Sakol Nakhon Basin, however Nongbualamphu covers both basins.

Rainfall of the study area is in the range 1146 mm for Chaiyaphum to 1457 mm for Udonthani. Since the western part of our study area is a rather rain shadow therefore the amount of rain is increasing in the northeastern direction toward the Mekong River. Due to the Phu Phan Range, the topography of Loei and Udonthani is sloping down northward to the Mekong while that of the other two provinces, Chaiyaphum and Khonkaen is descending southward to the Chi River. Nongbualamphu is a special one because its northern part drains northward to the Mekong River while the southern drains southward to the Chi River. Drainage channels of the northern area are the Loei and the Huai Luang Rivers and those of the southern areas are the Nam Pong River and its tributaries. Undulating terrain is the typical landscape with majority of sandy soil which derived from the sandstone of the Khorat Group. Saline soil and groundwater are the environmental problems of the area.

The main land-uses are upland crops and forest covering the upper terrains and paddy fields on the lower and swampy areas. The main type of rice is glutinous rice of more than 80 % and other is white rice [6], [9], [10]. The major variety is RD6 which is a short plant and photosensitivity therefore it must be transplanted as early as possible to obtain higher production. Since being rain-fed agriculture, it is sensitive to both drought and flooding, especially drought at the vegetative period (first half) and flooding at the maturing period (later half) [9].

Three types of data to be used namely rice production and yield, hydrometeorological, and ENSO index data. The data of rice cultivation during 2005 to 2015 were obtained from the Office of Agricultural Economics (http://www.oae.go.th) for each province and nationwide. The data are planted areas, harvested areas, production, and yield. The hydrometeorological data for 2005 to 2016 were collected from the Department of Alternative Energy Development and Efficiency (DEDE) of Thailand and the Thai Meteorological Department (TMD). These data are essential for SPEI evaluation which are daily precipitation and referent crop evapotranspiration (ETo). The precipitation data were collected from provincial rain gauges. The ETo has to be determined from FAO-Penman-Monteith formula refer to Eq. (11) which is required a range of meteorological data, e.g. maximum and minimum temperatures, solar radiation, relative humidity, and wind speed, etc. The last set of data is ENSO indices which comprise several indices. We decided to use Oceanic Nino Index (ONI), which is the atmospheric pressure anomaly at Nino 3.4, for its simplicity and effectiveness. The ONI data set for 2005 to 2016 were retrieved from NOAA's National Weather Service's Climate Prediction Center [11].

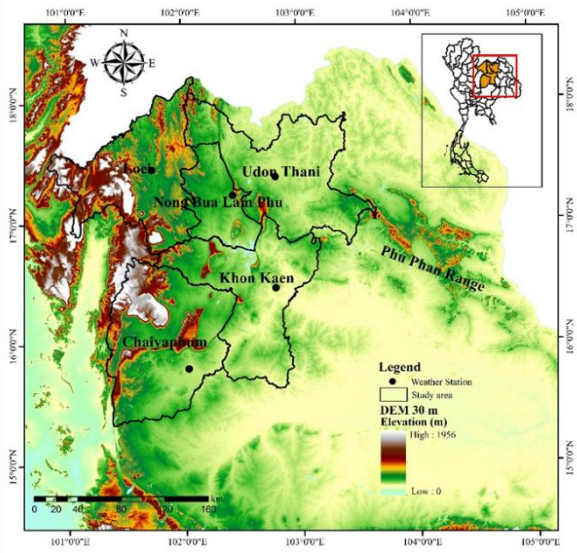

Fig. 1 Topography area of the five-province study region in Thailand.

METHODOLOGY

We hypothesized that the rice production and yield of the northwestern region of Northeast, Thailand, should be related to the appropriated amount of water availability for rice growing. The crop water supply for rain-fed agriculture depends on the timing amount of rainfall and evapotranspiration. Too much rain creates flooding whereas too much ET creates drought. Both flooding and drought deteriorate rice production and yield. We tied rainfall and ET together using an index of SPEI which is the function of the difference of rainfall and ET [12]. We also presumed that SPEI is related to ONI index, if so ONI can be used a proxy to forecast the rice production and yield of the interested area.

Standardized precipitation evapotranspiration index (SPEI) is an index to classify climate variable condition from the discrepancy of rainfall and ET. It was derived from standardized precipitation index (SPI) by adding the effect of ET. Its determination procedure is the same as that of SPI just by replacing rainfall by rainfall minus ET (D_i, mm) as:

$$D_i = P_i - ETo_i \quad (1)$$

We used log-logistic probability distribution to fit the monthly D data. It was found that 1-month time scale is the most appropriate for the Northeast [13]. The cumulative probability distribution function (cdf) for 3-parameter log-logistic distribution can be written as [12].

$$F(Di) = \left[1 + \left(\frac{\alpha}{D-\gamma}\right)^{\beta}\right]^{-1} \quad (2)$$

where α, β, and γ represent the scale, shape, and location parameters, respectively. These parameters can be estimated by several methods e.g. method of moment, probability weighted moment (PWM), maximum likelihood, and principle of maximum entropy [14]. For PWM, we compute frequency estimator F_i from [15],

$$Fi = \frac{(i-0.5)}{N} \quad (3)$$

where i is rank of observation in increasing order and N is number of data points. Then w can be determined from,

$$w_s = \frac{1}{N}\sum_{i=1}^{N}(1-F_i)^s D_i \quad (4)$$

where s is the order of PWMs ranking from 0 to 3, N is total number of data, and D_i is the data of rank i. The three parameters are now ready to be calculated from [14],

$$\beta = \frac{(2w_1 - w_2)}{(6w_1 - w_0 - 6w_2)} \quad (5)$$

$$\alpha = \frac{(w_0 - 2w_1)\beta}{\left[\Gamma\left(1+\frac{1}{\beta}\right)\Gamma\left(1-\frac{1}{\beta}\right)\right]} \quad (6)$$

$$\gamma = w_o - \alpha\Gamma\left(1+\frac{1}{\beta}\right)\Gamma\left(1-\frac{1}{\beta}\right) \quad (7)$$

where w_0, w_1, and w_2 can be obtained from Eq. 4, Γ is the gamma function.

Knowing α, β, and γ, we can calculate non-exceedance probability of D_i, $F(D_i)$, from Eq. 2. To transform $F(D_i)$ from log-logistic probability distribution to normal distribution we should compute exceedance probability first as:

$$P = 1 - F(Di) \quad (8)$$

For P is less than or equal to 0.5, then

$$W = (-2\,ln(P))^{0.5} \quad (9)$$

otherwise, for P is larger than 0.5, then P is replaced by 1-P. The value of W gives SPEI as [16]:

$$SPEI = W - \frac{(C_0 + C_1 W + C_2 W^2)}{(1 + d_1 W + d_2 W^2 + d_3 W^3)} \quad (10)$$

in which the values of the constants are C_0 = 2.515517, C_1 = 0.802853, C_2 = 0.010328, d_1 = 1.432788, d_2 = 0.189269, and d_3 = 0.001308.

Type of ET to be used in SPEI determination is critical. We decided to use crop reference ETo as in [17]. The ETo is the hypothetical ET of a large area of growing uniform grass at 12 cm high without lacking of water. It can be calculated from [18]:

$$ET_o = \frac{0.408\Delta(R_n - G) + \gamma\frac{900}{T+273}U_2(e_s - e_a)}{\Delta + \gamma(1 + 0.34U_2)} \quad (11)$$

Where
ETo: reference evapotranspiration [mm day^{-1}],
R_n: net radiation at the crop surface [MJ m^{-2} day^{-1}],
G: soil heat flux density [MJ m^{-2} day^{-1}],
T: mean daily air temperature at 2 m height [°C],
u_2: wind speed at 2 m height [m s^{-1}],
e_s: saturation vapour pressure [kPa],
e_a: actual vapour pressure [kPa],
e_s-e_a: saturation vapour pressure deficit [kPa],
Δ: slope vapour pressure curve [kPa °C^{-1}],
γ: psychrometric constant [kPa °C^{-1}]

RESULT AND DISCUSSION

Climate variability is the fluctuation of wet and dry condition along the time period which can be shown as the time series of SPEI. The main cause of climate variability is thought to be the interaction of the Pacific Ocean and the atmosphere which reflects through ENSO index e.g. Oceanic Nino Index (ONI). We therefore compared time series of ONI to SPEIs of the 5 provincial areas. We only illustrate the results of Udonthani province in Fig. 2a. The rice production and yield time series of the same province are also shown in Fig. 2b and 2c, respectively.

We only show the Udonthani's results however the other four provinces' results are very similar. ONI changes gradually with time while SPEI changes rapidly (Fig. 2a). The La Nina condition is represented by negative ONI whereas EL Nino by positive. For climatic condition, the wet one is shown by positive SPEI but the dry condition is by negative SPEI. Fig. 2a shows strong La Nina years at 2 periods 2007-2008 and 2010-2011, it shows El Nino at 2 periods at 2009-2010 and 2014-2015. Fig. 2a shows opposite signs for most of the time, by showing wet condition for La Nina and dry one for El Nino periods. When considering the time series of production and yield in Fig. 2b and 2c, both curves show their increases at the periods of La Nina at 2007 and 2011. The rising trends in both production and yield indicate the progress of rice breeding and

modern technology e.g. RD6 variety and combine harvesting have been popularly increasing [9], [10].

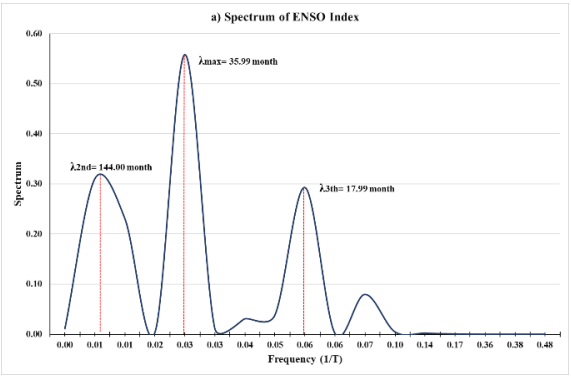
c)

Fig. 2 The time series of a) ONI and SPEI, b) rice production, and c) rice yield of Udonthani Province.

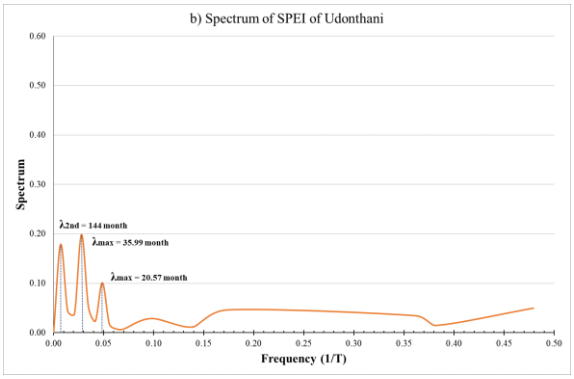
The spectral analyses were performed to the time series of ONI and SPEIs to see the dominated spectrums as shown in Fig. 3. The highest peaks together with second and third of these curves are shown as wave lengths in Table 1. The dominant return periods of ONI and SPEIs of the five provinces are shown in Table 1.

Table 1. The wave lengths of the highest, second, and third highest peaks of the spectrums of ONI and SPEIs.

		Return Period (year)		
		λmax	**λ2nd**	**λ3rd**
ENSO index		**3.00**	1.50	12.00
	Udonthani	**3.00**	12.00	1.71
	Loei	0.21	**3.00**	0.86
SPEI	**Khonkaen**	0.17	**4.00**	0.23
	Chaiyaphum	**12.00**	0.48	0.60
	Nongbualamphu	**6.00**	12.00	1.50



a)



b)

Fig. 3 Spectrums of ONI and SPEI time series of Udonthani.

Table 1 shows that the recurrent time of ONI should be approximately 3 years which is the same as the SPEIs for Udonthani and Loei, while that of Khonkaen and Nongbualamphu are 4 and 6 years, respectively. The longest return period of SPEI is that of Chaiyaphum region which is 12 years. Drought in Chaiyaphum is common because it locates in the strong rain shadow and the longest distance from the landfall of tropical cyclone (Fig. 1).

An essential characteristic of SPEI is its time scale. We did check correlation of 5-time scales SPEIs with the rice production and yield of each

provincial regions using Pearson's correlation coefficient. Udonthani and Loei are both the provinces in Sakol Nakhon Basin, where Loei is mountainous but Udonthani is rather flat. For Udonthani, 2-month time scale of May-June is the best correlation at 0.66 and 0.71 for production and yield, respectively (Table 2). However, for Loei, the best ones are 5- month and 3-month time scales for production and yield. Khonkaen and Chaiyaphum are in Khorat Basin. Khonkaen is flatter whereas Chaiyaphum is rather hilly or more undulating. Khonkaen's production and yield are related to SPEI at 3- month and 2-month time scales, respectively (see Table 2). The best time scale for Chaiyaphum for both production and yield are at 2-month. The last province is Nongbualamphu which its area covers both basins (Fig. 1). Only its rice production correlates with SPEI at 0.42 of 2-month time scale, but not for the rice yield.

Table 2 The Pearson's correlation coefficients of SPEIs with rice production and yield at several time scales.

		Ud	L	KK	Ch	NB
Rice Production	May	-0.12	-0.28	-0.05	-0.25	-0.13
	May-June	0.66	0.15	0.25	0.50	0.42
	May-July	0.16	0.23	0.75	0.19	0.27
	May-August	-0.13	-0.06	0.20	-0.45	-0.20
	May-September	0.11	0.45	0.12	0.07	0.29

	May-September	0.09	0.16	0.48	0.17	-0.14

CONCLUSIONS

The glutinous rice is the major staple food of the northwestern region of Northeast, Thailand. Orographic effect and the lengthy distance from tropical storm landfall render the region being drought prone. The rice productions and yields from 5 provincial regions of this northwestern part was correlated to the climatic conditions of the region using SPEIs and ENSO index using ONIs. The time series of 1-month SPEIs of all 5 provinces go against with that of ONI index. This means that positive SPEI (wet condition) is agreeable with La Nina (negative ONI) and vice versa dry condition go along with El Nino. From spectral analyses of ONI and 1-month SPEI time series, we found return period of ONI at 3 years and SPEIs at 3-12 years. Pearson correlation coefficient was used to determine the best time scale of SPEIs and found that two-month time scale is the most reasonable. The effect of climate variation on rice cultivation of the northwestern region of the Northeast of Thailand is needed to deeper study to get more information and understanding.

STUDY ON EXTRACTION FROM CESIUM IN CONTAMINATED SOIL PACKED IN FLEXIBLE CONTAINER BAG AND ADSORPTION USING RICE HUSK

ABSTRACT

A large amount of radioactive cesium was diffused by the accident at Fukushima Daiichi nuclear power station. Most of the diffused radioactive cesium deposited on Fukushima soil, and most of the contaminated soil was recovered by the stripping work. The contaminated soil including the radioactive cesium is currently placed in a flexible container bag and stored in a temporary storage facility. In the future, the contaminated soil is going to be burned at the intermediate storage facility. However, the storage facilities are insufficient and a disposal method has an agenda. In order to solve these problems, it is demanded to reduce the contaminated soil by decreasing the dose of radioactive cesium in the contaminated soil. Therefore, in this study, the test equipment simulating the actual flexible container bag is primarily made. Secondly, the two methods are combined; one is the extraction method using the electrophoresis, and another is the adsorption method using an adsorbent in order to decrease the concentration of cesium included in the simulated contaminated soil. As the adsorbent, the rice husk is focused on. Its material cost is reasonable and it can be acquired in bulk. Two types of the electrophoresis test are carried out, one with the use of the rice husk and another with the use of zeolite. The test with the zeolite is positioned as a control test for the test with the rice husk. It is clarified that the adsorption effect of rice husk for cesium is similar to that of zeolite.

INTRODUCTION

The huge tsunami caused by the Great East Japan Earthquake brought devastating damage to the Pacific coast of the Tohoku and Kanto regions. Even now, about eight years have passed since the tsunami disaster, and the reconstruction of Fukushima Prefecture has not been completed due to the serious nuclear accident of the diffusion of a large amount of radioactive materials at the Fukushima Daiichi Nuclear Power Plant of Tokyo Electric Power Company. Among the released radioactive materials, the radioactive cesium is still detected in a wide range in Fukushima Prefecture since it is released in large quantities and has a long half-life as in [1]. In addition, it is known that it is difficult to extract cesium due to the elective fixation of cesium by the clay mineral in soil as in [2]. The soil distribution map in Fukushima prefecture is shown in Fig.1 as in [3], [4]. From Fig. 1, the soil in Fukushima prefecture has a relatively large amount of clayey soil, and cesium is likely to be incorporated into the soil under these circumstances. Fig. 2 shows the abundance of radioactive cesium in multiple soils when one year has passed since the nuclear accident as in [5]. It can be seen that almost all of the radioactive cesium is fixed in the soil as a fixed state. It has been confirmed that a large amount of fixed radioactive cesium is fixed between the layers, called as Frayed Edge, in which mineral particles such as vermiculite are involved. The vermiculite is broadly distributed in the soil of Fukushima prefecture. Therefore, the development of effective removal technology of cesium from vermiculite is an urgent issue. The biggest issue in the decontamination project in Fukushima prefecture is how to treat the contaminated soil generated by decontamination. Since much of the deposited radioactive cesium exists in the surface layer of about 10 cm of the contaminated soil, the radiation dose has been reduced by the surface decontamination such as the peeling of the topsoil. Large amounts of collected contaminated soil are temporarily stored in flexible container bags in temporary storage areas in Fukushima prefecture. The contaminated soil enclosed in the flexible container bags is scheduled to be sequentially delivered to intermediate storage facilities in Fukushima prefecture in the future. However, it is not easy to carry out a large amount of contaminated soil from the temporary storage place to the intermediate storage facility, in fact, only about 2.18 million m3, which is about 15.6% of about 14 million m3 of the transported objects which should be transported to the intermediate storage facility, has been carried out of the temporary storage place. Furthermore, the contaminated soil transported to intermediate storage facility will be sorted by a sieve,

and incinerated at a high temperature of 800 ° C or higher as in [6]. However, not only the transportation cost of a large amount of contaminated soil but also the incineration cost has not been clarified. Therefore, it is necessary to establish a technology for reducing the volume of contaminated soil by removing cesium from the contaminated soil in the flexible container bags at a temporary storage place. The technology can reduce the radiation dose of the contaminated soil without transporting it to an intermediate storage facility. Thus, in this, study, the simulated flexible container bad is produced on the assumption of the removal of cesium in the flexible bag at the temporary storage place, and the test is conducted with the sand in which vermiculite and Toyoura standard sand are mixed as a simulated contaminated soil. As a cesium removal method from the contaminated soil, and it is verified whether cesium in the soil can be moved and adsorbed to adsorbents by means of the electrophoresis method. The purpose of this study is to examine the effective cesium extraction conditions and the possibility of volume reduction of contaminated soil through the obtained results of various tests.

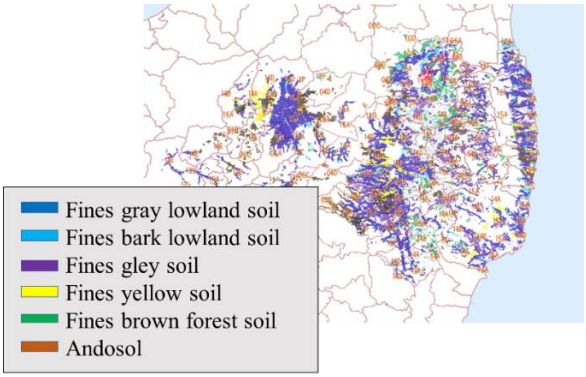

Fig. 1 Soil distribution map in Fukushima prefecture

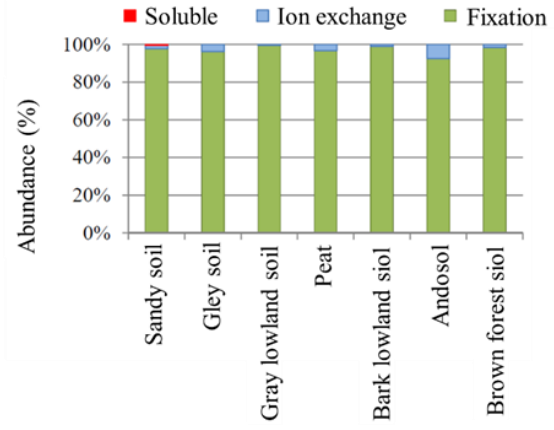

Fig. 2 Abundance of cesium in the soils

CESIUM IN SOIL

Cesium exists as a monovalent cation in soil and is adsorbed to the soil particles which is charged with a negative in soil. Additionally, cesium is easily adsorbed in and on the clay particles whose size is small. It is the 2: 1 layered silicate constituting a clay mineral that cesium adheres to the soil. The 2: 1 layered silicate is a generic term of the minerals in which the relation between the thickness of silicon tetrahedral sheet and those of aluminum octahedral sheet is 2: 1. In a silicon tetrahedron sheet and an aluminum octahedron sheet, either sheet or both of the sheets become insufficient in positive charge when a part of silicon or aluminum is replaced with another element having a small amount of positive charge. After that, the negative charge is appeared by the lack of positive charges in the sheet, and the cations are adsorbed to neutralize the interlayers of the sheet. The layer charge shows high selectivity to cesium ions as in [7]. This is because the size of cavity called a six-membered ring formed by oxygen atoms on the basic plane of a silicon tetrahedral sheet is approximately equal to the ionic radius of cesium ion. In addition, the bonding strength to the six-membered ring increases as the hydration energy decreases, which means that cesium ion has the highest bonding strength. However, the potassium ion occupies the six-membered ring because the abundance of potassium ion is decisively large in the soil (see the top of Fig. 3). The end of the clay mineral layer is frayed by weathering of soil, and the potassium ion is released. As a result, the region into which other cations can penetrate is formed and called as frayed

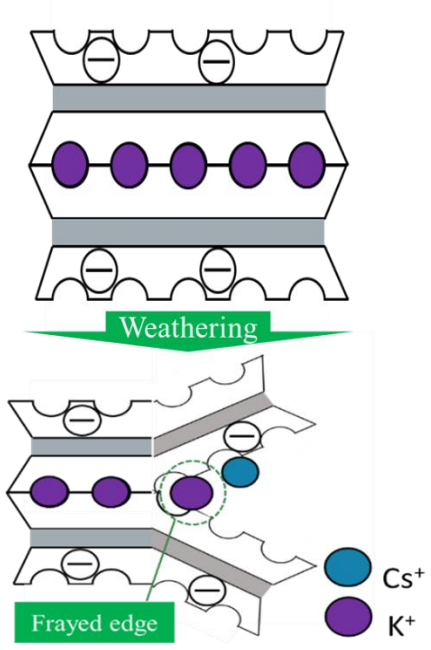

Fig. 3 Top part of 2:1 type of lamellar silicate and bottom part of the Frayed edge

edge site (see the bottom of Figure 3). It is difficult to replace cesium ions fixed to the frayed edge site with other cations as in [8].

ADSORBENTS

Rice husk and Rice husk powder

A large amount of rice husk is generated in the process of threshing and hulling after harvesting, and 2 million tons are discarded every year. In this study, the cesium adsorption ability of rice husks is focused on in order to effectively utilize it as a resource. Various researches on the adsorption ability for cesium of rice husk have been studied as in [9], [10]. For example, the research by Shozugawa et al. states that radioactive cesium is trapped by viscous fungi on the rice husks as in [11]. The possibility as a new adsorbent to replace zeolite is examined by using rice husk as an adsorbent in an electrophoretic test. Raw rice husk and commercially available rice husk powder as shown in Photo 1 are used in the test.

Photo 1 Rice husk (left) and Rice husk powder (right)

Zeolite

Zeolite is a clay mineral with regular tubular pores and cavities. Zeolite crystals have adsorption properties and ion exchange properties because they have many pores. In particular, it is known that the zeolite has high ion exchange properties against cesium. Thus, the zeolite is selected so as to exam the adsorption ability of the rice husk through the results of adsorption tests as a comparative material for rice husk. In the test, powdered rice husk is used (see Photo 2).

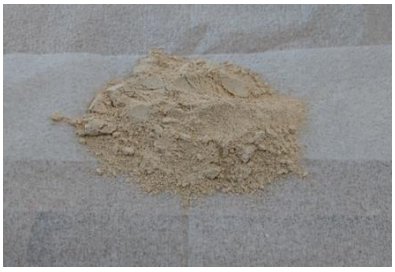

Photo 2 Powdered zeolite

TEST METHOD

Electrophoresis

In this study, the electrophoretic method is employed in order to transfer cesium ions extracted from clay minerals in soil. The cesium ions transferred to the cathode are adsorbed by an adsorbent placed in front of the cathode. An electrophoretic phenomenon is the movement of charged particles in a liquid medium under an electric field. Cesium ions are transferred to the cathode side by using the electrophoretic phenomenon, and are adsorbed in or on the zeolite or rice husk which are placed in front of the cathode side.

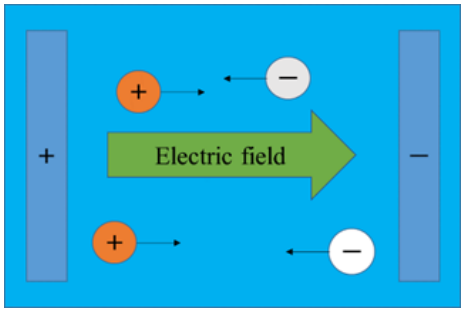

Fig. 4 Mechanism of electrophoresis

Electrophoresis test

The experiment device which simulates the flexible bag packing the soil contaminated by radioactive cesium is produced in the course of conducting the electrophoresis test. First, a simulated contaminated soil is prepared by adding 1 mL of the cesium standard solution so as to assume a real contaminated soil. The simulated soil consists of vermiculite and standard sand. Next, the simulated contaminated soil is placed in an acrylic container bag, and a carbon rod (diameter of 15 mm and length of 40 mm) serving as an anode is placed vertically in the center of the soil. Additionally, the simulated contaminated soil is placed in a simple container that combines filter paper and bolding cloth (mesh size 37 μm) to prevent mixing with the adsorbents. Moreover, the simulated contaminated soil is immersed in ammonium acetate aqueous solution (3.0% of concentration, 60 - 70 mL) and the adsorbent is placed in front of an aluminum plate so as to enclose the simulated contaminated soil (see Fig. 5). After an energization for a specified time, the soil is collected and washed out by stirring. The extracted amount of cesium contained in the solution and soil after the test is quantified by an atomic absorption spectrophotometer for the solution separated through filtration. The extraction rate is determined by the following equation (1).

Extraction ratio (%)
= extracted amount (mg)
/added amount (mg)
× 100 (1)

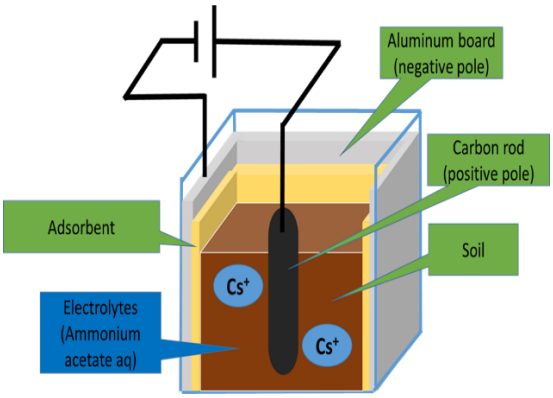

Fig. 5 Test device

TEST RESULTS

The volume ratio of standard sand to vermiculite contained in simulated contaminated soil is 1: 1, and the mass of simulated contaminated soil is 120 g. The current values during the electrophoresis test are 25, 50, and 100 mA, and the energizing time is 48 hours. The results of tests using three types of adsorbents are shown in graphs, respectively. Each test is conducted three times to ensure a reproducibility, and the average value for three batches is listed in the graphs. The test conditions are shown in Table 1.

Table 1 Test conditions

Soil		Standard sand: 114 g, Vermiculite: 6 g
Electrolyte		Ammonium acetate aqueous solution (3.0 %): 60-70 mL
Sample		Cesium standard solution: 1mL
Adsorbents	Zeolite	10 g
	Rice husk	3 g
	Rice husk powder	10 g
Curing time		168 hours
Energizing time		48 hours
Current value		25, 50, 100 mA (under 40 V)

Test results of zeolite

Fig. 6 shows the test results when zeolite is used as the adsorbent. The vertical and horizontal axes of the graph represent the extraction ratio of cesium and the current value, respectively. The results of the test with and without zeolite are compared. As a result of the test, the extraction rate of cesium decreases with increasing of the current value regardless of the presence or absence of the adsorbent. It is found that about 20% of the added cesium is extracted, which can help the volume reduction of the contaminated soil. On the other hand, about 80% of the added cesium remains in the soil. These facts indicate the difficulty of extracting cesium from the soil. Before the electrophoretic test is carried out, the curing period of 168 hours is set to fix the cesium sufficiently to the soil. Most of the cesium is adsorbed to the vermiculite during the curing period, which makes it difficult to extract the cesium from the vermiculite. Alternatively, the most effective extraction of the cesium form the soil appears when the current value is 25 mA in the electrophoresis test. It is found that the extraction of cesium is inhibited if the current value becomes too high. This is caused by the re-adsorption of cesium, temperature rise, the promotion of evaporation of electrolyte, etc. The investigation of the cause should be examined in the future. Considering the practical operation, it can be said that the low current value is advantageous from the viewpoint of running cost. Suppose the difference between the extraction ratios of specimens with and without zeolite is the adsorption ability of zeolite for cesium, the adsorption ability hardly changes with increasing or decreasing current value. In other words, it is found that the current value has little significant influence on the adsorption ability.

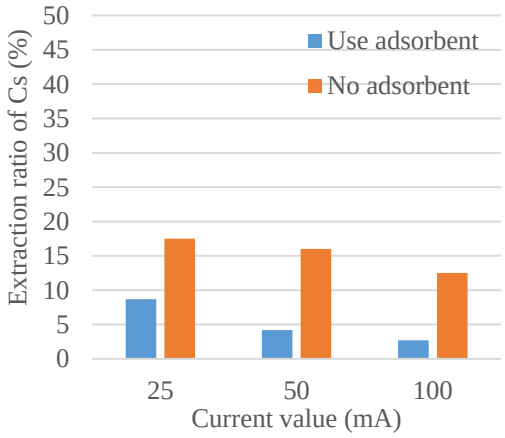

Fig. 6 Extraction ratio of Cs using zeolite

Test results of rice husk

Fig. 7 shows the test results when the rice husk is used as the adsorbent. The test results are very similar to those of zeolite. The smaller the current value, the larger the extraction ratio r, and the current value has little significant influence on the adsorption ability of rice husk. It is clarified that the rice husk has almost

the same adsorption capacity for cesium as the zeolite. It is noted that the used amount of adsorbent is 10g of zeolite and 3g of the zeolite. There is a difference in mass since the apparent volumes of both adsorbents are tried to be equalized. Thus, from the viewpoint of mass, the rice husk has higher adsorption capacity per unit volume than the zeolite. As these results, it may be most useful to use raw rice husk as adsorbent from the viewpoint of both volume reduction and processing cost of rice husks when the amount of adsorbent and adsorption performance is focused on.

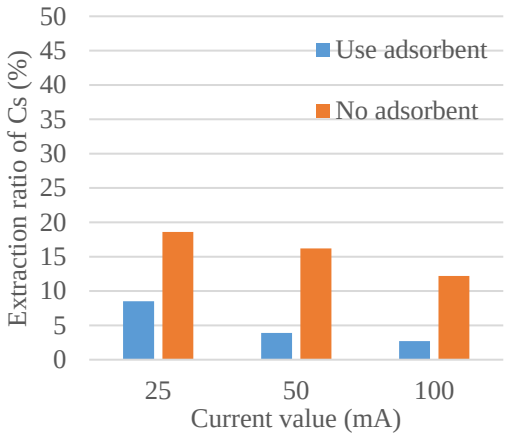

Fig. 7 Extraction ratio of Cs using rice husk

Test results of rice husk powder

Fig. 8 shows the test results when the rice husk powder is used as the adsorbent. The test results are similar to those of zeolite and rice husk. The mass of the adsorbent is 10g of rice husk powder as well as zeolite, and the rice husk powder has the more or less same adsorption ability as zeolite. The adsorption to cesium is largely due to the micorpore distribution of the adsorbent and the constituent elements. In the future, it is necessary to investigate the cause by comparing the micropore distributions with using a facility such as a BET specific surface area measurement device.

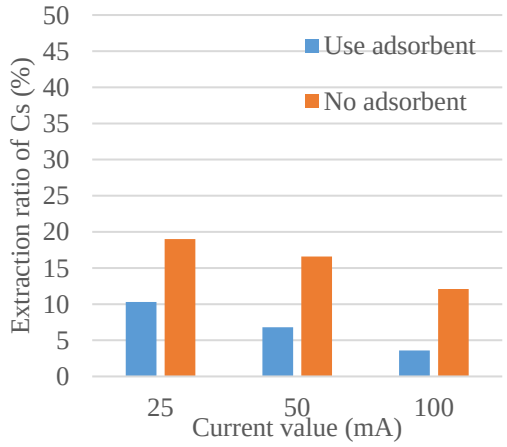

Fig. 8 Extraction ratio of Cs using rice husk powder

CONCLUSIONS

・In this study, the experiment device which simulates the flexible bag packing the soil contaminated by radioactive cesium is produced, and the electrophoresis tests are conducted under various conditions in order to investigate appropriate transfer conditions of cesium to the adsorbents (zeolite, rice husk and rice husk powder).

・ The extraction rate of cesium is the highest at the minimum current value (25 mA) when the cesium is extracted by electrophoresis without an adsorbents.

・ The adsorption rate of cesium at 50 mA of current value shows the maximum value to compare with the other current value (25, 100 mA) when the zeolite is used as the adsorbent. However, the difference due to the current is not so large.

・ The adsorption rate of cesium at 50 mA of current value also shows the maximum value to compare with the other current value (25, 100 mA) when the rice husk or the rice husk powder are used as the adsorbent, the difference due to the current is not so large.

・ The test results with zeolite, rice husk and rice husk powder as an absorber for cesium are similar, which shows that their adsorption properties for cesium are more or less same.

・ It is not clear whether there is a clear correlation between the mass and the amount adsorbed, but it is venture to discuss them here. It can be seen that the rice husk adsorbs the cesium in a smaller amount. It is considered that the adsorption principle of rice husk is one of the factors that enables rice husk to adsorb cesium in a smaller amount than rice husk powder.

・Some of the cesium can be trapped by viscous fungi that attach to the rice husk surface. The reason why the absorbent performance of rice husk powder is inferior to that of rice husk can be that the adsorption property mentioned above is lost during the powder processing from rice husk to powder form.

・ It is identified that a rice husk is an excellent adsorbent for cesium because the powder processing is not necessary and the required amount is small.

ABSTRACT

Effective water resources planning and management need accurate historical hydrological data for simulation and prediction. Many watersheds in Thailand are ungauged and many have unreliable or incomplete data. This study focuses on using available meteorological data to generate accurate monthly hydrological data, including direct runoff, evapotranspiration, and groundwater recharge for Lam Takhong watershed in Buriram Province, Thailand, as a case study. The Lam Takhong River is a tributary of the Mun River in northeastern Thailand covers an area of 1,560 square kilometers. This study examined nine years of daily meteorological data, including rainfall, temperature, relative humidity, and solar radiation obtained from a meteorological station, Buriram 436401, Royal Meteorological Department, from January 1, 2006 to December 31, 2014. Direct runoff values were evaluated from rainfall data using SCS-CN method. The CN and λ parameters were evaluated from accurate GIS maps of soil and land-use. Evapotranspiration values were determined from recorded climatic data using Morton's CRAE method. Results from the study period indicated that the wettest and driest years were 2008 and 2007, respectively. Groundwater recharge occurred every year except in 2007 with the greatest recharge occurring in 2011. Water balance was demonstrated to be a valuable tool for generating accurate historical hydrological data.

INTRODUCTION

Burirum is a fast growing township located in southern part of Northeast, Thailand. Lam Takhong (Burirum) is a small river that supports livelihood of its population. It is one of the main tributaries of the Mun River that flowing to the great Mekong River. The Lam Takhong, apart from the only water supply source for the Burirum township and its satellites, is responsible for surrounding agriculture, ecology, and socio-economic of the area. The river is subjected to flood and drought almost every year and recently increasing in frequency and intensity. There are three medium reservoirs and several small scale ones along the river. Water resource and watershed planning and management are therefore extremely important so that river flood and droughts are to be mitigated and so water pollution.

The hydrological data of the area in the past are crucial for the river and its watershed planning and management studies. Surprisingly, the past hydrological data of the Lam Takhong (Burirum) watershed are very scarce and not reliable even though serious problems are always at hand. The river is so called ungauged river [1]. Fortunately, meteorological data from the township's weather station are fairly reasonable, therefore, historical, hydrological, data can be generated.

The foremost driving force of river flow is the rainfall on the watershed. Total rainfall can be divided into vegetation interception, surface detention and retention, direct runoff, interflow, and groundwater flow. The interception, detention, and retention are evaporated back to the atmosphere. The interflow and groundwater flow become base flow. The direct runoff together with base flow constitutes the river flow [2]. The Burirum weather station recorded precipitation and other meteorological data since 2006. The objective of this study was to construct monthly hydrological data namely river flows and groundwater recharges of the Lam Takhong (Burirum) watershed from 2006 to 2014 by utilizing the daily meteorological data. The SCS-CN method was used for rainfall-runoff modelling. Monthly actual evapotranspiration was evaluated by Morton's CRAE method. The water balance tool was used to generate the time series of direct runoffs and groundwater recharges of the watershed. The river flow was finally the results of direct runoff and base flow.

STUDY AREAS AND DATA SETTING

Our study area is the Lam Takhong (Burirum) watershed which is located in the southern part of Northeast Thailand (Fig. 1). It is a sub-basin of the Mun River, one of the main tributaries of the Mekong River. It covers the area of 1560 km2 in between 14º41’ 54” to 15º 17’ 51” latitude and 102º 56’ 15” to 103º 17’ 15” longitude Takhong flows northward with a length of about 95 km. From the two southern most tributaries Huai Jorkhemak and Huai Raj, they form the Lam Takhong

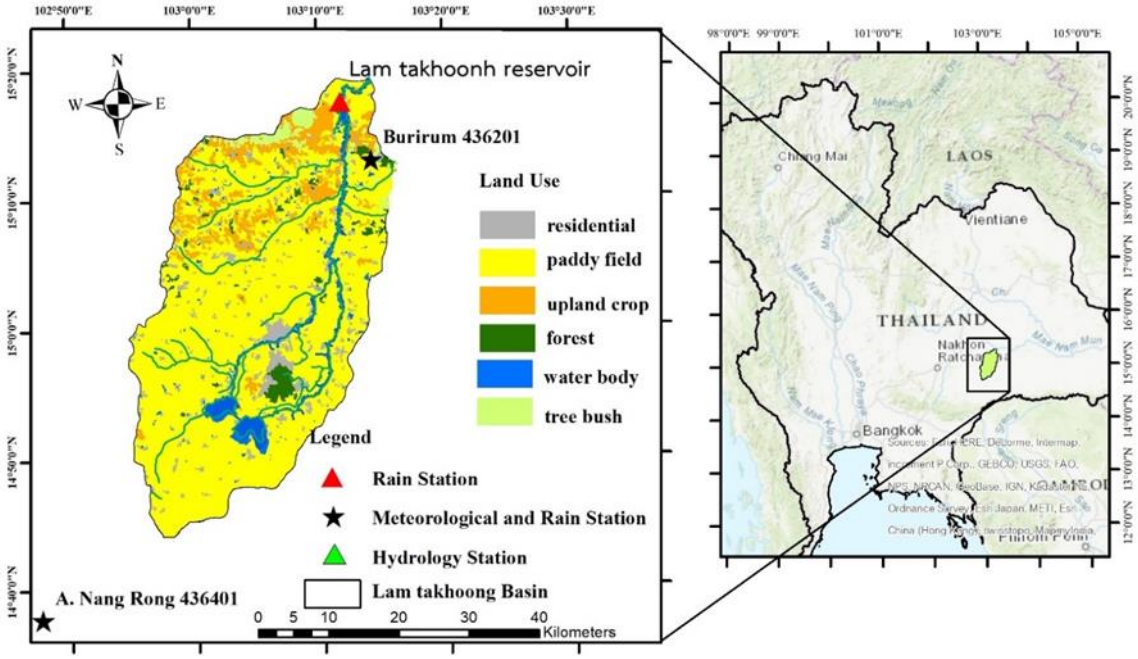

Fig. 1 Study area with drainage networks and other information.

River which drains in to the Mun River. The climate of Lam Takhong is the typical Northeast, Thailand, climate demonstrating wet and dry cycle each for half a year. Humidity causes of rainfall come from two sources namely, the southwest monsoon and the tropical cyclone. The mean annual rainfall of the region is 1,420 mm (2006 to 2014) and normally peaks in August. The mean annual of actual evapotranspiration of the same periods as rainfall is about 910 mm and also peaks in August due to large amount of soil water availability (Fig. 2).

The landform of the study area is a mild undulating terrain with highest elevation of 180 m (from the annual mean sea level) at the southernmost of the watershed and the lowest at the confluence with the Mun River of about 140 m (amsl.). Its geology is the Khorat Group with the majority of Mahasarkham formation. The formation consists of sandstone, mudstone, and rock salt producing sandy, clayey, and saline soils. The soils of the whole watershed were studied for hydrological properties and classified into 4 hydrological soil groups as shown in Table 1 and Fig. 3. The main soil groups are C and D which can produce large amount of runoff. This is one of the reasons for frequent flooding of the downstream area.

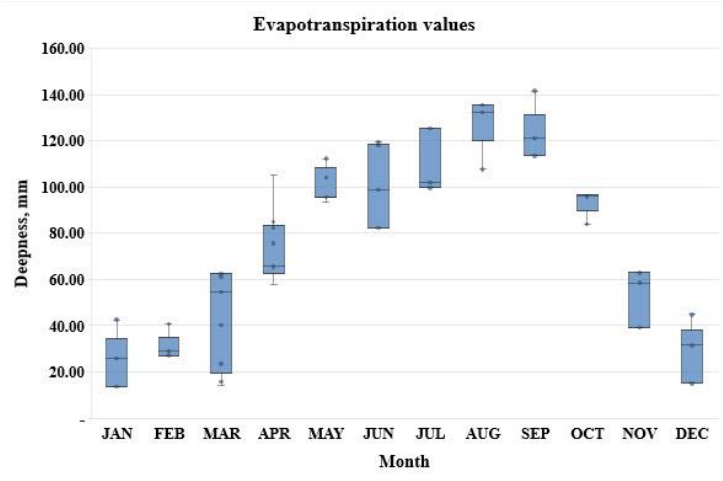

Fig. 2 Actual evapotranspiration of the region.

HSG	Description	Area km^2	Final Infiltration Rate (mm/h)	Field capacity (%)	Wilting point (%)
A	Lowest Runoff Potential. Includes deep sands with very little silt and clay, also deep	128.21	8-12	5.5	2
B	Moderately Low Runoff Potential. Mostly sandy soils less deep than A	201.23	4-8	28.4	12.15
C	Moderately High Runoff Potential. Comprises shallow soils and soils containing considerable clay and colloids,	604.75	1-4	33.95	13.4
D	Highest Runoff Potential. Includes mostly clays.	626.84	0-1	33.5	20.2

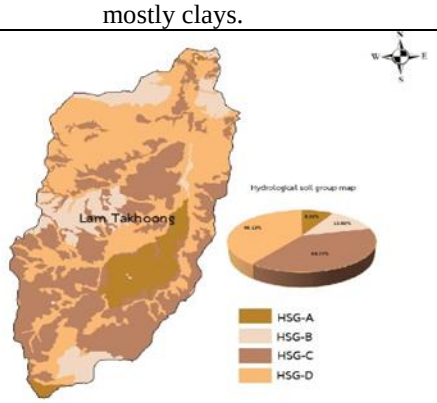

Fig. 3 Hydrological soil groups of the Lam Takhong Watershed.

The land-use of the study area was derived from the two land-use maps (2010 and 2014) of the Department of Land Development of Thailand. The land-use types were classified into 6 types with the majority of paddy fields and upland crops (Fig. 1 and Table 2). The change of 2010 land-use to 2014 one is negligibly small therefore we used the 2014 one in our curve number (CN) calculations. The CN value is the function of soil, land-use, and antecedent soil moisture. We normally estimate CN2 first from look-up tables then it is changed to CN1 or CN3 for dry or wet conditions, respectively, using antecedent rainfall see Eqs. (6) and (7).

METHOLOGY

Water balance of Lam Takhong watershed

Water balance can be defined as inflow rate subtracted by outflow rate equals to time rate of change of the soil water. We are only interested in the critical zone which range from the base of effective root zone up to the crown of the plant [3]. Considering the whole watershed, the only input is assume to be precipitation even though there are some other inflows but they are so negligibly small [4]. There are three outputs namely runoff, evapotranspiration, and groundwater recharge. Water balance equation for the effective root zone can be written as [3]:

$$\frac{Zd\theta}{dt} = P - E - R - D \quad (1)$$

where Z is thickness of effective root zone, θ is moisture content of the soil, P is precipitation, E is evapotranspiration, R is runoff, and D is deep drainage below the root zone. In the form of finite difference Eq. 1 is:

$$Z(\theta_t - \theta_{t-1}) = P_t - E_t - R_t - D_t \quad (2)$$

where subscript t and t-1 are the present time and the past time for one period, respectively. In case of daily time series t and t-1 are today and yesterday. The definition of effective root zone, Z, is loosely defined as the depth of soil with rather constant moisture content plant root can however penetrate much deeper than that [3]. Several studies of variability of soil moisture content in the Northeast of Thailand found that northeastern soil profiles normally keep moisture constant at about 1 m depth [5]-[6]. So we presume Z value at 1 m deep that $Z\theta_t$ and $Z\theta_{t-1}$ are the soil water depths of today and yesterday, respectively. The equation to predict soil water depth for today can be written as:

$$Z\theta_t = Z\theta_{t-1} + P_t - E_t - R_t - D_t \quad (3)$$

The upper and lower limits of soil moisture content are the field capacity and permanent wilting point conditions, respectively. By deducing from the study of, for example, [5]. we obtained soil water depths of 10 and 150 mm for lower and upper limits.

Direct runoff

A direct runoff (R) is a part of the whole precipitation that flow along the soil surface and shallow interflow to constitute the river flow. One of the most popular methods to evaluate direct runoff is the soil conservation service curve number (SCS-CN) method [7]. It is the function of total precipitation (P) and potential retention of soil (S) at the time of runoff occurring which can be written as [8],

$$R = \frac{(P - Ia)^2}{(P - Ia + S)} \quad \text{for } P > Ia \quad (4a)$$

$$R = 0 \quad \text{otherwise} \quad (4b)$$

where I_a is initial abstraction (mm) meaning the volume of precipitation loss before runoff to begin and is a function of potential retention, S, as

$$Ia = \lambda S \quad (5)$$

where λ is the ratio of initial loss to potential retention which was assigned to 0.2 at the beginning [9]. Several studies found the values of λ in the range of 0 to 0.3 [10]-[11]. Most of the studies in semiarid regions obtained the λ values less than 0.2 at the average of 0.05 [12] however for the area of humid climate the λ values are higher than 0.2 or up to 0.3 [13]. Lam Takhong (Burirum) watershed is in sub humid climate which its initial abstraction may be in the middle between humid and semiarid climates. We decided λ to be 0.1 in this watershed.

For simplicity, the value of S is related to a dimensionless parameter called curve number (CN) which depends on land use, soil type, and antecedent soil moisture [7]. The CN values are classified with antecedent soil moisture into three groups. The values of CN1, CN2 and CN3 are for antecedent wet soil, normal, and dry soil respectively. The CN2 value can be determined from the prepared tables e.g. [2] then CN1 and CN3 can be evaluated from CN2 as:

$$CN1 = \frac{4.2CN2}{(10 - 0.058CN2)} \quad (6)$$

$$CN3 = \frac{23CN2}{(10 + 0.13CN2)} \quad (7)$$

The antecedent soil moisture in this study was classed using the depth of rainfall of two previous days plus half of today. The potential retention of watershed, S, can be calculated from CN value as

$$S = \frac{25400}{CN} - 254 \quad (8)$$

Evapotranspiration

In majority of water balance models the value of actual evapotranspiration (E_a) is always the unknown or output of the model, but in this study we estimated E_a directly from climatic data with the model of Morton's complementary relationship areal evapotranspiration (CRAE). [14]. extended the assumption of [15] which stating that the sum of regional actual evapotranspiration (E) and potential evapotranspiration (E_p) rates equals to twice the wet environment evapotranspiration rate (E_w), namely

$$E + E_p = 2E_w \quad (9)$$

Morton (1983) solved this equation using two equations, the energy balance and vapour transfer equations, respectively,

$$E_p = R_T - [\gamma f_T + 4\varepsilon\sigma(T_P + 273)^3](T_P - T) \quad (10)$$

$$E_p = f_T(e_P - e_d) \quad (11)$$

in which T_P and T are the equilibrium and air temperatures, respectively, in degree C; R_T is the net radiation at critical zone at air temperature; γ is psychrometric constant; σ is the Stefan-Bolzmann constant; ε is the surface emissivity; f_T is the vapour transfer coefficient; e_P and e_d are the saturated vapour pressure at T_P and at dew point temperatures, respectively. Eq. (10) and (11) can be solved for Ep and Tp by iterative technique. The value of E_w can be estimated from [16]:

$$E_w = b_1 + b_2[\frac{\Delta_p}{(\Delta_p+\gamma)}][R_n - 4\varepsilon\sigma T_P{}^3(T_P - T_a)] \quad (12)$$

where b_1 accounts for large scale advection during season of low net radiation is equal to 14 W/m^2, and b_2 equals to 1.20, Δ_p is the slope of the saturated vapour pressure curve at T_p. Eqs (9) to (11) can be solved for actual evapotranspiration, E, [14].

Since solving simultaneously Eqs (9) to (11) is very complicated however [17] presented a computer programming in R language to solve them. The daily climatic data from 1/1/2006 to 31/1/2014 were used in this calculation. The accurate output results from MortonCRAE model must be in monthly forms.

Groundwater recharge

Groundwater is one of the important hydrologic components. It resides in aquifers far below the bottom of effective root zone. Top of the upper most aquifer is a water table. The drainage water from the root zone feeds the groundwater system through the unsaturated zone down to the water table called groundwater recharge. The drainage from root zone begins when the root zone reaching field capacity which is about 150 mm of soil water of the root zone [18]. Groundwater can be lost from an aquifer by two ways discharging to rivers as baseflow and flowing upward to a root zone as capillary action.

River flow

River flow is composed of direct runoff and baseflow. The former comes from precipitation whereas the later from groundwater discharge. The baseflow of the interest region is one of the lowest in the Mekong Basin which is about 53 mm/year [18]. We estimated baseflow from the concept of baseflow index, i_b, which is

$$ib = \frac{R}{Q} \quad (13)$$

where R and Q are runoff and river flow, respectively. We obtained the value of baseflow index from [19]. Which is about 0.17.

RESULTS AND DISCUSSION

The time series of rainfall, runoff, and actual evapotranspiration of the study area from 2006 to 2014 are shown in Fig. 4**.** It shows the distributions of rainfall, runoff, and ETa for each year. The runoff and ETa are always followed the pattern of rainfall. The daily distribution of rainfall for each month of the years dictates the amounts of runoff and ETa.

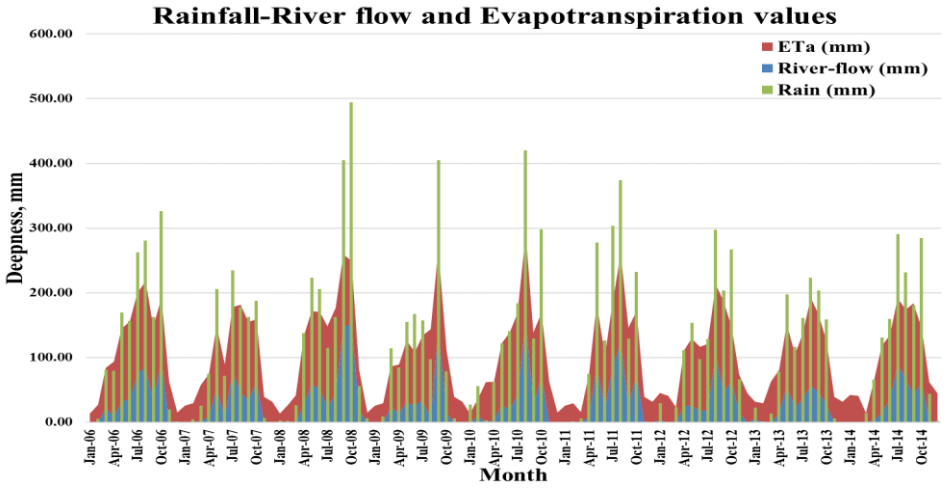

Fig. 4 The time series of rainfall, runoff, and actual evapotranspiration of the study area.

Table 3 Summarized results of water balance.

Year	Rain	Runoff	Eta	GW	Base flow	River flow	ETa/ Rain	Runoff/ Rain	River-flow/ rain
	(mm)	(mm)	(mm)	(mm)	(mm)	(mm)	(mm)	(mm)	
2006	1,545.03	391.52	964.04	160.90	80.67	472.19	0.62	0.25	0.31
2007	1,152.68	291.90	878.96	0.00	60.06	351.97	0.76	0.25	0.31
2008	1,838.57	524.08	963.29	294.96	89.19	613.27	0.52	0.29	0.33
2009	1,302.67	295.65	882.40	148.58	50.26	345.91	0.68	0.23	0.27
2010	1,445.71	362.14	920.77	125.66	62.99	425.13	0.64	0.25	0.29
2011	1,527.00	425.30	838.90	255.59	72.49	497.79	0.55	0.28	0.33
2012	1,378.98	318.42	934.55	93.69	54.91	373.33	0.68	0.23	0.27
2013	1,183.48	265.18	885.48	44.69	45.43	310.61	0.75	0.22	0.26
2014	1,404.69	316.67	901.27	190.57	54.29	370.96	0.64	0.23	0.26
Mean	1,419.87	354.54	907.74	146.07	63.36	417.91	0.65	0.25	0.29

Table 3 summarizes the results of the water balance during 2006 to 2014 period. The highest annual rainfall were in the years 2008, 2006, and 2011 at 1839, 1545, and 1527 mm, respectively which produced runoff at 524, 392, and 425 mm while ETa at 963, 964, and 838 mm, and river flow at 613, 472, and 498 mm. The second largest precipitation (2006) produced the least river flow among these three years due to its lower runoff and higher ETa. This shows that the higher precipitation does not mean to produce higher river flow.

The lowest annual rainfall were in the years 2007, 2013, and 2009 at 1,153, 1,183, and 1,303 mm respectively which produced surface runoff at 292, 265, and 296 mm, ETa at 879, 885, and 882 mm, and groundwater recharge at 0, 45, and 149 mm. The precipitation of the year 2007, even though, was much less than that of the year 2013 but it produced runoff as high as that of the year 2013, that is why it could not produce groundwater recharge, it was the only year without groundwater recharge.

From Table 3, we can evaluate runoff coefficient of the study area as 0.25 for surface runoff and even higher for that of river runoff at 0.3 which is quite high for the mean value of Northeast region e.g. for the Chi-Mun Basin the runoff coefficient is 0.1-0.15 [20]. This discrepancy indicates that the runoff from the study watershed is exceptionally very large due to soil and land-use types. The soils of the watershed are mostly clayey and compact sandy soils of Roi-et series which is the paddy soil (Fig. 2). The main land-use of the study area is paddy field which is saturated most of the time during rice growing season (Fig. 1). The saturated and heavy soil creates high rate of runoff [2].

CONCLUSIONS

We presented an effective water balance tool for generating hydrological data from the available and accurate meteorological data for an ungauged or poorly gauged watershed. Rainfall data as well as other essential meteorological data were needed for our procedure. The soil water conservation service-curve number (SCS-CN) method was used to transform rainfall data to surface runoff values with the helped of land-use and soil information. The actual evapotranspiration (ETa) was evaluated from meteorological data using Morton's CRAE method. Knowing 3 hydrological components namely rainfall, runoff, and ETa, the water balance of the root zone was proceeded. The groundwater recharge and the river flow were evaluated with the help of baseflow index. The generation of hydrological data for a watershed is very useful for watershed and reservoir management. It is interesting to compare this method to any accurate gauged data in the future.

ABSTRACT

Rainfall is one of the most valuable natural resources for northeastern Thailand, a region whose livelihood of more than 80% of the population depend predominantly on rainfed agriculture. Rainfall events can also cause severe natural hazard, therefore proper water resources and flood management is crucial to this region. Regionalization of rainfall can facilitate the management of water resources and floods by delineating a region with rainfall patterns that vary in both time and space into areas with more homogeneous rainfall characteristics. This study applied both hierarchical and K-means clustering methods to separate the entire Northeast into three precipitation zones using monthly rainfall data from 38 stations over 30 years from 1987 to 2016. The temporal variation of zoning was also investigated by dividing the data into three 10-year periods, 1987-1996, 1997-2006, and 2007-2016. The regionalization by both methods gave similar results that are comparable to the mean annual rainfall of the entire region. Mean annual rainfall values were highest in the northeastern part of the region with a gradual decreasing trend to the southwest. The clustering methods, on the other hand resulted in the highest rainfall zone in the northern part, the moderate rainfall on the southeastern, and the lowest on the southwestern part. As it relates to temporal variation, the results from 1987-1996 for both methods are mostly the same but those from 1997-2006 and 2007-2016 are not quite the same especially results from the last decade. Homogeneous rainfall regionalization by clustering methods is preferable to merely geographical and mean annual rainfall values because they take into account several factors such as monthly rainfall distribution.

Keywords: hierarchical clustering, K-means clustering, homogeneous rainfall, temporal variation, northeastern Thailand.

INTRODUCTION

Rainfall is the primary cause of flood, drought, and other hydrological consequences. Many hydrological and water resources analyses, designs, and operations are needed to know the rainfall homogeneous regions [1]. Traditionally, homogeneous rainfall region has been determined from the mean annual precipitation and geography of the region [2]. Since the northeastern Thailand climatic condition is monsoonal the area is wet during the southwest monsoon from mid-May to mid-October and dry from mid-October to mid-May by the northeast monsoon [3], [4]. This is actually the result of the dynamics of Intertropical Convergence Zone (ITCZ) [5], [6] that moves across the northeast region during the wetting period by touching the southern boundary of the region at about mid-May and keep on moving up passing the northern boundary at about early July and moving further north then returning to touch the northern boundary again at about mid-July then slowly moving southward across the Northeast region again until mid-October then passing the southern boundary of the region. Mobility of the ITCZ causes rainfall pattern of the Northeast region to be ever changing [7].

The Northeast topography is a plateau-like with mountain ranges on the west and the south boundaries. The rainy season starts when the ITCZ band first approaching the southern boundary about mid-May and ends when the ITCZ about to leave the same boundary at mid-October. During the ITCZ band moving further north, the rainfall of the Northeast decreases allowing dry spell to interfere with its rainfall pattern. Two types of wind bring moist air from the oceans to the Northeast region namely the southwest monsoon from the Indian Ocean and the tropical cyclone from the Pacific Ocean. These phenomena make the rainfall pattern very complicate. Regionalization of rainfall in this part of Thailand cannot be performed just by subjectively observing the mean annual rainfall and its geography but must be applying cluster analyses. Two well known clustering algorithms being generally used for this type of work are hierarchical and k-means methods [1], [8].

Our study objective is to partition the whole Northeast region into three uniform precipitation sub-regions using the two cluster analyses with monthly rainfall data on scatter rainfall stations all over the region during three 10-year periods.

STUDY AREA AND DATA ACQUISITION

Our study area is the whole northeast region of Thailand. It covers the area of 168,854 km^2 of a relatively mild rolling plain with the elevation of about 150 to 500 m above mean sea level. Due to its plateau-like topography it is called the Khorat Plateau [9]. There are mountain ranges on the west and south borders, the Phetchbun and Dong Paya Yen on the west boundary which border with the Central and the Sankambeng and Phanom Dangreg Ranges on the south which border with the Central and Cambodia (Fig. 1). These mountain ranges create orographic effects as rain shadows retarding the flow of southwest monsoon to the region. The Phu Phan Range divides the Khorat Plateau into two basins the upper is smaller called the Sakol Nakhon Basin and the lower part is called the Khorat Basin. Both basins drain to the Mekong River in the north and east boundaries by the Songkhram River for the upper basin and the Chi-Mun System for the Khorat Basin. Geology of the northeast composts of sandstone of the Mesozoic Khorat Group [10]. Following the parent materials of sandstone, typical soils of the northeast are sandy soils which are very infertile and sometime saline [9]. Hydrologically, there are only wet and dry seasons in the northeast, Thailand, each sharing half of the year. Two sources of humidity to produce rainfall in the northeast region namely the southwest monsoon and the tropical cyclone. The topographic and climatic conditions complicate the rainfall pattern of the northeast region, therefore it is essential to partition the whole northeast region into more compact, homogeneous areas. We used monthly rainfall data from 38 rainfall stations for 30 years during 1987 to 2016 from the Thai Meteorology Department for our study. The names, locations, and elevations of the rainfall stations are shown in Table 1 and Fig. 1.

METHODOLOGY

Traditional method of rainfall regionalization is by using mean annual depth of precipitation e.g. low, modulate, and high rainfall [11]. Objectively, rainfall regionalization can be performed by mean of a cluster analysis [12], which is a set of algorithms to group the similar objects from a diverse observations. In this study we tried to partition 38 rainfall stations of the whole Northeast region (Fig. 1 and Table 1) into 3 groups of homogenous rainfall characteristics as in [13]. From 30-year data we investigated each of three 10-year periods, i.e. 1987-1996, 1997-2006, and 2007-2016, to evaluate temporal variation.

Two types of clustering algorithms, i.e. hierarchical and k-means, were used with monthly rainfall depths which were arranged in the forms of 3 tables. Each table contains monthly rainfall data with 120 columns of months of the years, say from January 1987 to December 1996 for the first table, and 38 rows of the stations in Table 1. The hierarchical algorithm and the k-means one are totally different [8]. The former produces a dendrogram of the stations with similar rainfall characteristics [14].

At the beginning procedure the two most similar rainfall characteristics being merged together and then the third station (or another cluster of stations) to be merged with the Ward's criteria that is the sum of euclidean distances among the stations in the new cluster must be minimum [8]. Each dendrogram (not shown herein) illustrates 38 clusters at its base and 1 cluster at its top.

The k-means algorithm needs to be provided with k seeds randomly [12] among each of the three data sets. In our case, we set up 3 seeds since we need to group into three clusters as probably of low, medium, and high rainfall. From the 3 predetermined seeds, the rainfall data that are more similar to a seed are grouped together with the seed, therefore we have three groups for the whole data. Consequently, new seed is to be determined for each group e.g. at the centroid of the group, then the process to be

performed all over again until the stations in each group do not change [8].

The similarity are always measured by euclidean distance which is not really a distance but it is a square root of sum square of the coordinates difference between two points. The points are the rainfall stations and their coordinates are monthly rainfall data from each ten year period. Since rainfall depths in the wet seasons are much larger than those in the dry seasons, therefore the data in each station must be normalized so that the wet season data do not dominate the dry season ones.

Tables of monthly rainfall data from 38 stations were prepared using Excel software then transformed into text files to be used with the R programming. The text file tables of rainfall data were input as data frames. The data frames were normalized using *scale* function. The normalized table can be clustered by hierarchical method using *hclust* function together with the Ward's criteria, e.g.

```
ne.rainh1  <-  hclust(table1, method = 'ward')
```

This is an R code to cluster by hierarchical algorithm the data fame of 10-year monthly rainfall data of 38 rainfall stations called table1 with Ward's method for merging criteria. The result of hierarchical clustering on the data frame is kept in *ne.rainh1*.

For k-means algorithm we use *kmeans* function to group the similar rainfall stations from the same data frame *table1* into 3 clusters in R code as:

```
ne.raink1  <-  kmeans(table1, 3)
```

RESULTS AND DISCUSSIONS

The three 10-year rainfall data (1987-1996, 1997-2006, and 2007-2016) were grouped into three clusters using the hierarchical and K-means algorithms. The results are shown in Fig. 2 as triangles, squares, and hexagons for each group, the results from hierarchical on the left and those from K-means on the right, the three pairs represent each period from the first to last. The isohyets are also shown on Fig. 2 illustrating that the highest rainfall is in the northeastern part of the region and the lowest is in the southwestern part for all three periods. The annual means rainfall of the region were 1306, 1391, and 1438 mm, for the first to the last periods, respectively. The increases of annual means from the first to the second period is 6.6 % and from the second to the third is 3.4 %. These are likely to be the effect of climate change [15].

The top pair of Fig. 2, the first period of 1987-1996, demonstrate hexagons to occupy the northern part of the region, the squares the southeastern, and the triangles the southwestern part. The positions of the three symbols from both algorithms, left and right in Fig. 2, are exactly the same. We presumed that the hexagons represent the high rainfall region, the squares the moderate, and the triangles are the low rainfall.

The positions of the three symbols from both methods for the second period are not exactly the same as in the first period. For this 2nd period, the hexagons still occupy the northern region, but the squares cover most of the middle zone including the southeast portion. The K-means method give preferable pattern for this period.

For the last period, the hierarchical algorithm gives preferable pattern of the 3 symbols to the K-means one. The hexagons cover the north and northwest zones, the squares on the eastern, while the triangles occupy the southwestern region. We cannot conclude that the hexagons are indicated the high rainfall zone and the triangle the low rainfall one. For the K-means method of the 3rd period showing 4 hexagons in the zone of low rainfall (Fig. 2).

Fig. 3 illustrates rainfall distributions throughout the year. The triangles are of the top pair, the squares of the middle, and the hexagons of the bottom one. The hierarchical clustering is on the left and the K-means on the right. Fig. 3 and Table 2 show that peaks of hexagon group of rainfall always being in the month of August but for those of square and triangle groups being in both August and September. The dry spell during rainy season were in the month of July for all groups of the 1st period. For the 2nd and 3rd periods, there was no dry spell during the rainy season except for the triangles were in June. These phenomena were the consequence of the movement of ITCZ rain band. The ITCZ band moved much farther north creating dry spell in July for all groups (triangle, square, and hexagon). Only the triangle group did show the dry spell in June, there was no dry spell for other groups.

The above phenomena demonstrate that the hexagons always peak before the others since the ITCZ band, on the way back, reaching the hexagons before the others. The absent of dry spell with a few in June, for the 2nd and 3rd periods, show the ITCZ band did not move too far off from the north border of the Northeast.

CONCLUSIONS

The regionalization of homogeneous rainfall pattern of the Northeast, Thailand, was done by hierarchical and K-means methods with data from 38 rain gauges for three periods, 1987-1996, 1997-2006, and 2007-2016. The rainfall characteristics were partitioned into three groups illustrating by triangle, square, and hexagon. These groups did not exactly match with the amounts of the mean annual rainfall. However, the triangle group got along with the low

rainfall zone, the square with the moderate, while the hexagon agreed with the high rainfall region. The hexagon group occupied the northern part of the Northeast, the square the southeastern, whereas the triangle covered the southwestern part. The movement of the ITCZ band went farther from the northern boundary of the region creating dry spell during rainy season in July for the 1st period (1987 to 1996). For the 2nd and 3rd periods, rainy season came early and the ITCZ band did not move further away from the northern border, by majority no dry spell existed. The mean annual rainfall of the region increased from the 1st period to the 2nd then to the 3rd at 1306, 1391, and 1438 mm, respectively. This is a sign of climate change.

ABSTRACT

It has been pointed out that the vegetation succession brings out the reduction of the *Luehdorifia japonica*. But some researcher insisted that thinning cannot increase the population of the butterfly. Then we cut down half of the forest and reverse succession, in order to study the influence of the population of *Asarum rigescens* var. *brachypodion*, larval food plant, and the mass of reward of the butterfly by cut off the forest. It was being thought that thinning in a forest obstructed growth of forest floor plant, but the growth of *A. rigescens* that was famous of forest floor plants, was promoted. On the other hands, *A. rigescens* did not grow up in the climax forest despite of survive. In the green house experiment we can get the proof of the growth condition. The growth of open light condition was superior to that of the 40% light penetration condition. And more the number of flowering of plants was more increased than ever. It was indicated that the thinning in a forest is important for the habitat of the symbolic butterfly, *L. japonica*, and it increased other plants bloom, and to secure source of nutrition of much insect kinds

Keywords: thinning, light condition, larval food plant, the mass of flowering, biodiversity

INTRODUCTION

The 2005 World Exposition, Aichi, Japan, Nature's Wisdom, was held at Aichi Prefecture. Some *Accipiter gentilis* built nests and many *Luehdorfia japonica* grew up in the main site, so that area would be conserved in order not to develop [1] [2]. The main site of the 2005 World Exposition moved to the next place. The area was divided 6 sections along the objection for the natural conservation [3]. Almost sections were adopted as untouched nature conservation.

Almost 10 years passed from the 2005 World Exposition, Aichi, Japan, we cannot find out the feature of *L. japonica* anymore. The untouched conservation management is not good for the butterfly. In 2012 only one *L. japonica* observed and in 2013 and 2014 there was no *L. japonica* in the area [4].

Ishii (2005) pointed out the half of the endangered species in Japan was distributed in Satoyama [5]. Satoyama has been affected by human disturbance in order to get energy, construction and food materials for some centuries. The moderate disturbance maintained high biodiversity. It suggested the moderate disturbance is important for the *L. janonica*.

But some researchers insisted that the disturbance is not good for the forest floor plants, *Asaram* species, that is larval food plants of *L. japonica* [6]. And some conservationists argue that the conservation should be un-disturbed. The cause of the butterfly decrease should be explained for the conservation management. The insects cannot live when the decrease of larval food plant and the decrease of adult food resource occurred. Then we investigate the influence of the thinning to both the larval food plant growth and the mass of flower resources.

We have three hypothesis, 1) the thinning doesn't increase the death rate of *Asarum rigescens* var. *brachypodion*, 2) The lighter condition promote the growth of *A. regescens* var. *brachypodion*, 3) the thinning increase the mass of flower reward. It was paid attention to the three points and analyzed.

MATERIALS AND METHODS

The Study Site

The study was carried out on the Kaisho-no-mori Conservation area (600 ha) at the center of Aichi Prefecture, the middle of Japan (Fig. 1).

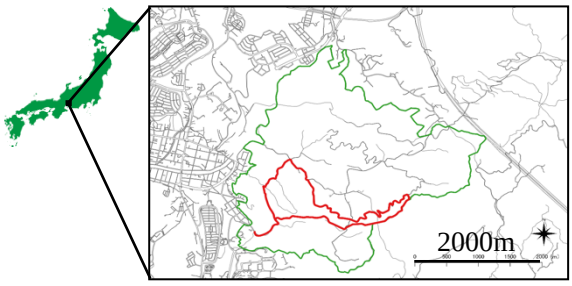

Fig. 1 The area of the study site (green line) and route of the phenology census (red line).

The area has been conserved from 2005 in order to prevent the disorder construction and over use. Especially no one step into northeastern conservation area. The geological feature of the area assumes rich groundwater and the soil of the oligotrophy base. 16 Tokai hilly land elements [7] that are endangered species grown up in the area.

The Study Plant

Asarum rigescens var. *brachypodion* (ARISTOLOCHIACEAE) is a perennial herb in the temperate forest distributed in Chubu Japan (Fig. 2). The habitat of the species is deciduous or evergreen forest floor. From January to March the species is flowering close to the ground 1 to 10 flowers. From April to May the seed dispersal is occurred by some kinds of ants. The each of seeds has elaiosome that is nutritional source for many ants. The seedling emergence is occurred in April. Despite of the leaves of the species have aristolochic acid, the leaves of the species is larbal food of *L. japonica* (Fig. 3), then the butterfly species have tolerance to the toxin.

Fig. 2 Photos of *A. rigescens* var. *brachypodion*, under right photo shows the flowers of the species.

Fig. 2 Photos of *L. japonica* and under right photo shows the eggs of the species.

The Field Census

To know the distribution of *A. rigescens* var. *brachypodion*, we walked everywhere of Kaisho-no-mori along the ridges and the valleys using GPS from January to March in 2016 and made a distribution map.

In order to investigate the effect of shinning, we set up the quadrat (10 m x 10 m) and cut off every woods and weeds except *Asarum* in June 2016. And we set up the same size quadrat at 100 m away. At each quadrat we made a map of distribution of every *A. rigescens* var. *brachypodion*, and measured the size of the species. The individual size was estimated by five index, number of leaves (n), largest leaf length (l_{max}), largest leaf width (w_{max}), smallest leaf length (l_{min}), and smallest leaf width (w_{min}). Then size index (S_{index}) showed equation (1).

$$S_{index} = \frac{n}{2} (l_{max} \text{ x } w_{max} + l_{min} \text{ x } w_{min}) \quad (1)$$

From June 2016 to Nov. 2018, we measured every individual size index in early summer and autumn in each year to detect the difference of growth rate in each quadrat.

And we took the photographs to investigate light condition at each individual location using omnidirectional camera (RICOH THETA S) and calculated the open sky degree using software (CanopOn2).

To measure the mass of flowering reward, we took every flower photographs a week interval from March to April in 2016 and 2018 along the field census route 4m wide 20m long (Fig. 1 red line). Using the phots we grasped the number of flowers. In 2016 to measure the honey amount of each flower of Rhododendron and Viola (the flowers attract the butterfly). To compare the reward of the flowers, we counted another place (where we can observe a lot of *L. japonica*).

Comparison of Growth Rate

Two condition were prepared to measure the growth rate of the species. One condition was open light condition (where 50% open sky) and the second condition was closed by cheesecloth (where 20% open sky). We collected from the field 84 individuals of *A. rigescens* var. *brachypodion* on October 2017. After collecting, each individual was washed to remove the soils in order to measure fresh weight. After wiping water by paper towel, we measured fresh weight, we planted 10cm diameter pot with cultivation soils. We divided two groups that has same size distribution, one group lay in open area, and the other lay in closed area. One years later, we measured fresh weight and calculated the growth rate.

RESULTS

The Field Census

Fig. 4 showed the distribution of now and two decade ago [4]. The distribution of the present time is very different from 20 years ago. Half of the populations disappeared, and we can find out new populations in the different area.

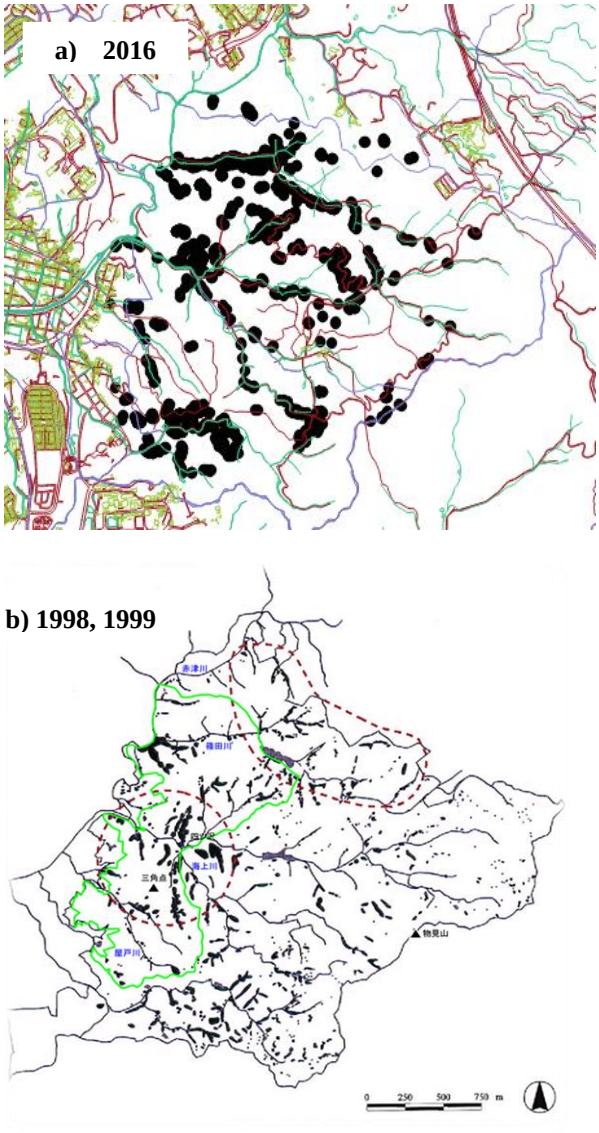

Fig. 4 The distribution of *A. rigescens* var. *brachypodion*, a) in 2016 and b) from 1998 to 1999.

Fig. 5 showed the size distribution between shinning area and controlled area from 2016 to 2018. In the shinning area, we can find out the increase of $S_{index,}$ especially from autumn to summer. There was a difference between the growth of shining area and that of the control area. From the Steel Dwass test of each season distribution 15 pairwise within each area, there were 8 significant differences ($p<0.05$) observed in shining area, but in control area there were 3 significant difference observed. The growth rate of shining area was superior to that of control area. We also found out the difference between the variance. The variance of the sinning area was largerer than that of the control area.

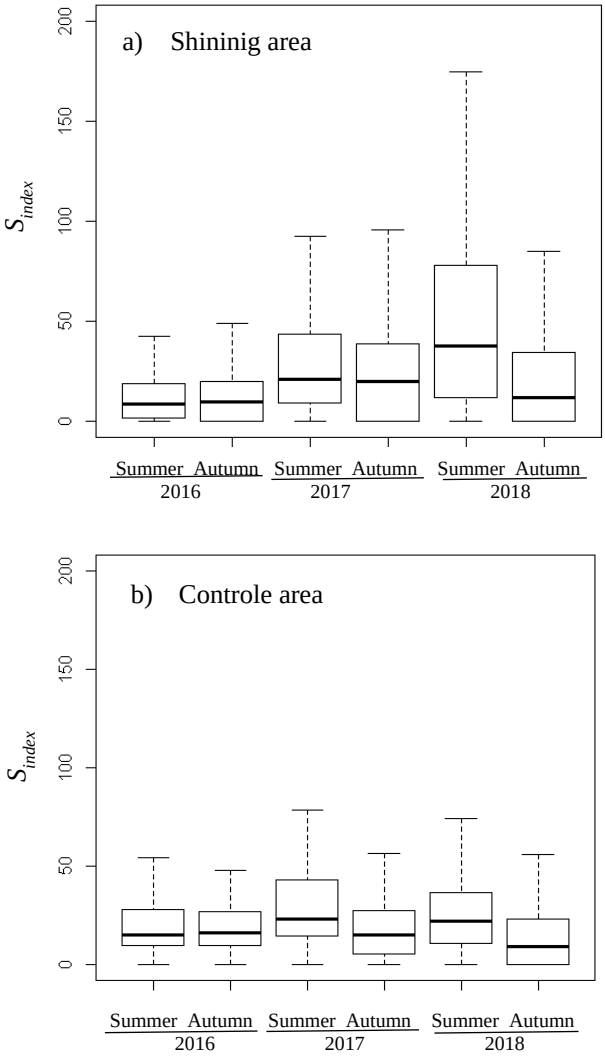

Fig. 5 The S_{index} distribution of *A. rigescens* var. *brachypodion*, from summer in 2016 to autumn in 2018. a) shinning area, b) controle area.

Fig. 6 showed the relationship between light condition (open sky percentage) and the growth rate (increase percentage of S_{index}) from summer in 2016 to summer in 2018. Remarkably growth rate was observed in 40% to 50% open sky percentage condition.

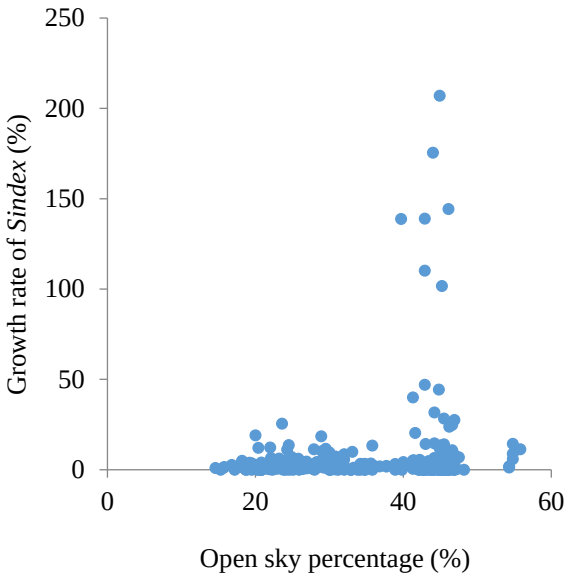

Fig. 6 The relationship between light condition and growth rate of S_{index} of each individual.

The amount of flower from 2016 and 2018 in spring showed in Fig.7. Amount of the nectar was increasing after shining. The histogram skewed to right. The number of the increased nectar quadrats was larger than that of decreased quadrats.

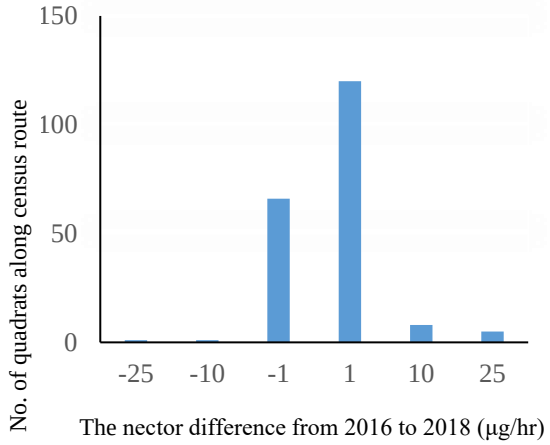

Fig. 7 The difference of nectar at each quadrat along the route of phenology census from 2016 to 2018.

The growth amount at open environmental condition and closed condition showed in Fig. 8. From the Wilcoxon test, the growth rate of open condition was superior to that of closed condition ($p<0.05$). And we could observe the variance difference between the two condition.

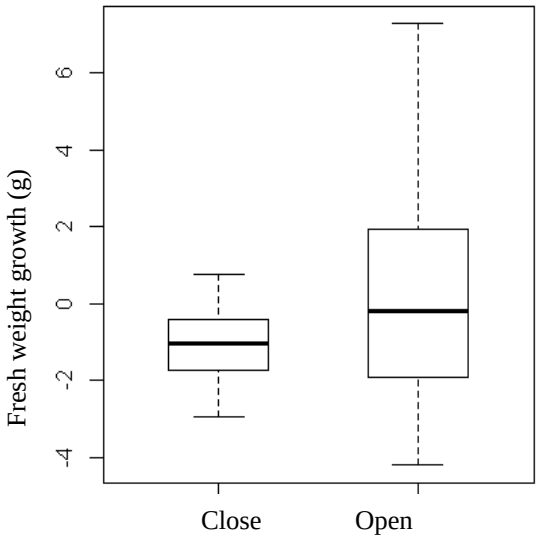

Fig. 8 The growth amount in closed by cheese cloth and open for one year.

DISCUSSIONS

IUCN (International Union for Conservation of Nature) has developed a system of classifying protected areas that ranges from minimal (nature reserves, national parks, etc.) to intensive use of the habitat by humans, with six categories [8]. There strict nature reserves and wildness areas have the high quality of biodiversity. So almost people believe that the untouchable nature is very precious. Nature should be leave as they are. That is a true because the development destroys the biodiversity. But recently the role of moderate disturbance regard as important.

Jacobson et al. (1991) reported the human moderate disturbance reverse the vegetation succession and formed the valuable biodiversity [9]. The mechanism of disturbances were reported many other researchers [10][11]. These researches were about wetlands and grasslands where affected vegetation succession seriously. Stop the succession is very important for the special vegetation. In the forest, people think that biodiversity of forest will be increasing along succession. Because there were many kinds of species that likes closed, humidity and nourishment condition can live under the condition, so the disturbances destroy such a condition and shade species.

The data of the biodiversity was investigated because of the 2005 World Exposition, Aichi, Japan, Nature's Wisdom. After 18 years passed some nature conservation association reported the decrease of biodiversity, especially *L. japonica*. The cause of butterfly decrease was undetected. Every conservationist insisted the conservation area closed and no one affect the biodiversity.

In order to realize the cause of butterfly decrease,

the resource condition of both larva and adult were investigated. The distribution of larva food plant, *A. rigescens* var. *brachypodion* was changed from 18 years ago. The center of distribution moved to the area of Japanese oak die. It was suggested that the light condition is darker and darker, the growth condition is worse and worse. *A. rigescens* var. *bracypodion* is a famous of forest floor plant, but almost individuals have a few leaves only. It is not sufficient to serve larva, because it is needed at least 3 leaves to nurse the butterfly. The difference about the condition of the forest is disturbance. 20 years ago, the forest supply as fuel, building materials and food to near agriculture village people. Utilization by people can make the oligotrophic and intolerant tree forest.

In fact, the growth rate of the species accelerates by shining, and growth experiment showed the light condition is very important for the species. Each light condition in the field, the 40-50% open sky conditions are very good condition for the growth. By the experiment the light condition is very important of the forest floor plant. But there is large variance observed in shining, it is showed the open light condition is very strict condition, some individuals can grow up, but the other cannot grow up. The severe natural selection occurred in open condition, especially more than 50% open sky. Perhaps drying and strong light inhibition prevent the growth.

The shining brought another effect of the mount of reward to the adult butterfly. The increase amount of reward is not so much, but the light condition brought a good condition for photosynthesis and rhododendron (short tree) and viola (herb) can produce many flowers than before. The condition will be good for the butterfly and other insects.

From the experiment, the cause of the butterfly decrease is succession of the forest. Shinning is very important of the management for biodiversity. But there is problems in the management. How much may we cut down in order to maintain biodiversity? The best condition for *A. rigescens* var. *bracypodion* is 40 to 50% open sky. But it is very difficult to cut down such a condition, and it is very difficult to maintain the condition because of vegetation succession.

The management plans are needed to maintain the biodiversity. Succession is always progress, the zoning is needed to shining. Every 10 years interval each zone should be cut off. The first year 1/10 forest part cut, and the second year the next section of forest cut of, the third year and so on. The moderate disturbance management is very difficult, but the succession will repair the over shining condition.

CONCLUSIONS

We get four main conclutions.

1) The forest thinning is important for the iconic butterfly habitat, increasing the flowering of other plants and securing nutrients for many insect species.
2) The distribution of *A. rigescens* var. *brachypodion* greatly changed for 18 years.
3) The growth rate of *A. rigescens* var. *brachypodion* that is forest floor plant, is larger in shining area than that in closed area.
4) In light control experiment, growth of *A. rigescens* var. *brachypodion* in open area was accelerate than in closed area.
5) The shinning increased the flower nectar amount in spring.

From these conclusions, it is suggested that t the cause of the decline of *L. japonica* is the decline of larval food plant and adult food plant.

Based on the conclusions, two proposals about the conservation activities

1) Human disturbance is very important to maintain the biodiversity at the mountain named ‘Satoyama’ near the agriculture field because of the light condition maintenance.
2) The conservation activities should be done by shining or felling instead of untouchable nature conservation.

We should remake the zoning of Kaisho no mori for maintain the biodiversity return to the 20 years ago.

ACKNOWLEDGMENTS

We wish to thank the members of Kaisho no mori Conservation Association for research support and section of environment at Aichi Prefecture Government for permission to work in the conserved area. We also thank Mr. Kamio and the members of our laboratory for their assistance in the field works.

GROUNDWATER VULNERABILITY OF THAILAND'S LOWER CHAO PHRAYA BASIN

Pinit Tanachaichoksirikun[1], Uma Seeboonruang[2] and Graham E. Fogg[3]

ABSTRACT

Since global warming effects water resources, especially, surface water sources, groundwater is an essential water source, when facing the critical drought, because groundwater in less sensitive than surface water. However, groundwater response is delayed in some area. Thus, groundwater vulnerability is a tool to identify critical areas for maintaining water quantity and quality. The Fuzzy-Catastrophe-based DRASTIC model, drought persistence and several climate scenarios were combined to estimate the vulnerability on the confined aquifers of Thailand's Lower Chao Phraya basin. Thus, critical areas that may face groundwater shortage were identified. Our analysis predicted that most of basin would have few effects on climate change. However, vulnerability maps showed that 5% of the basin may be critical areas that may show groundwater shortage, especially, drought persistent areas with low rainfall. Generated maps identify 'hotspots' and can help decisions on groundwater development and economic growth and aid planning policy.

Keywords: DRASTIC, Climate change, Groundwater vulnerability, Groundwater resource, Groundwater resources planning

INTRODUCTION

Groundwater is a very important natural resource and can be a second source of water supply, when facing critical droughts or limited accessible surface water, since surface water is more sensitive than groundwater to climate fluctuation. So, groundwater is an important water source because groundwater response is delayed relative to climate changes on the surface water (Seeboonruang, 2014) [1]. Decrease in surface water level contributes significantly to the groundwater decline. Although groundwater is a renewable resource, much groundwater cannot be renewed in the human life spans (Foster and Chilton, 2004) [2]. Then, groundwater will become a limited resource and must be conserved.

Hydrological systems and water resources affect the global climate change, such as flood, drought and seawater intrusion. They are very significant in the tropical climate, especially, groundwater vulnerability and sustainability (Chris et al., 2012 [3]; Green et al., 2011 [4]; Taylor and Callist, 2012 [5]; White and Tony, 2012 [6]). Thailand is in the tropical zone. Then, groundwater resource in Thailand will face these problems. The linkage between groundwater and climate change is inherently complicated. Therefore, these are the need to study the impact of climate on groundwater quickly, before it becomes exhausted.

The effect of drought on water resources has been studied by Wongsa (2015) [7]; Rangsiwanichpong et al. (2016) [8] and several others. Tanachaichoksirikun et al. (2018) reported that groundwater affected the climate change: especially, in Thailand's Lower Chao Phraya (LCP) basin, groundwater is still sustainable but shortage may be faced in some aquifers [9].

The DRASTIC framework consists of seven indices i.e. depth to water table (D), net recharge (R), aquifer media (A), soil media (S), topography or slope (T), impact of the vadose zone (I) and hydraulic conductivity (C). These factors were assigned by ratings and weighting by Aller (1987) [10]. The model succeeded in predicting groundwater quality in unconfined aquifers (Huan et al., 2012 [11]; Ouedraogo et al., 2016 [12]; Shrestha et al., 2016 [13]). Seeboonruang (2016) modified DRASTIC to show that the groundwater vulnerability affected climate change in the unconfined aquifers [14]. However, the DRASTIC model has disadvantages,

because the regional characteristics vary the appropriate weightings and ratings (Sadat-Noori and Ebrahimi, 2016) [15]. So, the DRASTIC framework was modified to the Fuzzy-Catastrophe DRASTIC Framework (FCF) for confined aquifers by Nadiri (2017) [16] and Nadiri (2018) [17]. However, the modified DRASTIC has not been used to determine climate change impact on groundwater vulnerability.

Therefore, we investigated the impact of climate change on the groundwater vulnerability, by combining climate change, history of drought persistent and FCF, to investigate critical areas that affect the climate change. This is the first time, FCF has been used to evaluate the challenge of confined aquifers: it was applied to the LCP basin, because it is a confined aquifer, that was affected by climate change (Tanachaichoksirikun et al., 2018) [9].

STUDY AREA

Thailand's LCP basin locates in the central plain; it covers ~41,300 km^2, which covers Bangkok, the capital city, and 21 provinces. Groundwater flows from the north to south. The Tenasserim Hills are located in the north and west and there are small hills in the east, while the south connects to the Gulf of Thailand. The northeast connects to the Upper Chao Phraya basin - see Fig. 1. The hydrogeology is Tertiary-Quaternary formation that the depositions are coastal and fluvial deposits (Piancharoen, 1977 [18]; Piancharoen and Chuamthaisong, 1978 [19]). The aquifers consists mainly of sands, gravels and clay lenses, that can be divided into eight confined aquifers - the Bangkok (BK), Phra Pradaeng (PD), Nakorn Luang (NL), Nonthaburi (NB), Sam Khok (SK), Phayathai (PT), Thonburi (TB), and Pak Nam (PN) aquifers (Seeboonruang, 2014 [1] and Tanachaichoksirikun et al., 2018 [9]).

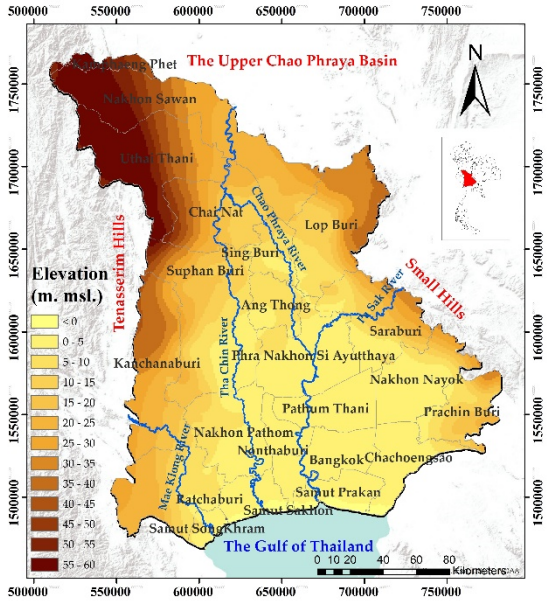

Fig. 1 Lower Chao Phraya basin, Thailand

DATA AND METHOD

Climate and rainfall

Climate records from LCP monitoring stations indicated that the average annual temperature has increased from 27.1°C (1983-1998) to 27.4°C (1999-2014) and the maximum temperature is nearly 40.6°C in April, while the minimum temperature is ~12.7°C in December. In addition, the average annual rainfall had increased from 1,191 mm (1983-1998) to 1,208 mm (1999-2014) and the maximum monthly rainfall is ~348 mm in September, the minimum rainfall is ~11 mm in December and the average monthly rainfall is 83-139 mm.

Wattanasetpong (2015) predicted the future climate in the LCP basin based on 30 years weather records and several other criteria [20]. Future climates were separated into the 'near' future predictions for 2020-2049 and 'far' predictions for 2050-2099. We preferred the IPSL-CM5A-MR climate model, from the Coupled Model International research group (CMIP5) from the Institute Pierre Simon Laplace, which offers the minimum bias and root mean square error on past data for the annual precipitation in the Chao Phraya watershed which closely covers the LCP basin (Ruangrassamee, 2015) [21].

Representative Concentration Pathway (RCP) is a map of greenhouse gas concentration (not emissions) trajectory in the fifth Assessment Report (AR5) 2014 (IPPC, 2014) [22]. We selected three pathways for climate modeling, which could be considered, depending on the quantity of greenhouse gases emitted in 2100. Three RCPs - RCP2.6, RCP4.5 and RCP8.5, which cover the range of likely future radiative forcing values, were selected.

Climate exposure

Climate exposure is an index level for the fluctuation of rainfall between past and future (Fig. 2a and 2b). The south boundary produces the local increase in rainfall. The maximum increase in rainfall occurs near the Gulf of Thailand ~10% (RCP8.5) and the minimum increase in rainfall occurs near the Tenasserim Hills ~6% (RCP2.6). We classified the climate exposure into four classes (ΔR^0, ΔR^{1+}, ΔR^{2+} and ΔR^{3+}) as shown in Table 1. The worrisome factor is rainfall increase because it contributed to flood. Therefore, the basin may show groundwater vulnerability from future rainfall which will affect climate change.

Drought persistence

Drought persistence is the historical report and frequency of droughts. It was monitored and calculated by several factors of Thailand Land Development Department (LDD). Drought persistence was divided into four classes, 0, <3, 4-5

and >6 times/10 years as shown in Table 1 and Fig. 2c. Drought persistence highlighted the adaptation of groundwater management. In this basin, droughts occurred near the boundary, but the central area remains fertile.

Impact of climate change

Droughts contributed to change in climate change index (Fig. 2d), that divided into six classes, as shown in Table 1. When an area did not have enough rainfall and a high frequency of droughts, it had a high impact of the climate change on that area, but if the area had high rainfall and no drought, the area had no impact on climate change.

Table 1 Impact of climate change index

Climate exposure	Drought persistence (times/10years)			
	0	≤ 3	4-5	> 6
$\Delta R^{3+} > 3.36\%$	I^{2+}	I^{+}	I^{0}	I^{-}
$1.68\% < \Delta R^{2+} \leq 3.36\%$	I^{+}	I^{0}	I^{-}	I^{2-}
$0.36\% < \Delta R^{1+} \leq 1.68\%$	I^{0}	I^{-}	I^{2-}	I^{3-}
$-1.68\% < \Delta R^{0} \leq 0.36\%$	I^{-}	I^{2-}	I^{3-}	I^{4-}

Note: I^{2+} = best, I^{+} = good, I^{0} = no impact, I^{-} = low impact, I^{2-} = moderate impact, I^{3-} = high impact, I^{4-} = very high impact

Fuzzy Catastrophe DRASTIC Framework

DRASTIC was designed by the US Environmental Protection Agency (Aller et al., 1987) [10]: it is a method that describes the allowable pollution potential hydrogeologic setting. The system has two major steps: (a) is the hydrogeologic settings map design, and (b) overlaying the relative rating system. DRASTIC uses seven parameters to classify the pollution potential of an aquifer. The sensitivity index of our study modified weightings and ratings for FCF by Nadiri et al. (2017) [16] and Nadiri et al. (2018) [17] shown in Table 3.

The DRASTIC index (D_i) was analyzed:

$$D_i = D_r D_w + R_r R_w + A_r A_w + T_r T_w + I_r I_w + C_r C_w \quad (1)$$

where D_i = DRASTIC index for a mapping unit, r = rating, w = weighting factor for D, R, A, S, T, I, C.

Depth to water (D) = depth from ground surface to the top of the confining layer. If the groundwater aquifer is deep, water is harder to infiltrate.

Net recharge (R) = average monthly infiltration from the ground surface and becomes groundwater.

Aquifer media (A) = the porous media between bedrock and the confining layer. An aquifer, that has larger grain size or more openings, leads to higher permeability and lower attenuation capacity.

Soil media (S) = media between ground surface and unsaturated zone. Soil has a significant impact on the recharge that infiltrates the aquifer.

Topography (T) = slope of land surface. It makes recharge take longer to infiltrate.

Impact of vadose zone (I) = material above the water table below topsoil, which is clay in the confined aquifer. Hence, the impact of vadose zone was set to 1 due to the clay lenses.

Hydraulic conductivity (C) = ability of an aquifer to transmit water, controlling the rate at which groundwater will flow under a given hydraulic gradient.

Groundwater vulnerability

Groundwater vulnerability is a major problem because it is a key to groundwater management. The groundwater vulnerability was derived from the combination of FCF and the impact of climate change. The indicators used are shown in Table 2. The groundwater impact is critical, when the impact of climate change and the FCF is high, it implies the risk of change is very high. The degree of groundwater-climate change vulnerability can affect the groundwater management. In addition, in the red areas, identified as highly sensitive areas – high drought persistence, a slight increase in rainfall and high values of DRASTIC – are causes for concern (Fig. 4).

Table 2 Groundwater vulnerability indices

Drought exposure	DRASTIC index				
	33-41	42-49	50-57	58-65	66-73
I^{2+}	Ex	Vg	B	G	N
I^{+}	Vg	B	G	N	N
I^{0}	B	G	N	N	L
I^{-}	G	N	N	L	M
I^{2-}	N	N	L	M	H
I^{3-}	N	L	M	H	Eh

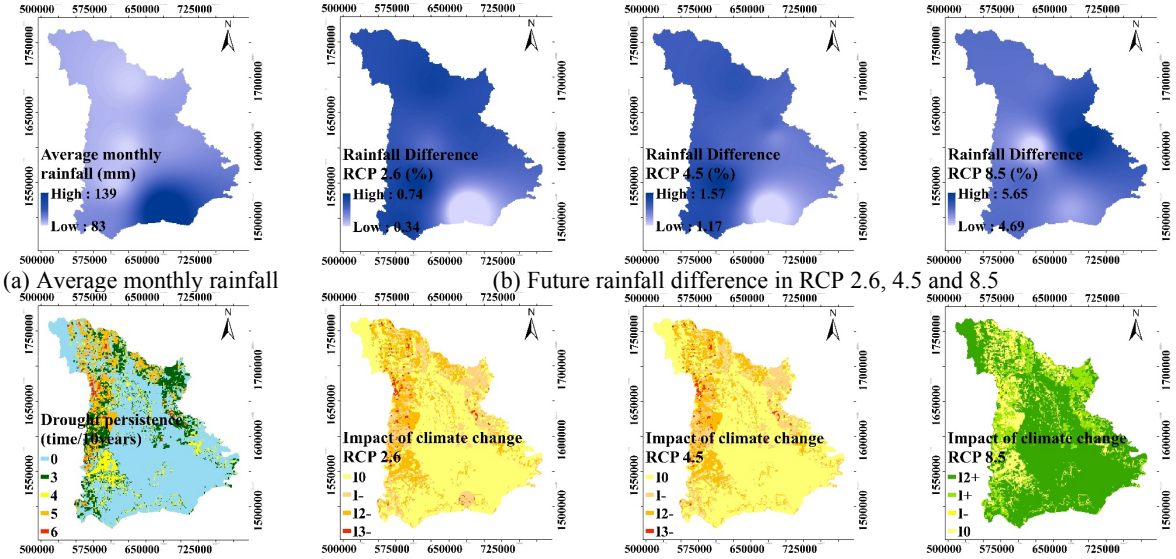
Note: Ex = excellent, Vg = very good, B = better, G = good, N = none, L = low, M = moderate, H = high, Eh = extremely high vulnerability

RESULTS AND DISCUSSTION

Future groundwater vulnerability

The future groundwater vulnerability map is represented in Fig. 4. The extreme risk values are shown in warms tone and change to better qualities are shown with cold tones. When the RCP 2.6 was used for 2020-2049 and 2050-2099, it shows highest vulnerability indices (5%) of the total area that the area may face future drought. Most of these areas are located near the boundary of basin, where lower rainfall rate recharged the groundwater and there was the history of drought. However, the RCP 8.5 model, for the same periods, shows the highest groundwater resilience, i.e. the groundwater would cause only small climate change: the high rainfall would recharge and there would be few droughts. However, in RCP 4.5, groundwater vulnerability was predicted for 2050-2099, because this period would have relatively high rainfall near the Gulf of Thailand but low rainfall near the Tenasserim hills.

The main reason of the greater vulnerability to impact of climate change in the central area is the area



(a) Average monthly rainfall (b) Future rainfall difference in RCP 2.6, 4.5 and 8.5

Fig. 4 Groundwater vulnerability maps of LCP basin, Thailand

is relatively flat and the soil media is clay lenses. Whereas, near the area with persistent drought, it has slight vulnerability because the rainfall is low.

CONCLUSION

We investigated the groundwater vulnerability under climate change in Thailand's Lower Chao Phraya (LCP) basin to aid decisions in groundwater management. We combined the Fuzzy Catastrophe DRASTIC Framework (FCF), climate scenarios, and drought persistence to consider groundwater characteristic, climate exposure and history of drought occurrence. The climate scenarios used in Representative Concentration Pathway (RCP) were 2.6, 4.5 and 8.5. The Geographic Information System technique was used to analyze the periods 2020-2049 and 2050-2099.

The critical areas in the LCP basin had 5% because that area has low rainfall, history of high drought frequency and high values of FCF. However, the groundwater vulnerability continuously decreased in all scenarios, because the rainfall increased, especially under the RCP 8.5 scenario. Although with RCP 2.6 was lower rainfall (but higher than the base case (1983-2014)), the groundwater vulnerability still resilient.

The climate change has lower impact on groundwater vulnerability in a confined aquifer when compared with the unconfined aquifers, because the FCF index shows that the low impact of the vadose zone value. However, the topography, soil media, and depth to groundwater are the most important factors in the LCP basin because they show the high FCF weight.

The impact of climate change was significantly affected on the drought persistence. However, we did not include future land use, which should probably be considered in an extension of this work.

We concluded the groundwater vulnerability in the Lower Chao Phraya basin has a little impact in RCP 2.6 scenario and no impact on the RCP 8.5 scenario, because it included increased rainfall.

At this stage, we did not consider human activities, e.g. land use and pumping, which can have more impact on the groundwater system. However, these will be considered in the future work.

ACKNOWLEDGMENTS

We thank the Thailand Research Fund through the Royal Golden Jubilee PhD Program, Grant No. PHD/0189/2556. Special thanks to the Thailand Land Development Department, Thailand Meteorological Department, and Thailand Department of Groundwater Resources for the data.

RESILIENCY OF A TWO-STOREY DEPEd STANDARD SCHOOL BUILDING USING THE REDi FRAMEWORK

Ray Anthony V. Ausan[1], Kyle Didacus V. Cabatit[2], Megan Angela S. Quiaem[3], and Richard M. De Jesus[4]
[1,2,3]Undergraduate Students, De La Salle University (Manila), Philippines;[4]Faculty, De La Salle University (Manila), Philippines

ABSTRACT

Public school buildings in the Philippines are built with a code-based design philosophy, wherein the life safety of the occupants is the sole performance objective. While the loss of life is the primary consideration for design, other losses such as cost of repair or replacement and service losses are to be expected after an earthquake. The 2017 Surigao Earthquake damaged 47 schools and caused a 10-day suspension of classes. Three years after the 2013 Bohol Earthquake, 279 classrooms from 696 schools are still under construction. A resilience-based design philosophy takes into consideration safety and other losses including recovery. To assess the resilience of a structure, a resilience-based seismic assessment methodology was adopted after the REDi Framework. Other tools utilized for the seismic assessment were the FEMA P-58, their accompanying software PACT, as well as SeismoStruct. It consists of the identification of losses in terms of cost and time, as well as the evaluation of proper building management and design practices. As a pilot study, a two-story four-classroom template designed by the Department of Education was assessed for seismic resilience. Numerical simulations and analysis showed that upgrade/retrofit must be done for both non-structural and structural components to comply with minimum resiliency requirement.

Keywords: Resilient buildings, School buildings, loss assessment, REDI rating

INTRODUCTION

The Philippines is a seismically active country due to its location along the Ring of Fire, or the Circum-Pacific belt. This Circum-Pacific belt is defined as a 40,000 kilometer-long zone of earthquakes, volcanic eruptions, and plate boundaries where the majority of the world's earthquakes occur [1]. Due to the frequency of earthquake occurrence within the Ring of Fire, structures in these countries must be built to withstand seismic activity. In Metro Manila, the looming threat of a high-magnitude earthquake named "The Big One" prompts the revisiting of seismic resistance of essential structures, most especially public school buildings, in the country. These public schools serve a dual purpose: the first and primary cause of operation is as centers of education for Filipino children and the second is as evacuation facilities during times of disaster [2].

In the event of an earthquake, the damaging or collapse of the school building will put the lives of youth at risk of injury or loss of life. Similarly, a collapsed school building will not be able to serve its second purpose as temporary shelters for victims of the disasters. Past instances wherein school buildings were affected by seismic activity include the 2013 earthquake located in Bohol wherein 696 schools were either damaged or destroyed and a student population of 270,000 individuals was affected [3].

Public school buildings in the Philippines follow the design philosophy of code-based design, wherein they designed based on the National Structural Code of the Philippines (NSCP). Adapting this design philosophy ensures that structure are life-safe when a certain magnitude earthquake occurs, though it does not ensure that the building suffers no damage nor will it remain operational after the seismic event, as per Section 208.1.1 of the NSCP [4]. The performance of a school after an earthquake is an essential aspect in its operation, and total collapse will render it unusable for an extended period of time. The Bohol Earthquake rendered 279 classrooms inoperational three years after the event [5].

Seismic resilience is defined as the ability for an organization or a community to recover from an earthquake [6]. The existing and prevalent design philosophy is the code-based design, which addresses the loss of life after an earthquake but fails to consider structural damage. Resilience-based design (RBD) takes additional factors into consideration to improve the seismic performance of a building. A key component in RBD assessment is the minimization of structural and non-structural damage during an earthquake. Such damage minimization increases occupant confidence in the structure as there is a level of unpredictability on the performance of the building as it reaches its limits.

Additionally, the goal of a prompt recovery after the occurrence of a disaster is greatly emphasized in the RBD philosophy. This parameter can be measured using the investigation of both the building performance and the building environment after the earthquake.

The REDi Rating System was developed by Arup to measure the level of resiliency of a structure by assigning a certain resilience rating, namely gold, silver, and platinum. Each resilience rating has certain criteria that a building needs to achieve under three resilient design and planning categories: organizational resilience, building resilience, and ambient resilience. Organizational resilience includes the assessment of factors beyond the structure itself, such as emergency evacuation systems and procedures and plans for utility disruption. Building resilience quantifies the performance of the building components during an earthquake event. Ambient resilience considers the environmental factors and other facilities that may impact the building in consideration. The final method of quantification is the criteria under evaluation, in the form of a loss assessment. This is done to determine the financial losses and the downtime of the structure in the event of an earthquake.

The resilience objectives for loss assessment can be seen in Table 1. Once all the criteria are met, the building qualifies for a resilience rating [7].

Table 1 REDi Baseline Resilience Objectives for Different Resilience Rating

Rating	Re-occupancy	Functional recovery	Direct financial loss	Occupant safety
Platinum	**Immediate**	**< 72 h**	**< 2.5%**	**Injuries Unlikely**
Gold	**Immediate**	**< 1 month**	**< 5%**	**Injuries Unlikely**
Silver	**< 6 months**	**< 6 months**	**< 10%**	**Injuries Possible**

This study aimed to perform an RBD assessment on a two-storey standard school building by the Department of Public Works and Highways (DPWH) and Department of Education (DEPEd).

Fig. 1 Two-Storey Standard School Perspective

METHODOLOGY

In order to determine the resiliency of the two-storey public school building, the following analyses procedure were used to determine the resilience rating.

Checklist

The REDi Rating System was used as the basis for the creation of the assessment tool used to determine the seismic resilience of the structure. The criteria taken under consideration to be adapted in the checklist were the silver-required, gold-required, and the platinum-required criteria from the REDi Framework.Within the checklist are the four resilience categories explained beforehand, namely: building resilience, ambient resilience, organizational resilience, and loss assessment. Each category is assessed differently and further elaborated below.

Direct Financial Loss Assessment

First, a loss assessment was conducted to assess whether the building will minimize injuries, repair costs, and repair times at the scenario expected earthquake. This was done by following the FEMA P-58 [8] procedure for the seismic assessment of buildings. The procedure comes with the accompanying software PACT, which can be used to estimate the earthquake losses.

First, basic building information were inputted into PACT. These include the number of stories, the total replacement cost, the core and shell replacement cost, the replacement time, floor areas per floor, and the max number of workers per square foot. The replacement cost was estimated to be around Php 11,250,000 as the typical project cost for the construction of a two-storey four classroom building is around Php 9,000,000. Additionally, according to the REDi, rating system, demolition costs could increase replacement costs by around 20-30%. Thus, an additional 25% of the project cost was added to the replacement cost, totaling at Php 11,250,000.

Then, the population of the building was modelled. The type of occupancy and population distribution per floor was inputted. As the classroom holds an estimated 40 people and each floor is around 2500 square feet, the number of occupants per 1000 square feet was set to 33.

Next, the component fragilities were determined. Since the building is a reinforced concrete building and a special moment resisting frame, the fragilities for concrete column and beam joints were selected. The closest possible size to the actual column dimensions (24” by 24”) was selected. For the non-structural components, a distribution panel was

selected. The panel was specified to have a capacity from 100 to 350 Amperes and not vibration isolated. For piping, the fragility for SDC D, E and F piping were selected.

Next, the performance groups were specified. Performance groups are the components of the building per floor that are subject to the same earthquake demands such as story drift, floor acceleration, and floor velocity. They can be directional or non-directional. The quantity of components per performance group was specified.

Next, structural analysis was conducted using the procedure for Intensity-Based Assessment as per FEMA P-58. The Simplified Analysis procedure (FEMA P-58 3.2.2) was used as the building is regular in plan and only two stories high. Through the procedure, the collapse fragility of the structure was determined. Also, the distribution of demands such as story drift, peak floor acceleration, peak floor velocity, and residual story drift were determined.

Next, PACT calculated the expected fatalities, repair costs, and repair time at the scenario expected level. The median number of fatalities and repair cost was compared to the baseline REDi objectives. The repair time needs further modification using the REDi Modified Downtime Methodology.

Static Pushover Analysis

First, the structure was modelled in the Building Modeler facility of SeismoStruct. The Building Modeler is a tool provided for easier visual modelling of the structure. A static pushover analysis with a uniform distribution of lateral loadswas used. The columns were laid out according to the plan. The beams were connected between columns. Slabs were added to the corresponding bound boxes. Longitudinal and transverse reinforcements of the elements were inputted. A project was made after exiting and saving the model.

Then, the project was setup for analysis. Project properties can be changed in the Pre-Processing Tab. Acceptance criteria based on Tables 10-7 and 10-8 of ASCE 41-17 were used for the performance criteria of the structure. SeismoStruct computes the yield chord rotation capacity automatically. A residual strength of 20% was used when chord rotation capacity was reached based on ASCE 41-17.

Next, the analysis was run in the Processing Tab. The results were seen in the Post-Processing Tab. The pushover curve graph and values were obtained from the Hysteric Curves under the Global Response Parameters.

For the pushover curve in the y-direction, project properties under loading phases and applied loads were changed to the y-direction. The same procedure for the y-direction will follow. For convergence and loading problems, the model was checked for errors.

User Defined Stair Fragility Curve

First, the staircase was modelled in the building Modeler facility of SeismoStruct. An Incremental Dynamic Analysis (IDA) was used. Ten earthquake records were matched to the response spectrum of the school using SeismoMatch. The records were incremented by 0.1 Peak Ground Acceleration(PGA). The results yielded IDA curves with a damage measure of maximum inter-storey drift ratio and an intensity measure of PGA. The drift ratio at the threshold of structural damage is based on FEMA Hazus MR4. The mean of the lognormal cumulative distribution was obtained from the average of the natural logarithm of the PGA at the drift ratio threshold for the ten records. The standard deviation was obtained from natural logarithm of the PGA at the drift ratio threshold for the ten records.

Downtime Assessment

First, repair times and damage states were extracted from the analysis from PACT. The median repair time for each component accordingfloor from the maximum direction on all realizations was calculated. The average damage state for each component according to floor from the sum of both directions on all realizations was calculated.

Then, repair classes for each component were assigned based on the average damage state. Repair classes for structural and non-structural components for each corresponding damage state were provided by the Framework. A desired probability of non-exceedance was selected. The median probability of non-exceedance was advised.

Next, downtime due to repairs was considered. The number of workers was computed based on building area and damage units corresponding to the repair sequence. Repair time at each floor was then computed based on the worker days required for each repair sequence at each floor and the number of workers. A repair schedule that considered the series of work according to floor and number of workers was made.

Then, downtime due to delays was considered. Impeding curves, median and dispersion values of delay based on building characteristics were provided by the Framework. The probability of non-exceedance was used in determining the delay times. Delays caused by post-earthquake inspection were based on building importance. Delays caused by engineering mobilization were based on the maximum structural repair class and the engineer on contract. Delays caused by financing were based on the type of financing availed. Delays caused by contractor mobilization were based on the maximum repair class, number of stories, and building

importance. Delays caused by permitting were based on maximum repair class. The highest delay of post-earthquake inspection & financing, post-earthquake inspection, engineering review & permitting, and post-earthquake inspection & contractor mobilization was selected.

Then, downtime due to utility disruption was considered. Utility disruption curves for electrical, water, and natural gas systems were provided by the Framework. The probability of non-exceedance was used in determining the delay times. Delays due to natural gas and water system disruption were based on repair rate. Repair rate was calculated based on the peak ground velocity.

Full recovery is required for repairs with repair class 1. Functional recovery is required for repairs with repair class 2. Reoccupancy is required for repairs with repair class 3. Reoccupancy downtime is the sum of downtime due to repairs and delays. Full and Functional downtime is the sum of downtime due to repairs, delays, and utility disruption.

Seismic Resilience

The checklist was evaluated for whether the building is resilient or not. The final output was the rating of the structure as either platinum, gold, silver or not resilient. In order for the building to be considered as seismically resilient, it should be able to fulfill all of the silver-required criteria. If all silver-required criteria were met, then the next resilience tier is taken into consideration. If it did not fulfill even one of the silver-required criteria, it was not considered to be resilient and retrofitting was done in the form of adding CFRP wrapping. Only the detailed analysis will be repeated for the modeled retrofitted structure. In the case that the building was not seismically resilient, the researchers outlined the suggested plans and retrofitting methods in order to make the structure resilient.

DATA AND ANALYSIS

Fig.2 shows the derived fragility curve of the reinforced stairs. The demand parameter chosen was peak ground acceleration. The damage states based on drift were matched to the qualitative description from the fragility library. The median of the three curves are 0.072, 0.228, and 0.457. The dispersion of the three curves are 0.250, 0.250, and 0.249.

Fig. 3 shows the derived collapse fragility curve of the structure. The demand parameter required by PACT was spectral acceleration. The median collapse is 0.6. The dispersion is 1.7.

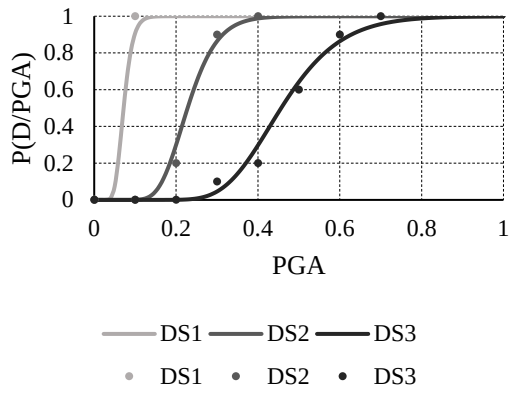

Fig. 2 User Defined Stair Fragility

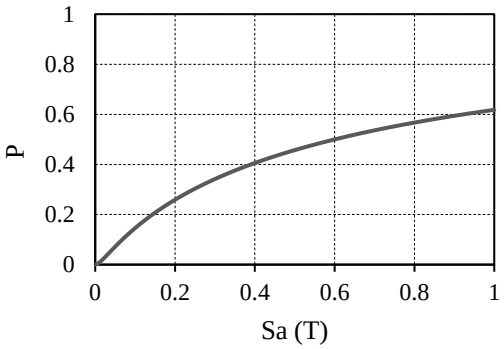

Fig. 3 Simplified Procedure Collapse Fragility

The probability of non-exceedance of the repair cost against the repair cost is presented in Fig.4. The abscissa presents the probability at which the total repair cost is less than or equal to the total replacement cost of the structure at total collapse. The median value of repair cost is taken to be equal to USD 218,360.00. The repair cost is almost equal to the replacement cost of USD 218,998.00. This puts direct financial loss at 99.7%. REDi suggests replacement for a structure with a direct financial loss greater than 40%.

The median values for repair cost indicate that the structure is not resilient in terms of direct financial loss.

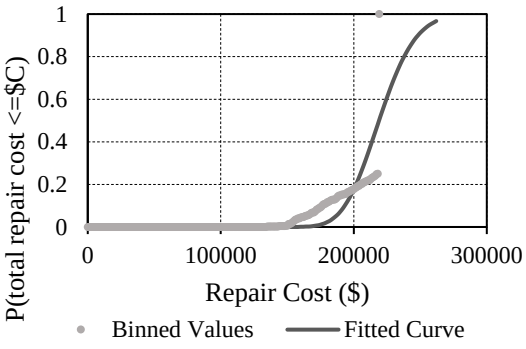

Fig. 4 Repair Cost

Fig. 5 determines the probability of non-exceedance of total fatalities against the number of deaths that occurred after the earthquake was simulated. The median value of deaths is taken to be equal to 0.

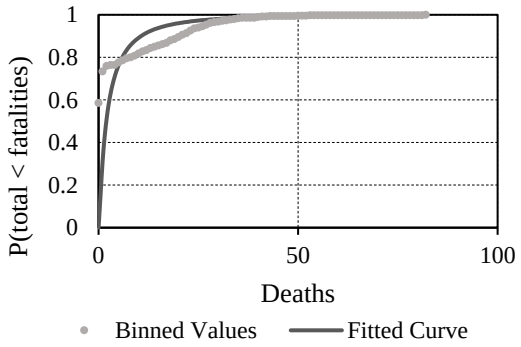

Fig. 5 Deaths

In Fig. 6, the probability of non-exceedance of total number of injured individuals versus the number of injuries is also presented. The plot provides a median value of 0.

The median values for deaths and injuries indicate that the structure is resilient in terms of occupant safety.

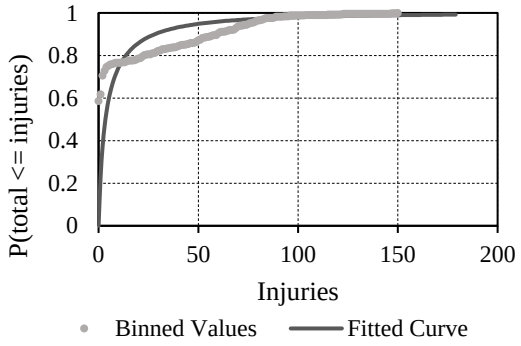

Fig. 6 Injuries

Fig. 7 illustrates the repair sequence of the structure. The structural repairsequence is first considered before other sequences. The interior and stair sequence occur simultaneously. The per floor sequences occur consecutively.Using modified repair time, the total delay due to repairs is 31.13 days.

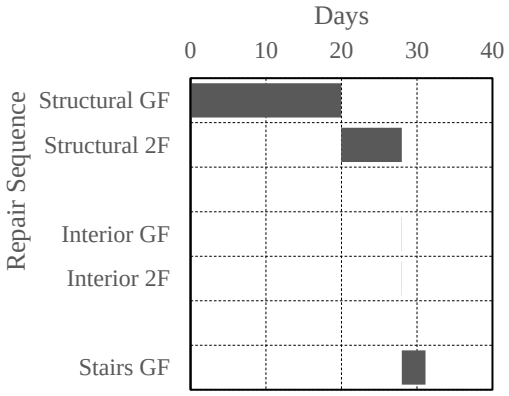

Fig. 7 Modified Repair Time

Fig. 8 shows the Reoccupancy, and Functional Recovery. All components to be repaired was of repair class 3. No component to be repaired was of repair classes 2 or 1. The Reoccupancy and Functional Recovery are the same. It would take 442.13 days for the Reoccupancy and Functional Recovery of the structure.

The median values for Reoccupancy and Functional Recovery for a year and two months indicate that the structure is not resilient in terms of recovery

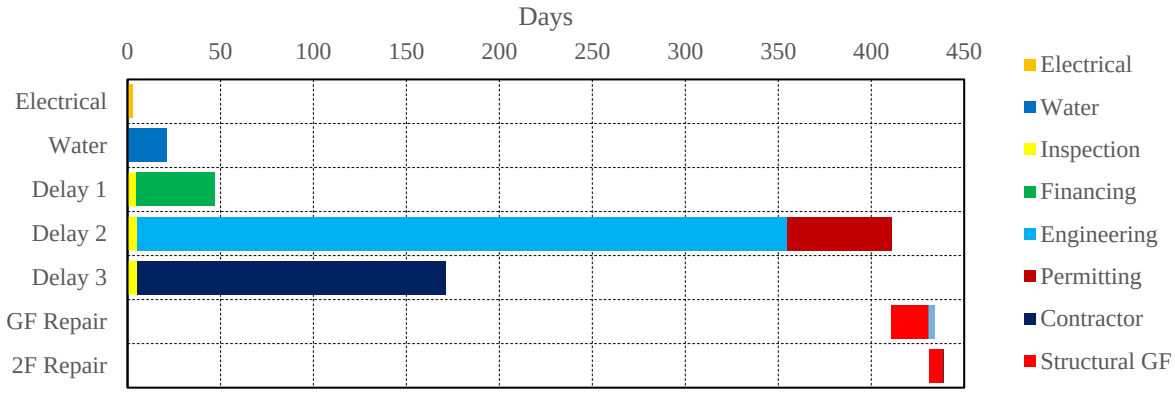

Fig 8. Total Downtime Timeline

CONCLUSIONS

In conclusion, the two-storey four classroom DPWH standard school building is not resilient based on the REDi Framework as it failed to comply with all of the silver-required criteria.

BLACK CARBON IN PM2.5 AT ROADSIDE SITE IN BANGKOK, THAILAND

Pornsuda Phanukarn[1], Hatairattana Gariyavech[2] and Sopa Chinwetkitvanich[3,*]
[1,3] Faculty of Public Health, Mahidol University, Thailand;
[2]Department of Environmental Quality Promotion, Ministry of Natural Resources and Environment, Thailand

ABSTRACT

Traffic is typically a major source of air pollution in urban areas of developing countries. The exhaust emissions include gaseous substances and particulate matter, which PM2.5 (particulate matter less than 2.5 micrometers in aerodynamic diameter) is the majority. In urban areas, the composition of PM2.5 at roadside site dominated by the carbonaceous combustion component, the major constituent wherein was represented as black carbon (BC). This study aimed to investigate the diurnal concentrations of BC related to PM2.5 by using a seven-wavelength aethalometer. Study site was located near one of congested roads in Bangkok, Thailand. The correlation between traffic volumes and BC concentrations at roadside were also discussed. Results showed that the 24-h average BC concentrations of this site were in the range of 1.5 – 15 μg/m^3. The diurnal pattern of BC levels exhibited two peaks of BC concentrations occurring during 0500 to 0700 LST and 2100 to 2300 LST. The morning peak of BC evidently governed by traffic condition while the evening peak resulted from traffic associated with meteorological effect. In addition, the density of heavy-duty diesel vehicles (HDDVs) played an important role to the diurnal pattern of BC concentrations. Interestingly, the highest BC level from this study site was observed on Sunday, where the lowest was found on Monday and Friday. This involved with traffic volumes caused by particular activity around this study site.

Keywords: Black carbon, PM2.5, Heavy-duty diesel vehicle, Bangkok urban area, Air pollution.

INTRODUCTION

Black carbon (BC) is a major constituent of particulate matter (PM) in urban environments resulted from incomplete combustion processes of fossil fuels or burning of biomass and biofuels. BC plays an important role in climate change [1]. It has been estimated that the direct radiative forcing of BC aerosol is around 0.2 – 1 W/m^2, suggesting that BC is the second contributor to climate warming next to carbon dioxide [1], [2]. In addition, BC also causes harmful health effects, including several respiratory diseases and cardiovascular system [3], [4].

The rapid growth of industrialization and urbanization has created high levels of air pollution in Thailand, especially in urban areas. Vehicles and factories were stated to be major contribution to air pollution, particularly in Bangkok [5]. The Asian Development Bank [6] reported that the main source of inhalable particulate matter at roadside of Bangkok came from in-use diesel vehicles. Health risk assessments for Bangkok indicated that as much as a third of all heart disease deaths might be caused by air pollution, primarily from motor vehicles exhausts [7]. Likewise, several studies reported high levels of air pollutants, including PM and BC, at roadsides in Bangkok Metropolitan Region. The increasing severity of road transportation has the potential to greatly increase pollutant emissions, which also have the effect on health, economy and society. Nowadays, the routine automatic ambient air quality monitoring of roadside stations in Bangkok mainly focuses on parameters of NO_x, CO, O_3 and PM10, while PM2.5 was only an addition available in some monitoring stations. The measurements of BC, which are more health damaging, are not included in routine monitoring programs.

At present, BC concentrations in Thailand are only reported by researchers, and mostly related to biomass burning and its haze problem in Northern provinces of Thailand. Though BC observed in Bangkok area was noticeably traffic-related, the correlation between measured BC and traffic characteristics was not clearly stated. Thus, the purpose of this study was to investigate the diurnal concentrations of BC related to PM2.5 and traffic characteristics nearby roadside site in Bangkok area.

MATERIALS AND METHODOLOGY

Study area

Bangkok is the capital of Thailand, covering an area of 1569 km^2, and has a population of 6 million inhabitants [8]. In 2016–2017, there were about 9.4–9.8 million registered vehicles in Bangkok, including 65% gasoline vehicles and 25% diesel vehicles [9]. Samples of BC were collected at an automatic

continuous air quality monitoring station operated by Bangkok Metropolitan Administration (BMA), namely Ratchathewi station, situated at Ratchathewi District Office. This was a roadside station located at the west-northwest side of Phayathai Road (Fig.1), which was 5 meters away from the curbside of the road and approximately 150 meters from Phayathai Intersection. Phayathai Road is one of the main roads in the center of Bangkok with high traffic density and congestion in rush hours. This road is surrounded by several commercial buildings, hospitals and academic institutes. Moreover, there is the BTS Skytrain structure covering some part of this road, especially near this monitoring station. Black carbon sampling was conducted on the rooftop of the monitoring station, which was approximately 5 meters above the ground.

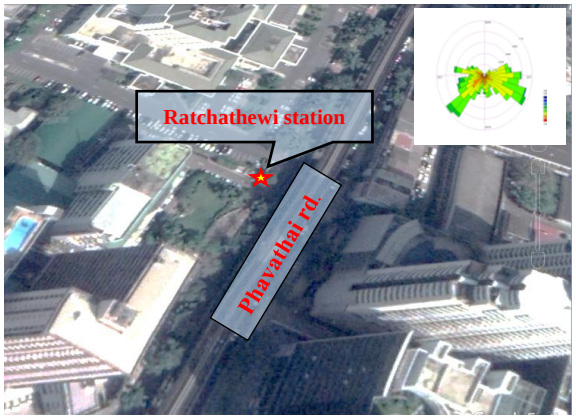

Fig. 1 Location of Ratchathewi monitoring station

Samples collection and data analysis

Real-time measurement of BC concentrations was conducted at the Ratchathewi station during the dry season (January 4 – 30th, 2017). Measured data was separated into two groups of weekday (Monday to Friday) and weekend (Saturday and Sunday). Total days of measured BC data were 27 days, consisting of 19 days of weekday data and 8 days of weekend data (four Saturdays and four Sundays). However, there were some missing data during January 10 – 11th due to heavy rain.

Black carbon measurements were carried out using the equipment called aethalometer, Model AE-42 (Magee Scientific, USA) with seven different wavelengths (370, 470, 520, 590, 660, 880, and 950 nanometer). The aethalometer was equipped with a cyclone to allow only particles smaller than 2.5 µm in aerodynamic diameter. Sampled particles were collected on a quartz fiber tape. The flow rate was controlled at 2 liters/minute, and the measured cycle was set at every two minutes. Hourly averaged values from the measurement at 880 nanometer wavelength were regarded as BC mass. If measured BC data in any hour or any day were missing more than 40%, their hourly or daily averages were not calculated and presented.

Traffic volumes passing by the monitoring site were evaluated from CCTV camera obtained from Traffic and Transportation Department, Bangkok Metropolitan Administration. The number of vehicles passing in the image were manually counted for twenty minutes' duration for every hour, then, they were interpolated to be hourly data. Eight different vehicles; passenger car, pick-up, van, taxi, motorcycle, three–wheeler (or "Tuk–Tuk"), bus and truck were categorized. Particulate matter (PM2.5) data simultaneously monitored at the same sampling station were provided by Bangkok Metropolitan Administration (BMA).

RESULTS AND DISCUSSION

BC concentrations and BC/PM2.5 ratios

The daily concentrations of BC observed at Ratchathewi station were in the range of 1.5 to 15.0 µg/m^3, which their average and median were 4.5±1.9 and 4.1 µg/m^3, respectively. Secondary data of PM2.5 concentrations from BMA were in the range of 1.0 – 58.0 µg/m^3, with the average of 27.2 µg/m^3. In comparison to several studies monitoring BC nearby roadways (Table 1), BC concentrations measured in this study were somehow lower than those previously reported, e.g., the average BC concentration of 17.9±6.6 µg/m^3 observed in Bangkok area during dry season [10], the ones of 8.9±3.6 µg/m^3 monitored in Istanbul, Turkey [11], and 9.7 ± 0.8 µg/m^3 reported in London, UK [12].

Table 1 Reported BC concentrations at different locations during dry season

Location	BC (µg/m^3)	BC/PM2.5 (%)	Ref.
Bangkok, Thailand	18±6.6	30	[10]
Istunbul, Turky	8.9±3.6	38	[11]
London, England	9.7 ± 0.8	–	[12]
Shanghai, China	3.3±2.1	5.0 – 12	[13]
Gwanju, Korea	2.4±2.2	–	[14]
Ostrava, Czech republic	3.5±4.1	–	[15]
Jiaxing, China	5.1	7.1	[16]
Guadalajara, Mexico	1.3 – 14	1.4 – 9.6	[17]
Bangkok, Thailand	4.5±1.9	18	This study

However, this average BC concentration was slightly higher than those observed in Shanghai, China (3.3±2.1 μg/m^3) [13], or in Gwangju, Korea (2.4±2.2 μg/m^3) [14] and Ostrava, Czech Republic (3.5±4.1 μg/m^3) [15]. During the period of BC monitoring (January 4 – 30th, 2017), total of 557 hourly data of BC concentration were gathered, excluding missing data. The majority of BC data (76.5% of total data) were in the range of 2 – 5 μg/m^3 and the second (20.5% of total data) were found in the range of 6 – 10 μg/m^3. Those of BC data, which were smaller than 2 μg/m^3 and higher than 10 μg/m^3, were observed only 2.2 and 0.9%, respectively.

The mass fraction of BC in PM2.5 (or BC/PM2.5 ratios) in this study were ranging from 6.2 to 69.8%, the average of which was 18.0% while the median was 16.1%. These BC/PM2.5 ratios on weekdays and weekends obviously peaked during morning hours (6:00 – 8:00) and night hours (20:00 – 21:00), while they remarkably decreased in the afternoon (15:00 – 16:00). Those peaks of BC/PM2.5 ratios in the morning and the night were related to traffic flow.

Moreover, the mass fraction of BC in PM2.5 (BC/PM2.5) of weekdays data were significantly different ($p<0.05$) from weekends data. Throughout the sampling period, the results between daytime and nighttime either on weekdays or weekends did not show significant difference. The average BC/PM2.5 ratio (18.0%) from this study was clearly lower than the previous studies at roadside site in urban Bangkok (30.0 – 37.0%) [10] and in Instunbul, Turkey (38.0%) [11]. However, it was relatively higher than those found in Shanghai (5.0 – 12.0%) and Jiaxing (7.1%) of China, and in Guadalajara of Mexico (1.4 – 9 .6%) (Table 1). The fraction of BC in PM2.5 depended on pollution sources and meteorological conditions. Reddy et al. [18] mentioned that their high BC/PM2.5 ratios of Anantapur in India during winter affected by biomass burninng, while increase of non-carboneceous PM2.5 during monsoon period might decrease the ratios.

Effects of day of the week on BC concentrations

Due to the sampling site represented a roadside type, traffic emission was expected to be a major contribution of BC and PM2.5 mass. Therefore, the sampling period was assigned to obtain enough data of weekdays and weekends BC concentrations. In addition, daytime and nighttime data were separately considered in order to understand the diurnal variation of BC. Daily BC concentrations categorized as weekly pattern were averaged and illustrated in Fig.2. The average daily BC concentrations on weekdays (Monday to Friday) ranged from 4.1 to 4.9 μg/m^3, with their average of 4.4 μg/m^3. For Saturdays and Sundays, these averages were 4.4 and 5.3 μg/m^3, respectively. Surprisingly, higher BC concentrations were observed on Sundays and they were significantly higher than those on Saturdays or weekdays ($p<0.05$).

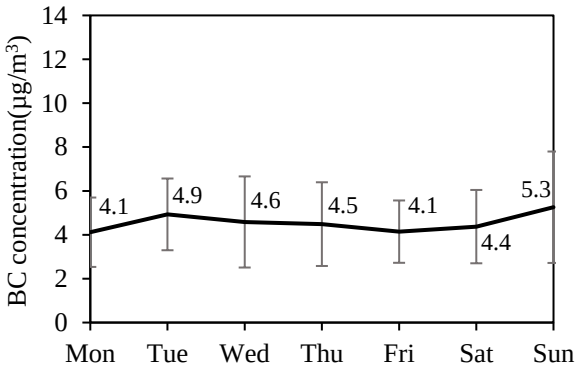

Fig. 2 The average daily BC concentrations in weekly pattern.

The hourly BC concentrations during weekdays were in the range of 1.5 – 12.1 μg/m^3, and their average was 4.4±0.2 μg/m^3. During weekends, the hourly BC were in the range of 1.7 – 15.0 μg/m^3 with the average of 4.8±2.2 μg/m^3. Though the average daily BC concentration on Sundays was significantly different from others as mentioned above, there was no significant difference between hourly BC concentrations of weekdays and weekends data ($p=0.075$).

Diurnal BC concentrations

During weekdays, hourly BC concentrations recorded between daytime (06:00-18:00) and nighttime (18.00-06.00) were in the ranges of 1.8 – 12.1 and 1.5 – 9.2 μg/m^3, respectively. Their averages were 4.1 and 4.8 μg/m^3, respectively. On weekends, hourly of BC concentrations during daytime ranged from 1.8 to 15.0 μg/m^3, while those of nighttime ranged from 2.6 to 11.6 μg/m^3. The averages of weekends were 4.6 and 5.1 μg/m^3, respectively. Interestingly, these results showed that the average BC concentrations during daytime were significantly lower than nighttime ($p<0.05$).

All hourly BC concentrations of weekdays and weekends were averaged, and their diurnal patterns were plotted as shown in Fig.3. Two curves of average daily BC concentrations representing weekdays and weekends data in diurnal pattern exhibited similar two peaks in the morning (5:00 – 7:00) and the night (21:00 – 23:00). During weekdays, the average hourly BC concentrations started to increase from 5:00 and reach its peak (6.2 μg/m^3) on 6:00, while the peak of weekends (6.4 μg/m^3) occurred at 7:00. In addition, some data higher than 10 μg/m^3 were mostly observed during these hours. The second peak happened in the night (21:00 to 23:00), which the evening peak of weekdays and weekends were 5.2 and 6.0 μg/m^3, respectively.

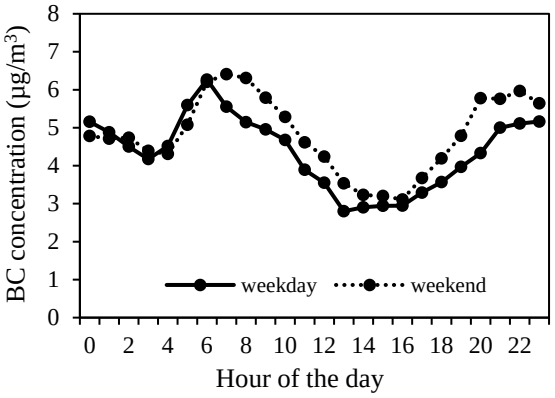

Fig. 3 Diurnal variation of BC concentrations

These two peaks of BC concentrations presented in the morning and the night, which should be related to traffic emission and the formation of boundary layer height, [10], [15]. Due to Thailand is the tropics, sunrise usually occurs during 5:00 – 6:00. The solar heat may disturb the nighttime stable layer and agitate nocturnal aerosols with some residuals near the surface. The lowest BC concentrations were found during 13:00 – 16:00 both weekdays and weekends data. The decrease after rush hours was mentioned to be associated with the atmospheric turbulent mixing and meteorological conditions [19]. Nonetheless, the diurnal pattern of BC observed at Ratchathewi station was unlike those observed in other urban cities such as London [12] and New Delhi [20] due to traffic rush hours on Phayathai road was uncommon.

Traffic characteristics on Phayathai road

Traffic volumes on Phayathai road were also counted during the same period, the traffic density ranged from 510 to 5342 vehicles/hour, resulting in the average of 2671 vehicles/hour. When weekdays and weekends data were categorized, their average densities were 2759 and 2451 vehicles/hour, respectively. The diurnal patterns of traffic flow pass through Phayathai road near the sampling station on weekdays and weekend are presented in Fig.4. The most congested traffic flows were observed during 7:00 – 8:00 and 16:00 – 17:00, which the traffic densities increased up to 3796 and 3871 vehicles/ hour, respectively.

However, Figure 4 illustrated that traffic densities during 8:00 – 16:00 were not drastically decreased in comparison with those peaks. This should be due to Phayathai road leads to Victory monument (a center of public transportation), and several public hospitals located nearby, resulting in substantial traffic congestion almost all daytime. Besides, there were several public organization or academic institutes nearby Victory monument. Their office hours mostly ended at 16:00, resulting in traffic congestion happened since 16:00 and started to decrease after 17:00. For weekends, traffic congestion still exhibited substantially, but not the same early hours as those on weekdays. The morning traffic density during the weekends observed at 9:00 and reach the highest densities of 2844 vehicles/hour at approximately 10:00. For nighttime, their peak of 3722 vehicles/hour was found during the hour of 20:00 – 21:00.

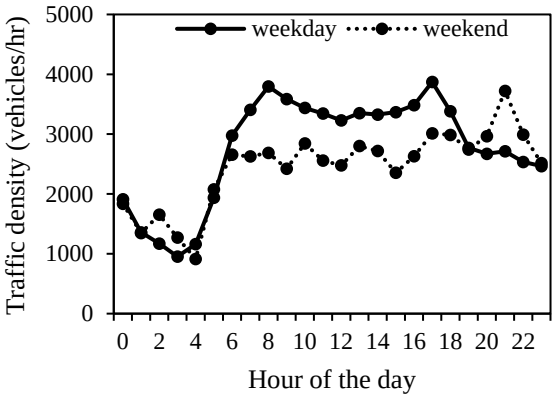

Fig. 4 Diurnal patterns of traffic density

The average traffic densities during daytime on weekdays was about 3382 vehicles/hour, which was clearly higher than the daytime average density on weekends (2675 vehicles/hour). In contrast, the average traffic densities during nighttime on weekdays (1969 vehicles/hour) was lower than that of 2185 vehicles/hour on weekends. This could be noticed that fluctuation of traffic densities on weekends were smaller than that of weekdays.

Table 2 categorized traffic composition passing through this station during the same sampling period. Traffic composition affected the emission of pollutants. The vehicle fleets were dominated by private car (29-30%), taxi (25-33%) and motorcycle (21-25%), while pickup, van, bus, and Tuk–Tuk (three-wheel vehicle) proportions were 8, 4, 4 and 2%, respectively. Truck showed the smallest proportion of less than 1%.

Table 2 Percentage of traffic fleets composition

Vehicle type	Weekdays	Weekends
Private car	30.0±4.0	29.0±3.9
Pickup	8.4±0.8	6.8±3.5
Van	4.1±0.8	3.3±0.8
Taxi	25.0±5.6	33.0±3.8
Motorcycle	25.0±13.0	21.0±6.5
Tuk–Tuk	2.0±0.2	2.2±1.0
Bus	4.7±1.7	4.0±1.1
Truck	0.4±0.1	0.6±0.0
Average (vehicles/hour)	2759±660	2451±679

The high proportions of private car, taxi, motorcycle and pickup were observed both on

weekdays and weekends while the proportion of Tuk–Tuk and truck were still smaller than other fleets. In comparison with weekdays, the major fleets (private car, pickup, motorcycle, etc.) showed smaller proportion on weekends. But, there were some fleet increased their proportions on weekends, e.g., taxi, Tuk–Tuk and truck.

Correlation between BC concentration and traffic

Figure 4 illustrated that traffic densities started to increase from pre-dawn at 4:00, similar to the increase of BC concentration in Fig. 3. However, BC concentration reached its peak at 6:00 and decreased afterward, while traffic densities still kept rising until 8:00. After the morning peak, the decrease of BC concentrations was more drastically than traffic densities. The BC concentrations lowered to the smallest during the hours of 13:00 – 16:00 (Fig. 3), but traffic densities were still substantial amount at the same hours. Therefore, the correlation between BC concentrations and traffic densities in this study could not be affirmative. Subsequently, traffic fleets were further considered, which truck vehicles (Fig. 5) showed interesting correlation with BC concentrations. (Remarks: Some other fleets also showed a weak correlation, but data were not discussed here.)

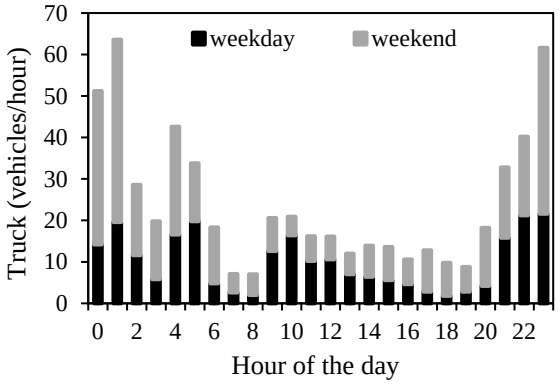

Fig. 5 The diurnal pattern of truck density

Trucks transportation within Bangkok area were regulated and allowed only between 10:00 – 15:00 and after 21:00, resulting in similarity of diurnal pattern of truck and BC concentrations. Figure 5 showed high densities of truck during 4:00 – 5:00 and drastically decreased afterward, as well as, another high truck densities during the night similar to diurnal pattern of BC concentrations (Fig. 3). In addition, more truck densities on weekends than weekdays were consistent with the higher averages BC concentrations on weekends. The possible explanation for this correlation between BC concentrations and truck densities might be due to diesel was their majority fuel. Particularly during nighttime, heavy-duty diesel vehicles should be an important source of black carbon emission.

Effects of meteorological parameters on BC concentrations

Wind speeds during the sampling period were monitored and found in the range of 0.5 – 2.5 m/s with their average of 1.3 m/s. Wind speed is an important factor related to accumulating BC concentration. Higher wind speed could contribute more emission dispersion, lowering pollutant concentrations in the ambient. Wind speed higher than 0.5 m/s illustrated a significant inverse relation with BC concentrations ($R_{pearson}$ = –0.377, P<0.01).

Predominant wind directions were observed from east–southeast (ESE), east (E), southwest (SW) and south–southwest (SSW), the frequency percentages of which were 16.4, 10.1, 13.7, and 10.6%, respectively. The contribution of hourly BC concentrations from different wind directions was shown in Fig. 6. During sampling period, BC concentrations larger than 5 µg/m^3 occurred when the wind blowing from the directions of ENE/E/ESE (28%) and SE/SSE/S/SSW directions (27%). As the monitoring station is located on the west–northwest curbside of the road, traffic emission from nearby roads and Phayathai road itself were clearly sources of these winds. The results indicated that BC mass should be influenced by traffic emissions, which was consistent to the relation between BC concentrations and heavy-duty diesel vehicles on weekends.

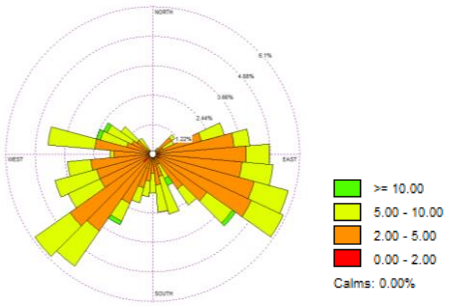

Fig. 6 Pollution rose of hourly BC concentrations

CONCLUSIONS

Hourly BC concentrations in this study were measured at roadside station in the center of Bangkok during dry season in year 2017. The averages of hourly BC concentration and BC/PM2.5 ratio were observed as 4.5±1.9 µg/m^3 and 18%, respectively. The results were lower than a previous study in Bangkok [10]. Diurnal pattern showed two peaks of BC concentrations during the periods of 5:00 – 7:00 and 21:00 – 23:00. Two peaks of BC concentrations in this study were more likely due to rush hour traffic concurrently with meteorological condidition. When the prevail wind direction blowed from traffic congestion on the road to the monitoring station, high BC concentrations were sometimes observed. Heavy-duty diesel vehicles should be an important

fleet affecting on BC concentrations, especially during nighttime and weekends.

ABSTRACT

The release of greenhouse gases from anthropogenic activities in many organizations of the country has induced the effect labeled global warming. In Thailand, a "petrol station" is considered an "organization" that not only sells fuels and engine lubricants for motor vehicles but also includes many other facilities provided to satisfy the modern lifestyle of customers. In other words, a petrol station in Thailand comprises a large complex service center offering a wide range of services that contribute greenhouse gas emissions to the atmosphere. This paper aimed to present a specific web application tool developed to estimate the carbon footprint for petrol stations in Thailand. The application system comprises three core components: 1) a web-based user interface; 2) a processing system, incorporating the carbon footprint of the organization (CFO) framework and the calculated model and 3) a database. The site-specific input data or activity data provided by the user was primarily required for the data entry in the system. The processing system will then quantify the amount of greenhouse gas emissions by multiplying the activity data by the emission factor (EF). A database was also created containing default EFs readily used for the calculation, but users can change these values at any time when a more appropriate one is indicated. Finally, the CF calculation results can be evaluated in various functional units: monthly or yearly, per fuel sold, or per area of the petrol station, and visualized in graphs. In addition, the results can be reported by categorizing the emission sources according to the scope of the CFO and the GHGs reporting guidelines (scopes 1, 2 and 3).

Keywords: Carbon footprint, Organization, Petrol station, Web application

INTRODUCTION

Petrol stations in Thailand have increased continuously. From 2007 to 2016 the number of petrol stations in Thailand has increased by 29%, corresponding to the increasing trend of fuel sales at 22% [1]. Currently, more than 26,000 petrol stations are located across the country [1]. In Thailand, petrol stations not only sell fuel and engine lubricants for motor vehicles, but also include many other facilities provided to satisfy the modern lifestyle of customers such as convenience stores, restaurants, souvenir shops, coffee shops, food stalls, toilet facilities, including automatic teller machines (ATMs) and auto mechanic services. In other words, the petrol station is a large complex service center with a wide range of activities that could contribute greenhouse gas emissions to the atmosphere, resulting in the effect labeled global warming.

Carbon Footprint for Organization (CFO) is a quantitative method to measure greenhouse gas emissions from all activities in the organization, including energy used in the building, industrial processes and company vehicles [2]. According to our previous research, studies have developed special carbon footprint calculation programs for food and beverage packaging using Visual Basic for Applications (VBA) in Microsoft Excel [3], [4]. One advantage of this type of program is that it works on Microsoft Excel in a desktop or laptop. However, the VBA's disadvantage is its unattractive appearance and limited functions compared with other types of available programs, like a web-based application (web app).

In fact, a web app is a subset of information technology (IT) that has become an integral part of modern lifestyle. People use it to facilitate the functioning of nearly all life domains. With the help of information technology, users now can acquire information, connect with people and achieve much more with speed and precision [5]. The web application has the advantage of being easily accessible to show users. Just by having a computer or smartphone device, a web browser and connecting to the internet, users can access the program from anywhere at any time. At the moment, although numerous web applications for carbon footprint calculation are available online, they are all simple carbon footprint calculators for individuals, events or businesses [6], [7], [8]. Researchers have paid little attention to the GHGs of an organization that are needed to estimate accurately the complex service activities that are common to petrol stations in Thailand.

As a result, the aim of this paper was to create a web application to analyze carbon footprint for petrol station in Thailand in the form of web application software. Thus, the owner or petroleum company in Thailand can use our developed web-based application to calculate greenhouse gas emissions released from their activities. The web app will be served as a supporting tool for carbon management of their organizations.

METHODOLOGY

Data Requirements and Calculation Method

To develop the web application in this study, petrol stations in Thailand were first surveyed to receive an overview of their various service activities. Activity data were collected relating to GHG emissions from different sources situated in the petrol stations including offices, convenience stores, fast food shops, restaurants, coffee shops, retailers and toilet facilities. The examples of data related to those activities were mainly electricity, water and chemical use and waste generated. In addition, the secondary data required in this study were emission factors (EFs). Main sources of the EFs include Thailand Greenhouse Gas Management Organization (TGO) and the international database, e.g., Ecoinvent. Other sources involve published and unpublished articles.

For carbon footprint calculation in this study, the method was based on guidelines for carbon footprints of organizations by the Thailand Greenhouse Gas Management Organization (TGO) [9] and World Business Council for Sustainable Development (WBCSD) [10]. The GHG emission is simply calculated by multiplying activity data with the related emission factor as expressed in Eq. (1) as shown below.

$$CF = \text{Activity Data} \times \text{Emission Factor} \quad (1)$$

where CF is the carbon footprint estimated in unit of kilograms carbon dioxide equivalent (kg CO_2eq); the activity data represents a factor that quantifies an activity used to calculate the emissions generated, and emission factor represents a factor that allows GHG emissions to be estimated from a unit of available activity data.

Programing Languages for Web App Development

To develop the web-based application, five programming languages were used to write the code to support two system components of the software – client and server side. The data processing is handled by the server while results are returned to the client. These five languages include Hypertext Markup Language (HTML), Cascading Style Sheets (CSS), JavaScript, Active Server Pages (ASP.NET) and Structured Query Language (SQL). At the client side, HTML is used to create a web application structure, in conjunction with CSS and JavaScript that are used to control the appearance and to make user interactions. At the server side, ASP.NET is used for server processing and to connect to databases, while the database management is achieved with Structured Query Language (SQL). A program called, "Microsoft Visual Studio Community 2017" was used as a platform tool to support writing the code of these five languages.

RESULTS AND DISCUSSION

Description of the Web Application

The developed web application is available online at http://www.carbonfootprintthailand.com /petrolstation. It can run on all electronic devices such as desktop computers, laptops, tablets and smartphones through a web browser. It can calculate the carbon footprint of a petrol station by referring to the resources used and activity information of the petrol station. Using the software, developers have designed three different functions of user access level: 1) general user for petrol station level; 2) group user for corporate level, e.g., Shell, ESSO, Bangchak, PTT, Chevron and 3) administrative user for general system management level. Using these levels, allows users to access various parts of the application. At the petrol station level, a general/owner user involves a group of users that can use the main part of the CF calculation system. The general user will be able to create, browse, edit and delete historical results, including being able to edit the EF values. At a corporate level, a group user is in the business level that provides a network of fuel distribution services across the country. This group of users can only browse the calculation results of petrol stations under their business group. The group users will not be able to edit any input data or results of any petrol stations. At the system management level, an administrative user can generally manipulate the overall software system such as deleting user and updating EF default values etc.

To calculate the carbon footprint, the developer has gathered all related EFs needed for the calculation by setting them as the software's default values, so they can be retrieved for the estimations instantly. The software also provides a special function that allows users to change these values at any time when a more appropriate one is indicated.

The CF calculation results can be evaluated in various functional units: monthly, yearly, per fuel sold or per area of the petrol station. These functional units can help entrepreneurs to calculate their GHGs (or CF), and to compare the CF results among petrol stations under the same corporate group.

The application system comprises three core components as shown in Fig. 1: 1) a web application user interface; 2) a processing system, incorporating the carbon footprint of the organization (CFO) framework and the calculation model and 3) a database. The user interface involves the display section of the web application, where the user can connect and send a request to the web server via a web browser. The processing system will then process the requests, connect to the database to manipulate data and send results to show to the user interface. The database of this developed web application is a data storage system called the Relational Database Management System (RDBMS). More details are described in a later section of this paper.

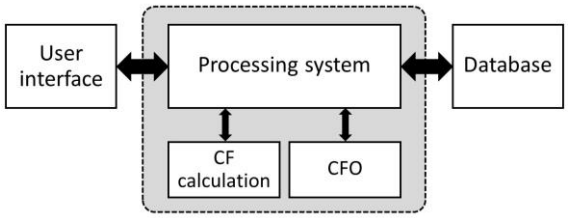

Fig. 1 Main components of the web application

Database Model with RDBMS

The database in this study involved a set of data stored in the application system, designed by using the SQL language of the Relational Database Management System (RDBMS). This database is a type of relational database model to organize and store data as a set of eight database tables (see Fig. 2). These database tables store account information, related companies or associations, petrol station information, EFs, shops and facility types and details, historical data of calculation options and input data related to carbon footprint results. To organize all databases, interaction needs to be created among tables, so a "primary key" which is a column in a database table that uniquely identifies rows in that table, and a "foreign key" which is a column of a table that is the primary key on another table, are assigned to define relationships between the two tables. The relationship was defined in this software as an one-to-many relationship. For example, one User ID of the 'User Table' may create many emission factor values in the 'Emission Factor Table'. Moreover, each user in the 'User Table' can create many petrol stations in the 'Company Table', and each petrol station can estimate CF many times in the 'Save Table'.

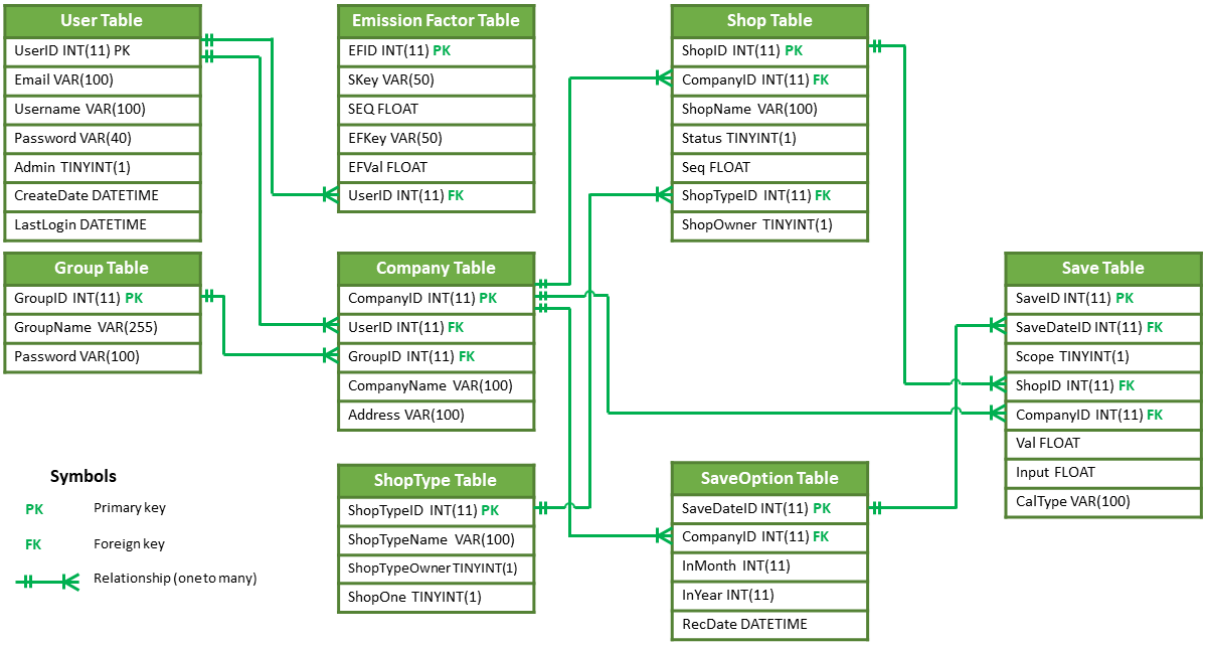

Fig. 2 Relational database model of the web application

Three Scopes of Emission Sources

According to the guidelines for CFO and the GHG reporting standard [9], [10], the application was designed to categorize and report the activity or emission sources of a petrol station separately in three scopes (scopes 1, 2, and 3), as presented in Fig. 3. Direct GHG emissions of scope 1 are released from sources that are owned or controlled by the petrol station while indirect GHG emissions of scope 2 are emissions from the generation of purchased electricity. Finally, indirect GHG emissions of scope 3 are emitted from sources not owned or controlled by the petrol station. Considering the definition of

these scopes and petrol station activities, scope 1 emissions involve onsite electricity generation, vehicle fuel consumption, onsite wastewater treatment system and use of chemicals, refrigerants and fire extinguishers while scope 2 emissions come from the consumption of purchased electricity. Lastly, scope 3 emissions come from several sources such as fuel consumption of outsourced vehicles, electricity consumption of the rental businesses, use of fuel sold and waste management by the local authority. Moreover, scope 3 also involves raw material acquisition such as use of paper, packaging and water.

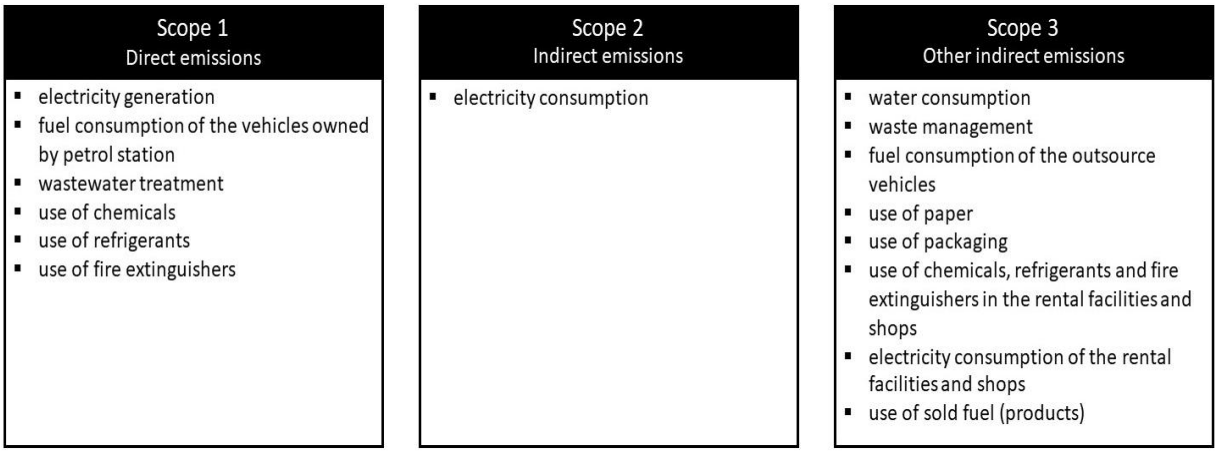

Fig. 3 GHG emissions from a petrol station relating to the scopes of GHG reporting guidelines

Calculation Sequence

Figure 4 shows the sequence of carbon footprint calculation, 12 processes connected to 3 user groups and 8 database tables (described above in database model section). First is process 1.0, where the general user has to create an account or log in to access the software. User information such as username, password and the level of user will be stored in the database named 'User table' and 'Group table'. After login, the general users can browse or modify EF values in process 2.0. In process 3.0, the general user has to create information about the petrol station. In the case the petrol station information is already created, the user can select the existing petrol station which he/she wants to calculate the CF. Process 4.0 allows a user to identify the time period of entering data, e.g., monthly or yearly meaning that all data have to be entered in relation to the selected time period. In process 5.0, the general user has to create and edit the details of shops and service facilities. Another important information needed is whether each shop/service facility is owned by the petrol station or rented. Such information will allow the software to categorize activities and emission sources according to the scope of the CFO and GHG reporting guidelines at a later step. Next, process 6.0 allows a general user to input activity data such as the volume of water, electricity, and fuel consumption for each shop/service facility previously selected. After completing process 6.0, the web app will use those data to calculate CF in process 7.0. Process 8.0 will use the CF results to create pie and bar graphs, comparing the CF among various shops, activities, the three scopes of the CFO guidelines and showing them all in process 9.0. Here the user can change the displayed functional unit to monthly, yearly, per volume of selling fuel or per petrol station areas. When the functional unit is selected, the software will automatically recalculate CF, recreate graphs and illustrate the results on the web page. The software can export all input data and results in PDF format at process 10.0. For process 11.0, the general user can browse the calculation history and edit the input data. Finally, process 12.0 is the system management tool, which only administrative users can access.

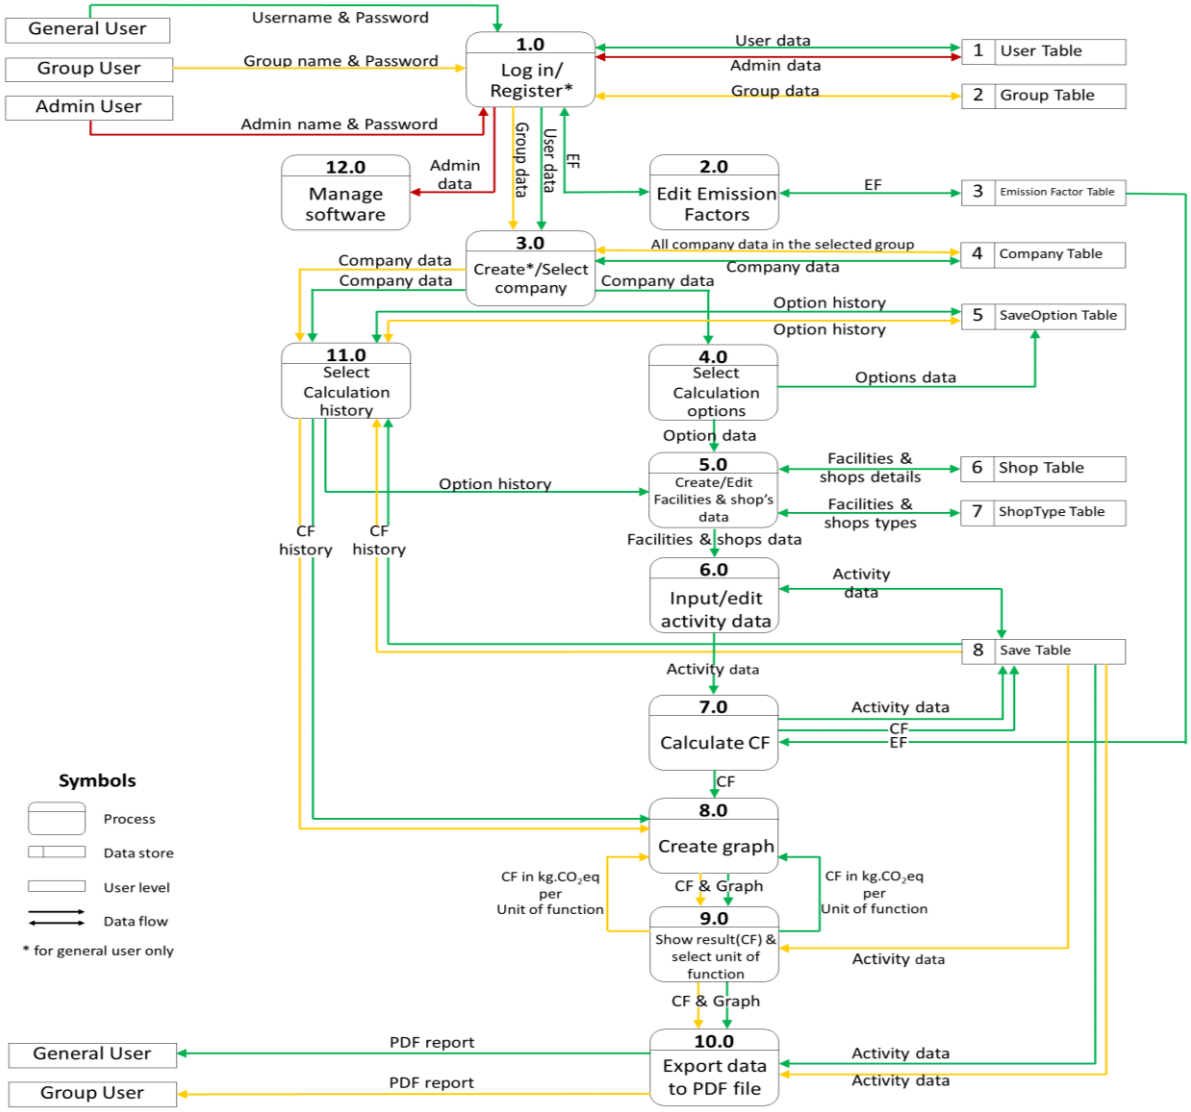

Fig. 4 The sequence of the carbon footprint calculation

Web Application User Interface

Figure 5 shows the main graphical user interface (GUI) of the developed web application, namely, main page, input data page and result page. Main page is well designed as a snapshot of a petrol station, consisting of all twelve categories of shops and service facilities currently provided in petrol stations of Thailand. This page allows users to work easily on relevant service facilities (see Fig. 5a). Fig. 5b depicts an example of an input data page where users have to fill in activity data and resource use. Several web pages of input data were enhanced by adding checklist options, drop down list options, and illustrations to make it more attractive and easier for users to enter their input data. The result page displays the calculated results in units of kilogram CO_2-eq relating to the functional units chosen: monthly, yearly, per fuel sold or per area of the petrol station and illustrated in graphs (Fig. 5c). In addition, the results can be reported following scopes 1, 2 and 3 of the CFO and the GHGs reporting guidelines as mentioned above.

(b) Input data page

(c) Result page

Fig. 5 Main graphical user interface

CONCLUSION

Clearly, the advantage of web application software is being easily accessible to any user. With a computer or smartphone device, a web browser and connection to the internet, users can access the web app from anywhere at any time. The CF calculation results of the web app can be estimated in various functional units: monthly, yearly, per fuel sold or per area of the petrol station. Therefore, the developed web application in this study can help petrol station owners, petroleum companies and associations in Thailand to account GHG emissions released from their boundaries and operations and to compare the CF results among petrol stations under the same corporate group. Ultimately, it will lead to guidelines for future planning to reduce their emissions.

DEVELOPMENT OF A WEB APPLICATION FOR ESTIMATING CO_2-EQUIVALENT EMISSIONS OF POULTRY AND SWINE SLAUGHTERING PROCESSES

Salinee Ratchadaariyachat[1] and *Suphaphat Kwonpongsagoon[2]
[1,2]Department of Sanitary Engineering, Faculty of Public Health, Mahidol University, Thailand;
Center of Excellence on Environmental Health and Toxicology (EHT), Thailand

ABSTRACT

Thailand is one of the top productions and trade of poultry and pig meat to the world, making the slaughterhouse an important contributor to the release of greenhouse gases (GHGs) in the environment. This study aimed to create a web application to evaluate GHG emissions of poultry and swine slaughtering processes. The development was based on the carbon footprint of the product and life cycle assessment approach. The designed scope involved a cradle-to-gate assessment. The CO_2-eq estimation results are based on the following functional units: per kilogram of animal live weight, or per number of live animals, or a product-based perspective as per kilogram of animal meat or carcass. The developed application can be conceptualized in three main components. First is a web-based user interface, separated in input and output parts. Slaughterhouse information and activity data were required to be entered as site-specific input data while CO_2-equivalent emission was shown as carbon footprint output. Next, the processing system was designed to function regarding various conditions of input data, ranging from minimum to detailed data sets providing a simple, coarse, and detailed estimation. Finally, the system database used to access and store emission factors, historical data, and carbon footprint results was created using a relational database model to organize data in a set of 6 tables. Moreover, many functionalities were considered and incorporated in the application to facilitate the user's estimation such as navigation tool, functional unit selection, data validation and null check, emission factor management, report/export documentation, and data confidentiality and security. The potential of this developed application is expected to aid the Thai slaughterhouse industry calculating their GHG emissions released in the environment, and subsequently leading to CO_2 mitigation.

Keywords: Carbon footprint, Slaughtering process, Poultry and swine, Web application

INTRODUCTION

The prediction of the world's population increase is expected to result in significantly increasing meat production possibly affecting the greatest environmental impacts as a result of global consumption [1], [2]. With the FAO report, it has become evident that the quantity of global meat consumption per capita is likely to continue increasing, which corresponds to the trend of meat production and slaughtered animals [3]. Slaughtering is a core sector of meat production for domestic consumption and export, especially in Thailand. During the last 20 years, overall meat production in Thailand has increased by almost 30%, especially poultry and swine, about 56% and 23%, respectively [3], [4]. It was reported that the Thai animal slaughtering industry is one of the most important and rapidly growing markets for poultry meat exports, placing Thailand in the Top 5 ranking of the world and the first among Southeast Asian countries [5]. Currently, international market opportunities are joining the environmental agenda, and more consumers emphasize green products. Especially consumers in developed countries are becoming concerned about climate change effects, so greenhouse gas (GHG) emissions during the slaughtering process in Thailand contributing to environmental degradation should be taken into account for industrial management and sustainability.

One method used to measure climate change impact in terms of the amount of GHGs generated from human/industrial activities is called, "Carbon Footprint (CF)" and is based on the life cycle assessment (LCA) approach. CF analysis of a product/process can provide an idea of resource consumption efficiency, affecting the amount of GHGs or CO_2 equivalent (eq) released in the atmosphere. The method can also identify hot spots where the most significant impacts occur for improving performance. In general, numerous studies have been conducted using CF and LCA to evaluate climate change and other environmental impacts for a variety of specific food products such as meat products, organic foods, wine, and milk [6]–[9]. In our previous studies, "CFPack" was first developed for carbon footprint analysis of food and beverage packaging [10], [11], using the Microsoft Excel Visual Basic for Application (Excel/VBA). In the current digital era with the popularity of the World Wide Web (www), most activities are conducted over the internet. According to researchers, the recent growth of web applications has been helpful in

developing environmental management and sustainability [12]–[14]. However, until now, few specific software packages have been developed and published to help entrepreneurs identifying their GHG emissions online. Therefore, this study aimed to create a web application to estimate CO_2-eq emissions of poultry and swine slaughtering processes in Thailand. The application is expected to aid the Thai slaughterhouse industry measure their greenhouse gas emissions, subsequently leading to reduced emissions.

METHODOLOGY

Scope and System Boundary

The web application was developed to estimate CO_2-eq emissions (or Carbon Footprint of Product – CFP) of the slaughterhouse industry according to the Life Cycle Assessment (LCA) concept. As can be seen in Fig. 1, the scope and system boundary of the estimation defines what is covered in the web application design and development starts by raw material acquisition, raw material transportation to the factory, the slaughtering process and product transportation to customers. In other words, the designed scope is a cradle-to-gate assessment. The CO_2-eq estimation results are based on the following functional units: per kilogram of animal live weight, or per a number of live animals, or a product-based perspective as per kilogram of animal meat or carcass. As all these functional units are the most commonly used in meat production [15], the estimation results will help the industry to monitor the emissions released and to compare the GHG inventory in terms of live animal-based units and carcass-based units.

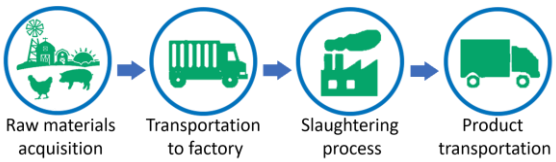

Fig. 1 Scope of this study

Data Requirements and Calculation Method

In this study, data involves all relevant activities of raw material acquisition, the slaughtering process, and transportation, for example, total amount of raw materials, energy, water, packaging, and chemical use, waste disposal, vehicle type, fuel type, and transportation distance. These activities are required to be entered in the software by users. In addition, the emission factors which are basically collected from Thailand Greenhouse Gas Management Organization (TGO), the international database, e.g. Ecoinvent and published articles, are also required to develop the web application.

The GHG emissions associated with the activities mentioned above can be generally estimated by multiplying the activity data with emission factors as expressed in Eq. (1) [16]

$$CF = \Sigma \text{ (Activity Data} \times \text{Emission Factor)} \quad (1)$$

where CF is the carbon footprint (or GHG emissions) estimated in kilograms of carbon dioxide equivalent (kg CO_2-eq), activity data represents a factor that quantifies an activity used to calculate the emissions generated, and emission factor represents a factor that emits the amount of greenhouse gases per unit of the activity data.

RESULTS AND DISCUSSION

Software Description

The web application was developed using a cradle-to-gate assessment scope to quantify the CO_2-eq emissions of poultry and swine slaughtering processes were conceptualized as comprising three main components: a web-based user interface, processing system and a database as shown in Fig. 2. The web-based user interface (UI) is separated in input and output parts. At the input UI, the user needs to provide site-specific data, namely, slaughterhouse general information, activity data, and the user's defined emission factor (EF) if any user wants to calculate with his/her own EF values. Next, the data/program processing system was designed to function using three different data entry conditions, ranging from minimum to detailed data sets providing a simple, coarse, and detailed estimation of the CO_2-eq emissions. Finally, the database was created to access and store EF, historical data, and calculated results. This database enables users to access, query, visualize, analyze, and download data. As a result, this increases the performance of the web application and user interactivity as a whole.

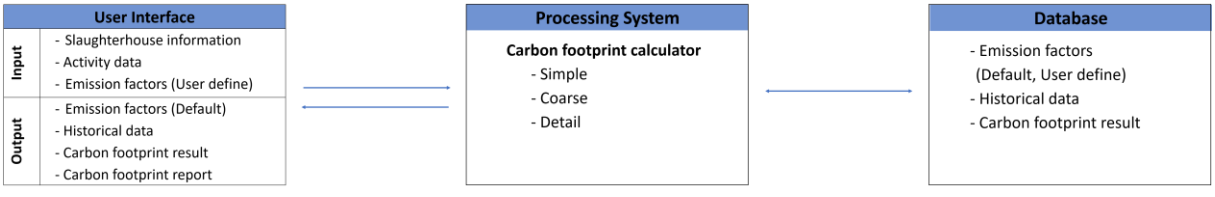

Fig. 2 Major components of the application

Data Processing Sequence

Figure 3 shows data flow of the developed web application. The tool is broken down in 11 sequential steps, six gather user input (process 1.0-6.0), two are background processing (process 7.0-8.0), two provide feedback to the user (process 9.0-10.0), and the last one manages software by an administrator (process 11.0). At the home page, a general/company user (non-admin and non-group user) can select either a new registration or log-in as current user to access the web application. The system will then connect to the database of the 'user table' and 'group table' to classify the user account in 3 levels as an administrator, the general user or group user, to receive the data accessibility level. After log-in, the general/company user could add a new company or select a company to estimate GHG emissions of the slaughterhouse. At process 2.0, the application will access the database of the 'company table' to show the historical information for the selected company. However, when 'add new company' is selected at this process, the pop up will appear for the data entry of its location and general information of the slaughterhouse. After finishing the process 2.0, the user could add new calculations (process 4.0) or go to process 5.0 to 'select historical calculation'. In the case of 'add new calculation' mode, the user has three options to select: simple, coarse or detailed for the data entry in the next process (process 6.0). The selected option will be stored at the database of 'save option table'. At process 7.0, while the calculation process is working, the EF value from the EF table (process 3.0) will be used to multiply with the inventory of activity data input to estimate the GHG emissions. However, when 'select historical calculation' mode is chosen, the user selects to open a previous estimation (process 5.0); he/she can see or edit the existing input data through the web application directly (process 6.0), and recalculate on process 7.0 or see the CF results (process 8.0-9.0). When each mode is running ('add new calculation' mode or 'select historical calculation' mode), the system will connect to the database of the 'save option table' and 'save input table' to record and retrieve all data to show on a web page. The CF result will be used to create graphs (process 8.0) to present in the next process. At process 9.0, the user is able to change the displayed functional units based on live animals, carcasses or product weight. Once the user changes, the web app will then recalculate and send back the new CO_2-eq results per the functional unit selected by the user. The results will be stored after finishing work at the back end and can be retrieved conveniently for reviewing and updating at the next visit. In addition, all inputs and results can be exported as a PDF file (process 10.0).

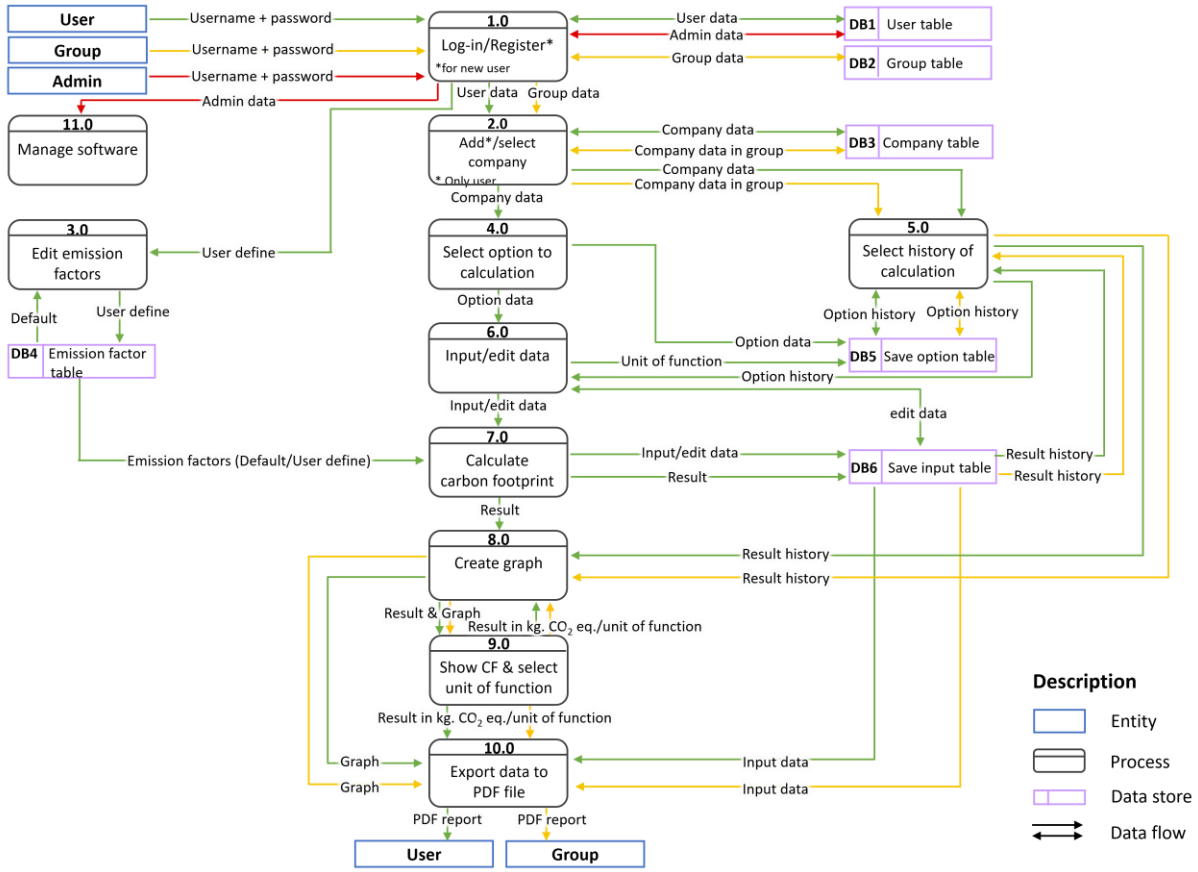

Fig. 3 Data flow diagram with entity, process, and data store

Relational Database Model

The database of this application was developed using a relational database model to organize and store data as a set of six database tables that has the primary key-foreign key rapport to create interaction among all tables (see Fig. 4). The database is the table storing account information, related companies or associations, slaughterhouse information, EFs, historical data of calculation options, and input data related to carbon footprint result. Databases (or tables) are linked in an one-to-many relationship, meaning the data which is a primary key of the first table is associated with the foreign key of the second table as multiple matching rows. For example, the user can create many companies under each user account and each company can estimate its carbon footprint many times. These relations can help to represent accurate data when the user accesses and queries the historical data of each slaughterhouse because the primary key of the 'User ID', 'Company ID', and 'Save Input ID' is uniquely identified in each row of this web application.

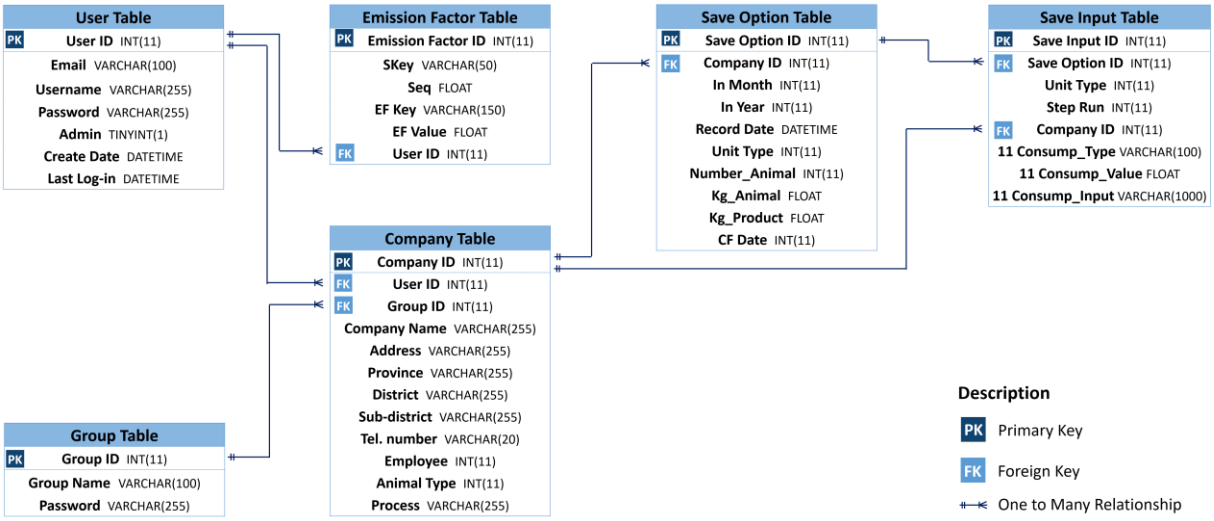

Fig. 4 Relational database model of the web application

Web User Interface

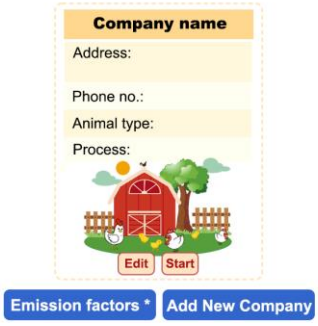
Figure 5 shows examples of the graphical user interface (GUI) of the developed web application: main page, input data page, and result page. The main page depicts the general information of the slaughterhouse involving address, contact number, and types of animal to be slaughtered. Regarding input data, several web pages of different activity data have been created for user's data entry, depending on the analysis option chosen as mentioned above (simple, coarse, or detailed). These pages contain several data items that were reviewed accordingly to the current slaughtering process of the country. In addition, the relevant graphic icons, visual indicators, and drop-down lists were added to the created web pages instead of texts. These features will give an easy-to-understand overview of the data input and make the application more attractive to the user. The result page can present the total CO_2-eq emitted based on live animal-based units or carcass-based units and illustrated as a pie chart or bar graph for different consumption categories or detailed slaughtering activities, respectively.

Web Application Functionalities

Three functions of various estimation levels

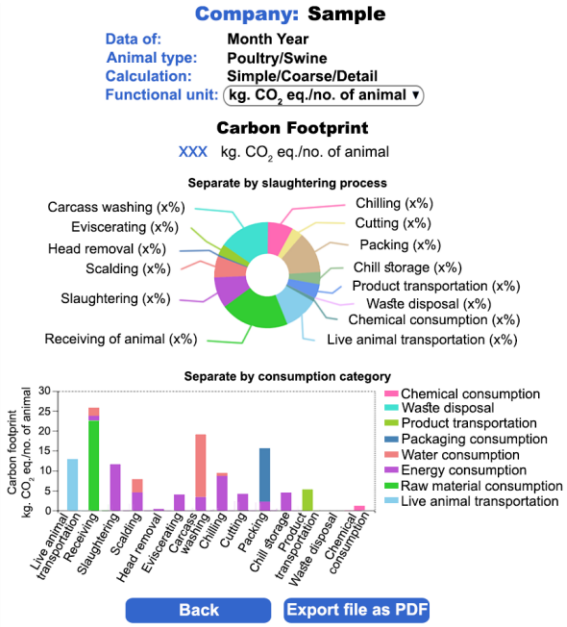
Unlike many other simple web apps, this tool offers three methods for entering consumables used at the slaughterhouse, covering the easiest to detailed ways to provide input data, called "simple", "coarse", and "detailed", so a small to large scale slaughterhouse will be able to use this tool. When using the easiest method by entering minimal input data, the user will receive a roughly calculated result of total CO_2-eq emissions. On the other hand, the coarse and detailed methods are more complicated but the informative results will be analyzed and visualized for further discussion on different resource type consumption and how the company uses resources for each slaughtering activity. In addition, because of a large number of such inputs is required for coarse and detailed estimation, a navigation tool is provided on the left menu to help the user easily navigate slaughtering steps to indicate where the data entering is up to. At the transition between steps, designed necessary data validation and null check are automatically implemented by

setting data requirements for user input to avoid errors. These involve functional units (number of live animals, carcasses, and product meat weight), and mass balance between live animals and meat product (product weight ≯ live animals).



(a) Main page

(b) Input data page



(c) Result page

Fig. 5 Examples of web user interface of the developed application

EF management

As mentioned in the methodology section, the default EFs basically collected from various databases can be categorized in eight groups, namely raw material, energy, water, packaging, chemicals, waste disposal, transportation, and product. They were stored and manipulated as in the database table named 'Emission Factor Table'. Most users do not know the EF related to the activity data, so these default values will allow users to immediately estimate the CO_2-eq emitted from their processes by using our web app. These EF values were well chosen from many reliable sources both national and international databases (when not available in Thailand). In addition, when any user knows his/her own EFs and desires to use them for the estimation, the tool is also designed to change, save, and reset these values easily.

Report/export documentation

In addition to displaying the CO_2-eq results over the web page, the application is also able to generate a report and export it in PDF file format. The report contains all general information of the slaughterhouse, the inventory of input data, and calculated CO_2-eq emission results (carbon footprint), including graphs. This will allow the user to easily print and view all information together. It will be useful to assist further discussion on reducing CO_2 emissions.

Confidentiality to Access the Database

The system offers confidentiality and security for the general/company user to access his/her data. All information including input data inventory and GHG emissions can be saved privately. This means it is available only to the specific company owner to open and edit the historical data and estimation results.

Software Availability

The developed web application to estimate CO_2-eq emissions (carbon footprint) of the Thai poultry and swine slaughtering industry can be accessed through any device such as desktop computers, laptops, tablets, and mobile phone over an internet connection using Hypertext Transfer Protocol (HTTP) via modern web browser. The web application can be found online at http://www.carbonfootprintthailand.com/Slaughter

CONCLUSION

The web application developed in this study is an analytical tool to estimate CO_2-eq emissions for poultry and swine slaughtering processes. The usefulness of this application is to aid Thailand

slaughterhouse industries to calculate and understand how much and how they contribute GHG emissions to the environment. It implies the current resource use (inputs) and change, subsequently leading to reduced GHG emissions. The output generated by the web application is reliable because of our careful emission facter selection. Moreover, many functionalities are considered and incorporated in the application to facilitate the user's estimation such as data input conditions (simple, coase, and detailed data entry), navigation tool, functional unit selection, data validation and null check, EF management, report/ export documentation, and data confidentiality and security. All these features are necessary, but the tool should not require too much effort from the user.

SAFETY AND OPERATIONAL ANALYSIS FOR MEDIAN U-TURN INTERSECTIONS IN THAILAND

Nopadon Kronprasert, Ph.D.[1], Pavee Kuwiboon [2] and Wachira Wichitphongsa[3]
[1,2,3]Department of Civil Engineering, Chiang Mai University, THAILAND

ABSTRACT

At major conventional intersections along high-speed divided highways, road users experience serious accident risks and long travel delay. Specifically, vehicles from minor roads at unsignalized intersections have to make a direct crossing at the main intersection. To solve safety and mobility problems at conventional intersections. a median U-turn intersection design has recently proposed among highway authorities in Thailand. This design removes the median opening at the main intersection, restricts vehicles from making a direct crossing, guides them to make a U-turn at the downstream median U-turn opening, and returns to the main intersection. For such design, the distance between the median U-turn opening downstream and the main intersection (called a median U-turn offset) is the most important design parameter that influences the safety and operating efficiency. Too short median U-turn offset will result in harsh lane-change conflict for minor-road traffic, while too long median U-turn offset will increase vehicle travel time. This paper proposes the framework to rationally recommend the median U-turn offsets of such design. The microscopic traffic simulation models are developed to estimate vehicle travel time, and the crash surrogates are used to estimate the number of vehicles involved in conflicts. The median U-turn offsets that balance the operating and safety efficiencies are recommended. It is found that the recommended median U-turn offsets are sensitive to volumes on major and minor roads, vehicle speed, and vehicle composition. The proposed framework is then applied to the real-world highway improvement projects.

Keywords: Safety, Surrogate safety assessment, Traffic simulation, Intersection, Median u-turn

INTRODUCTION

Managing traffic mobility and safety at intersections is one of the most challenging tasks for highway engineers. At major intersections, road users often experience travel delay during peak periods and suffer serious accident risks. To solve such problems, various alternative intersection designs have recently been proposed among highway authorities, such as roundabouts, restricted-crossing U-turn intersections. [1] The basic premise of such designs is to separate different traffic movements, provide more uninterrupted flow, and minimize severe traffic conflicts.

In Thailand, road users experience severe far-side angle accident risks and long travel delay at a conventional unsignalized intersection where a minor road intersects a high-speed multilane road. To improve safety and mobility at an intersection, a median U-turn intersection design is gaining acceptance. This design prohibits vehicles from a minor road to directly cross the main intersection, but guides them to make a U-turn at the downstream median U-turn opening and return to the intersection. [1]-[2] The design features of conventional unsignalized and median U-turn intersection designs considered in this study are shown in Fig. 1.

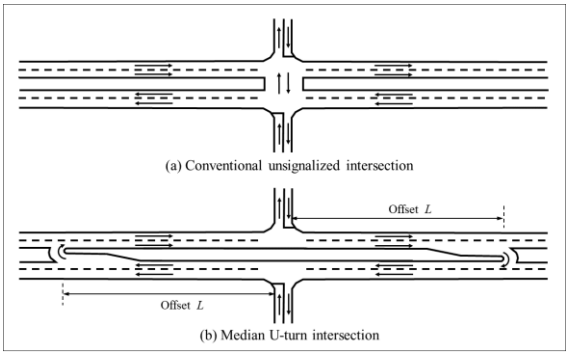

Fig. 1 Intersection configuration

For this type of intersection design, the distance between the median U-turn opening and the main intersection, called median U-turn offset (L) shown in Fig.1(b) is the most important design parameter that influences the operating and safety efficiency. Too far median U-turn offset will increase vehicle travel time, while too short offset will result in harsh lane-change conflicts for minor-road traffic. The objectives of this study are (i) to propose the model framework that can rationally recommend the median U-turn offsets for median U-turn intersection designs; and (ii) to apply it to determine the U-turn openings for a real-world highway intersection improvement projects.

LITERATURE REVIEW

Median U-Turn Intersection Design

A median U-turn treatment is an alternative low-cost at-grade intersection design that offers the potential to improve safety and mobility of conventional intersections along multi-lane divided highways. The design restricts some or all of the direct turn movements at the main intersection and provides the median U-turn downstream to make a turn. [3] Past studies on this subject mainly focused on determining the operational or safety benefits of intersection designs. For the operational benefits, the alternative design performs better than the conventional design in terms of average delay, average queue length, and total throughputs. [4-5] For the safety benefits, the alternative design theoretically reduces the number of conflicts by half.. The before-and-after studies also showed the reduction in numbers of crashes. [5]-[7]

By its design, there are a number of factors affecting the safety and efficiency of median U-turn intersections, such as the number of traveled lanes, the presence of acceleration lane, the U-turn opening configuration, and the median U-turn offsets.

In practice, the median U-turn offset are varied. For unsignalized types, the median U-turn offsets range from 100 to 900 m. [2], [9] For signalized types, the median U-turn openings are relatively short. The openings are located closer to the main intersection, typically 100 to 180 m based on signal timing [8]

Microscopic Traffic Simulation Model

A microscopic traffic simulation is a powerful tool that can analyze the complex traffic flow and represent traffic movement under various scenarios. It is used to simulate and replicate several driving behaviors. In highway and traffic engineering applications, a microscopic traffic simulation is widely accepted and used as a reliable decision tool. In general, the development of microscopic traffic simulation model involves network coding, model calibration, and model validation. [9]

Surrogate Safety Assessment Model

The surrogate safety assessment model is an analytical tool to identify conflict events by assessing surrogate safety measures, such as time to collision, post encroachment time, deceleration rate, maximum speed, and speed difference. The model analyzes the frequency of conflict events (or traffic crash avoidance) in a traffic network using vehicle trajectories recorded in a microscopic traffic simulation. Typically, three categories of conflict events can be identified: rear-end conflict events, lane-change conflict events, and path-crossing conflict events. [10]

METHODOLOGY

Model Framework

The study proposes the model framework to analyze the safety and operational performance of intersection designs as shown in Fig. 2. The details are as follows.

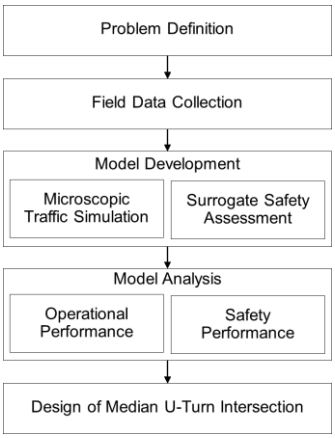

Fig. 2 Model framework

Problem Definition and Data Collection

This study focuses on recommending the median U-turn offsets of median U-turn intersections located on a 4-lane divided major road intersecting with a 2-lane minor road. Although the scope of the study is limited to this intersection configuration, the proposed model framework can be applied to other intersection configurations.

Next, the parameters required to develop traffic simulation models were identified. These parameters include road network geometry, input traffic on major and minor road, turning movements on all intersection approaches, traffic compositions, desired vehicle speed, and gap acceptance for all types of vehicle and movement.

All necessary data were collected from the intersections on a high-speed corridor. The relevant data are road geometry (i.e. the configuration of intersections and U-turn openings), traffic data (i.e. traffic volume, speed, traffic composition, gap acceptance), and socio-economic data (i.e. value of time, unit cost of accident)

Model Development

The simulation models were developed using the microscopic traffic simulation package (PTV Vissim) and surrogate safety assessment model (SSAM) for evaluating operational and safety performances. [11]-[12] The models were built for various sets of input variables including traffic volume ranges from 200 to 600 vehicles per hour per lane; the median U-turn offset ranges from 100 to 800 m.

Model Analysis

The recommended median U-Turn offsets were determined by minimizing the marginal user costs at an intersection**.** The marginal user costs represent the operational and safety effects of traffic flows at an intersection**.**

Operational Performance

The operational performance is measured by the excess travel time cost. Using a microscopic traffic simulation, travel times that all vehicles used to maneuver through the intersection for both conventional and proposed intersection designs were recorded. The excess travel time cost is then calculated by the difference of travel times between two designs, and conerting it to the annual costs by taking into consideration the annual traffic and value of time.

Safety Performance

The safety performance is measured by the accident cost saving. Using a surrogate safety assessment model, the reduction in number of conflicts that vehicles encountered when making a U-turn compared with the direct turn at the intersection. The accident cost saving is then calculated by converting the number of conflicts by taking into consideration the accident to onflict ratio and the unit cost of accident.

Determination of Median U-Turn Offset

The median U-turn offsets are then determined based on minimum total (marginal) user cost concept as shown in Fig. 3.

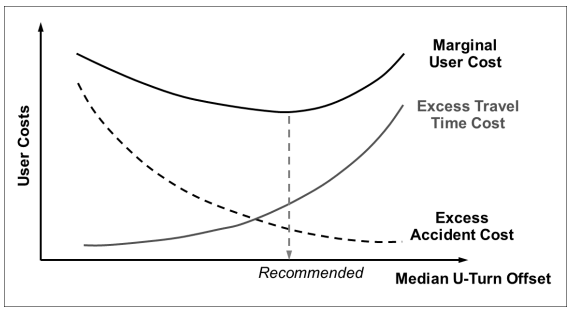

Fig. 3 Minimum user cost concept

APPLICATION TO INTERSECTION DESIGN

The proposed framework was applied to a real-world highway improvement project in Chiang Mai, Thailand. The existing corridor is a 12-kilometer 4-lane divided high-speed highway in a suburban area. There are many intersections and U-turn openings along this corridor as shown in Fig.4; and as a result, there are many road crashes at these locations. The goal of the improvement project is to relocate the median U-turn openings by introducing median U-turn intersection design concept along this corridor. Figure 5 illustrates the snapshot of traffic simulation model developed for evaluating the operational performance of this case study.

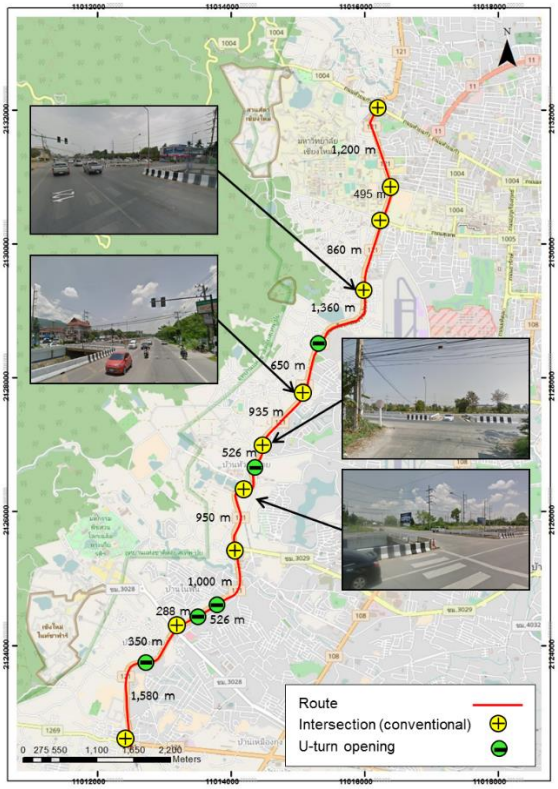

Fig. 4 Existing corridor

Fig. 5 Snapshot of simulation model

Using a microscopic traffic simulation model, travel time associated with conventional and proposed design were measured, and then travel time costs were calculated. The result shows that travel time cost increases with the increase in median U-turn offset for any given major- and minor-road traffic volumes as shown in Fig. 6. The figure also shows that the travel time costs increase significantly when the median U-turn offset increase greater than 500 m.

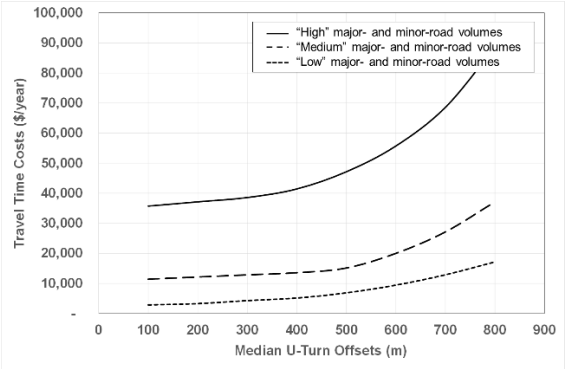

Fig. 6 Travel time costs with respect to different median U-turn offsets

Using a surrogate safety assessment model, the conflict points associated with a given intersection design can be measured. Figure 7 shows the conflict points obtained from a surrogate safety assessment model. Three conflict types were marked by different colors: red is for crossing conflict, green is for lane-change conflict, and yellow is for rear-end conflict.

The result intuitively shows that accident costs decrease with the increase in median U-turn offsets for any given major- and minor-road traffic volumes as shown in Fig. 8. The figure shows that the long median U-turn offsets can reduce the loss of accident.

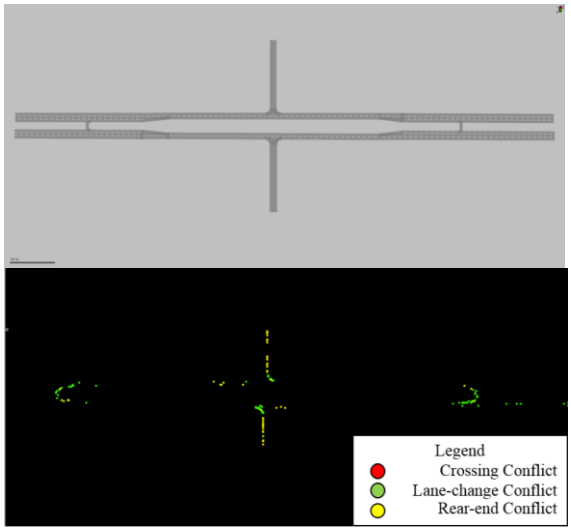

Fig. 6 Conflict points by surrogate safety assessment

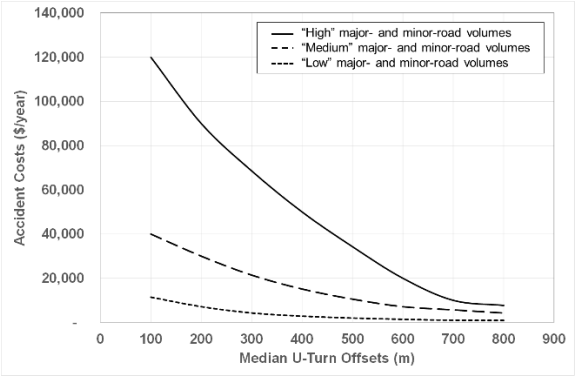

Fig. 8 Accident costs with respect to different median U-turn offsets

For a given traffic condition and design setup, the median U-turn offset can be determined by minimizing the total user cost (which combines travel time costs and accident costs.) Figure 9 illustrates the relationship of total user costs and median U-turn offsets. The results show that for a given traffic volume, there is an optimal value of median U-turn offset. Too short offset may cause low travel time cost with very high accident cost, while too long offset may cause very high travel time cost with low accident cost.

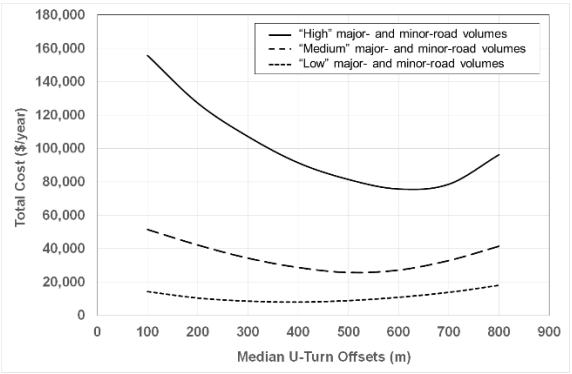

Fig. 9 Recommended median U-turn offsets based on minimum costs

Table 1 presents the set of recommended median U-turn offsets in meters for different traffic volumes on major and minor roads (100 to 600 vehicles per hour per lane).

Figure 10 plots the recommended offsets for different combination of major-road and minor-road traffic volumes. The higher traffic volumes, the longer median U-turn offsets are. Table I and Fig. 10 are complementary; the former shows in specific values, while the latter is a look-up chart for practitioners. The recommended offsets can be determined if traffic volume on a major- and a minor road are given.

Table 1 Recommended median U-turn offsets for different traffic volumes

Major road (veh/hr/ln)	Minor road (veh/hr)					
	100	200	300	400	500	600
100	270	295	310	330	340	345
200	310	330	347	360	370	380
300	345	370	390	410	430	445
400	390	420	435	470	495	520
500	445	475	495	520	550	570
600	535	550	565	580	595	630

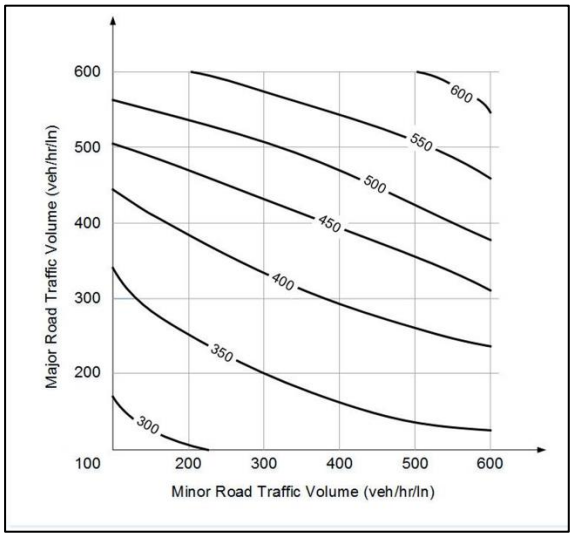

Fig. 10 Look-up chart on recommended median U-turn offsets for different sets of major-road and minor-road traffic volumes

Sensitivity Analysis

The study performs the sensitivity analyses to determine which parameters are significant and should be taken into account to the proposed model. The effects of some parameters on the median U-turn offsets are discussed below.

- Effect of heavy vehicles. The heavy vehicles require longer gap to merge the traffic and change lanes than other vehicles. The proposed model suggests the need to consider the percentage of heavy vehicles. The median U-turn offset should be longer than what is proposed in Fig. 10 by 15-20% for every 5% increase of heavy vehicles.
- Effect of vehicle operating speed. The operating speed on a major road significantly affect the median U-turn offset. The higher operating speed on a major road creates difficulties for vehicles to enter the major road, and at the same time force them to the risky situation.
- Effect of socio-economic factors. The economic factors that used to convert operational and safety performance to single comparable performance have insignificant effect on the optimal median U-turn offsets. For example, the value of time and unit of accident cost will proportionally shift the total costs, but not the recommended median U-turn offsets.

Recommended Median U-turn Offsets

To apply the simulation analysis to search for the optimal median U-turn offsets in the real-world situations, the recommended offsets from Table I and Fig. 10 can be used. It is however noted that the recommended offsets are proposed based on typical simulation models. When multiple intersections are considered or the intersections are varied from the typical one, the model framework must be applied together with the simulation model of the entire corridor. Figure 11 presents the locations of the median U-turns proposed for the highway improvement project in the application.

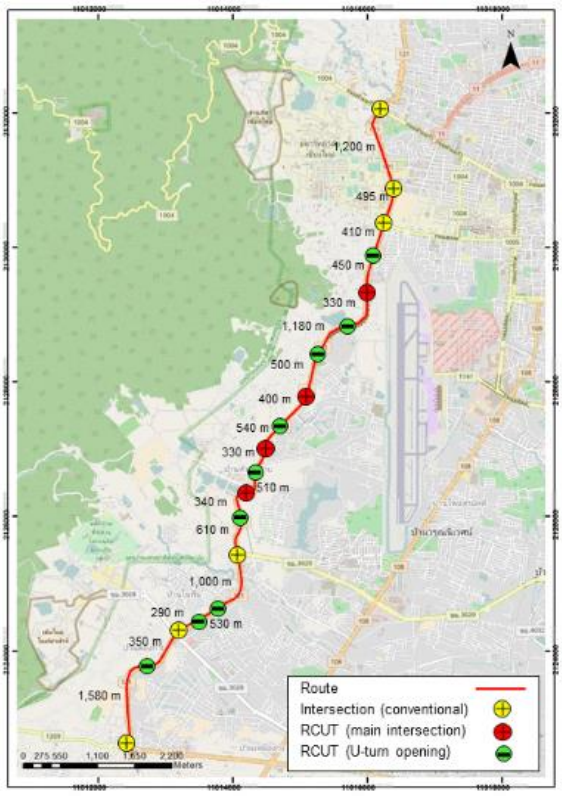

Fig. 13 Proposed RCUT intersections and their median U-turn offsets

CONCLUSIONS

A median U-turn intersection is an alternative

design that helps improve safety and mobility at major at-grade intersections by eliminating the median opening at the main intersection and converting severe crossing conflicts into merging and weaving conflicts. For its design, the distance between the main intersection and the downstream U-turn opening (or median U-turn offset) is the critical design parameter influencing efficiency and safety of the intersection.

This paper develops a model framework for determining the median U-turn offsets of median U-turn intersection design using simulation analysis. The analysis considers the trade-off between the increase of travel time required to make a U-turn downstream and the reduction of potential accident risks due to fewer number of conflicts. The study recommends the median U-turn offsets for a given traffic condition which minimizes the cost of road users including the travel time cost and accident cost. The results also note that the median U-turn offsets are sensitive to the major-road and minor-road traffic volumes, vehicle composition, and vehicle operating speed.

The proposed model framework and the exhibits allow the engineers to examine the proper locations of median U-turns for median U-turn intersection design. Therefore, the model framework is useful for both practitioners and researchers in real-world highway improvement projects.

EFFECTIVENESS OF RIVER INSECTS AND WATER PLANTS AS AN INDEX OF ZN AND FE CONTAMINATION FOR RIVER IN THE KINOKAWA RIVER CATCHMENT

Takuma Kubohara[1] and Hiroyuki Ii[2]
[1]Kinokawa City Office, Japan; [2]Faculty of Systems Engineering, Wakayama University, Japan

ABSTRACT

It has not been studied whether river insects and water plants are useful for an index of Zn and Fe contamination in the Kinokawa River catchment. Useful species as an index of Zn and Fe contamination needs a high metal concentration in a contaminated area, a low metal concentration in a non-contaminated area, and a high and a wide range of metal concentration. Zn and Fe concentrations of crane fly larva were high around the closed Cu mine area (88 to 420 and 1,300 to 9,300 mg/kg-dry for Zn and Fe) and were low in the other areas (81 to 180 and 110 to 5,700 mg/kg-dry for Zn and Fe). Crane fly larva had high and a wide range of Zn and Fe concentration among river insects. Zn and Fe concentrations of bryophyte were high around the closed Cu mine area (34 to 8,900 and 110 to 58,000 mg/kg-dry for Zn and Fe) and were low in the other areas (24 to 1,100 and 110 to 34,000 mg/kg-dry for Zn and Fe). Bryophyte had the highest and a wide range of Zn and Fe concentration among water plants. Therefore, it was thought that crane fly larva in river insects and bryophyte in water plants were useful species for an index of Zn and Fe contamination. Bryophyte was useful species for an index of Zn and Fe contamination among river insects and water plants because bryophyte had the highest and a wide range of their concentrations among them.

Keywords: Zn, Fe, Bryophyte, Crane fly larva, River

INTRODUCTION

Metal concentration of river water and river sediment (soil and mud) are measured in order to investigate the influence of heavy metals for aquatic life in river. However, metal concentration of river water is always very low and is changeable depending on the change of flow rate. Heavy metals of river sediment are soluble or insoluble. Many kinds of heavy metals of river sediment elute in river water. Then, total concentration of heavy metal of river sediment does not represent the heavy metal mass transfering in river. Therefore, the metal concentrations of river water and river sediment were not always useful for an index of the influence of heavy metals for aquatic life in river. On the other hand, it is thought that the metal concentrations of river insect and water plant to be useful for investigating the influence of heavy metals for aquatic life in river because river insect and water plant intake and accumulate heavy metal from river water and sediment in the long term.

At past, metal concentrations of caddice-worm [1]-[2], dobsonfly larva [3]-[4], stonefly larva [5], mayfly larva [5]-[6], reed [7]-[8], fern [9]-[10], bryophyte [11]-[12] have been studied. However, few reports were available on useful species as metal contamination index using river insects [13]-[14]. Then, we have studied Cu, Co and Ni concentrations of river insects and water plants in the Kinokawa River catchment and have determined useful species for an index of Cu, Co and Ni contamination for river [15]. However, it has not been studied whether river insects and water plants are useful for an index of other metal contamination, in particular Zn and Fe, in the Kinokawa River catchment. Therefore, Zn and Fe concentrations of river insects and water plants were measured in the Kinokawa River catchment and then the relation between Zn and Fe concentration of river insects and water plants and Zn and Fe contamination for river was analyzed. Useful species as an index of metal contamination needs a high metal concentration in a contaminated area and low metal concentration in a non-contaminated area. Moreover, it needs a high and a wide range of metal concentration and also very popular.

STUDY AREA

Figs.1 and 2 show location of study area and the Kinokawa River catchment. The Kinokawa River is located in the center of Kinki district and flows into the Kii Channel through the Kii plain. The Kinokawa River is classified into A river based on the Ministry of Land, Infrastructure, Transport and Tourism of Japan. The length and total area of the Kinokawa River are 136 km and 1,750 km^2 [16]. The Sanbagawa Belt composed of metamorphic rocks, serpentinite and crystalline schist is distributed in the southwest

part and the northeast part of the catchment. The Hidakagawa Group composed of sedimentary rocks, sandstone and shale is distributed from the southern part to the northeast part of the catchment. The Chichibu Belt composed of sedimentary rocks, sandstone, mudstone, limestone and chert is distributed in the eastern part of the catchment. The Izumi Group composed of sedimentary rocks, sandstone, mudstone and conglomerate is distributed in the northwest part of the catchment [17]. The Ryoke Complex composed of plutonic rocks, granite and gneiss is distributed in the northeast part of the catchment. In the Kinokawa River catchment, there are the closed Cu mines and serpentinite. The closed Cu mine produced a lot of Cu and Fe sulfide ore and the waste water was low pH and high concentration of sulfate with metal. The chemistry of serpentinite is quite different from the other rocks and in particular Mg and Ni concentrations of serpentinite are high.

STUDY METHOD

River insects and water plants in the river bed were sampled in the Kinokawa River catchment. Sampling points were shown in fig.2. Investigation period is July 2013 to April 2016. The number of sampling points was 109 points. Those sampling points were classified into three groups, the serpentinite area, the Cu mine area and the normal area. The kinds of sampled river insects were Japanese freshwater crab, caddice-worm, dobsonfly larva, dragonfly larva, stonefly larva, crane fly larva, mayfly larva and corixidae. However, crane fly larva was not sampled in the serpentinite area. The kinds of sampled water plants were reed, fern, moss, Japanese knotweed and coix. However, reed was not sampled in the serpentinite area. Moreover, Japanese knotweed was not sampled in the normal area. Zn and Fe concentrations of river insects and water plants were measured. The sampled river insects and water plants were desiccated by dryer at first. After drying, they were dissolved with concentrated nitric acid and it was filtered with the membrane filter with 0.45 micrometer of pore size before analysis. Zn and Fe concentrations of river insects and water plants were measured by ICP-AES (Seiko Instruments Inc., SPS1700HVR) in the laboratory of Wakayama University. The actual detection limit of ICP-AES is 0.01ppm for Zn and Fe. Water plants excluding bryophyte were divided into leaf, upper part stem, middle part stem, lower part stem and root and each part was separately analyzed.

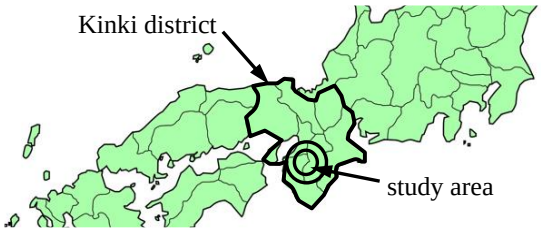

Fig.1 Location of study area.

RESULTS AND DISCUSSION

Effectiveness for Zn

Fig.3 shows Zn concentrations of river insects and water plants. Solid mark indicates Zn concentration of water plant under the detection limit, 0.01 ppm of concentration for sample solution.

Zn concentrations of caddice-worm, dobsonfly larva, dragonfly larva, crane fly larva and corixidae in the Cu mine area were 76 to 250, 310, 88 to 260, 88 to 420 and 370 mg/kg-dry, respectively. Zn concentrations of caddice-worm, dobsonfly larva,

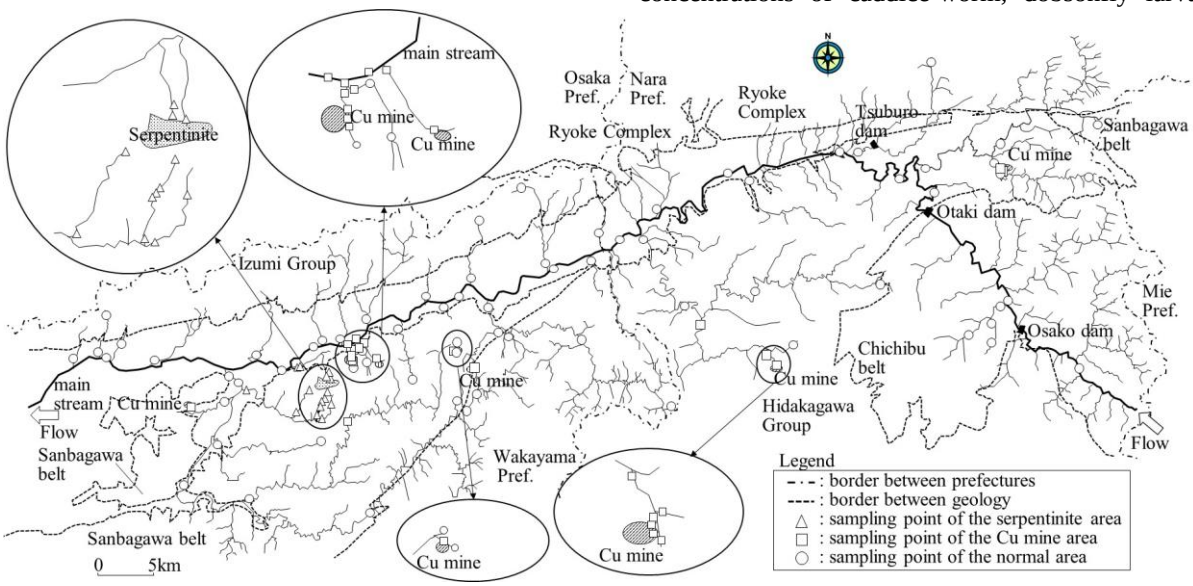

Fig.2 Study area.

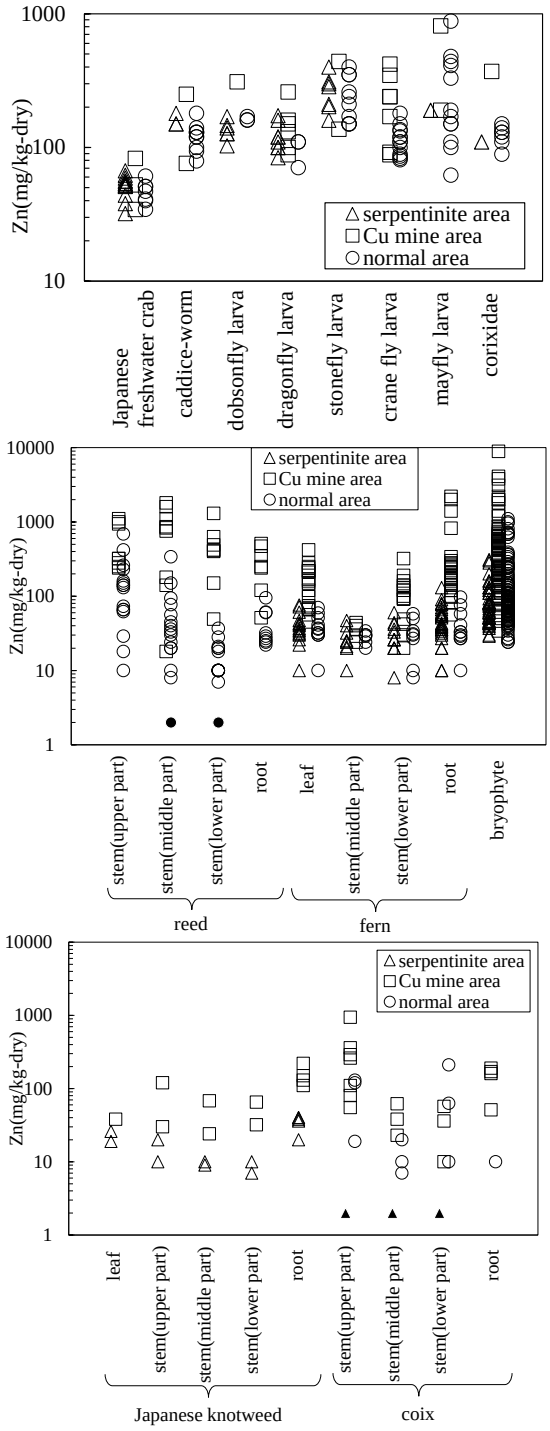

Fig.3 Zn concentrations of river insects and water plants.

dragonfly larva, crane fly larva and corixidae in the other areas were 79 to 180, 103 to 170, 70 to 173, 81 to 180 and 89 to 150 mg/kg-dry, respectively. Zn concentrations of reed, leaf and lower part stem and root of fern, bryophyte, stem and root of Japanese knotweed and upper and middle part stem and root of coix in the Cu mine area were 18 to 1,800, 20 to 2,200, 34 to 8,900, 24 to 220 and 23 to 940 mg/kg-dry, respectively. Zn concentrations of reed, leaf and lower part stem and root of fern, bryophyte, stem and root of Japanese knotweed and upper and middle part stem and root of coix in the other areas were 2 to 690, 8 to 130, 24 to 1,100, 7 to 40 and 2 to 130 mg/kg-dry, respectively. Therefore, their Zn concentrations in the Cu mine area were higher than those in the other areas. The closed Cu mine produced a lot of Cu and Fe sulfide ore and then the waste water was low pH and contained high concentration of sulfate with metal. It is reported that Zn concentrations of the cupriferous pyrite in the closed Cu mine in the Kinokawa River catchment were 100 to 25,000 ppm [18]. Therefore, it was thought that high Zn concentrations of caddice-worm, dobsonfly larva, dragonfly larva, crane fly larva, corixidae, reed, leaf and lower part stem and root of fern, bryophyte, stem and root of Japanese knotweed and upper and middle part stem and root of coix in the Cu mine area were caused by waste water and Cu and Fe sulfide ore from the closed Cu mines. On the other hand, Zn concentrations of Japanese freshwater crab, stonefly larva, middle part stem of fern and Japanese knotweed leaf in the Cu mine area were 34 to 82, 137 to 440, 24 to 44 and 38 mg/kg-dry, respectively. Zn concentrations of Japanese freshwater crab, stonefly larva, middle part stem of fern and Japanese knotweed leaf in the other areas were 32 to 67, 150 to 400, 10 to 47 and 19 to 26 mg/kg-dry, respectively. Therefore, their Zn concentrations in the Cu mine area were about the same as those in the other areas. Zn concentrations of mayfly larva and lower part stem of coix in the Cu mine area were 190 to 810 and 10 to 57 mg/kg-dry, respectively. Zn concentrations of mayfly larva and lower part stem of coix in the other areas were 62 to 880 and 2 to 210 mg/kg-dry, respectively. Therefore, their Zn concentrations in the Cu mine area were not higher than those in the other areas.

Zn concentrations of Japanese freshwater crab, caddice-worm, dobsonfly larva, dragonfly larva, stonefly larva, crane fly larva, mayfly larva and corixidae were 32 to 82, 76 to 250, 103 to 310, 70 to 260, 137 to 440, 81 to 420, 62 to 880 and 89 to 370 mg/kg-dry, respectively. Therefore, mayfly larva had the highest and a wide range of Zn concentration among river insects. Zn concentrations of reed, fern, bryophyte, Japanese knotweed and coix were 2 to 1,800, 8 to 2,200, 24 to 8,900, 7 to 220 and 2 to 940 mg/kg-dry, respectively. Therefore, bryophyte had the highest and a wide range of Zn concentration among water plants.

From the above results, mayfly larva had the highest and a wide range of Zn concentration among river insects. However, Zn concentrations of mayfly larva in the Cu mine area were not higher than those in the other areas. Useful species as an index of metal contamination needs a high metal concentration in a contaminated area and low metal concentration in a non-contaminated area. Therefore, mayfly larva was not useful species for an index of Zn contamination. On the other hand, crane fly larva also had high and a

wide range of Zn concentration among river insects. Moreover, Zn concentrations of crane fly larva in the Cu mine area were higher than those in the other areas. Bryophyte had the highest and a wide range of Zn concentration among water plants. Moreover, Zn concentrations of bryophyte were high in the Cu mine area and were low in the other areas. Therefore, crane fly larva and bryophyte were useful species for an index of Zn contamination.

Effectiveness for Fe

Fig.4 shows Fe concentrations of river insects and water plants. Solid mark indicates Fe concentration of water plant under the detection limit, 0.01 ppm of concentration for sample solution.

Fe concentrations of dobsonfly larva, dragonfly larva, crane fly larva and corixidae in the Cu mine area were 9,100, 280 to 9,100, 1,300 to 9,300 and 3,200 mg/kg-dry, respectively. Fe concentrations of dobsonfly larva, dragonfly larva, crane fly larva and corixidae in the other areas were 326 to 3,500, 250 to 2,500, 110 to 5,700 and 460 to 2,000 mg/kg-dry, respectively. Fe concentrations of middle and lower part stem and root of reed, leaf and root of fern, bryophyte, Japanese knotweed root and coix root in the Cu mine area were 10 to 13,000, 46 to 12,000, 110 to 58,000, 2,600 to 43,000 and 140 to 440 mg/kg-dry, respectively. Fe concentrations of middle and lower part stem and root of reed, leaf and root of fern, bryophyte, Japanese knotweed root and coix root in the other areas were 2 to 1,100, 79 to 3,500, 110 to 34,000, 1,600 to 6,000 and 130 mg/kg-dry, respectively. Therefore, their Fe concentrations in the Cu mine area were higher than those in the other areas. The closed Cu mine produced a lot of Cu and Fe sulfide ore and then the waste water was low pH and contained high concentration of sulfate with metal. It is reported that Fe concentrations of the cupriferous pyrite were 41.72% (417,200 mg/kg) [19]. Therefore, it was thought that high Fe concentrations of dobsonfly larva, dragonfly larva, crane fly larva, corixidae, middle and lower part stem and root of reed, leaf and root of fern, bryophyte, Japanese knotweed root and coix root in the Cu mine area were caused by waste water and Cu and Fe sulfide ore from the closed Cu mines. On the other hand, Fe concentrations of Japanese freshwater crab, caddice-worm, stonefly larva, mayfly larva, upper part stem of reed, fern stem and upper and middle part stem of coix in the Cu mine area were 46 to 465, 790 to 1,800, 183 to 240, 630 to 1,100, 20 to 370, 10 to 590 and 10 to 230 mg/kg-dry, respectively. Fe concentrations of Japanese freshwater crab, caddice-worm, stonefly larva, mayfly larva, upper part stem of reed, fern stem and upper and middle part stem of coix in the other areas were 32 to 3,500, 83 to 5,100, 11 to 1,300, 29 to 2,800, 20 to 1,500, 20 to 1,600 and 10 to 320 mg/kg-dry, respectively. Therefore, their Fe concentrations in the

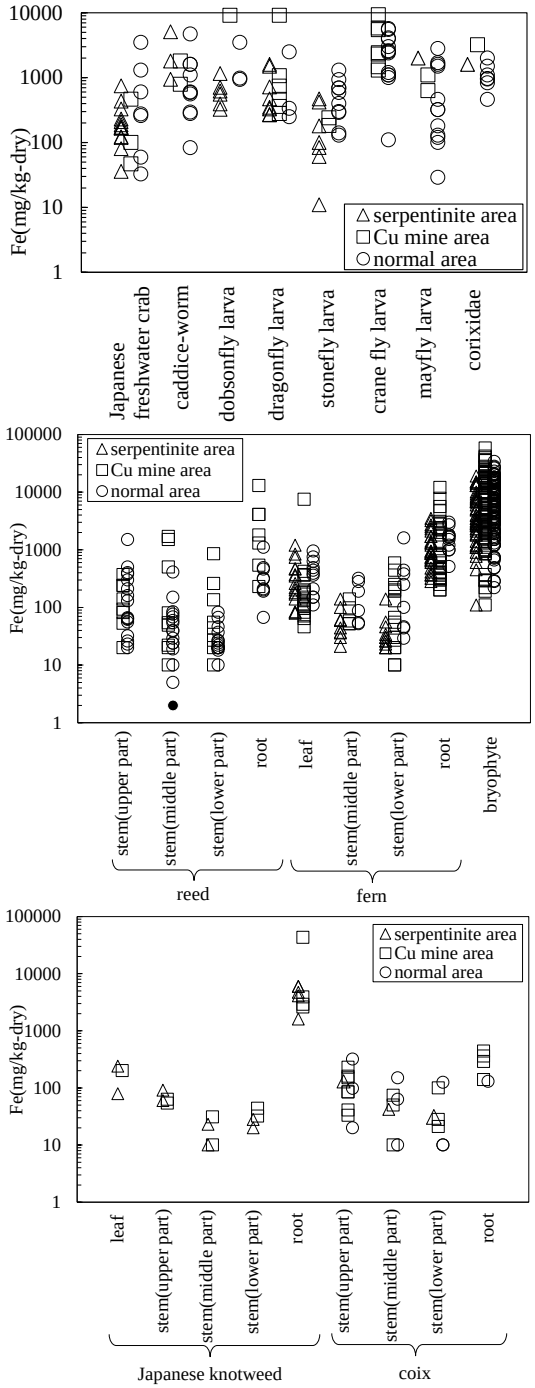

Fig.4 Fe concentrations of river insects and water plants.

Cu mine area were not higher than those in the other areas. Fe concentrations of leaf and stem of Japanese knotweed and lower part stem of coix in the Cu mine area were 10 to 200 and 21 to 100 mg/kg-dry, respectively. Fe concentrations of leaf and stem of Japanese knotweed and lower part stem of coix in the other areas were 10 to 240 and 10 to 125 mg/kg-dry, respectively. Therefore, their Fe concentrations in the Cu mine area were about the same as those in the other areas.

Fe concentrations of Japanese freshwater crab,

caddice-worm, dobsonfly larva, dragonfly larva, stonefly larva, crane fly larva, mayfly larva and corixidae were 32 to 3,500, 83 to 5,100, 326 to 9,100, 250 to 9,100, 11 to 1,300, 110 to 9,300, 29 to 2,800 and 460 to 3,200 mg/kg-dry, respectively. Therefore, crane fly larva had the highest and a wide range of Fe concentration among river insects. Fe concentrations of reed, fern, bryophyte, Japanese knotweed and coix were 2 to 13,000, 10 to 12,000, 110 to 58,000, 10 to 43,000 and 10 to 440 mg/kg-dry, respectively. Therefore, bryophyte had the highest and a wide range of Fe concentration among water plants.

From the above results, crane fly larva had the highest and a wide range of Fe concentration among river insects. Bryophyte had the highest and a wide range of Fe concentration among water plants. Moreover, Fe concentrations of crane fly larva and bryophyte were high in the Cu mine area and were low in the other areas. Therefore, crane fly larva and bryophyte were useful species for an index of Fe contamination.

Estimation of Most Useful Species among River Insects and Water Plants

From figs.3 and 4, Zn concentrations of bryophyte and river insects and other water plants were 24 to 8,900 and 2 to 2,200 mg/kg-dry, respectively. Fe concentrations of bryophyte and river insects and other water plants were 110 to 58,000 and 2 to 43,000 mg/kg-dry, respectively. Therefore, bryophyte had the highest and a wide range of Zn and Fe concentrations among river insects and water plants. Moreover, Zn and Fe concentrations of bryophyte in the Cu mine area were higher than those in the other areas. River insects absorb heavy metals included in the water and food from the intestine. Reed, fern, Japanese knotweed and coix are vascular plant and absorb heavy metals included in the water and soil from the roots. Therefore, the absorption path of heavy metals of river insects and their plants are limited. However, bryophyte absorbs heavy metals from the whole surface of the body [20]. Therefore, bryophyte is easy to absorb heavy metals compared with river insects and vascular plants. Furthermore, bryophyte in the river bed absorbs heavy metals from not only river water but also high concentration of sulfate with metal from the closed Cu mines. It is thought that bryophyte is little metal consumption because growth rate of bryophyte is generally slow [21]. From the above reasons, it was thought that bryophyte had the highest and a wide range of Zn and Fe concentrations among river insects and water plants. Therefore, bryophyte was useful species for an index of Zn and Fe contamination among river insects and water plants.

CONCLUSION

In this study, Zn and Fe concentration of river insects and water plants in the Kinokawa River catchment were investigated in order to find useful species for an index of Zn and Fe contamination for river. Useful species as an index of metal contamination needs a high metal concentration in a contaminated area and low metal concentration in a non-contaminated area. Moreover, it needs a high and a wide range of metal concentration and also very popular.

Zn concentrations of crane fly larva, mayfly larva and bryophyte in the Cu mine area were 88 to 420, 190 to 810 and 34 to 8,900, respectively. Zn concentrations of crane fly larva, mayfly larva and bryophyte in the other area were 81 to 180, 62 to 880 and 24 to 1,100, respectively. Zn concentrations of crane fly larva, mayfly larva and other river insects were 81 to 420, 62 to 880 and 32 to 440, respectively. Zn concentrations of bryophyte and other water plants were 24 to 8,900 and 2 to 2,200, respectively. Fe concentrations of crane fly larva and bryophyte in the Cu mine area were 1,300 to 9,300 and 110 to 58,000, respectively. Fe concentrations of crane fly larva and bryophyte in the other area were 110 to 5,700 and 110 to 34,000, respectively. Fe concentrations of crane fly larva and other river insects were 110 to 9,300 and 11 to 9,100, respectively. Fe concentrations of bryophyte and other water plants were 110 to 58,000 and 2 to 43,000, respectively.

Then, Zn and Fe concentrations of crane fly larva and bryophyte in the Cu mine area were higher than those in the other areas. Moreover, crane fly larva had the highest and a wide range of Fe concentration among river insects. Bryophyte had the highest and a wide range of Zn and Fe concentration among water plants. Mayfly larva had the highest and a wide range of Zn concentration among river insects. However, Zn concentrations of mayfly larva in the Cu mine area were not higher than those in the other areas. Useful species as an index of metal contamination needs a high metal concentration in a contaminated area and low metal concentration in a non-contaminated area. Therefore, mayfly larva was not useful species for an index of Zn contamination. On the other hand, crane fly larva also had high and a wide range of Zn concentration among river insects. Therefore, crane fly larva and bryophyte were useful species for an index of Zn and Fe contamination.

Bryophyte had the highest and a wide range of Zn and Fe concentrations among river insects and water plants. Therefore, bryophyte was useful species for an index of Zn and Fe contamination among river insects and water plants.

In future work, it is necessary to study whether this study results can be confirmed in other catchments.

EFFECT OF AUTOMATED SPEED ENFORCEMENT SYSTEMS ON DRIVING BEHAVIOR AND ATTITUDES ON MOUNTAINOUS ROADS IN THAILAND

Nopadon Kronprasert, Ph.D.[1], Chomphunut Sutheerakul[2]
[1,2] Department of Civil Engineering, Chiang Mai University, THAILAND

ABSTRACT

Speeding is one of the leading causes of road traffic accidents in mountainous areas in Thailand. Recently, the government has been gaining attention to employ automated speed enforcement systems for monitoring speeding behavior on major highways. This study aims to evaluate the effectiveness of an automated speed enforcement system implemented along mountainous road sections in Thailand. Specifically, the study examines whether such system changes driving behavior and attitudes. The study has two thrusts. First, the study conducted the observational before-and-after speed study and performed the statistical analyses to evaluate driving behavior. Second, the study conducted the questionnaire surveys and applied the sequential equation modelling analyses together with the Theory of Planned Behavior concept to evaluate driving attitudes toward speeding and speed enforcement system. The study used the Highway No.118, one of the most hazardous mountainous corridors in Thailand as a case study. The results showed the changes in both driving behavior and attitudes. After implementing automated speed enforcement system. there were significant reductions in speed and the number of violators. Moreover, psychologically, drivers believe that they would increase the opportunity to perform overspeed if there is no speed control. Therefore, this study provides decision-makers better understand the characteristics of driving attitudes and behavior in Thailand and ensures the effectiveness of automated speed enforcement system.

Keywords: Safety, Speeding, Automated speed enforcement, Risk, Theory of planned behavior

INTRODUCTION

Like many other countries, speeding is one of the most leading causes of road traffic accidents on highway networks in Thailand. According to the 2006-2016 national accident statistics [1], speeding contributes 75% in road traffic accidents as shown in Fig. 1. Reducing speeding is now becoming a high-priority target for many road safety authorities. To this aim, proper and effective safety countermeasures have been proposed to reduce speeding lowering crash risk.

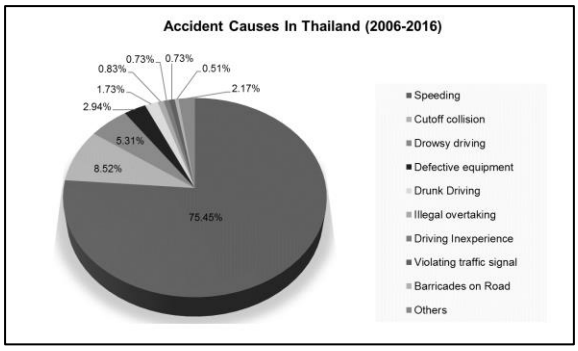

Fig. 1 Causes of accident on highway network in Thailand between 2006 and 2016.

An automated speed enforcement system is one of emerging speed control technologies, which has been proved to be a success safety measures in many developed countries. Recently, Thai government has been gaining attention to employ automated speed enforcement systems for monitoring speeding behavior on major highways. The main objective of this study is to evaluate the effectiveness of the proposed automated speed enforcement systems being implemented on mountainous roads in Thailand. The major contribution of this study is the examination of the changes in driving behavior and driving attitudes affected by the speed enforcement system on a high-risk mountainous corridor.

LITERATURE REVIEW

Various studies worldwide focused on evaluating the effectiveness of speed enforcement applied in different road functions and areas, such as freeways [2], arterial roads [3, 4], local streets [6], and residential streets and school zones [7, 8]. These studies measured the effectiveness of speed control in terms of speed reduction and the number of violators reduced. Table 1 lists some examples of research studies regarding the effectiveness of speed enforcement.

Table 1 Examples of Speed Enforcement Literature

Studies	Area	Measures of effectiveness
IIHS [3]	Freeways in Scottsdale, Arizona	Number of violators
Cunningham et al. [4]	14 corridors across Charlotte, North Carolina	Speed reductions and Crash reduction
Retting et al. [7]	Residential streets and school zones in Montgomery County, Maryland	Speed and Public attitude
D'Elia et al. [6]	Local streets in Melbourne and Victoria, Australia	Crashes, Casualty crashes,
Freedman et al. [8]	School zones in Portland, Oregon	Public awareness, Speed, Proportion of traffic exceeding the speed limit by 10 mph

The study by Lu [9] compared the effectiveness of different speed control measures. The study showed that the speed cameras have high efficiency and enhance the speed continuity of speed control. Moreover, the study by Marciano et al. (2015) [10] discussed the pros and cons of overt and covert speed cameras and suggested that the covert speed cameras (the drivers cannot notice) with the immediate feedback to the violators is the most efficient approach to motivate drivers to maintain their speeds.

While speed camera programs seem to be success in many countries today, the use of enforcement cameras is certainly contentious. It is found that several international programs were initially met with public resistance. There were a number of public concerns, which road safety professionals should consider when implementing a speed camera program. They include ticket procedures, how ticket revenues will be distributed, and whether or not automated enforcement results in reduced accident rates. [11]

RESEARCH APPROACH

This section is divided into three parts: the study area, the method to analyze driving behavior, and the method to analyze driving attitudes.

Study Area

Chiang Mai is the major city in the northern region of Thailand. About 89-percent of the area is mountainous terrain. Most of the roads connected to other neighboring cities are mountainous roads. One of the most dangerous roads is Highway No.118 (Chiang Rai - Chiang Mai) connected between Doi Nangkaew and Doi Saked districts. This road corridor has more than 7% grades and continuous curvy roads 3 kilometers or more. As a result, it has numerous road accidents. Most of the accidents on this road are caused by speeding and unfamiliarity of drivers. Drivers fail to control the vehicles and the accidents result in massive loss of life and property. The annual average daily traffic (AADT) of this corridor is 11,982 veh/day (both directions) in 2015 and the percent share of vehicle type is 11% of motorcycles, 39% of passenger cars, 36% of light trucks or pick-ups, 9% of heavy trucks, and 5% of buses. Figure 2 shows the example of road section on Highway No.118.

Fig. 2 Example of road section in a study area

Highway No.118 in Chiang Mai was built in 1984. It is about 52-kilometer long. It consists of 37-km two-lane mountainous road section and 15-km four-lane divided road section. At the end of 2016, five automated speed cameras were installed along this corridor at the following stations: km 50+400, km 43+050, km 35+800, km 21+700, and km 15+600. The first four stations are on a two-lane mountainous road section with the speed limit of 80 km/h, while the last station is on a four-lane divided road section with the speed limit of 90 km/h as shown in Fig. 3.

Fig. 3 Locations of automated speed camera

Analysis of Speeding Behavior

The study examines the speeding behavior by using the statistical *t*-test analysis of speed data. The observational before-and-after speed analysis is performed. The hypothesis of the speed study is that there is no difference between the vehicle speed data before and after implementing automated speed cameras along the corridor (H0). The *t*-test method calculates the *p*-value to find whether the difference between the means of two speed data groups is statistically significant within a specified confidence interval. The *t*-value is calculated using Eq. (1).

$$t = \frac{\overline{X_B} - \overline{X_A}}{\sqrt{\frac{S_B^2}{N_B} + \frac{S_A^2}{N_A}}} \quad (1)$$

where t = the value of statistical test, and $\overline{X_B}$ and $\overline{X_A}$ are the average speed of sample vehicles before and after installing automated speed camera, respectively. S_B and S_A are the standard deviation of sample vehicles before and after installing automated speed camera, respectively. N_B and N_A are the sample sizes of vehicles before and after installing automated speed camera, respectively.

Analysis of Speeding Attitudes

The study examines the speeding attitudes by using the statistical analysis of drivers' opinions. Questionnaire surveys are conducted by asking the opinions of drivers within the study area regarding speeding behavior, speed control measures, and factors affecting speeding behavior.

This study applies the Theory of Planned Behavior (TPB) to examine the psychological factors influencing the speeding behavior of road users. TPB firstly proposed by Icek Ajzen [12] in 1985 is one of the psychological theories explaining that the personal behavior is determined by three direct factors: attitude towards behavior (ATT), subjective norm (SN), and Perceived Behavioral Control (PBC), and one indirect factor: behavioral intention (I) as shown in Fig. 4.

Attitude towards behavior **(**ATT**)** is a personal belief accrued from individual attitude or feeling that he/she favors or does not favor the behavior**.**

Subjective Norm **(**SN**)** is a personal belief accrued from the people who are important to him/her think he/she should or should not perform the behavior**.**

Perceived Behavioral Control **(**PBC**)** is a personal perception of the ease or difficulty of performing the behavior**.**

Intention **(**I**)** is a willingness to perform the defined action or the behavior**.**

The more positive a person's belief, the stronger is his/her intention to perform the behavior.

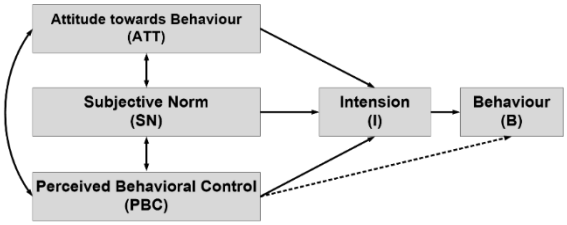

Fig. 4 Theory of planned behavior

RESULTS AND DISCUSSION

The analysis results are divided into two-fold: the analysis of driving behavior and driving attitudes. The details of each test are described as follows.

Results on Driving Behavior

The observational speed data were collected 2-month before and 2-month after introducing the speed cameras along mountainous roads in the study area. The speed of more than 3,000 vehicles at five station locations along the corridor were observed and three vehicle types were classified including passenger cars, trucks, and buses.

Figure 5 shows the frequency and cumulative frequency distributions of all speed data collected before and after the speed camera installation. The cumulative distribution of the observed "after" speed data is shifted to the left of the observed "before" speed data. The mean speed of all vehicles was reduced from 76.0 km/h to 70.4 km/h (or reduced by 8.0%). The 85th percentile speed of all vehicles was reduced from 93.0. km/h to 82.0 km/h (or reduced by 13.4%). It implies that most drivers lower their speed through the road sections in the study area.

Table 2 also summarizes the before-and-after speed data. The mean, 85th percentile, and the deviation of vehicle speed before and after the implementation of automated speed enforcement system are compared. The statistical *t*-test showed the significant reduction on the average vehicle speeds at 95% confident interval.

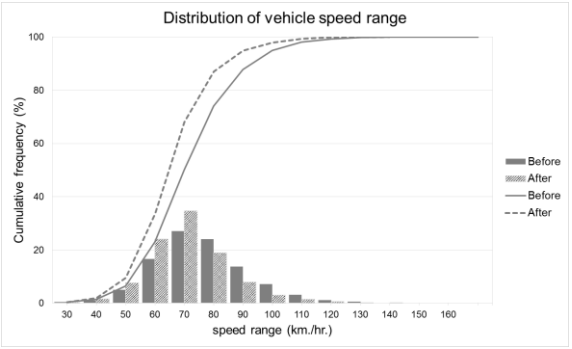

Fig. **5** Comparison of speed distribution

Table 2**:** Comparison of Driving Speed Before-and-After Implementation of Speed Enforcement System

Locations	Period	Speed Limit (km/h)	Sample Size	Speed (km/hr.)			*t*-value	Sig*
				Mean	85th percentile	Standard deviation		
Station 1: km 50+400	Before	80	244	72.9	84.0	12.1	4.90	0.00
	After		272	67.8	78.0	11.1		
Station 2: km 43+050	Before	80	258	68.7	82.0	11.8	4.24	0.00
	After		245	64.6	74.0	10.0		
Station 3: km 35+800	Before	80	267	80.8	94.0	13.0	8.39	0.00
	After		240	71.9	82.0	10.8		
Station 4: km 21+700	Before	80	321	68.3	77.0	9.0	5.89	0.00
	After		282	64.3	72.8	8.0		
Station 5: km 15+600	Before	90	516	83.5	103.0	19.7	4.60	0.00
	After		456	78.2	93.7	16.2		
All data	Before	-	1606	76.0	93.0	16.0	10.54	0.00
	After		1495	70.4	82.0	13.5		

Note: * Confident interval at 0.95

In this study, the numbers of violators before and after the implementation were also compared. The number of violators was considerably reduced at all station locations along the corridor. The percentage of violators was reduced from 31% to 11%, from 19% to 7%, from 53% to 19%, from 12% to 3%, and from 39% to 21% at Stations 1 to 5, respectively.

Results on Driving Attitudes

The questionnaire contains three parts**.** For the first part, the basic characteristics of 400 respondents are presented in Table 3**.**

Table 3**:** Basic Characteristics of Respondents

Characteristics		Number (Person)	Percent %
Gender	Male	275	68.6
	Female	125	31.4
Age	Less than 23 years	21	5.2
	23-40 years	217	54.1
	More than 40 years	162	40.6
Occu-pation	Government officers	82	20.4
	Private employees	80	20
	Students	27	6.7
	Private business	93	23.2
	Contractor	100	24.9
	Other	18	4.7
Educa-tion	High school or lower	185	46.4
	Undergraduate	194	48.4
	Graduate or higher	21	5.2
Type of vehicle	Motorcycle	18	4.7
	Passenger car	272	67.8
	Van	37	9.2
	Bus	23	5.7
	Truck	50	12.5

The classification of the respondents' characteristics represents the characteristics of driving population within the study area.

For the second part, the frequency analysis was performed. Some interesting statistics of drivers' opinions are summarized as follows.

- Sixty-four percent of respondents were aware that speeding is the major cause of road traffic accidents on mountainous roads, followed by illegal overtaking, drivers' unfamiliarity with the roads, and slippery pavement condition.
- Sixty-nine percent of drivers were unaware of the speed limit of mountainous roads.
- Seventy-one percent of drivers agreed with the speed enforcement measure on mountainous roads, and seventy percent agreed with automated speed camera enforcement.

It implies that the majority of drivers accept the speed control measure on mountainous roads because they realize the consequences of speeding behavior.

Psychological Factors Affecting Driving Behavior

For the last part of the questionnaire, the study uses Analysis of Moment Structure (AMOS) to perform the structural equation modelling (SEM) analysis. In the questionnaire, psychological factors are measured based on a seven-point Likert scale ranging from "Strongly Agree" to "Strongly Disagree". Each factor is measured by asking the respondents to rate different numbers of latent statements as follows: Attitude towards Behavior (ATT) factor group has four statements (ATT1 to ATT4). Subjective Norm (SN) factor group has four statements (SN1 to SN4). Perceived Behavioral Control (PBC) factor group has three statements (PBC1 to PBC3), and Intention (IN) factor group has three statements (IN1 to IN3). All the latent factors are listed in Table 4.

Table 4**:** Latent factors in each factor group based on Theory of Planned Behavior

Factor Group	Question	Variable
Attitude towards behavior (ATT)	For me, in the next time I drive faster than the speed limit, I think it is …….	
	Bad – Good	ATT1
	Not useful - Useful	ATT2
	Unacceptable - Acceptable	ATT3
	Wrong – Not wrong	ATT4
Subjective Norm (SN)	I believe that my important people (e.g. family members/friends) think next time I should not/should drive over the speed limit.	SN1
	I believe that my important people (e.g. family members/friends) will disagree/agree when I drive over the speed limit.	SN2
	I believe that my important people (e.g. family members/friends) will not support/support me to drive over the speed limit.	SN3
	I believe that speeding behavior of my important people (e.g. family members/friends) is impossible/possible.	SN4
Perceived Behavioral Control (PBC)	In my next driving, I am unconfident/confident that I can drive over the speed limit.	PBC1
	It is difficult/easy for me to drive over the speed limit in my next driving.	PBC2
	I feel dependent/independent to drive over the speed limit in my next driving.	PBC3
Intention (IN)	"I intend to drive over the speed limit in my next driving" is very impossible/possible.	IN1
	"I have a tendency to drive over the speed limit in my next driving" is very impossible/possible.	IN2
	"I am willing to drive over the speed limit in my next driving" is very impossible/possible.	IN3

The questionnaire was first tested for its reliability using the Cronbach's alpha in the SEM analysis. The result shows that the Cronbach's alpha ranges from 0.81 to 0.92, which represent the very high reliability of the questionnaire. Then the AMOS analysis was carried out and the TPB structure was constructed. The relationship among psychological factors and their latent factors were evaluated. The results of AMOS analysis are shown in Fig. 6.

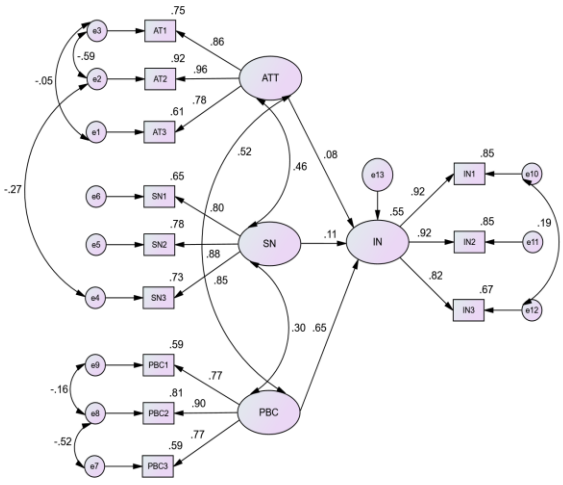

Fig**.** 6 The result of AMOS analysis

This diagram shows that three basic psychological factors: attitude towards behavior (ATT), subjective norm (SN), and perceived behavioral control (PBC) are highly influenced on intention (IN). All statistical indicators are accepted compared to their threshold values: Chi-square/df = 2.46 (recommended between 2 and 3), Goodness-of-fit indices (GFI) = 0.959 (recommended close to 1), Comparative Fit Index (CFI) = 0.981 (recommended close to 1), Standardized Root Mean Squared Residual (SRMR) = 0.045 (recommended close to 0.05), and Root-mean square error of approximation (RMSEA) = 0.061 (recommended close to 0.08) [13].

The diagram shows that among the three factors, PBC is the highest influential factor to the intention and to the speeding behavior. It implies that the speeding drivers are willing to drive fast whenever he or she has an opportunity to perform speeding. Therefore, breaking the opportunity to overspeed by introducing speed camera enforcement would affect the speeding behavior of drivers within the study area.

CONCLUSIONS

The paper presents the effect of automated speed enforcement system installed along the hazardous sections of mountainous roads in Thailand. Although the automated speed enforcement system has been successfully implemented in many developed countries, such system has not yet been widely introduced and comprehensively analyzed their effectiveness in Thailand. This study evaluated the effects in terms of the speeding behavior and drivers' perception and attitudes.

An automated speed camera enforcement system in this study becomes an effective speed control technology on mountainous roads because of three respects. First, the speed camera enforcement helps reduce the speed of vehicles significantly. The 85th percentile of vehicle speed is reduced by 13,4%, while the number of violators is reduced by 16%. Second, it helps increase public awareness of the risk of speeding behavior as the drivers perceive the speed limit more while driving on mountainous roads. In this study, the public resistance is minor because the drivers realize that the speed camera is a tool to enhance the speed regulation. Finally, the speed enforcement program helps minimize the opportunity of the drivers to perform overspeed. In other words, it enhances the safe driving speed and sustains the safe behavior.

This study has two further recommendations. One, this paper presents the 2-month before-and-after speed data. Data collection including speed data, speed tickets, and accident records should be carried out in a longer time period to ensure the sustainable speeding behavior and their positive consequences. Two, it should be noted that automated speed enforcement is one of the possible and practical safety countermeasures to improve the perceived behavioral control of drivers' speed on mountainous roads. More comprehensive studies on safety measures in other regards, such as engineering and education measures, should be emphasized in order to more effectively sustain the safe speeding culture.

ABSTRACT

Aging deterioration of reinforced concrete structures is mainly due to chemical reactions of rebar corrosion, carbonation, alkali-aggregate reaction, and the like, whereas collection of chemical information is effective to accurately grasp these signs. The recently introduced nondestructive measurement method of chloride ion concentration using a near-infrared (NIR) spectroscopy system detects an NIR peak of Friedel's salt that is immobilized on a concrete surface, followed by application of a multispectral method. Herein, a prototype of a small-scale, NIR spectroscopy system that does not require seismic isolation was developed, using imaging-type two-dimensional Fourier spectroscopy technology, and the applicability of two-dimensional imaging of chloride ion concentration on concrete surfaces by this system was evaluated. Apparently, measurement by the system could be performed in a short time and with measurable accuracy. Moreover, the two-dimensional imaging of chloride ion concentration was possible in an outdoor environment with almost no associated difficulty. In addition to measuring Friedel's salt, it was possible to observe cracks on the concrete surface by measuring water.

Keywords: Two-dimensional imaging, Chloride ion concentration, Near-infrared spectroscopy, Nondestructive measurement

INTRODUCTION

Since its period of economic boost, Japan has been engaged in the fast-paced reconstruction of social infrastructures that are reportedly estimated at present to cost around 800 trillion yen. Measures to slow down the aging of buildings and structural units is of dire need. Implementation of deterioration measures presupposes the collection of information on signs of degradation before deterioration and preventive maintenance measures. Present-day nondestructive inspections, however, which carry out every five years, such as visual inspection and concrete hammering test, are geared to obtaining information after deterioration. Time-related deterioration is mainly due to chemical wear-and-tear, i.e., corrosion, where chemical information is of vivid necessity for understanding the signs and pinpoint the source.

Nondestructive measurement of chloride ion on a concrete surface via near-infrared (NIR) spectroscopy is a recently developed method of collecting chemical information relative to deterioration of structures, which emerged subsequently after the discovery of the NIR peak of Friedel's salt immobilized on concrete surface by Dr. Kanada, followed by practical application of the multispectral method [1],[2]. A new NIR spectroscopy system is introduced in this paper, mainly to perform the objectives of measuring chloride ion concentration and moisture content on a concrete surface, and then the applicability of two-dimensional imaging obtained from the spectrum data is reported [3], [4].

NIR SPECTROSCOPY SYSTEM

Overview of the Conventional System

So far, with the spectroscopic measurement in the outer region of the NIR, the 1300–2350 nm band could not be covered with high sensitivity and two dimensions due to the characteristics of the detector. It was confirmed that the imaging-type two-dimensional Fourier spectroscopy technology developed by one of the authors, Prof. Ishimaru, could cover the required wavelength band cited [5].

In the conventional mechanism, if this instrument receives vibration during measurement, the mirror is shifted, and interference does not occur. The proposed method overcomes the disadvantage in that spectral data cannot be acquired and thus, is suitable for on-site measurements.

Additionally, an angle of view correction function to correct the error caused by the difference in optical path length caused by the difference in the pixel position of the camera, as illustrated in Fig. 1, was implemented.

Consequentially, the conventionally used

demonstration machine was reduced to 203.5 × 398 × 140.5 mm; its original mass of 9.0 kg with camera was lessened to 7.1 kg, and from 6.5 to 2.5 kg in the spectroscopy section alone, thus, showcasing improved portability.

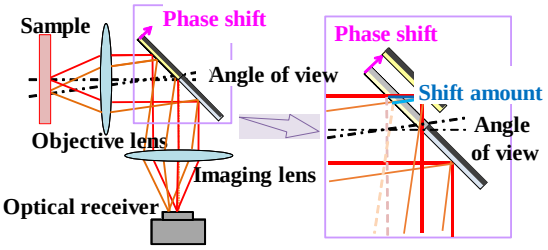

Fig. 1 Field angle correction technology of imaging-type two-dimensional Fourier spectroscopic technique

INDOOR MEASUREMENT

Outline of Indoor Measurement

Indoor measurements for mortar specimens was carried out to validate the accuracy of the system. Ordinary Portland cement (OPC) and blast furnace cement B (BB) were the cement samples considered. The water–cement ratio applied was 50 %, whereas the fine aggregate in the mortar specimens had a volume ratio of 48 %. Sodium chloride was added in specimens. The chloride ion concentrations are 0, 1, 2, 3, 4, 5, 10, 15, 20, 30 kg/m^3. Thirty plastic molds (10× 30 cm in size) were used for 10 kinds of specimens (3 molds each). Sealed curing was performed in a 20 °C environment for 7 days, before the molded specimens were exposed indoors. Specifically, the specimens were named according to the combination of cement type and chloride ion concentration. For example, an OPC paste sample with chloride concentration of 1 kg/m^3 was labeled as NP01, whereas a BB 30 kg/m^3 of chloride ion concentration is labeled as BBM30.

Indoor Measurement

The indoor measurements followed a schematic procedure depicted in Fig. 2. A standard reflector with 99 % reflectance was the reference, and a spot heater unit was used for illumination. A high-resolution SWIR lens was attached to the objective lens of the instrument, and measurement was performed at a sample angle of 0 degree and an illumination angle of 45 degrees to the sample.

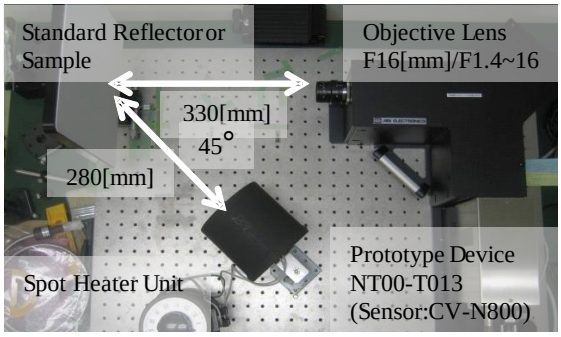

Fig. 2 Setup for indoor measurement

Measurement Results

Spectrum data of the specimens with each chloride ion concentration were examined. The relationship between the chloride concentration of the specimen and the absorbance value in the absorption wavelength range derived from Friedel's salt is shown in Fig. 3. Note that the absorbance value for 20 and 30 kg/m^3 of chloride concentration for the same specimen was almost identical, probably because the chloride fixed to the cement was saturated. Except for the 30 kg/m^3, the one for which the calibration curve was prepared is represented as a dotted line in the figure. The coefficient of determination was 0.9272.

It is considered that this calibration curve can estimate the chloride amount with high accuracy from the peak value of the absorbance of Friedel's salt.

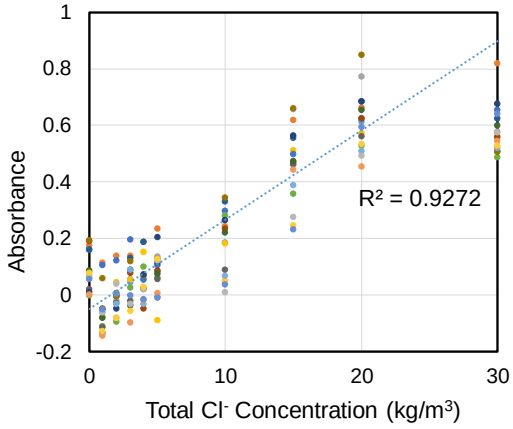

Fig. 3 Chloride concentration vs. absorbance of specimens

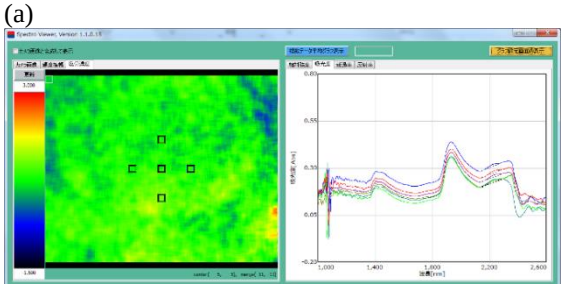
Use of Two-Dimensional Imaging Software

Along with the development of this NIR camera system was the creation of a two-dimensional imaging software. Accordingly, specimens BBP0, BBP30, and BBM30 were placed in a metal mortar and manually (hand) made into a powder, prior to

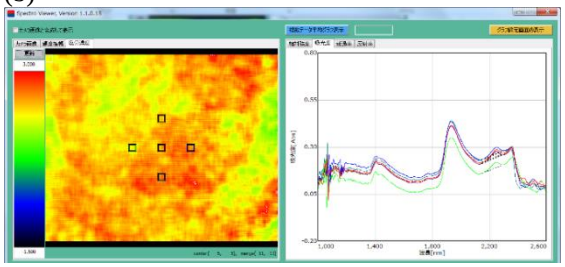
measurement. Sample output by the software is shown in Fig. 4.

The image on the left of the output plot was the result of the two-dimensional imaging, and that on the right side was the spectrum at five target points of the center in the left image. At the two-dimensional imaging, where the salinity is higher the color is closer to red and where the lower salinity is closer to blue.

(a)



(b)



(c)

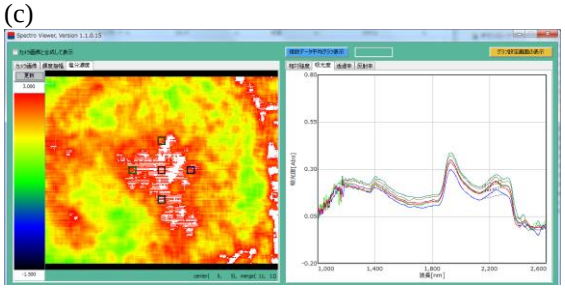


Fig. 4 Left: Output of two-dimensional imaging
Right: Output of absorbance spectrum
(a) Powdered BBP0
(b) Powdered BBP30
(c) Powdered BBM30

For example, in BBP0, the chloride concentration was almost 0, and the heat map was blue almost entirely. In contrast, almost the whole area in BBP30 was uniformly yellow-to-red, given the high chloride concentration. In the case of BBM30, in which the specimen was hand-pulverized (and thus powderization was insufficient), the presence of uneven colors was observed. Very high concentration appeared near the center, and low-density parts locally occurred in the heat map. Since pulverization of the aggregate was not enough. Accordingly, the difference in the properties of the specimens is apparent in the two- dimensional imaging. It was confirmed that such a difference could be measured indoors with no associated difficulty.

APPLICABILITY VERIFICATION BY OUTDOOR MEASUREMENT

Objects and Measurement Outline

The target structure was once used near the coastal area of Shikoku Chuo City, removed for salt damage, and transferred to the Shikoku Technical Office, Shikoku Regional Development Bureau, Ministry of Land, Infrastructure, Transport, and Tourism. Of the hollow girder bridges, one girder that was not relatively salt-damaged (Fig. 5, near side, girder 1) and another from which concrete cover was peeled off due to salt damage (Fig. 5, back-side, girder 2) were used in the measurement. Prior to removal, the girders were 15.6 m long and had served for 51 years since they were built in 1967.

Fig. 5 PC digit removed due to salt damage

Measurement Results

Measurement values for girders 1 and 2 are provided in Fig. 6, respectively. Here, the heat map for girder 1 confirmed the appearance of yellow-to-red areas that were larger than those for girder 2, whereas the degree of salt damage and the tendency of the amount of surface chloride tended to almost coincide. Moreover, the average values of the absorbance at the target points were respectively 0.32 and 0.41 for girders 1 and 2; it is considered that the difference in the degree of salt damage can be interpreted from the degree of the evaluation value.

Results of the Fourier transform infrared spectrophotometer (FTIR) analysis for the concrete powder that was scraped off the surface of the girder, to confirm the validity of the outdoor test, are displayed in Fig. 7. Moreover, the powder was collected from two places in girder 2, namely, girder 2-1 and girder 2-2. Although a clear peak could be confirmed in the portion indicated by the arrow in girder 1, this was not derived from Friedel's salt.

On the contrary, in girders 2-1 and 2-2, the peak derived from Friedel's salt could be confirmed in the

part shown by the arrow (Fig. 7), thus, indicating that the result of outdoor measurement with the system is generally appropriate. However, regardless of the presence of the absorbance peak of Friedel's salt, other peaks could be confirmed on the shorter wavelength side than that of the peak wavelength, which interferes with the result of absorbance of Friedel's salt. Thus, a study on peak separation was conducted, with the aim of improving the system's evaluation accuracy.

Improvement of Evaluation Accuracy by Peak Separation

The Friedel's-salt-derived absorbance spectrum of the indoor test shows the difference from the baseline created from absorbance values of 2180 and 2290 nm. Apparently, the wavelength at which the peak was taken differed depending on the measurement cases. Although this is under investigation, this waveform is not the peak derived from Friedel's salt. Therefore, assuming a Gaussian function, the waveforms not derived and that derived from Friedel's salt were decidedly separated.

For example, at a specimen with a total chloride ion concentration of 10 kg/m^3, both peaks could be separated by two Gaussian distributions (Fig. 8). The absorbance after peak separation is shown in Fig. 9, and what prepared the standard curve using the absorbance value after peak separation is shown in Fig. 10.

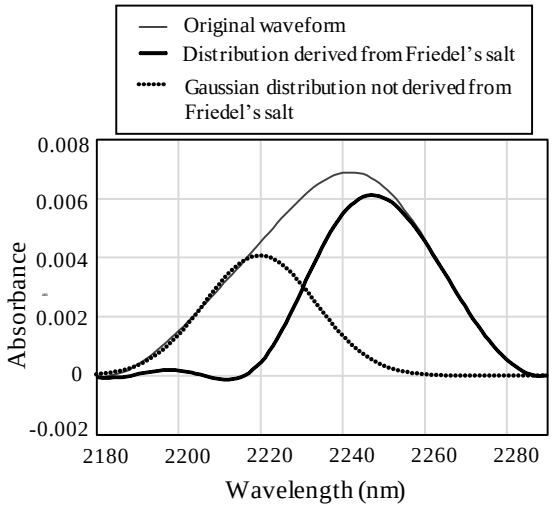

Fig. 8 Peak waveform separation

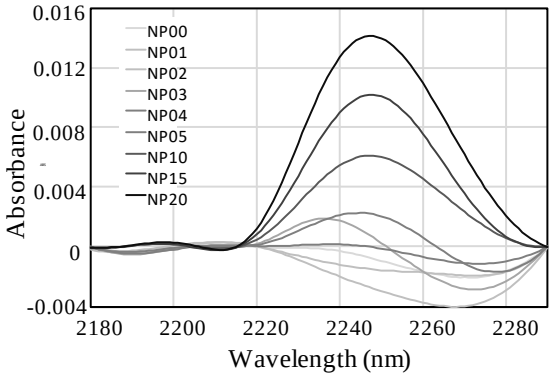

Fig. 9 Peak derived from Friedel's salt after separation and extraction of waveform

Here, the coefficient of determination was 0.9658, and accuracy was greatly improved. The same peak separation scheme was imposed on the BB type

specimens, and the result of preparing a calibration curve is shown in Fig. 11. Although not listed for the convenience of the paper, the coefficient of determination was 0.5494 before peak separation but rose to 0.7474 by peak separation. Such value of determination coefficient was small compared with that using OPC. The reason is under investigation.

A notable point in this measurement was the short measurement time. More specifically, the time required to obtain a single case of two-dimensional imaging results was approximately 60 s, including the time required for measurement on the imaging, which is much shorter than in conventional methods.

However, points that should pay attention are shown. Suspects of the progress of carbonation on the girder are typical, especially being constructed in a considerably long time, and such girders were also set outdoors for a long time in this study. With the system, the chloride content could be estimated from the amount of friedel's salt on the surface of the concrete; nonetheless, if friedel's salt gets liberated via carbonation, then the total amount of chloride actually attached to the surface of concrete may be larger than those confirmed by ftir or the proposed system. Interestingly, the preparation of a calibration curve that takes into account the effect of friedel's salt release due to carbonation is a future direction for the present study.

Accordingly, approximately 1 cm of the test piece of the NP group was cut dry with a concrete cutter, and the cut surface was subjected to the proposed measurement system. Results are shown in Fig. 12. Here, the heat generated at the time of the cutting may have caused alteration of the Friedel's salt; nonetheless, there were visible color shifts in the heat map from blue and green to yellow as the set chloride concentration increased. Based on the cross-sectional view of this specimen, two-dimensional imaging was possible.

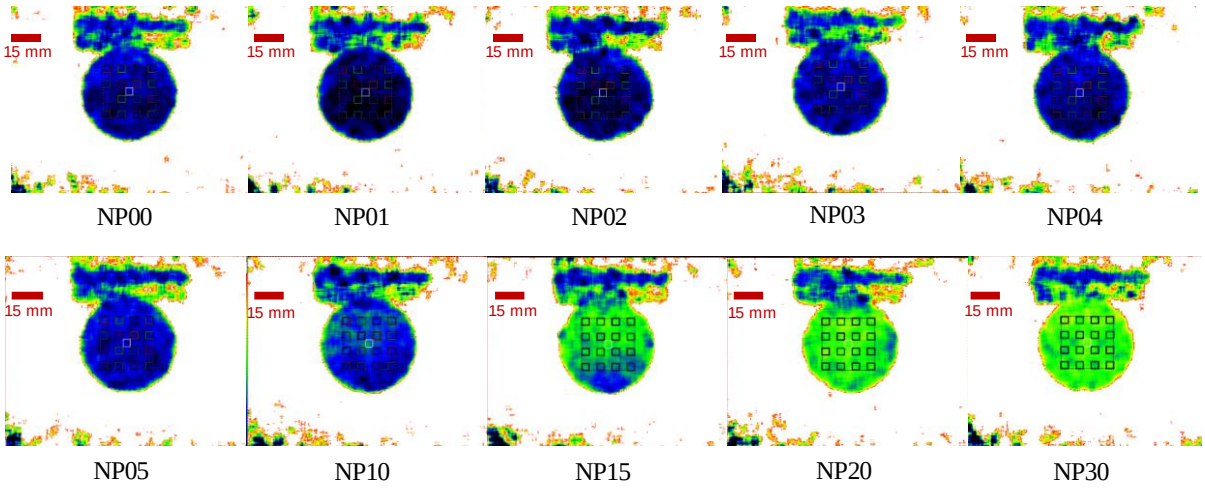

Fig. 12 Two-dimensional imaging of chloride in NP specimen cross section

Measurement regarding Water Distribution

In the NIR spectroscopy, a spectrum analysis on the OH group is frequently performed, especially on the spectrum of water. In this study, given that the concrete has water content, moisture measurement and imaging of water intrusion at the crack site were examined.

Using the proposed system, specimens that had been artificially cracked in advance were measured. A stone material with thermal expansion coefficients different from concrete was placed at the center of the specimen, and the specimen was heated to a maximum of 80 °C and then cooled. Cracks were generated due to the difference in the thermal expansion coefficients between the materials. The observed crack width was 0.15 mm at the top half and 0.10 mm at the bottom. Moisture content on the specimen was 3.3 %, as indicated by a concrete moisture meter.

Imaging results of the dried specimen are given at the left side in Fig. 13. Here, water was not confirmed in the original image of the NIR camera. After that, a specimen supplied with water from the outside by atomizing and re-imaged after visual confirmation that it had been substantially dried, is shown at the right side in Fig. 13. Moisture in the specimen could not be confirmed visually, but by imaging, this became possible with the moisture remaining in the crack. Here, moisture content was 4.3 %.

More accurately, through the proposed system, the presence of even the slightest amount of water adhering to concrete surface may be sufficient to make a proper evaluation, and fine cracks that cannot be grasped by visual inspection were shown. This issue is another direction for future study.

CONCLUSIONS

The NIS system presented in this paper was fundamentally geared to the measurement of chloride concentration on concrete surfaces and the evaluation of applicability of two-dimensional imaging of the chloride concentration. These points can be generalized from the findings: (1) A compact, non-seismic-free two-dimensional imaging spectrometer was developed using Fourier spectroscopy technology; (2) Because the peak waveform considered to be Friedel's salt is adhered to a waveform other than it, waveform peak separation was essential to extract that of Friedel's salt. Doing so, the determination coefficient of the calibration curve increased greatly; (3) The two-dimensional imaging for the chloride concentration in the cross section of the specimen could be performed in a short time and with high accuracy; (4) Moreover, the two-dimensional imaging of chloride concentration is possible for measurement in open air with no associated difficulty.

RECYCLED POROUS CONCRETE EFFECTIVENESS FOR FILTRATION MATERIAL ON WASTEWATER TREATMENT

Evi Nur Cahya[1], Eva Arifi[2] and Riyanto Haribowo[3]
[1]Faculty of Engineering, Universitas Brawijaya, Indonesia; [2,3] Universitas Brawijaya, Indonesia

ABSTRACT

The use of concrete waste from demolition of buildings is one of the conservation efforts to reduce its environment impact. In this study, concrete waste was destroyed by the size of coarse aggregates, then made into porous concrete. Porous concrete from recycled coarse aggregate was used as filtration media to reduce the pollutants in wastewater to satisfy the water quality standards. For this purpose, wastewater from communal wastewater treatment plant was filtrated through two layers of porous concrete made of recycled coarse aggregate with several different sizes, and the water quality output of the system was measured according to water quality parameter standard. The objective of this study is to examine the effectiveness of the aggregate sizes of normal coarse aggregate compared to recycled coarse aggregate as filtration media. From the result of water treatment filtration model, it was found that size of coarse aggregate in porous concrete mix has a significant effect for reducing the water pollutants, as biological oxygen demand (BOD), chemical oxygen demand (COD) and total suspended solid (TSS). As a result of this study, porous concrete made from recycled coarse aggregate shows better performance on filtrating the water pollutants.

Keywords: wastewater treatment, porous concrete, recycled coarse aggregate, water quality

INTRODUCTION

Domestic wastewater comes from residential businesses and activities, restaurants, offices, commerce, apartments and dormitories. It is generally called grey water and black water, which is very influential in decreasing water quality. Some parameters such as the total coliform content, BOD (Biological Oxygen Demand), COD (Chemical Oxygen Demand), Ammonia, pH, temperature, and TSS (Total Suspended Solid) are very dominant and each is affected in different ways [1, 2, 3].

Porous concrete is concrete which is permeable or can absorb water. By relying on the absorption and pore power of the porous concrete, it is expected to be a filtration medium to reduce some contaminants in the wastewater. Porous concrete is composed of water, cement and coarse aggregate. The coarse aggregate used in this study, is recycled aggregate which is derived from concrete that has been unused and reused. The use of concrete waste from demolition of buildings is one of the conservation efforts to reduce its environment impact.

Porous concrete is also called previous concrete which generally only use coarse aggregates with a uniform gradation size so that it has a larger size pore, which allows drainage to drain water through the pore. Porous concrete has several advantages, including a high void content of about 30%, so it is potential to reduce run off to the drainage system with a flow rate of 0.34 cm/second, making it effective for pavement, footpaths, and sidewalks [4], beside that it can be a constructive alternative with low environmental impact and protect water quality. Porous concrete also has a higher void ratio and permeability compared to conventional concrete, so that it can be used for construction of wastewater treatment plants and as a construction material for sea walls [5]. In addition, porous concrete can also be used for groundwater refilling [6]. Also, as a detention system, porous concrete can remove stormwater pollutants from the runoff, which significantly decreases the concentrations of total suspended solids, nitrite, chemical oxygen demand, and increases the values of pH and sulfate [7].

Recycle aggregate is an aggregate derived from conventional concrete that is no longer used, and then destroyed to become an aggregate for a new concrete mix. Coarse aggregates used in this study were natural concrete aggregates (NCA) and recycle concrete aggregates (RCA). The aggregate variations used are aggregates with a diameter of 0.5-1 cm, 1-2 cm, and well graded 0.5-2 cm for RCA and NCA. NCA comes from natural aggregate material, while RCA was taken from conventional concrete crushing with f'c compression strength of 22.5 MPa.

Water absorption in concrete is obtained from the ratio of the weight of pore absorbable water to dry concrete, which is expressed in percent, which serves to determine the amount of water content in the concrete. Void can be interpreted by the total percent of the pore number on the total volume. For the average, porous concrete has a pore percent value of 15-25% and the permeability is generally between 2 -

30 mm/sec [8]. The pore number is determined according to ASTM CI688.

Permeability is generally influenced by aggregate size and proportion [8]. Permeability measurements are calculated based on ACI-522R. The falling head method is used for measuring permeability in concrete. This permeability measurement usually uses a cylindrical test object with a size of 150 mm x 150 mm. the cylinder is placed in a PVC pipe. For testing is done after 28 days of curing [8]. Urban water needs include 25-35% for industry, 5-10% for public use, 10-20% for commercial, firefighting, and 30-50% for housing [9].

Wastewater released by disposal can be analyzed through the discharge of the needs of each resident. According to Tchobanoglous [9], the amount of wastewater produced ranges from 50-80% of the use of clean water. For the calculation of the amount of wastewater produced by the service area, 80% of the consumption of clean water is determined. The value of 80% versus 20% is the comparison between direct connections to urban public hydrants for medium economic communities, while the value of 30 L/person/day is the standard of clean water needs for urban public hydrants. The wastewater factor for drinking water is 0.5-0.8 [9].

Quality standards for domestic wastewater according to the Minister of Environment and Forestry of the Republic of Indonesia as a reference for this study can be seen in Table 1.

Table 1 Quality standards for domestic wastewater

Parameter	Units	Maximum level
pH	-	6 – 9
BOD	mg/L	30
COD	mg/L	100
Oil and Grease	mg/L	5
Amonia	mg/L	30
Total Coliform	Amount/100 ml	3000
Discharge	L/person/day	100

The parameters of domestic wastewater are a measure of the waste water content that can calibrate the wastewater. This parameter is used as a reference for domestic wastewater to achieve quality standards. Parameters for each type of waste vary. In domestic wastewater, the parameters used as reference quality standards are pH, BOD, COD, TSS, oil and grease, ammonia, total coliform and discharge.

The purpose of this study is to examine the effectiveness of the aggregate sizes of normal coarse aggregate compared to recycled coarse aggregate, on filtrating the water pollutants to satisfy the water quality parameter standard.

METHODS

The research sets at a local integrated domestic wastewater treatment plant in Malang, Indonesia, which covered domestic wastewater (gray water and black water) from 112 family with a total of 14 tanks. In this study the concrete material uses natural concrete aggregates (NCA) and recycle concrete aggregates (RCA) with three variations, namely, 0.5-1 cm, 1-2 cm and 0.5-2 cm.

The tested domestic wastewater treatment plant single model is 60x60x100 cm in size with two slab concrete dividers as filtration mediums, which is 60x60x5 cm. The water used as a sample is domestic wastewater (gray water and black water) from a local wastewater treatment plant in the first tank (after the crushing tank). Inlet discharge is 2 L/min, with calculation of deposits every 18 hours, calculation of water level every 1 hour and samples were taken at the end of the three hours running experiment.

Water quality of wastewater treatment plant in the original tanks and at the experiment tank model after filtered is tested at the time of each layer (BOD, COD, TSS, Ammonia, Oil and grease, Total Coliform) in addition to measuring pH and temperature, water level and height of sediments. Void ratio of porous concrete and concrete permeability are tested separately.

The output of water quality testing is the effectiveness of porous concrete as a filter for wastewater treatment where normal porous concrete aggregates become a comparative material for porous recycle aggregate concrete.

Comparison of the ratio of the proportion of weight in the manufacture of porous concrete, namely Cement: Gravel: Water is 1: 4: 0.3. The composition of NCA (Normal coarse aggregate) and RCA (Recycled coarse aggregate) aggregate sizes can be seen in Table 2.

Table 2 Aggregate size compotition in porous concrete

Aggregate		A (0.5 cm - 1 cm)	B (1 cm - 2 cm)	C (0.5 cm – 2 cm)
I	NCA	100% NCA 0.5-1	100% NCA 1-2	100% NCA 0.5-2
II	RCA	100% RCA 0.5-1	100% RCA 1-2	100% RCA 0.5-2
III	NCA: RCA	50%RCA 50% NCA 0,5-1	50% RCA 50% NCA 1-2	50% NCA 50% RCA 0.5-2

From each variation, two slab test specimens were made for each trial session in the form of concrete plates measuring 60 cm wide, 60 cm long and 5 cm thick. Concrete samples will also be made specifically for the calculation of void ratio and permeability of the nine existing variants.

RESULT AND DISCUSSION

This study is aimed for the efficiency value of the aggregate sizes of normal coarse aggregate compared to recycled coarse aggregate, on filtrating the water pollutants to satisfy the water quality parameter standard.

Void Ratio and Permeability

The pore number shows the number of pores in the concrete. The concrete pore number is in line with the amount of porosity in the concrete. This permeability analysis is used to see how much absorption by the porous concrete is displayed with the symbol k. Permeability measurements are calculated based on ACI-522R. The results of pore and permeability calculation are explained in Table 3. The relationship between pore number and permeability does not appear to be significant because the pore number testing method uses fresh concrete while permeability using dry concrete is 28 days old.

Table 3 Calculation Results of Void Ratio and Permeability

Coarse Aggregate Mix	Void Ratio %	Permeability (mm/s)
100%NCA 0.5-1	9.772	4.878
100%NCA 1-2	10.615	4.824
100%NCA 0.5 -2	8.720	9.248
50%NCA50%RCA 0.5 -1	8.587	7.317
50%NCA50%RCA 1-2	11.672	11.367
50%NCA50%RCA 0.5-2	5.940	7.332
100%RCA 0.5-1	4.865	6.264
100%RCA 1-2	5.186	8.865
100%RCA0.5-2	8.263	8.052

Analysis of Water Quality and Efficiency Results

The water quality tested in this study is in accordance with the quality standards of domestic wastewater namely temperature, pH, BOD, COD, TSS, Oil and grease, Ammonia and Total Coliform. To see the relationship between the efficiency of the reduction of the parameter and the void ratio and permeability, several graphs are made. In this graph the value of oil and grease and total coliform is not included because there is no reduction value of these parameters in this study. Oil and grease and total coliform can only be decomposed and reduced using biological and chemical methods [10, 11, 12].

For comparation of the effect of aggregate sizes to the filtration ability, one of the results from the 50%NCA 50%RCA is shown for COD, BOD and TSS, as shown in Figure 1. It can be seen, that aggregate size of 0,5-1 cm and 0,5-2 cm show good numbers of efficiency compare to concrete with bigger aggregate size of 1-2 cm, due to it bigger pores.

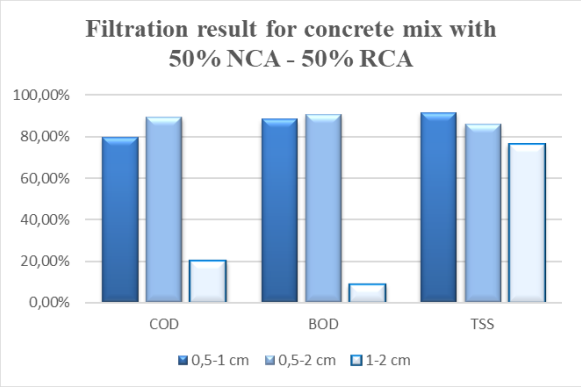

Fig. 1 Filtration result for different aggregate sizes for COD, BOD and TSS parameters

Comparison of aggregate types with various sizes can be seen in Figure 2, 3 and 4. In these figures, the effectiveness is compared for different type of coarse aggregate in concrete mixture with the same sizes.

In Figure 2, for an aggregate size of 0.5-1 cm, the best percentage of efficiency is seen in the 50%RCA 50%NCA mixture type. But it has the lowest ammonia efficiency. This is because ammonia is not reduced only by physical methods, but by the addition of biological methods or by adding aeration to processing.

While for 1-2 cm aggregate size, the highest value of TSS efficiency in 50%NCA 50%RCA mixture while BOD, COD is at 100% NCA. However, the highest ammonia reduction efficiency value is 100% RCA.

The largest pore number is at 100% NCA. The biggest permeability is at 50% RCA 50% NCA. For 0.5-2 cm aggregate size, it can be seen, that the efficiency value of TSS, COD, BOD has the highest value at 50%NCA 50%NCA. With a pore value lower than 100% NCA and higher than 100% RCA as well as its permeability value.

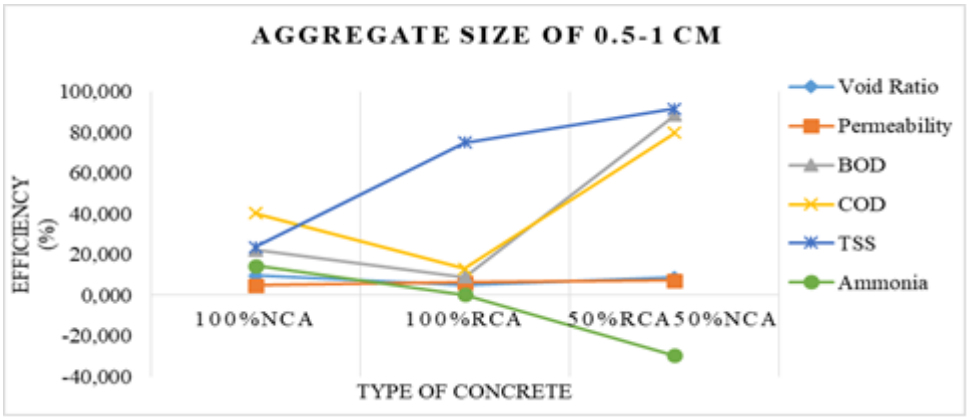

Fig. 2 Void ratio, permeability and efficiency for every mixture with aggregate size of 0.5-1 cm

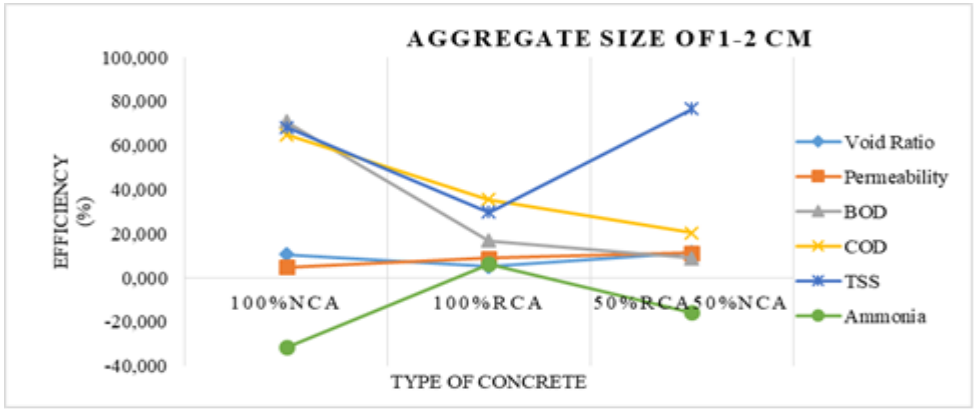

Fig. 3 Void ratio, permeability and efficiency for every mixture with aggregate size of 1-2 cm

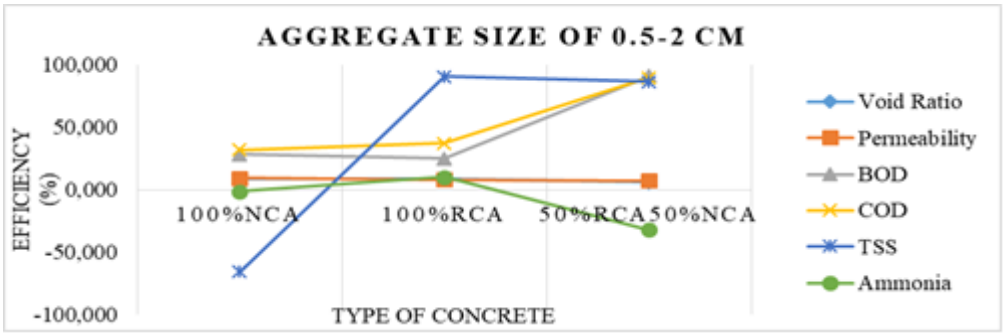

Fig. 4 Void ratio, permeability and efficiency for every mixture with aggregate size of 0.5-2 cm

Comparison of the types of aggregates in each type of concrete mixture is presented with a graph in Figure 5,6, and 7. In these figures, the effectiveness is compared for different size of coarse aggregate in concrete mixture with the same coarse aggregate type. For the 100% RCA aggregate type, it can be seen that the highest efficiency values of TSS, BOD, COD and Ammonia are in the mixture of 100% RCA size 0.5-2 cm. But the highest value of the pore is 1-2 cm. Whereas permeability is at 0.5-2 cm. In 100% NCA mixture 1-2 cm aggregate size has the highest efficiency for TSS, COD, BOD parameters. However, the lowest ammonia reduction efficiency is 1-2 cm. In 1-2 aggregate sizes with 100% NCA mixture types, the pore value is the largest compared to 0.5-1 and 0.5-2. 100% NCA 1-2 has the smallest permeability compared to 0.5-1 and 0.5-2 cm. For the 50% RCA50% NCA aggregate type, the greatest efficiency of TSS, BOD and COD is 0.5-2 cm. But the biggest ammonia reduction efficiency value is 1-2 cm. Efficiency results of 0.5-1 and 0.5-2 in the 50% RCA50% NCA mixture are not much different.

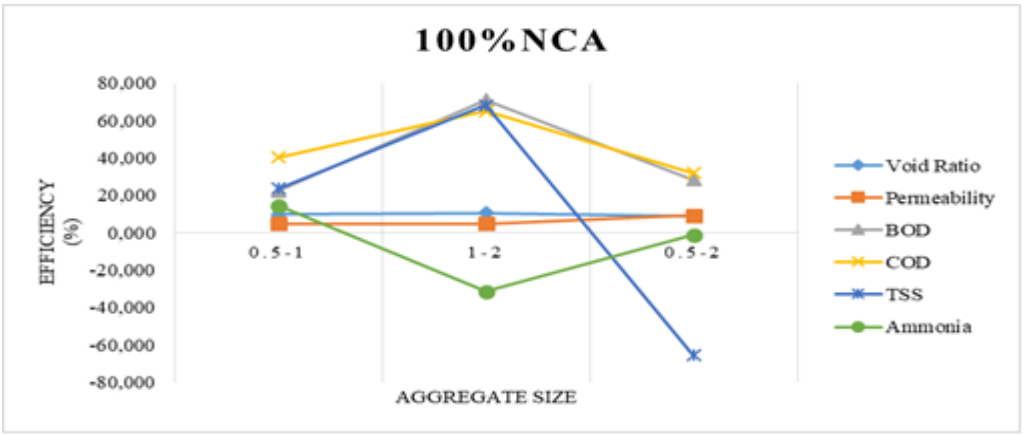

Fig. 5 Efficiency for water quality parameter at porous concrete with 100% of natural coarse aggregate

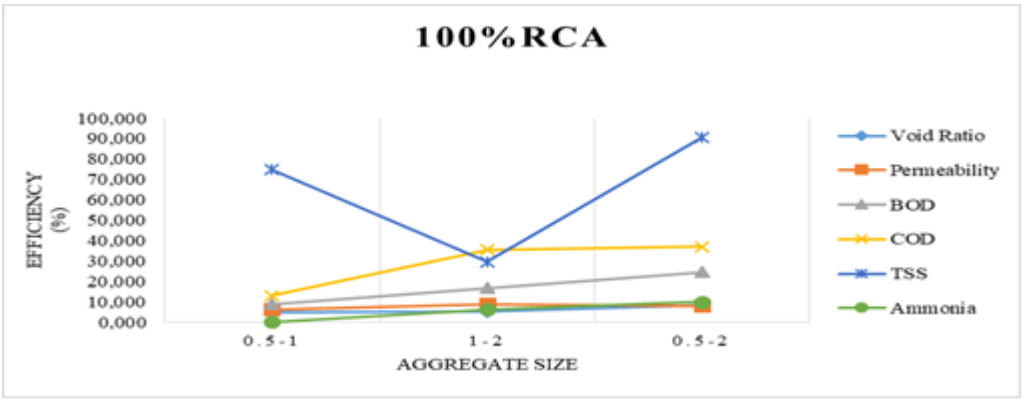

Fig. 6 Efficiency for water quality parameter at porous concrete with 100% of recycle coarse aggregate

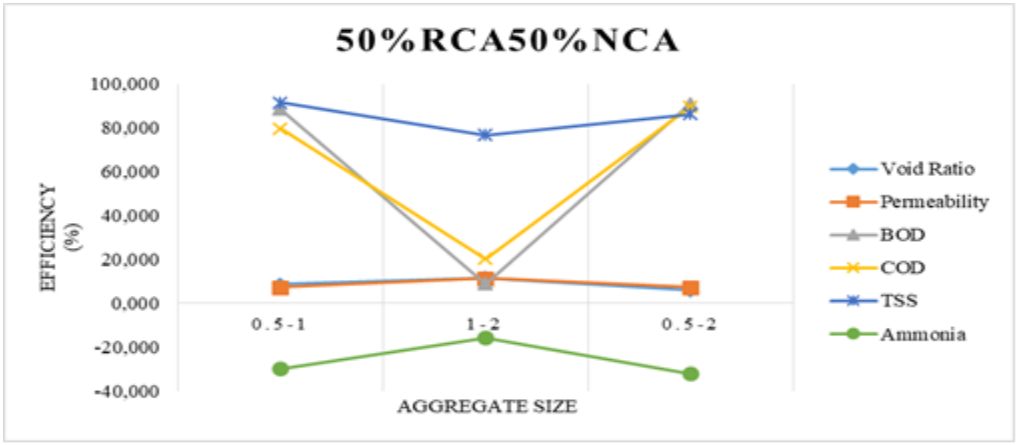

Fig. 7 Efficiency for water quality parameter at porous concrete with 50% RCA and 50% NCA

From the results of the analysis, the size of coarse aggregate in porous concrete mix significantly affected to its filtration ability for reducing water pollutants. Generally, concrete mix with 0.5-2 cm agreggate sizes gives the best result, for the decrease of biological oxygen demand (BOD), chemical oxygen demand (COD) and total suspended solid (TSS), due to its well graded sizes. The porous concrete made from recycled coarse aggregate (RCA) shows better performance on filtrating the water pollutants compared to one made from natural coarse aggregate (NCA).

CONCLUSIONS

In conclusion, the size of coarse aggregate in porous concrete mix has a significant effect and highly efficient for reducing the water pollutants, as biological oxygen demand (BOD), chemical oxygen demand (COD) and total suspended solid (TSS), with 0.5-2 cm agreggate sizes for best result, due to its well graded sizes. The porous concrete made from recycled coarse aggregate (RCA) shows better performance on filtrating the water pollutants compared to one made from natural coarse aggregate (NCA). Void ratio and permeability values cannot determine the efficiency of reducing pollutants by porous concrete. The outcome of this study can be used to develop an improved filtration system model of wastewater for residents with limited land in urban areas. In order to appropriately meet the water quality standart criteria, it is recommended in the future work to improve the filtration model by considering adding more layers, adding wetland system, or combining with adding some additives. The cumulative sediments in the model should be well predicted as well.

ABSTRACT

In 2013, a number of shallow landslides triggered by heavy rainfall affected a mountainous area which located on Izu-Oshima island (Eastern Japan). These slopes are consist of fine soil layers and coarse soil layers which have a different permeability coefficient and soil water characteristic curves. To clarify the characteristics of water infiltration in such unsaturated multi-layered slope and to assess the influence of the water content distribution on slope failure, 4 column tests and 2 groups of inclined slope model experiments were conducted. Silica No 1(D_{50}=3.10 *mm*) and silica No 7(D_{50}=0.16 *mm*) were used as the slope materials. The results indicated that advancing wet front apparently stopped at the interface between the silica No 7 layer and silica No 1 since the capillary barrier works and then lateral water flow occurred along with the interface and infiltrate into next layer when soil approaches saturation. It was found that when lower water content θ in fine and coarse layer, unsaturated permeability coefficient *K* in coarse layer (*K*=5.54E-06 *cm/s*) is smaller than fine layer (*K*=1.08E-04 *cm/s*) since matric suction is 2.5 kPa, which result that capillary barrier works. In addition, higher water zone still exists at the bottom of the fine layer after drainage for a long period which results in the failure in this zone firstly when second rainfall was applied. Piping occurred at the bottom of the model when amount of water exists inside the slope. Although toe of slope reach to saturated condition is later in multi-layer slope, failure time is earlier.

INTRODUCTION

This study deal with a slope consist of fine layer and coarse layer. It has a deep influence on the process of rainfall water infiltration and volume water content distribution in slope, thus governing the failure of slope. These kinds of multilayer slopes are present in many landscapes. For example, the catastrophic landslides that occurred in May 1998, involved pyroclastic covers laying upon the slopes of Pizzo D'Alvano, in Campania Southern Italy [1]. Another example is the multi-layer slope consists of volcanic sand and loess in Japan, which have the failure on the surface in Izu-Oshima in 2013. Rainfall infiltrating water owing to the build-up of capillary barriers [2] that occur at the interface between unsaturated fine and coarser soil layers. Capillary barriers can maintain a high degree of saturation in the soil above them which result into a different failure part in multi-layer slope [3]. These phenomena are related to capillary tension that limits the downward movement of water from a finer soil into underlying coarser soil. In some situations, capillary forces in the upper fine layer can no longer hold water, any additional infiltration is transmitted to the lower coarse layer. This situation happens at a critical distance from the top of the slope that can be estimated using a model proposed by Ross [4].

In this paper, building up and breakthrough point of the capillary barrier has been taken into consideration and its influences on slope failure time and failure modes are discussed based on column tests, inclined model slope experiments and mathmatic calculation.

The main objectives of this study are to evaluate the influence of capillary barrier and its diversion capacity on slope failure and the different failure modes between single layer and multi layer slope. SWCC tests of fine sand and coarse layer were also conducted to estimating the different hydraulic conductivities to explain how the capillary barrier works.

TESTING MATERIALS AND METHODS

Two soils from Japan, Silica No 1 and Silica No 7 were used in the lab experiments, which were excavated from Tono-Area Gigu Province. The sieve tests were conducted using the JGS Geotechnical Society standard test methods (JGS0131-2009). The details of the experiment properties are shown in Fig 1. The dry density of the coarse layer is 1.43 g/cm^3 while that of the fine layer is 1.33 *g*/*cm*^{3}. In addition, Table 2 and Fig 5 show soil water characteristic

curves of silica No 1 & 7 in both drying and wetting process and the fitting parameters by the VG model. It was found that saturated water content and residual water content in silica No 1 is lower than silica No 7, and volume water content is also lower under the same matric suction condition.

The other basic physical properties of test materials, including specific gravity G_s, maximum dry density, soil grain size distribution was measured in accordance with JGS standard test methods and the result are shown in Table 1. According to the soil classification system (USCS), Silica No 1 is classified as the coarse sand while No7 is fine sand.

Table 1 Basic properties of Silica No 1 and No 7

Description	Silica No 7	Silica No 1
Specific gravity G_s	2.63	2.62
Gravel content (>4.75*mm*; %)	0	97.13
Sand content (%)	87.31	2.86
Fines content (<0.075*mm*; %)	11.64	0
D_{10} (*mm*)	0.043	2.26
D_{50} (*mm*)	0.152	3.52
D_{60} (*mm*)	0.165	4.21
Maximum dry density (g/cm^3)	1.556	1.52
Minimum dry density (g/cm^3)	1.271	1.38

SWCC Tests and Unsaturated Hydraulic Conductivity of Testing Materials

SWCC and unsaturated hydraulic conductivity of sands was obtained in lab. Fig. 1 shows the relationship between matric suction and volume water content. Both drying process and wetting process experiments were conducted showing a difference in both sands. In this case, hydraulic conductivity increased with water content increase in coarse and fine sand.

The soil-water characteristic curves of the soil have been modeled with the van Genuchten-Mualem model [5], namely:

$$S_e = \left\{1+(-\alpha h)^n\right\}^{-m}$$
$$S_e = \frac{\theta-\theta_r}{\theta_s-\theta_r} \quad (1)$$
$$m = 1-\frac{1}{n}$$

In the above equation, the water retention curve has been expressed in terms of effective degree saturation. Where θ is the volumetric water content; θ_r and θ_s indicate residual and saturated values of the water content; a, m and n are the fitting parameters. h is the matric suction. a is a scaling parameter (units of m^{-1}) and the exponents n and m are parameters that determine the shape of the retention curve The hydraulic parameters are given in Table 2.

Table 2 Hydraulic properties of the silica No 1 and silica No 7

Description	Symbol (unit)	Soil	
		No 7	No 1
Drying curve			
Saturated volume water content	θ_s	0.44	0.42
Air-entry value	ψ_a (kPa)	2.44	0.62
Residual volume water content	θ_r	0.12	0.05
van Genuchten model	a	0.41	1.59
Fitting parameter	n	4.07	3.11
	m	1.42	0.67
Wetting curve			
van Genuchten model	a	0.42	0.03
Fitting parameter	n	4.51	1.42
	m	0.78	0.29

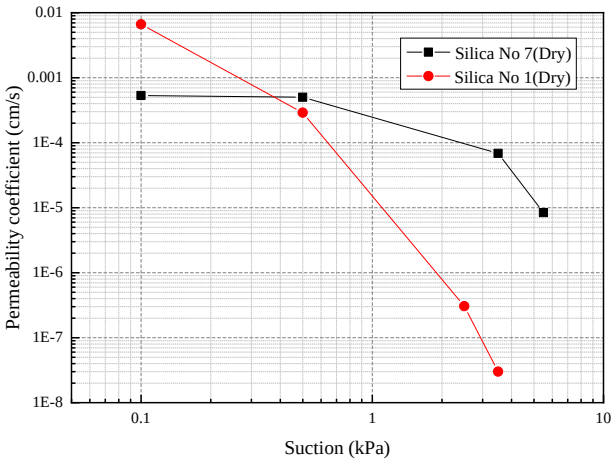

Fig. 1 Hydraulic conductivity of Silica No1 & No 7 in drying process and wetting process

Fig. 1 shows that the volume water content in silica No 7 is higher than No 1 when under the same suction, which could explain how the capillary barrier works. Suction in fine layer decrease as the water content increase, capillary will breakthrough and rainwater start to infiltrate into the next layer.

MODEL EXPERIMENTS

Column Infiltration Tests Through Layered Soil

A series of laboratory column infiltration tests have been performed in the laboratory to observe and to analyze the capillarity barrier behavior at the laboratory scale. The apparatus consisted of the transparent column, whose diameter is 155mm and height is 450mm. In the experiments, moisture sensors (METRE, EC-5) were placed, at various locations, at four different depths within the three soil layers (at 10 *cm*, 15 *cm*, 22.5 *cm* and 30 *cm* below the top surface, respectively) in test I and II while 5 different depths in test III and IV(at 10 *cm*, 15 *cm*, 22.5 *cm* and 30 *cm* below the top surface, respectively). HOBO-loggers were used to get the data of water content every 10 seconds. The density of coarse layer and the fine layer are 1.43 g/cm^3 and 1.33 g/cm^3 while the initial water content is 5%. Results from four sets of tests are reported on Fig. 6. In the column Test I ,II, III and IV.

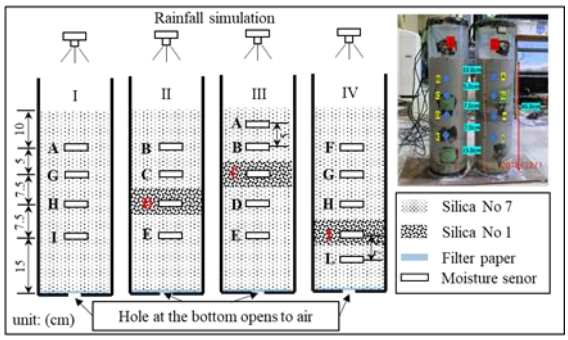

Fig. 5 Schematic view and photo of the experimental apparatus for column Test I, II, III and IV

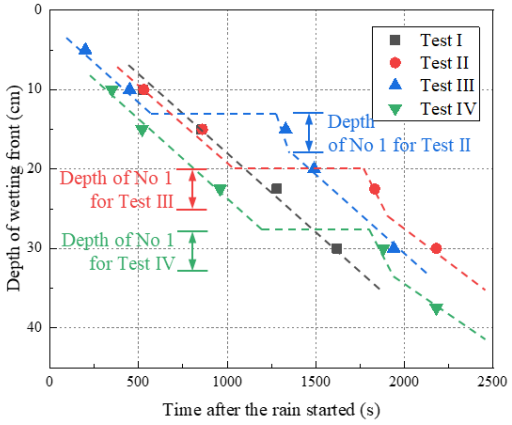

Fig. 6 Measured wetting front advancement for test I, II, III, and IV

Test procedures

The sand was packed into the cylinder and hammered to get the designed density in 5cm increments. During the wetting experiments, all of the column tests I, II, III and IV (Fig.5) has been subjected to a rainfall intensity of 75*mm*/*h* for about 2 hours (rainfall stage) until the attainment of a nearly steady state condition. And to a water drainage process of about 72 hours (dry stage). The bottom of the column has a hole (diameter = 35*mm*) covered with filter paper, which is open to the atmosphere.

Test results and analysis

Fig. 6 shows the progress of the infiltrate wetting front to a different depth. The advancement in the beginning of rain for 4 tests of the wetting front was similar for all cases because they had the same soil types in the upper soil layer. The difference occurred at the interface of the fine layer and coarse. For example, in tests I and II, the arrived time of water at the depth of 100 *mm* and 150*mm* are 510 seconds and 890 seconds respectively. However, the arrived time at central coarse layer (depth of 225 *mm*) were 1380 seconds and 1890 seconds respectively, which showed a time delay around 13minutes at this area. These results show that the progress of the wet front apparently stopped at the interface between the silica No 1 & No 7 when fine layer overlying the coarse layer since capillary barrier worked. In tests III and IV, the same phenomenon could also be observed at the interface when the depth of upper fine layers were different.

In addition, time histories of the volume water content of Test I ,II, III and IV (in Wetting Process) at different depths are illustrated in Fig. 7. Taking the original dada of Test I as an example (Fig. 7 I), Point B, C, D and E showed a sharp increase of soil water content when the wetting front arrived, which soon reached a stable and nearly saturated value. The probe D and E were higher than that at Probes B and C. This indicated that ponded infiltration had caused sealed air and result in an unsaturated condition in the top soil layer while it was not so obvious in the bottom layer. For Probes E in column, the obvious increase of soil water content not only occurred when the wetting front arrived but also after the wetting front had reached the bottom of the soil column (at about 56 min).

The reason is that the wetting front stopped for a while above the interface between the silica No 7 (which was fine layer) and silica No 1(which was coarse layer) while rainfall on the surface did not stop and rainfall water accumulated. Therefore, water started accumulating from the bottom and upwardly rewetting the sand.

As a result, the bottom of the upper fine layer had a higher water content in the multi-layered model (Tests II, III, IV) while it is lower in single layer test (Tests I). It means that water accumulation at the interface results a higher water content zone above the coarse layer in the multi-layer test. Compared Test III with IV, the area of higher water content zone became lager while the thickness of the fine layer overlying the coarse layer is lager.

Model Tests of the Multi-layered Slope Under Rainfall

To evaluate the effect of capillary barrier acting on a slope resembling, the experiments of multi-layered slope have been set up. The apparatus for the physical model experiments consisted of an inclined steel box, a rainfall simulator, water content sensors and in soil (Fig. 8 b). Details pertaining to each subsystem are as follows: (i) the inclined steel box was 1.0 m long, 0.3*m* wide, and 0.5*m* high; (ii) the sidewalls of the box were made of acrylic plate to visually observe the advance of the wetting front and failure process during rainfall infiltration; (iii) pictures were taken every 30 seconds by cameras (Fig. 8).

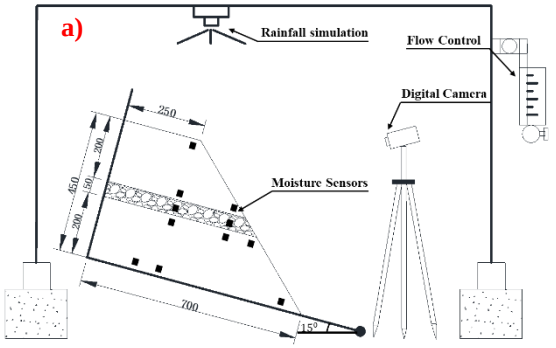

Fig. 8 a) Schematic diagram of the experimental apparatus for multi-layered slope under rainfall: side-view of the multi-layered slope

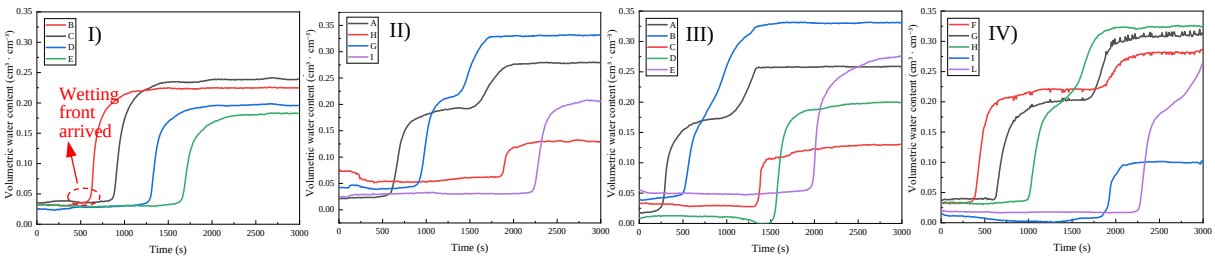

Fig.7 Variation in water content versus time in different observation points in the column tests. I) single layer column; II) multi-layer column; III) upper multi-layer column; IV) lower multi-layer column.

Fig. 8 b) Schematic diagram of the experimental apparatus for multi-layered slope under rainfall: apparatus for the physical model experiment

Testing procedure

Soil preparation. The silica No 1 and silica No 7 used to make the slope was dried in an oven for 48 hours. Then, the amount of water was added to the soil to achieve the initial water content.

Compaction of soils. Slope model was constructed in the model box when the soil has been prepared. The prepared soil was compacted and placed in a series of horizontal layers. Silica No 7 and No 1 were placed into the model box in layers and compacted to achieve the dry density of 1.33 g/cm^3 and 1.43 g/cm^3, respectively. Each layer was tamped equally rod to a thickness of 5cm and repeat the procedures until the height of slope was achieved. Fig. 8 a) shows the information about slope completed. Layers of Silica No 1 was placed as the coarse layer in multi-layer slope.

Positions of sensors and cameras. During the soil placement, moisture sensors were placed at the specific locations within the slope and time of recording the quantity of water content was 10 seconds. Cameras were put in 6 different locations to record the failure condition of the slope every 30 seconds. And 6 blacks dots were inserted laterally into the surface of the slope to as the marks.

Rainfall Simulation. When the initial readings of all sensors and camera were stable, the rainfall simulation commenced. A rainfall sprinkler (Fig. 8) was used to simulate artificial rainfall at different intensities from 45 *mm/h* to 85 *mm/h*. During the first rainfall, 4 hours was applied with 45 *mm/h*. Then the slope model was subjected to a drying process without rainfall; The second rainfall was applied for 4 hours with intensity was 45 *mm/h*. The experiment was stopped with the assumption that seepage had reached a steady-state condition.

Table 3 General information for the slope model experiment

		Group 1	Group 2
Inclined degree		0	15
Initial water content		5%	5%
Unit weight of dry soil (g/cm^3)		No 1 14.4 No 7 13.3	No 1 14.4 No 7 13.3
Rain 1	Intensity	45 *mm/h*	45 *mm/h*
	Duration	4 *h*	4 *h*
Drying Period 1		72 *h*	72 *h*
Rain 2	Intensity	45 *mm/h*	45 *mm/h*
	Duration	4 *h*	4 *h*
Drying Period 2		72 *h*	72 *h*

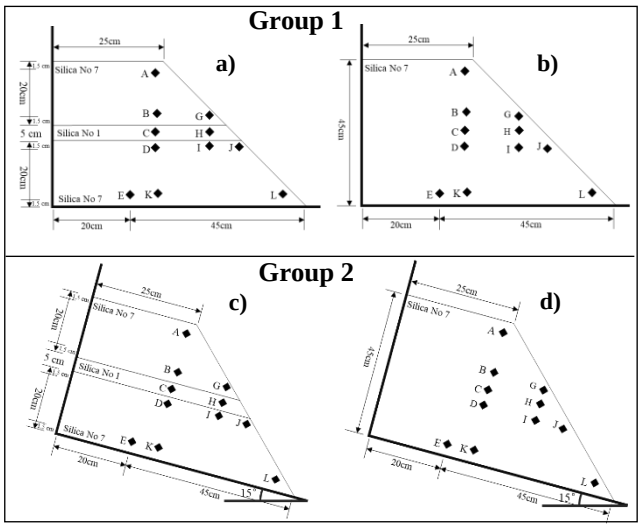

Fig. 9 Schematic diagram of the experimental apparatus for different groups of slopes under rainfall

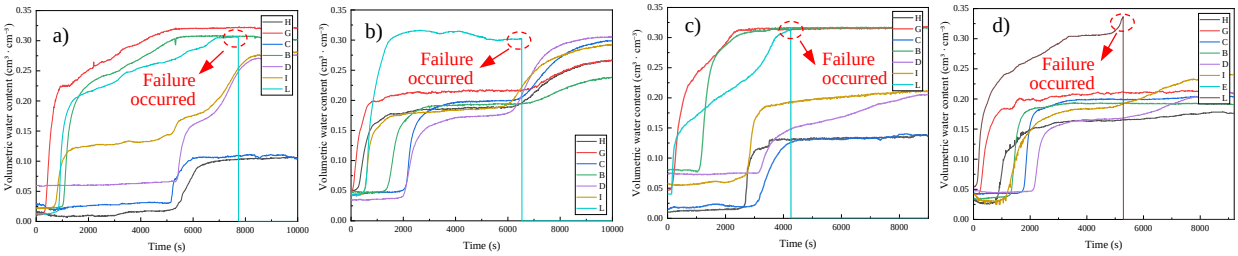

Fig. 10 Water content variation with time at different locations in the flat and inclined groups slopes. a) flat multi-layer slope; b) flat single layer slope; c) inclined multi-layer slope; d) inclined single layer slope.

Experiment result and discussion

In Fig. 10, water content decreases sharply which means the failure occurred at this point since the separation of sensors and soil. Comparing the water content at point L in the flat group (Fig. 10 a and b), point L reached to the saturated condition later in multi-layer since capillary barrier prevents the water infiltrate into the bottom which makes the slope more stable and caused a time delay in failure time. Comparing the water content at point L in the inclined group (Fig. 10 c and d), point L reached to saturated condition still later but the failure time is earlier (about 20 minutes) than single layer slope which means the multi-layer slope is more dangerous under rainfall situation.

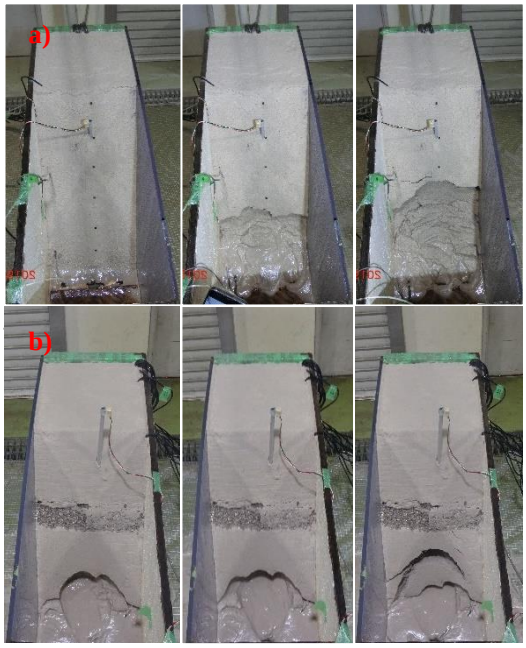

Fig. 11 Different failure modes occurred in the toe of slope under rainfall condition. a) sliding from toe in inclined single layer slope; b) piping occurred at the bottom in inclined multi-layer layer slope.

From Fig.11, different failure modes were observed during the slope experiments. Sliding occurred from the toe of slope (Fig. 11 a) gradually in single layer slope when the rainfall was applied. In the inclined multi-layer slope, piping occurred at the bottom of the slope. Piping (Fig. 11 b) occurred at the bottom when amount of water exists in inside the slope. Although point L reach to saturated condition is later in multi-layer slope, a failure time is earlier.

In order to clear the water movement across the interface, more sensors were put in the coarse layer (Point H, M, C, N and O) in inclined multi−layer slope experiment, 1st and 2nd rainfall were also applied which durations were 20 minutes and 50 minutes respectively.

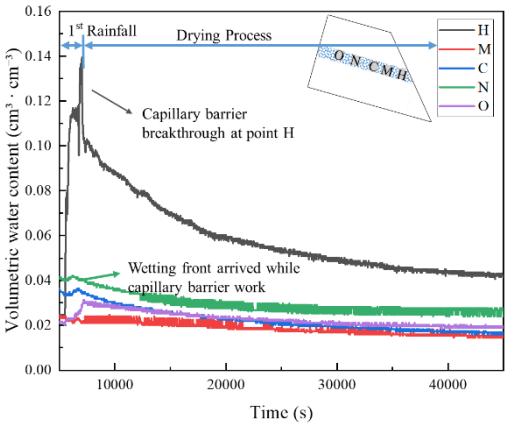

Fig. 12 Volume water content variation with time at different locations along the coarse layer during the first rainfall (20 minutes)

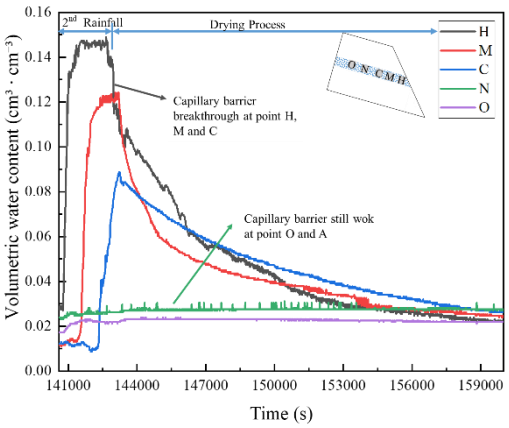

Fig. 13 Volume water content variation with time at different locations along the coarse layer during the second rainfall (70 minutes)

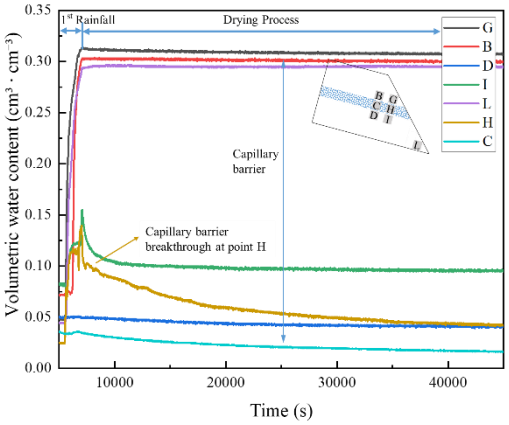

Fig. 14 Comparison between water content in different layers during the first rainfall (20 minutes)

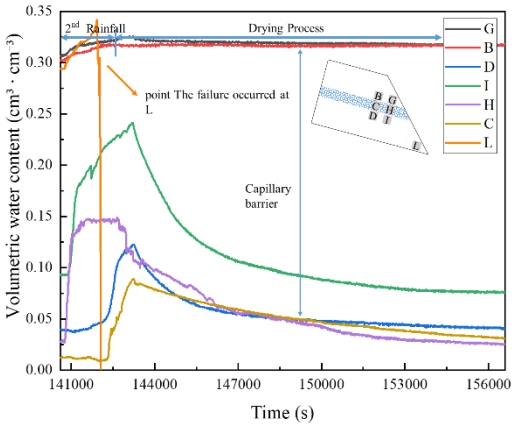

Fig. 15 Comparison between water content sensors in different layers during the second rainfall (70 minutes)

Fig. 12 (case c) shows the water content at point H, M, C, N, and O which at different locations in the coarse layer. The graph shows that when 1st rainfall was applied, the water content at point O and M increased firstly since the location was closest to surface, then N, C and M increased when wetting front arrived the interface and have a small flux before capillary barrier breakthrough. Meanwhile, water content at point H increased quickly and showed a higher water content in Silica No 1 since the capillary barrier didn`t work. When rainfall was stopped and the dry process started, water drained down easily with a rapid reduction in water content in the coarse layer. Similar behavior was also observed when the second rainfall was applied. It was found that the water content in point H, M and C increased gradually with the rainfall continued while water content at point O and N were stable (Fig. 13).

Fig. 14 shows the water content history of point B and G (above the coarse-grained layer), C and H (in the coarse layer) D and I (below the coarse layer) which were put in three different soil layers. This graph shows that water content above the coarse layer (point B and G) remain wetter than the soil below the coarse layer (point D and I). The sand above coarse layer showed 30% of volume water content all the time, suggesting that water didn`t drain down through the coarse layer when first rainfall was stopped while the below showed a sharp reduction in the dry process. A similar phenomenon was also observed when the second rainfall was stopped. When the second rainfall started, the sand above coarse layer at point B and G approached to saturated condition, and capillary barrier breakthrough at point H with water content increased quickly from H and I. Meanwhile, water content at point C and D were still in a lower condition and capillary barrier still work at the same time. Then water content increased at point C infiltrate into the next layer (point D). since the capillary barrier breakthrough gradually from point H to point C in the coarse layer.

DISCUSSION

The diversion capacity is the maximum flow that a capillary barrier can divert water flux and the diversion length is the horizontal length from the top of the slope to the breakthrough. In order to evaluate the diversion length of a capillary barrier, following assumptions are made: (1) suction profile in the fine layer could be estimated using the linear method [6]; (2) upper fine layers are thick enough; (3) the interface is inclined and longer than the diversion length; (4) continuous rainfall is applied on the top of the slope.

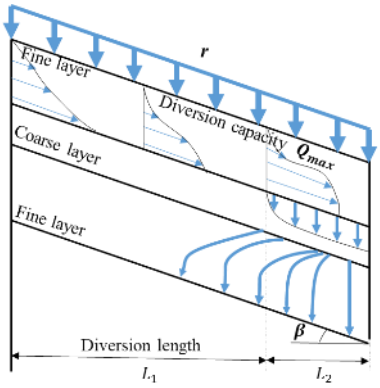

Fig. 16 Calculation of diversion length and capacity in an inclined slope

Based on these situations [4], diversion capacity and diversion length of capillary could be calculated, as the equation:

$$Q_{max} = \int_{z_{0_c}}^{z_{con_c}} v_h(z)dz \tag{2}$$

Where, Q_{max} is the maximum unsaturated lateral diversion capacity (cm^2/s); $v_h(z)$- velocity profile as the function of elevation (cm^2/s); z_{0c} - elevation of base of the upper fine layer (cm); z_{conc} - elevation where the maximum suction in the upper coarse layer (cm);

According to the linear method, elevation can be transformed into suction, and matric suction ψ at the contact interface between two layers must be continuous across the boundary:

$$\begin{aligned} z_{0_f} &= z_{con_c} \\ \psi_{0_f} &= \psi_{max_c} \end{aligned} \tag{3}$$

According to the equation (2) and (3), equation (4) can be obtained and can be deducted via Darcy`s law.

$$Q_{max} = \int_{\psi_{con_c}}^{\psi_{con_f}} v_h(\psi)d\psi = \int_{\psi_{con_c}}^{\psi_{con_f}} i_h k(\psi)d\psi \tag{4}$$

Where, i_h - the lateral hydraulic gradient, which equals to the tangent of slope tan β; $k(\psi)$– k function; β -inclined angle of slope(°).

The maximum lateral diversion flux is

$$\begin{cases} Q_{max} = k_{sat} tan\beta \int_{\psi_{con_c}}^{\psi_{con_f}} k_{rw}(\psi) d\psi \\ k_{rw}(\psi) = \dfrac{\left\{1-(\alpha\psi)^{mn}\left[1+(\alpha\psi)^{n}\right]^{-m}\right\}^{2}}{\left[1+(\alpha\psi)^{n}\right]^{m/2}} \end{cases} \quad (5)$$

According to the formulas (5), the lateral diversion capacity of the inclined capillary barrier can be diverted downdip per unit time per unit length along with the interface. Assuming the water lateral diversion length is L_1, the water lateral flux $Q(x)$ can be calculated by

$$Q(x) \approx r * L_1 < Q_{max} \quad (6)$$

Substituting the equation (6) into equation (5), Equation (7) can be

$$r * L_1 < k_{sat} tan\beta \int_{\psi_{con_c}}^{\psi_{con_f}} k_{rw}(\psi) d\psi \quad (7)$$

Diversion length is bounded by

$$L_1 < \frac{k_{sat} tan\beta \int_{\psi_{con_c}}^{\psi_{con_f}} k_{rw}(\psi) d\psi}{r} \approx 0.56m \quad (8)$$

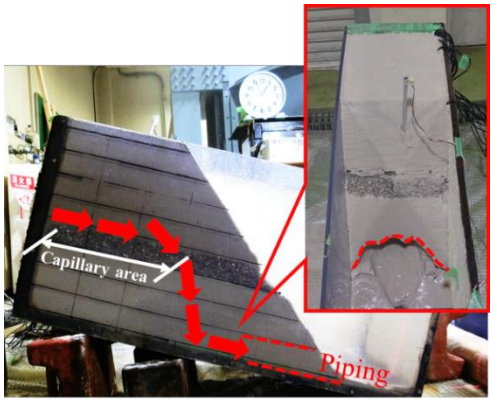

Fig. 17 Accumulated rainfall water infiltrate into the middle part of the slope which cause soil piping

According to the calculation of diversion length by simplified model, length of capillary area (Fig. 17) of this case is smaller than the length of interface. As a result, infiltrating water accumulated above the coarse layer and lateral water flow occurred along with the interface and capillary barrier breakthrough in the middle part of interface which results that water starts to infiltrate into the lower coarse layer at this location. A large amount of rainfall water will pass across the coarse layer and exist in the middle part of the lower fine layer, with rainfall event continued, soil pipes contribute to the quick discharge of rainfall water which results in slope stability.

CONCLUSIONS

The following conclusions are drawn from the present study. Different failure modes occurred in under rainfall condition in inclined multi-layer slope and single layer slope.

In the flat group, multi-layer slope was safer since capillary barrier works which prevent the rainwater infiltrate into coarse layer. Failure occurred at the bottom of slope, the toe of slope reach to saturated condition is later while failure time is also late. In inclined group, failure occurred at the same location, Although toe of slope reach to saturated condition is still later, the failure time is earlier.

According to calculate the length of capillary area and compared with experiment pictures, the diversion length is smaller in this case which allows the accumulated rainfall water infiltrate at the middle part of slope, which causes the soil piping and has an influence on the slope stability.

EVALUATING PASSENGER EVACUATION STRATEGIES IN A MASS RAPID TRANSIT STATION IN THAILAND

Nopadon Kronprasert, Ph.D.[1], Wisarute Kussalanuparb[2] and Thodsapon Hunsanon[3]
[1,2,3]Department of Civil Engineering, Chiang Mai University, THAILAND

ABSTRACT

Rail transit plays a significant role to serve major commuters in many metropolitan areas. In Bangkok metropolitan region in Thailand, several mass rapid transit (MRT) lines and stations are currently being constructed and operated. To perform efficient safety and operational performances, the analysis of pedestrian traffic flow within transit stations under normal and emergency circumstances is a crucial step for planning, design, and operations of station facilities. This study focuses on applying the pedestrian traffic simulation to model the characteristics of passengers and then evaluate passenger evacuation strategies in mass rapid transit stations. The pedestrian's walking behavior and characteristics were observed. Three evacuation strategies were examined including (i) Evacuation to Ground Level; (ii) Evacuation to Train; and (iii) Evacuation to Track Level. The evacuation times under a given number of evacuate occupants were evaluated, and the bottleneck of evacuation strategies was identified. A case study of Tao Poon mass rapid transit station was carried out. The results showed that the pedestrian traffic simulation technique provides great flexibility in modeling different scenarios in emergency situations and evaluating the dynamic nature of pedestrian flow characteristics. It is also useful to planners, designers, and operators of rail transit systems in practice.

Keywords: Rail transport, Evacuation, Safety, Pedestrian simulation, Station design

INTRODUCTION

Rail transit plays a significant role to serve commuters in many large and congested cities. In Bangkok metropolitan area, Thailand, two mass rapid transit (MRT) lines are now being operated: Blue Line and Purple Line; and ten more lines are being planned and constructed. According to the ridership data, the growth of passenger ridership is about 6% each year. With the increasing number of MRT lines and stations along with the estimated growth of passengers, evaluating the performance of station facilities and emergency evacuation strategies in MRT stations are needed.

Many international standard codes defined minimum evacuation requirements and calculation procedures, such as China CDM, Japanese Safety Evacuation and National Fire Protection Association (NFPA 130) [1]-[3]. For instance, NFPA 130, which is also being implemented by Mass Rapid Transit Authority of Thailand, specified two criteria for station evacuation efficacy. The first is referred to the time required to evacuate the platform within 4 minutes or less; and the second gives the time frame to evacuate the whole station and reach a point of safety within 6 minutes or less.

However, such standard codes provide macro-scale equations, which rely on static hand calculation. To overcome the limitation, a microscale study on evacuation using microscopic traffic simulation models is proposed. It is capable to simulate the dynamic environment of evacuation situations and to provide visible results through 3-D animations. More importantly, the use of simulation models in emergency situations provides great flexibility in modeling and evaluating various evacuation strategies.

This research aims to evaluate the effectiveness of evacuation strategies for passengers within mass rapid transit stations in Thailand. The focus of this research is on applying a microscopic pedestrian traffic simulation model to the evaluation of evacuation plans.

LITERATURE REVIEW

Research studies on emergency evacuation of passengers in a metro station have mainly focused on the development of sound and applicable evaluation methods for emergency evacuation. Two leading approaches were found in the literature.

First, the traditional approach, is a macroscopic equation of traffic flow theory [1]-[2]. The macro approach has failed to deal with interactions among pedestrians and between pedestrians and facilities [3]. However, they are still widely used due to its simplicity.

Second, the groundbreaking approach, is a microscopic pedestrian traffic simulation. The number of research studies on pedestrian evacuation using microscopic pedestrian traffic simulation have been increasing greatly since last decade. This is

because the micro approach accounts for the detailed representation of space, individual person and personal abilities and characteristics [4]. As a result, it is more reasonable and more realistic.

Using a micro approach, research studies have focused on determining the effects of a proposed policy on pedestrian facilities, evacuation behavior, and evacuation process. For example, Credit [5] developed various microscopic simulation scenarios to gain more understanding about pedestrian characteristics. The study compared one-way and two-way pedestrian traffic; examined the effect of an elderly pedestrian on system behavior; and evaluated the performance of lane-like segregation policy.

Moreover, Asano [6] proposed a microscopic simulation model for pedestrian flow evaluation. The study combined an operational model with a tactical model. The former considered anticipation behavior between two pedestrians based on collision avoidance concept and using the two-player game, and the latter considered the route choice behavior of individuals. The study suggested the usefulness of a micro simulation for precisely evaluating the Level of Service of the building design layout.

However, limited studies were a consideration of different evacuation strategies on pedestrian facilities, such as escalators and staircases. This subject is in fact needed for the safety design. Shi [7] investigated safety strategy of evacuation in a metro station in China by proposing a calculation method for evacuation time, and taking into consideration the metro station structure and layout features. The study used an agent-based simulation model to compare the evacuation time with the China CDM requirement.

Kallianiotis [8] compared two evaluation methods of evacuation performance in an underground metro station: the calculation method based on NFPA 130 design guidelines and Pathfinder software evacuation simulation package. The study showed both static hand calculation and dynamic environment simulation produce consistent results, but the static hand calculation requires a number of assumptions.

RESEARCH APPROACH

Study Area

The research selected Tao Poon MRT station, an aboveground interchange station connecting between 2 train lines (Blue and Purple Lines) as a case study. The station consists of 4 levels and details on station facilities of each level are shown in Fig. 1 to Fig. 4.

- Ground level (with four entrances/exits);
- Concourse level (with six emergency exits and two staircases);
- Blue-line platform (with six emergency exits and two staircases); and
- Purple-line platform (with two emergency exits and two staircases).

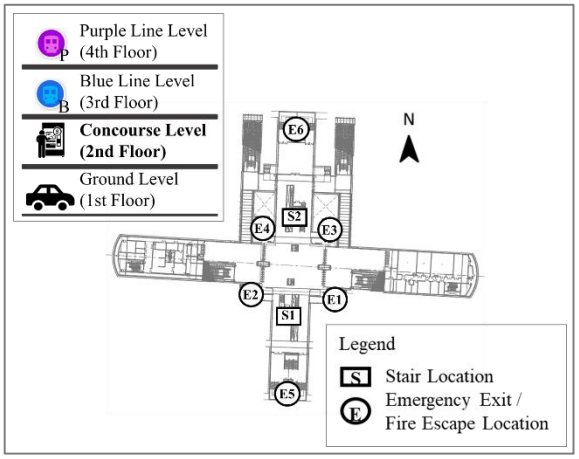

Fig. 2 Locations of emergency exits and staircases on Concourse Level

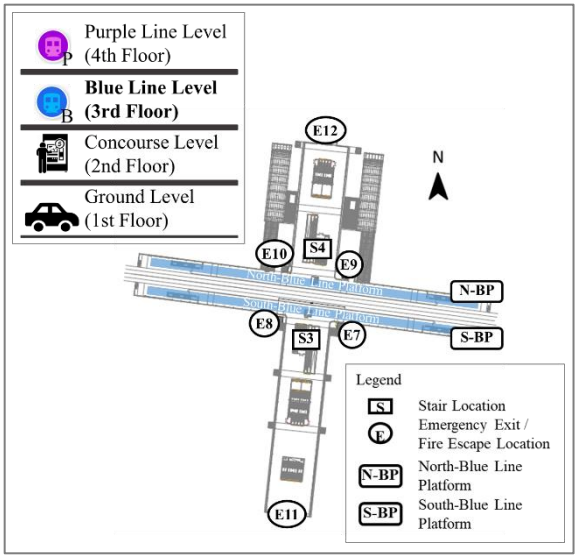

Fig. 3 Locations of emergency exits and staircases on Blue-line platform Level

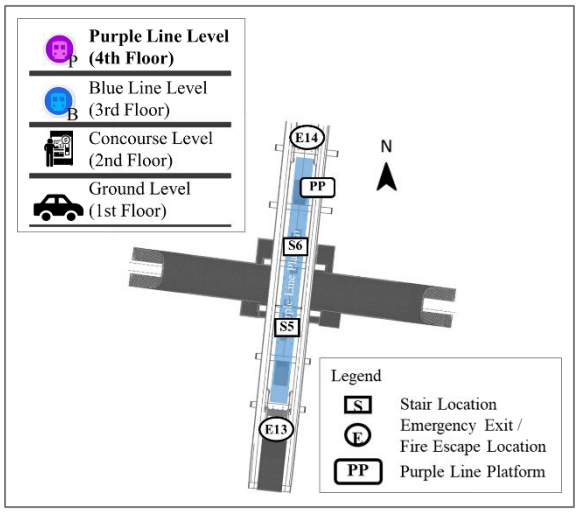

Fig. 4 Locations of emergency exits and staircases on Purple-line platform Level

Data Collection

To build up the model, the data collection is necessary to improve the model accuracy and realistic. Data needed for building the models include

Occupant Load

One of the key inputs in developing the evacuation model is the occupant load, which directly affects evacuation time. For Tao Poon MRT station, passenger volume was first collected during October to December in 2016 as shown in Fig. 5. The peak-hour period passenger volume was converted to occupant load.

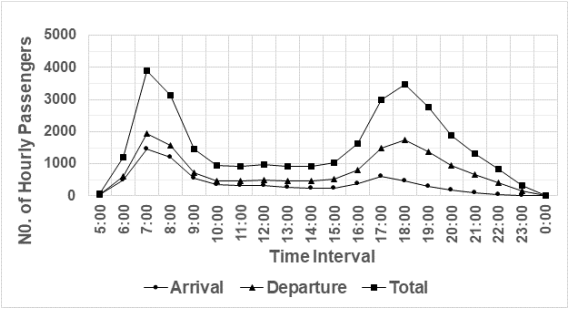

Fig. 5 Hourly passenger volume

The total number of occupants to be evacuated in the model is 1,010 passengers during the peak hour. They include 50 occupants on the Concourse level, 483 on Blue-Line platform, 322 on Purple-line platform, 105 occupants boarding on Blue-Line trains, and 50 occupants boarding on Purple-Line trains.

Walking Speed

Walking speed is another important parameter affecting the performance of evacuation strategies. Walking speed on different facilities: concourse and staircase were measured from CCTV installed in the station. Table 1 presents the calculated average walking speed by age group. A cumulative distribution function of Walking Speed is also shown in Fig. 6.

Table 1 Average walking speed by age group

Age	Average walking speed (m/s)		
	Concourse	Staircase (upward)	Staircase (downward)
Children	1.36	0.61	0.75
Adult	1.45	0.82	1.15
Elderly	1.06	0.55	0.81

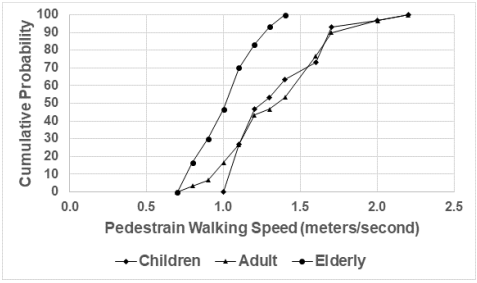

Fig. 6 Walking speed distribution by age group

EVACUATION MODEL

Evacuation situations of the case study were developed using a microscopic pedestrian traffic simulation program, PTV Viswalk. Figure 7 shows the snapshot of the simulation model of the Tao Poon MRT station.

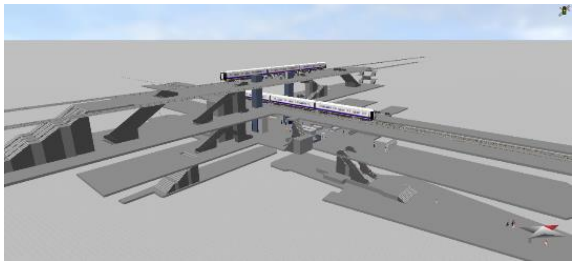

Fig. 7 Snapshot of Tao Poon MRT Station model

Three emergency evacuation strategies are proposed according to MRTA evacuation action plans. The effectiveness of each evacuation strategies were evaluated in the model.

- Strategy I: Evacuation to ground level: applied when fire is present.
- Strategy II: Evacuation to trains: applied when entrances and exits are not accessible or not considered as a safe area.
- Strategy III: Evacuation to track level: applied to the same situations as Strategy II, but trains are unable to operate by any means.

Strategy I: Evacuation to Ground Level

In this evacuation strategy, evacuation occupants in Tao Poon MRT station from all floors need to evacuate to the Ground Level through 4 entrances including Entrance A, B, C, and D. There are in total 6 designated evacuation routes as shown in Fig. 8.

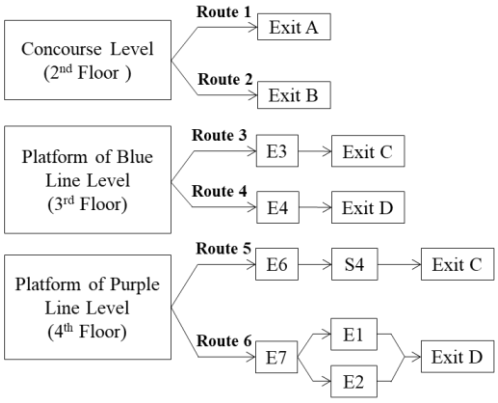

Fig. 8 Evacuation routes to Ground Level

Strategy II: Evacuation to Train

This evacuation strategy is to evacuate all occupants in the station to the nearest platforms and evacuated them by trains. This strategy consists of 9 designated evacuation routes, of which 6 routes evacuating from Concourse Level, 2 routes from Blue-line platform and 1 route from Purple-line platform as shown in Fig. 9.

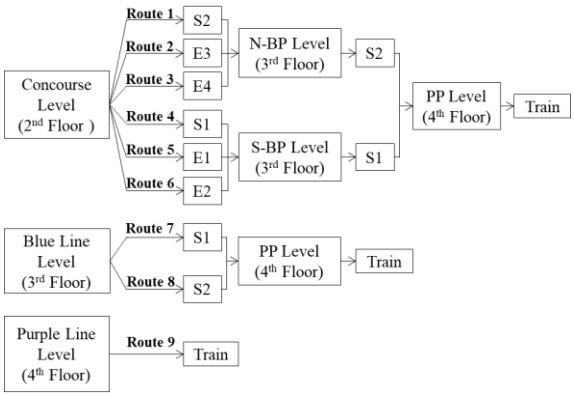

Fig. 9 Evacuation to Train Platform Strategy

Strategy III: Evacuation to Track Level

This evacuation strategy is similar to the Evacuation to Train strategy (Strategy II). Instead of evacuating occupants by trains, this strategy evacuates them to railway tracks, which are out of operation. It should be noted that to deploy this strategy, the electrical system needs to be cut off for the safety reason. This strategy consists of 9 designated evacuation routes as shown in Fig. 10.

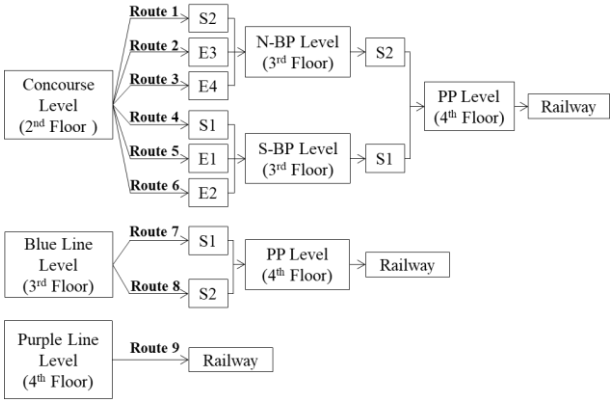

Fig. 10 Evacuation to the Track Level Strategy

RESULTS AND DISCUSSION

Evacuation time and pedestrian density of three strategies were measured, and their level-of-service (LOS) were evaluated based on Highway Capacity Manual [10] criteria shown in Table 2.

Table 2 Level-of-Service Criteria

LOS	Pedestrian Density (peds/sq.meter)	Color defined in the model
LOS A	≤ 0.179	Blue
LOS B	0.180 – 0.269	Cyan
LOS C	0.270 – 0.454	Green
LOS D	0.455 – 0.713	Yellow
LOS E	0.714 – 1.333	Orange
LOS F	≥ 1.334	Red

Strategy I: Evacuation to Ground Level

This strategy evacuates occupants to Ground Level or where entrances are located. Table 3 suggests that the evacuation time of 6 different evacuation routes meets the NFPA 130 thresholds. Route 2 evacuated occupants from Purple-Line platform has the longest evacuation time, yet it meets NFPA standard.

It should be noted the evacuation preparation time is excluded in the model. If 1-minute preparation time are included, the total evacuation time will be no more than 4 minutes.

Routes 3 and 4 are evacuating routes from Blue-line platform. They result in the evacuation time less than 2 minutes. Routes 5 and 6 are evacuating routes on Concourse Level, which are not as crowded as the platform levels. Thus, the evacuation times are also

less than 2 minutes including preparation time. Evacuation time and evacuation rate are shown in Table 3. The heat maps presenting pedestrian density are shown in Fig. 11.

Table 3 Evacuation time and Evacuation rate of Evacuation to Ground Level Strategy

Route	Evacuation time (mins)	Evacuation rate (peds/min)
Route 1	0.87	11
Route 2	0.72	11
Route 3	1.83	82
Route 4	1.62	94
Route 5	2.85	57
Route 6	2.95	58

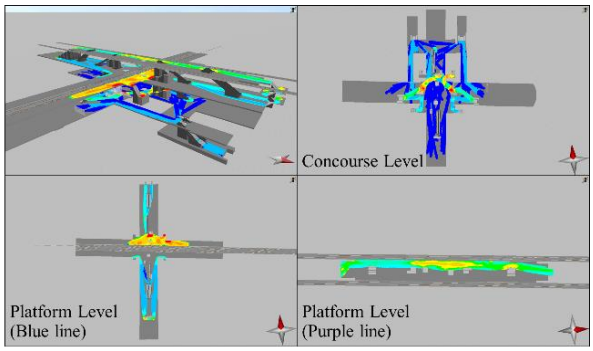

Fig. 11 Pedestrian Density in Evacuation to Ground Level Strategy

Strategy II: Evacuation to Train

In this evacuation strategy, all occupants are evacuated through trains. Table 4 shows that the longest evacuation time including 1-minute preparation time is below 6-minute threshold. However, if the preparation stage takes longer than 1 minute, this strategy may fail. Hence, more trains should be allocated in this evacuation situation. The pedestrian density heat maps are in Fig. 12.

Table 4 Evacuation time and Evacuation rate of Evacuation to Train Strategy

Route	Evacuation time (mins)	Evacuation rate (peds/min)
Route 1	3.6	1
Route 2	3.7	2
Route 3	4.5	1
Route 4	4.3	1
Route 5	4.3	1
Route 6	4.4	2
Route 8	3.9	87
Route 9	2.1	154

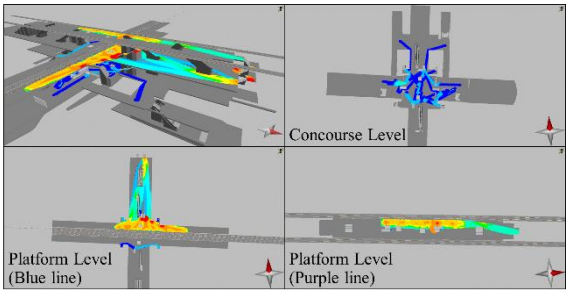

Fig. 12 Pedestrian density of evacuation to train strategy

Strategy III: Evacuation to Track Level

Evacuation to Track Level strategy can be deployed when the ground level or the road outside the station is not safe anymore, or in the case that trains are not available to help evacuate. In this strategy, occupants will be evaluated through train tracks. The results showed that evacuation time of this strategy are less than 3 minutes including preparation time. This is because occupants can evacuate immediately when an emergency occurs.

When deploying this strategy, safety concern is needed. There should be trained staff helping navigate occupants to the safe areas, and no train must be operated. The evacuation time in each route and density heat map are shown in Table 5 and Fig. 13.

Table 5 Evacuation time and Evacuation rate of Evacuation to Track Level Strategy

Route	Evacuation Time (mins)	Evacuation Rate (peds/min)
Route 1	1.8	4
Route 2	1.8	5
Route 3	1.7	2
Route 4	1.8	2
Route 5	1.9	2
Route 6	1.8	4
Route 8	1.6	211
Route 9	1.0	337

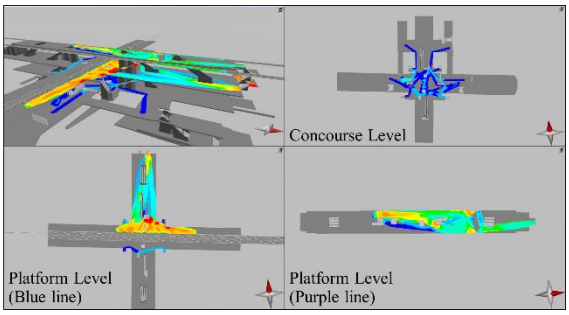

Fig. 13 Pedestrian density of evacuation to track level strategy

CONCLUSIONS

This research applies the microscopic pedestrian traffic simulation models to evaluate the effectiveness of passenger evacuation strategies within mass rapid transit stations in Thailand. Three strategies: Evacuation to Ground Level, Evacuation to Train, and Evacuation to Track Level. Input parameters in the models are the number of occupants, the distribution of walking speed and the locations of station facilities.

Evacuation strategies were evaluated in terms of the evacuation time, evacuation rate and pedestrian density. The results showed that all three evacuation strategies meet the requirement of NFPA evacuation time.

This research emphasizes the capability of a microscopic traffic simulation in modeling dynamic environment of evacuation events and its flexibility in testing different evacuation routes and strategies. It allows planners, designers, and operators of rail transit systems to determine whether certain building designs meet the requirement of a standard.

In future research, more operational strategies should be taken into consideration in order to obtain the most effective evacuation strategy, such as the use of escalators, and types of exit gates. Moreover, the severity of emergency incidents should be included in the model to evaluate more comprehensive and realistic passenger evacuation strategies for a mass rapid transit station.

ACKNOWLEDGMENTS

The authors would like to gratefully acknowledge the Excellence Center in Infrastructure Technology and Transportation Engineering (ExCITE) of Chiang Mai University for technical support and also appreciate the Mass Rapid Transit Authority of Thailand and Bangkok Expressway and Metro Public Company Limited for providing data and financial supports of this project.

SPACE RHYTHMS AND TECHNOLOGIES OF ASTRONOMIC NAVIGATION AS FACTORS OF CULTURAL GENESIS AND SAPIENTATION

Alina Paranina
Faculty of Geography, Herzen State Pedagogical University, Russia

ABSTRACT

The article proposes a new approach to these problems, developed on the basis of the navigation concept of the information modeling of the world. From the position of the navigation concept, the development of the geographical space-time played a leading role in the processes of human biological and supra-biological adaptation. Such an approach takes into account the fundamental role of the planetary-cosmic factors in shaping the structure of the geocultural space of the Earth and is consistent with the main provisions of the modern scientific picture of the world. On the basis of field and laboratory research, the instrumental possibilities of stone labyrinths and other prehistoric cultural heritage sites are determined. According to the results of the analysis of the structure of uneven-age objects, the reconstruction stages of the development of prehistoric astronomical orientation technologies are proposed. Comparison of classical signs and symbols with sun shadow charts allowed to substantiate the astronomical nature of the sign. The analysis of ethnographic materials has provided the preservation of archaic navigation technologies in everyday life practice, ornaments, mythological scenes, and sacral traditions. On the basis of generalization of materials, new models of cultural genesis and anthropogenesis, based on solar navigation, have been developed.

The results of the study show that the invariant structures of genetic and social memory are associated with the order of geographical space-time, which is determined by the shape, daily and annual movements of the planet Earth.

Keywords: Adaptation, Evolution, Intellect, Culture, Astronomical navigation technologies

INTRODUCTION

The primary process in the system of biological and supra-biological adaptation is navigation – movement and orientation in the geographical space-time. The main source of energy and information for processes occurring on the surface of the Earth is the sun. For most living organisms, sunlight is, at the same time, a “signal” and a “food” (productivity of nursing populations).

The exploration of space and its resources, the survival and development of living organisms provide various types of astronomical navigation: phototaxis, geo- and heliotropism, photoperiodism, biological clock, near and far migrations, orientation reflex. The ancestors of modern human were nomadic and accumulated skills of instrumental astronomical navigation, representatives of *Homo erectus* settled most widely.

By examples of historical time, it is possible to trace how transport communications and product flows shaped the structure and maintained the stability of socio-natural and socio-economic systems. Today, the direction of flows of matter, energy and information determines the network of water, land, air routes. However, even with a well-developed communications infrastructure, the need for navigation tools is preserved, and space remains the most reliable basis for navigation (while both GPS navigation and popular methods of orientation by the Sun and the stars are widely used).

The purpose of the article is to show the role of instrumental astronomical navigation in the processes of anthropogenesis and cultural genesis.

OBJECTS AND METHODS

The navigational models of cultural genesis and anthropogenesis were developed by the authors based on studies of the instrumental functions of cultural heritage sites (Stone and Bronze Ages). Reconstructions of algorithms for creating and navigating the use of northern labyrinths and petroglyphs of Karelia, objects of the Central Russian Upland, the Urals, the Caucasus and Gorny Altai and other objects were proposed.

We used standard field and cameral methods of geography and astroarcheology. The measurements of object sizes and distances, the definition of azimuths in the structure of objects, paleoastronomic calculations and anthropometric analysis were carried out. Lineament analysis of surrounding landscapes was carried out on the basis of maps and satellite images: lineaments were distinguished in

the landscape design – linear structures (straightened relief elements, chains of lakes, borders of wetlands, forests), rose diagrams of measured directions were constructed.

Studies have shown that at all sites, regardless of age (from 12,000 to 4,000 years old), the main tool was the shadow of the gnomon (reverse sighting). However, in the surrounding landscape stands out coarse and heavily destroyed boulder material, convenient for conducting near-horizon observations (direct sighting). In addition, linear relief elements and the shape of the horizon at the location of objects are convenient for astronomical observations, since they correspond to astronomically significant azimuths (*azimuth* is the angle between the direction to the north and the object or point of the horizon). The technological multi-layeredness of such complexes testifies to the continuous tradition and rational basis of the sacral status associated with the information function of the object and its place.

A comparative analysis of the graphs of the shadow of a sundial for the year (Fig. 1) and the structure of signs and images of different ages – from the Stone Age to our days (petroglyphs, solar signs, mythological images, modern sign systems) was carried out. Proof of the astronomical nature of the sign was received.

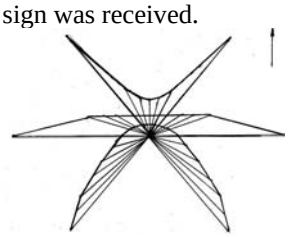

Fig. 1 The scheme of drawing the shadows of the gnomon in the days of the equinoxes and solstices is the basis of the solar signs and images: "horns", "wings", "fish tail", "lotus".

The results of the research have been summarized by the authors in the navigation concept of information modeling of the world [1, 2, 3]. The concept served as the basis for further research and theoretical constructions.

RESULTS AND DISCUSSION

Solar navigation as the basis of abstract thinking

Astronomical signs are abstract in shape (directions to horizon points, shadow graphics), but are specific in terms of content aimed at life support. The lack of road infrastructure, ready-made calendars and timers forced the ancient human to constantly reproduce information about space and time. This suggests that it was not the person who created the sign, but *the sign created the person.*

Let us list some arguments confirming our thesis that navigation in space-time by the Sun could become the basis for the formation of abstract thinking.

1. Astronomical landmarks are more reliable than objects in a dynamic landscape (because the super-system is more inert).

The dynamism of objects is determined by their mass (mass is a measure of the inertia of bodies). The mass of the Sun and the Universe is greater, and the rate of change is smaller compared to landscapes covering the surface of the Earth. The relative stability of astronomical landmarks was emphasized by ancient philosophers, who called the space surrounding the planet, the cosmos – "order". The dynamism of the elements of the landscape is reflected in ancient sayings "one cannot enter the same river twice", "everything flows, everything changes", "nothing lasts forever under the Moon". The inertial properties of objects of nature were taken into account in everyday practice. Thus, for astronomical observations of fixing important dates of the calendar, the most stable elements of the landscape were selected: weathering-resistant bedrock, tectonic cracks, large erosion and tectonic forms (outcrops, mountain peaks and ravines). High resistance to movement and destruction allowed to use the tool for a long time, to transmit information from generation to generation, thanks to the monumentality, many objects have survived to this day.

2. Light is the most powerful signal in geographic space.

This provision probably does not require special explanation. It is obvious that all living organisms obey daily and annual rhythms of illumination, because the whole range of environmental conditions (temperature, moisture, food supply) depends on the mode of lighting. The main correlations of the mode of illumination, physiological processes and behavioral reactions are "recorded" in the genetic program of biological species. Human evolution is associated with instrumental activity in general and instrumental astronomical navigation – in particular. In general, the development of technology is a factor in increasing human emancipation from environmental conditions. Reducing the power of direct environmental influences mitigates the effect of natural selection and the "editing" of genetic programs for space-time orientation. Hence the role of instrumental navigation technologies (positive feedback) is increasing.

3. Regular repetition of the light signal, with food reinforcement, shapes a conditioned reflex.

This provision is formulated in the studies on the physiology of higher nervous activity. It is based on the well-known experiments of academician I.P. Pavlov, who explained the mechanisms of formation of the conditioned reflex. Experiments with the dog, in the stomach of which the fistula was sewn to divert part of the gastric juice. Repeated combination of feeding with switching on the lamp leads to the formation of a stable connection between the two stimuli (1st irritant – light, 2nd – food). Subsequently, it was enough to switching on the lamp so that the dog started secreting gastric juice, which confirmed the excitation of the two nerve centers between which the connection was formed. Other conditioned reflexes are formed in the same way. Regular reinforcement of connections underlies the development of automatism (a dynamic stereotype is formed), and the lack of reinforcement leads to a complete weakening of communication. Navigation in space-time is carried out in order to efficiently use resources and predict adverse conditions that should be avoided. The combination of the sun's light signals and actions supported by food or other obvious success can form a stable link between the visual and other nerve centers.

4. The orientation reflex is paramount for adaptation.

This position is formulated in ethology – the science of animal behavior. It has been experimentally proved that the main unconditioned reflex that solves the problem of self-preservation of the body is the orientation reflex. For example, an animal placed in an unfamiliar room (or other new conditions) will not start eating until it has examined the room. All life requirements, including manifestations of the breeding instinct, are inferior in strength and meaning to the orientation reflex. When traveling in unfamiliar territory, the primacy of orientation can be felt on personal experience. According to the rules of navigation at each stop for rest, you should navigate around the map and compass, mark a point and record the track in the GPS navigator.

5. Language, as a model of the surrounding world and means of communication, begins with the designation of a place and time.

In the presence of road infrastructure it is much easier to navigate. However, the questions most frequently asked by strangers in a locality relate to the location of objects and directions. Since the information on space-time is of paramount importance, it can be assumed that the first words created by human meant space, time, distance and direction. The global invariant of the main geographical areas and universal solar navigation technologies easily explain the phenomenon of the Nostratic kinship of languages.

6. Position in space-time is unique for each object and can be the basis of its designation.

More than one object cannot be located at one point in space-time. The coordinates of an object in the geographical space-time reflect its functional connections in the structure of the system, and hence its quality. The positioning system is based on measurement and is associated with a number. Many languages have personal names and pronouns derived from numerals: Ivan is the first, Ben is the second, Thor is the third; I am the first, you are the second.

7. In anthropogenic, the average temperatures on Earth were negative, which increased the value of astronomical navigation.

A decrease in temperature is accompanied by a decrease in biomass, a restructuring of landscapes, a change in the ranges of biological species, and massive migration of biological species outside a well-developed and intuitively recognizable territory. By the example of the polar regions of the planet it can be seen that the increase in continental climate is accompanied by an increase in its contrast in space and in time, and a decrease in biomass is accompanied by a decrease in the stability of the landscape to any effects. Therefore, in a cold climate, it is advisable to nomadic (extensive) management of natural resources, the distribution of anthropogenic loads over large areas.

8. About 2.62 million years ago human led nomadic lifestyle and accumulated navigation skills.

The Paleolithic occupies 99% of anthropogenesis, this is the time of the Pleistocene cold spells and the appropriating economy (hunting, gathering). In the Holocene (about 10-14 thousand years ago), in the conditions of global climate warming, the human moved to a productive type of economy and settlement. In navigation, as in other activities, the complexity of practical tasks determines the level of mass knowledge and skills. Ethnographic studies on the comparison of the culture of hunters and farmers showed a significant simplification of the calendar, inventory and vocabulary in conditions of exhausting work in a limited space. This is consistent with the general rule of evolution – slow-moving and attached forms, as a rule, are simpler in

their organization than moving related biological species. Similar differences associated with the level of mobility can also be observed in individuals who are representatives of the same species.

9. Astronomical navigation is most in demand at sea, where there are no other landmarks.

There are no landscape landmarks in the open sea, and it is impossible to avoid access to the open sea (as a last resort, this may be the result of a storm). Sailing along the coast is dangerous: you can be aground or hit the ship on the rocks. Coastal waters are particularly variable in tidal seas with a shallow shore. The rugged coastline (with strongly inlet bays) makes one move from cape to cape. The development of the islands also makes you move away from the mainland and sail without landmarks on the way.

10. Solar navigation has no competition in polar days and white nights.

In the polar regions and in circumpolar regions, such phenomena of illumination as polar days and white nights are observed. Under the conditions of the polar day, the Sun is the only astronomical reference point that can be observed. During the white nights, the stars lightly stand out in the bright sky. The season of marine navigation in the seas of the Arctic Ocean is in the summer. In the polar regions, the summer season is a period of vigorous economic activity; the connection between solar heat and life is most noticeable here, which may not be so obvious in subtropical and tropical regions (especially in the arid part). For this reason, the ancient solar cult is most closely associated with the North. In ancient sources, the North is called the House of the Sun and by the fact that it spends the night there (goes beyond the horizon).

11. The regions of the Arctic are the most dynamic in the lighting regime (56° N – the Arctic boundary according to Eudoxus Cnidus).

In ancient times, classifications were created, with the release of the Tropic, the Arctic Circle, and other important boundaries. In the model of Eudoxus Cnidus, the boundary of the Arctic was drawn at a latitude of 56 °; in the history of science, this boundary was associated with the conditions of orientation according to the constellation Ursa Major. The azimuth calculations for each degree of latitude in the northern hemisphere show an additional navigational meaning of this boundary. At latitude 55.5 ° (latitude of Moscow), the points of sunrise / sunset at the solstice deviate from the meridian by 45 ° (azimuths drawn from the center of observation form a regular oblique cross, which, together with the main geographic directions, forms a wind rose or a solar sign with radial symmetry). Moreover, the navigation conditions to the north and south of this latitude differ dramatically: from the equator to this latitude (0 ° - 55.5 °), the azimuth of the sunrise changes gradually by 21.1 ° (66.6 ° - 45 °), and when moving north to the polar circle (55.5 ° - 66.5 °) – very dynamic: at 45 ° (45 ° - 0 °).

Solar navigation as the basis of cultural genesis

In the studies on historical geography V.I. Paranin showed that navigation by the Sun became the basis of the spatial structure and toponymic labeling of territorial systems [4]. These results are consistent with our results and conclusions obtained earlier – in studies of near-horizon observatories and the history of astronomical and mathematical knowledge [5, 6].

Today it is known that the images of the maps are preceded by the written language, and the earliest known maps are the maps of the starry sky. The oldest read entries are the tables by Ancient Babylon (6000 years ago) with calculations of the angular height of the midday Sun and the shadow of the figure of average height measured by the feet. The tables are compiled for seven latitudes (90° / 7) • n (where n = 1, 2, 3, ... 7), which are marked by the most grandiose ancient structures and graves of chiefs. For example, at a latitude of about 51.5 ° Stonehenge, Arkaim, Arjan, and many large cities in Europe are located. At latitudes 52 ° and 38°, the length of the shadow at the winter and summer solstice is 7:1 and can be recorded on a standard staff 7 feet long (the wish “7 feet under the keel” is associated with depth measurements of a pole of this size).

The development of navigation and the lack of state borders ensured freedom of movement and extensive intercultural communications, an intensive exchange of products and technologies. Still in the studies of V.I. Paranin it was proved that the Great Mussel of ancient authors was not a country in the modern view, but was a steppe region, symmetrical about 45 ° N. – the golden mean between the pole and the equator. The characteristics of the nomadic way of life, when in the summer the herds were distilled to the north and in the winter to the south of the Caucasus, is in good agreement with the conditions of the steppes of the temperate and subtropical belt and the position of the Caucasus as a regional climate-section. This model well explains the significant concentration of hydronyms with Iranian roots in the steppes of the European territory of Russia. The meridional connections are well traced along the major rivers of Eurasia, along the distribution areas of labyrinths in northern Europe, in the Mediterranean and in the Caucasus.

As was shown in our study on the ecology of

civilizations, the development of navigation technologies played the role of a locomotive of public consciousness and became the basis of the socio-cultural paradigm. Based on the technology of near-horizon observations, a model of consciousness is inevitably formed, reflecting the systemic "unity of significant parts". Examples of such thinking can be: the pantheon of the gods – the planets, the Moon and the Sun, the personification of the 12 months of the year and the forces of nature. In the structure of society, such ideas correspond to the institutions of chiefdom, social equality and democracy.

The gnomon sundial calendars allowed us to determine the geographical latitude and increase the reliability of the navigation system, link existing observatories to a regional and global network, measure the planet – i.e. create a world of chaos. But, the altered space was broken by a system of borders, and the mono-instrument itself became a model of the organizing center. Reflection in consciousness of the processes of polarization of reality (center – periphery, one's own – alien, living – inert, good – bad) is first noted in the culture of the Iron Age, and in the artificial urban environment reaches its apogee (war, all forms of dependence and the systemic crisis of civilization a consequence of limited thinking).

In the epoch of new technologies of navigation and communications, the humankind has the opportunity to return to holistic thinking, restore ties and, therefore, stability in the "human-nature" system.

We list some of the main directions of the influence of navigation technologies on culture.

1. Measurement forms a system of notation.

This item can also be considered primary for sapientation, since its processes are inseparable from the development of social culture and modern civilization. It is the *measurement with the help of tools* – the new field of activity on which a new system of concepts could have formed (all other spheres of life activity exist in animals, especially in social forms: construction, raising offspring, moving long distances). The very first measuring tool, a landscape transformed for orientation in space-time, is a powerful factor in the development of abstract thinking, since makes read artificially introduced markers, reflecting its vital quantitative characteristics (positive feedback).

2. On the petroglyphs of the Stone and Bronze Ages, simple geometric signs precede more complex artistic images.

The researcher of the Karelian petroglyphs F. Ravdonikas was the first to measure the azimuths of simple geometric signs (solar and lunar) and showed their high correlation with the astronomically significant azimuths of the Sun and the Moon (at the time of imaging, 6000 years ago). Our studies on synchronous objects of Karelia and Gorny Altai show that rocks with petroglyphs everywhere function as a scale / dial of a sundial calendar, and their creation and use is based on shadow fixation [7].

The sequential drawing of the shadow of the vertical gnomon gives an idea of the origin of the solar signs and typical attributes of mythological images (horns, fishtail, lotus and others). The shadow of a bent or T-shaped staff continuously draws the sign of the swastika. On the Tiunovsky stone (Vologda region, Russia), you can trace the stages of creating images from the Stone Age to the Middle Ages: first, graphical signs (lines, grids, radial labyrinths) oriented astronomically significant directions appeared, and a graphic image of a deer, a marquee , wood), then runic writing, and finally Christian crosses added.

3. The shadow graphics of the gnomon of sundial calendars correspond to a matrix of modern signs and sign systems;

It is known that the Phoenician script consisted of solar signs, and in linguistics and philology the first successful steps were taken in solving the task of "throwing a bridge" from solar signs to modern sign systems. Hermann Wirth created the phonetic systems of vowels and consonants associated with the annual solar cycle. In the studies of Olzhas Suleimenov, continuity in the morphology of existing sign systems is analyzed. The discussed communication is so obvious that it became a subject for discussion at classes in preschool educational institutions of St. Petersburg (children perform the task: on the matrix of 6 intersecting lines to find all the letters of the alphabet). It remains to add that the graph of the shadow of the gnomon in the days of the solstices and equinoxes represents the same six directions, but fills them with a concrete meaning.

4. On the height of a person, two basic measurement systems of the ancient world are intersected - anthropometric (fathom, foot) and astronomical (the length of the shadow of the figure measured by the feet).

Anthropometric measures of length were used almost everywhere until the twentieth century [8]. However, there is still no correlation of this measurement system with the astronomical system. Since they are related, it is obvious that all anthropometric measurements have an astronomical standard, i.e. linked to space.

5. Archaic measures of weight, money supply and nominal retain connection with the solar calendar system.

Studies in the history of the use of the gnomon have shown that many standards of measures and weights, a measure of money supply, music theory and the practice of creating musical instruments are associated with this astronomical instrument and calendar.

6. The consolidation of territorial boundaries, the development of all forms of social dependence, the struggle of urban religions with popular culture led to the loss of navigation skills and traditions.

Oases of traditional culture are preserved in different regions of the world. The territories that preserve the continuity of cultures from the Stone Age include the North and East of Russia. For example, the Mari people maintain the ecological traditions of respectful care for the landscape as a living organism, non-antagonistic world perception (there is no “evil”, there is only good and un-manifest good) cosmogonic thinking (Mari is the day of the heavenly girl, daughter Yume, who descended to Earth the sunbeam through the top of the birch; the holidays of the year – the creation of the universe, the solar system, the earth, life). In the culture of the Mari preserved traditions that are described by ancient authors during the practice of the Hyperborean peoples (voluntary death, burial in a basket on a tree, recollections of how a person knew how to joke and gave joy – laughter at the wake of the funeral immediately after the funeral). Many images of the gnomon have been preserved (a stick in the courtyard, an image of a golden needle and an embroidered shawl along which one can find a way, the word "bull" means "time"). However, the tradition of orientation is forgotten, because the territories are well known.

7. Improvement of technologies and the transition to new navigation tools is accompanied by the loss of the primary rational content of ancient objects of tangible and intangible culture.

Oblivion of ancient technologies is associated with the development of new technologies and road infrastructure. However, as revered objects and objects of tourism, they continue to provide a link between generations and cultures. Moreover, the ancient navigation tools continue to perform information functions – these are sources of information about the nature and culture of the prehistoric past.

Solar navigation in traditional culture

Based on an analysis of Paleolithic art, B.A. Frolov concluded that combined astronomical and mathematical knowledge manifests itself invariantly from the Atlantic to the Pacific Ocean, and the calendar can even be very different in the embodiment with peoples who live next to each other.

Traditional cultures retain the system of festivals tied to the astronomical calendar and the concept of the divine-cosmic nature of human (the goddess-mother, gods who preserve life on Earth: the Sun, planets, constellations). According to the literature and oral reports of the respondents, until the end of the twentieth century, in all regions of Russia and in adjacent regions, the gnomon was used for navigation (a human figure, a staff or a shepherd’s whip, wood and stone, as well as the shadow of an object sandwiched between the fingers, move on the palm).

In ethnography, only formal similarity of objects and contexts is considered, but functional analysis is also possible. In practice, you can make sure that there is no difficulty in uncovering objectively the reflection of astronomical navigation technologies in the structure and decoration of clothing and household items, sacred objects and mythopoetic subjects. As an example, we compare the gnomon of sundials, calendars, and a number of the most typical images presented in all archaic cultures and with surprising similarities.

World tree

In terms of shape and characteristics, the World Tree is one of the most obvious options for reflecting the real gnomon and the abstract concept of the earth axis: the Tree of Life, as it is called, connects cosmic and terrestrial space, cyclical and linear time. The crown of a tree can be represented as a set of rays passing through the top of the gnomon, into the roots – as lines of shadows radially diverging from its base. But another option is also possible – an inverted tree (in the hands of Varuna): its roots go back to Space, and the branches are directed to Man. In all cases, it seems that the real instrument-gnomon is primary in relation to the abstract concepts "earth axis" and "axis of the world", since they could be formed only on its basis.

The Maypole is still set on the eve of May 1 in the center of many European settlements – it is a birch, spruce or a tall trunk cleared of bark, decorated with ribbons and a wreath. In calendar (astronomical) holidays, the world tree is placed in the center of the labyrinth, on the main square, in the house. Round dances lead, gifts and ribbons are hung on the top.

In the labyrinth, the place of the world tree can be occupied by a girl, with ribbons in hand, the other ends of the ribbons can be held by the participants of the round dance. Archaeologists note that even in the art of Paleolithic, the theme of the world tree is closely intertwined with the theme of the Great Goddess.

Mother Goddess image

Research conducted by P.I. Kutenkov, devoted to the female calendar of the Eastern Slavs, allow us to distinguish the features of the Mother Goddess in dress and status of the woman, preserved in traditional culture from the Stone Age.

Comparing the image of the Mother Goddess in different cultures allowed Yu. Ratnikova to show the continuity of the main functions (fertility and ancestor worship) and the relationship with the equinoxes (Beltyne and Samhayn of the Celtic calendar), which for several millennia have shifted due to the precession of the equinoxes. The image of the goddess with snakes (figurines from Crete) is convincing as a symbol of the equinox axis, which divides the annual circle into winter and summer, the time of withdrawal, immersion in deep sleep (anabiosis), and the time of returning to life.

The researcher of the traditional cultures of the Volga region I. Kulyazheva gives evidence that the image of the Mother Goddess is the embodiment of the earth's axis. The horses held by the Mother Goddess in the canonical plot (in some cases, birds or deer) symbolize the unity of the diametrical positions of the starry sky, describing a 360° circle in 24 hours (the constellation Ursa Major and Ursa Minor, the cosmogonic legends of the Mari people can be replaced by elk or bird).

It should also be remembered that the formation of ideas about the axial rotation, shape and size of the planet is associated with the practical use of the vertical gnomon, one of the variants of which was a human figure. The traditional account of the months of the year among the peoples of Siberia is connected with parts of the human body. In parts of the palm of your hand were the solar-lunar calendar and the countdown of the hours of the day, many peoples of Europe and Asia. Calendar functions in traditional culture were performed by jewelry and clothing items (hats, embroidery and ornament).

Mount Meru

The use of the first protractor, the solar gnomon, in contrast to previous technologies at near-horizon observatories, allows us to determine the spherical shape of the Earth, the geographic latitude of the observation point, to build a regional and global geodetic network. The oblique gnomon can be viewed as a projection of the earth's axis.

From the epoch of mastering gnomon technology and the information function of a spear, whip, belt and staff, *the World* exists as *measured* chaos, and the centers of territorial systems are the starting points and the place where standards are preserved. In local territorial systems, the role of the gnomon and the markup can be performed by the combination “Sacred tree-stone” (traditionally symbolically preserved in the Baltic States), “The sacred grove with elements oriented along the horizon is stone” (in Mari El), a pole in the yard of a rural house (Mari El, Poland), stone stela (in villages of Armenia, Dagestan). The centers of large territorial systems at different times were Kailas – In Tibet, omphaly – Delphic (Greece), Tours (Ireland), Jerusalem and many others.

According to the authors of the article, in the considered navigation context, the center of the planetary scale could only be a pole – a point on the earth's surface, lying on the axis of rotation of the planet and the celestial sphere. Today, the poles are the fixed base of the network of coordinates, the intersection of the *meri*dians "meridianus" is "midday" (from "meridians" to "noon", the addition of the *medius* "middle" and dies "day"). In ancient culture, the pole and the earth's axis could receive the status of sacred objects, thanks to its stability and reliability (the direction to the north is easily determined and therefore serves as the main reference point and reference point). In this context, the location of the mythical Mount *Meru* in the North is the result of the fusion of mathematical, conceptual and mythological modeling of reality, characteristic of science as a form of knowledge.

Bowl

The axial rotation of the Earth and the time of day can be determined using a bowl filled with water. This tool replaces the gnomon at night and in cloudy weather. Water, like Foucault's pendulum, retains its initial position in space, and the bowl rotates along with the earth and the meridian (like a dial). The role of an arrow in such a watch can be performed by a light object placed on the surface of the water mass, and the time stamps are the shape of an edge or an ornament. Observation of a circular motion of such an “arrow” (15° per hour) inevitably gives rise to the idea of the axis of rotation, and the absence of a tangible physical body leads to the search for means of expression of this important knowledge. So the bowl is combined with the image of the world tree. Another option for combining the bowl and the gnomon is scafis (Fig. 2).

In ethnography, steady (canonical) compositions

depicting a bowl and a world tree are considered as a display of three levels of the world: the lower one – the roots (the older generations, the past, the underworld, a different light), the middle world – the earth (the human world, the family, the present), the upper – the sky (world of gods, future). Two birds facing the trunk are a pair ready to make a nest.

Comparison with astronomical navigation technology allows us to associate the three-part composition as a whole (the presence of the 3rd axial element) with the definition of the middle of the day, and the triplicity of symmetric elements with three nodal points in the trajectory of the midday shadow, which allow to distinguish astronomical seasons: solstice, medium – at equinox, short – in summer solstice.

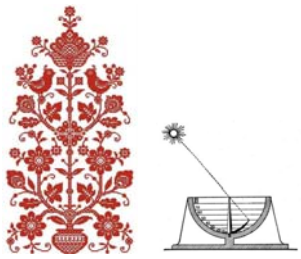

Fig. 2 The World Tree in the Bowl and the Tool – Bowl with a needle of Eratosthenes.

In ancient art this story has a wide distribution and independent significance (sometimes birds are replaced by two half-opened flowers submerged in water). It can symbolize the relationship of astronomical navigation, the cycles of the planet and biological rhythms (birds singing and blooming at the dawn – the biological clock). The consistency of astronomical and phenological cycles is also recorded in folk calendars.

INFORMATION POTENTIAL OF ASTRONOMIC NAVIGATION TECHNOLOGIES

Planetary invariant, regional specificity and unique local conditions

From the definition of culture as a form of suprabiological adaptation, it follows that its diversity is associated primarily with the dynamics of the geographic environment. Then the cultural invariant reflects the general that is necessary and accessible anywhere in the geographic space.

The universality of solar navigation technologies is based on the Earth-Sun global invariant: at every point of geographic space at noon the N-S direction can be determined, at sunrise / sunset at the equinoxes – the W-E direction.

The greatest regional differences can be observed in different zones of illumination (separated by the tropics and the polar circles).

The ratio of the general and the particular in the objects of navigation purpose transfers the rule “technologies are universal – the objects are unique”. Objects are unique because they differ: in latitude, position of the earth's axis at the time of creation, height above sea level, the shape of the horizon.

Unified language of the Universe

Since there are planetary systems like ours, extrapolation of this experience beyond the limits of the geographical envelope allows us to simulate a single language of the Universe.

CONCLUSIONS

The navigation concept of information modeling provides a holistic view of the development of the "nature-man" system as a breed and an inseparable part of the Universe.

DRAINAGE DENSITY AND RAINFALL INTENSITY AS SLOPE FAILURE SUSCEPTIBILITY INDEX IN SMALL CATCHMENT AREA

Hirohisa Kinoshita[1], Shuichi Hasegawa[2], Shinji Nakai[1], Atsuko Nonomura[2], Minoru Yamanaka[2]
[1]Fukken Co., Ltd, [2] Faculty of Engineering and design, Kagawa University

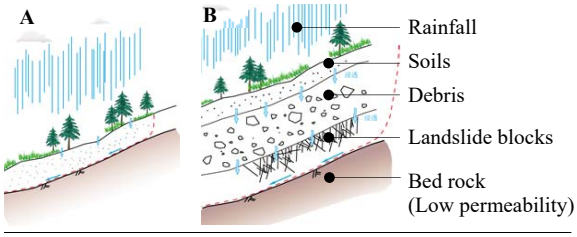
ABSTRACT

Drainage density exhibits spatial characteristics that provide important information about the nature of the drainage basin. For example, permeability of the bedrock, ground-water movement, infiltration capacity of the soil mantle, surface-water discharge, erodibility of the surface materials. These characters represent the dominant factors that affect to frequency of slope failure, landslide and debris flow. And mainly incentive of slope failure is rainfall. The rainfall intensity is proportional to the susceptibility of slope failure occurrence. The authors investigated the relationship between drainage density and rainfall index, through the past disasters in southwest Japan. The drainage density of occurred debris flows are higher than the basin of occurred landslide. And the rainfall intensity leading to slope failures are higher than debris flows. Drainage density would be good index for evaluation of susceptibility that rainfall-induced landslide, slope failure and debris flow in small catchment area.

Keywords: Drainage density, Slope failure, Small catchment area, Rainfall index R', Risk management

1. INTRODUCTION

Recently, extreme weather related to global warming frequently occurs with many record-setting rainfall event all over the Japan, which have induced slope failure. Examples of recent rain-induced slope failure and debris flow are Hiroshima disasters in 1999 and 2014, West of Japan disasters in 2018. Slope failure and debris flow are shown to be parts of denudational processes that developing drainage net. The geomorphic character of drainage basin has suggested by Horton [1], thus defined drainage density as total stream length per unit area of a river basin. Drainage density varies according to several environmental factors. For example, highly erodible and impermeable rocks tend to have higher drainage density than areas dominated by resistant or permeable rocks, slope, mean relief and vegetation cover can also affect drainage density. Carlston [2] described the relation between hydrology and geomorphology, which presented evidence that drainage density, surface-water runoff, and the movement of ground water are parts of a single hydrologic system controlled by the transmissibility of the bedrock and its overlying soil mantle. Transmissibility or permeability is the most important characteristic that provide drainage density in terrain. Onda [3] stated that terrain with higher drainage density and thin soil layer was comparatively damaged more by shallow seated landslides, because of perched ground water at the soil-bedrock interface. On the other side, in the lower drainage density area occurred deep seated landslides due to the rise of ground water level in the fractured bedrock. Hasegawa [4] noticed that during heavy rainfall, area having higher drainage density is usually prone to shallow seated landslide , in the other hand, Large scale landslide tend to occur in area with lower drainage density, And large scale landslide is frequent in area having lesser than drainage density (Fig.1).



Model	Thickness of soil and debris	erodibility of slope	infiltration capacity	runoff character
A	thin	less resistant	small	surface water
B	thick	more resistant	large	ground water

Fig. 1 Relation between drainage density and hydrological structure of slope [4].

Consequently, drainage density may indicate the slope failure type of mass movement and proportional to susceptibility or frequency of slope failure. In this study, relation between drainage density and the rainfall index for landslides and debris flows occurrence are analyzed in southwest Japan. The area of study comprises 45 debris flows, slope failures and landslides whose occurrence times are confirmed were selected from Hiroshima disasters in 1999 and 2014, 2004 Typhoon 21 and 23 disasters in Shikoku, 2009 Hofu rainstorm disasters, 2010 Shobara rainstorm disasters and 2011 Kii Peninsula rainstorm disasters (Fig.2).

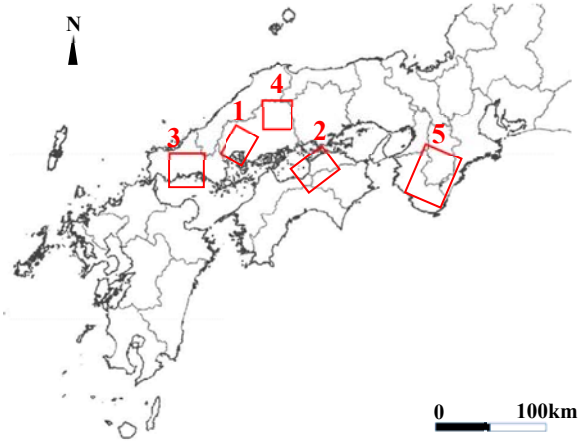


Fig. 2 Study area. 1: 1999 and 2014 Hiroshima disaster of debris flows by rainstorm, 2: 2004 Typhoon 21 and 23 disaster of slope failures in Sikoku, 3: 2009 Hofu disaster of debris flows by rainstorm, 4: Shobara disaster of debris flows by rainstorm, 5: 2011 Kii Peninsula and Mountains disaster of landslide and rock avalanches by Typhoon 12.

2. METHODS

We examined relationship between drainage density and frequency of debris flows and slope failures occurred by intensity of precipitation.

2.1 Drainage density measurement

The extent of channelization can be represented by measuring drainage density (Dd), where Dd=L/Ad, the total length of all channels (L) divided by the area of the drainage basin (Ad). In this study, measurement of drainage density conformed to methods that proposed by Kinoshita [5]. In the paper, dissected correlation coefficients between drainage density (Dd) that were calculated from several scale base map, basin area, channel line and density of slope failures (Df) of a small catchment area. It was derived the approximately equation, Df=2.50×Dd+0.28. In the measuring of drainage density several criterions and rules were used following, (1) Base map; Using base map is 10-m resolution DEM, (2) Definition of valley; Valley is defined by pixel whose average curvature is equal or larger than 1.0. (3) Draw thin line on valley; If width of valley is over one pixel, the maximum pixel is selected. (4) Calculation of drainage density; Drainage density [km^{-1}] is total pixel of channel lines per unit area, where numbers of pixels defined as valley by 10m per numbers of pixels defined as catchment area. (5) Size of catchment area; Catchment areas were selected by topographic map. Area of a catchment area is around 1km2 that located in divides. Fig.3 shows an example of measuring drainage density of small catchment area.

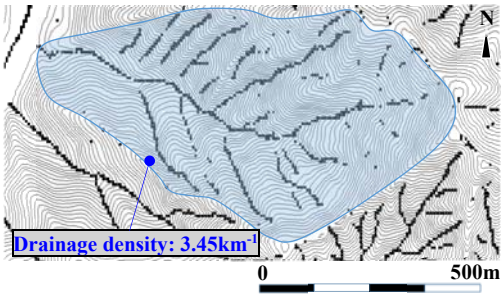

Fig. 3 An Example of measuring drainage density, using 10-m resolution DEM. The extracted channel lines are comprised of pixels. Drainage density equal number of channel line pixel per all number of drainage basin.

2.2 Rainfall index R'

Generally, the probability of slope failure occurrence varies with the precipitation. Rainfall indexes relating to rainfall-induced landslides and debris flows have two parameters which long-term rainfall such as duration and rainfall intensity for a short term. But it is difficult that using two parameters for comparison with drainage density. So, in this study, we apply a new rainfall index R' proposed by Nakai [6]. It became possible to express influence of both preceding-long term rainfall and present-short term rainfall by a single value of R' showed Figure 4 and Equation (1).

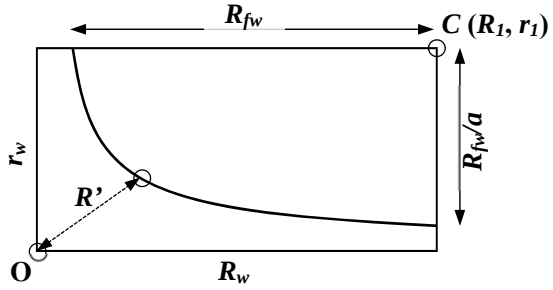

Fig. 4 Definition of the rainfall index R_{fw} and R' [6]. This parabola model depicting the variation of R' value from long-term effective rainfall to Short-term effective rainfall.

$$R' = R_{fw0} - R_{fw} \quad (1)$$

$$R_{fw} = \sqrt{(R_1 - R_W)^2 + a^2(r_1 - r_w)^2}$$

Where
R_w: Long-term effective rainfall (mm)
r_w: Short-term effective rainfall (mm)
R_1: Point of reference on horizontal axis
r_1: Point of reference on vertical axis
a: Weight of coefficient
R_{fw0}: Value of R_{fw} when Long-term and short-term effective rainfall are zero

3. RESULT

3.1 Drainage density in the basin of include slope failures

At the measurement of drainage density, we have adopted slope failure and debris flow disasters which can be referred to occurrence place and time record. The extent of calculation is set a limit to small catchment area where ranged from 1 to 1.5 km^2, abide by Kinoshita [5]. Figure 5 showed an example of drainage density in the basin of include landslide which induced by 2011 Typhoon 12 in the Kii Peninsula and Mountains. Upper of Fig.5, showed the aerial photograph around the landslide that occurred in Nosegawa village, Nara prefecture. The topographical map (lower figure) express the aspect of drainage net which represented by pixel lines. Red area and line are approximately moving body and point of main scarp of landslide. Table.1 shows the values of drainage density in the basin where occurred disasters of landslide, rock avalanche, slope failure, debris flow. As previous studies stated, the frequency of debris flow where Granite region are higher than the other bedrock region. And the drainage densities are larger than other lithologic basins.

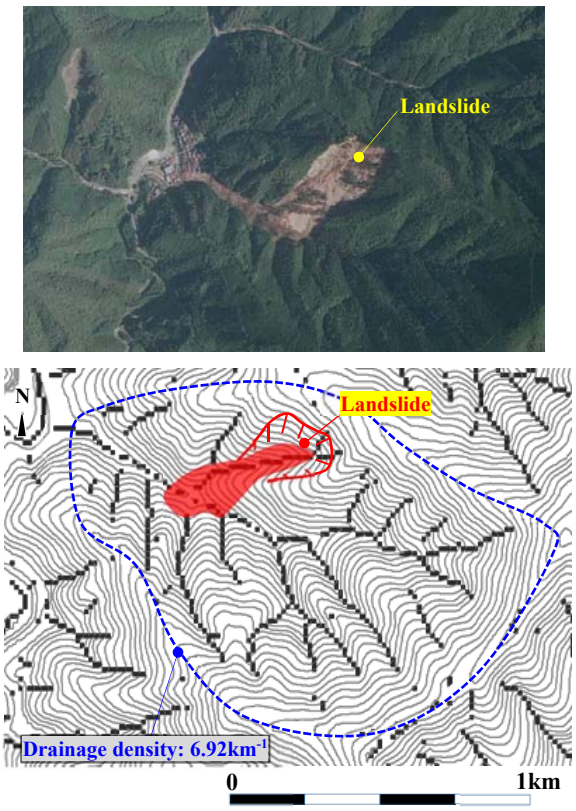

Fig. 5 A result of measuring drainage density where occurred landslide in Kitamata, Kii Mountains. The measuring area (blue dashed line) is monolithologic basin.

Table 1 Drainage density of past disaster region

No. (fig.1)	Facter of failure	Main type of failure	Bedrock lothology	Average of D_d (km^{-1})
1	1999 rainstorm	debris flow slope failure	Granit Rhyolite	8.34
1	2014 rainstorm	debris flow slope failure	Granit Andesit	7.86
2	2004 Typhoon21	slope failure debis flow	Sandstone Mudstone	6.64
2	2004 Typhoon23	slope failure landslide	Metamorphic -rock	4.81

Figure 6 shows example that drainage density in the basin formed large landslide block. This site located in metamorphic rocks area, in Tosa town, central Shikoku Mountains.

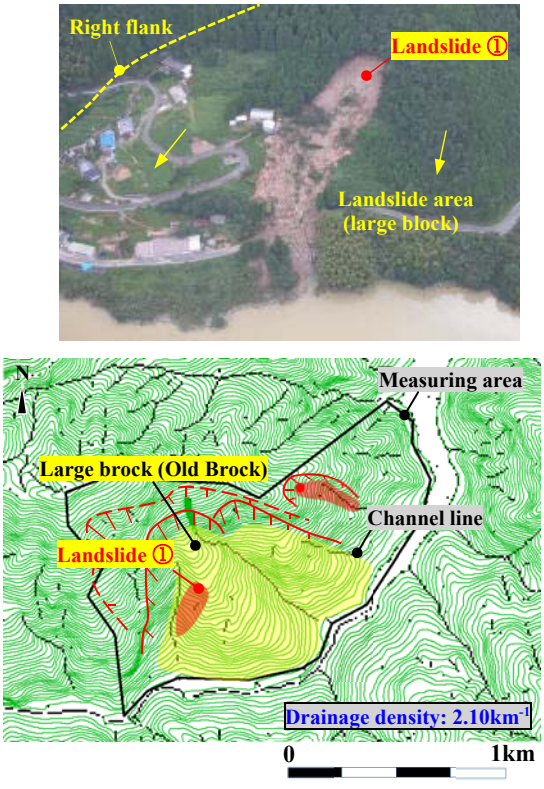

Fig. 6 Example of landslide that included larger landslide brock (old brock).

Lower part of fig.6, result of measuring drainage density around large landslide basin. The channel lines are fewer than the other basin (in this case, D_d=2.10 km^{-1}).

3.2 Application of the rainfall index R' to past rainstorm disasters

We establish rainfall index R' that adjusted to regional rainfall properties. Equation (1) indicate the state that the risk of landslide increases into increment of R'. The calculation of R' value may be affected by distance from drainage basin to gaging station. Therefore, in this study, the rainfall data adopted gaging station data, less than 2.5 km. Table 2 shows R' values on several place where occurred debris flow or landslide disasters.

Table 2 The results of estimating R' in the basin of disaster occurred (examples of 1 and 5, fig1).

The average of R' in landslide site, are larger than debris flow site.

Figure 7 showed one measuring result of R' values spatial distribution that involved by rainstorm of2011 typhoon12, in Kii Mountains. The R' value increase into warm color. Middle and Lower map of Fig.6 are expanded A (Ui) site and B (Tsubouchi) site with round number contour.

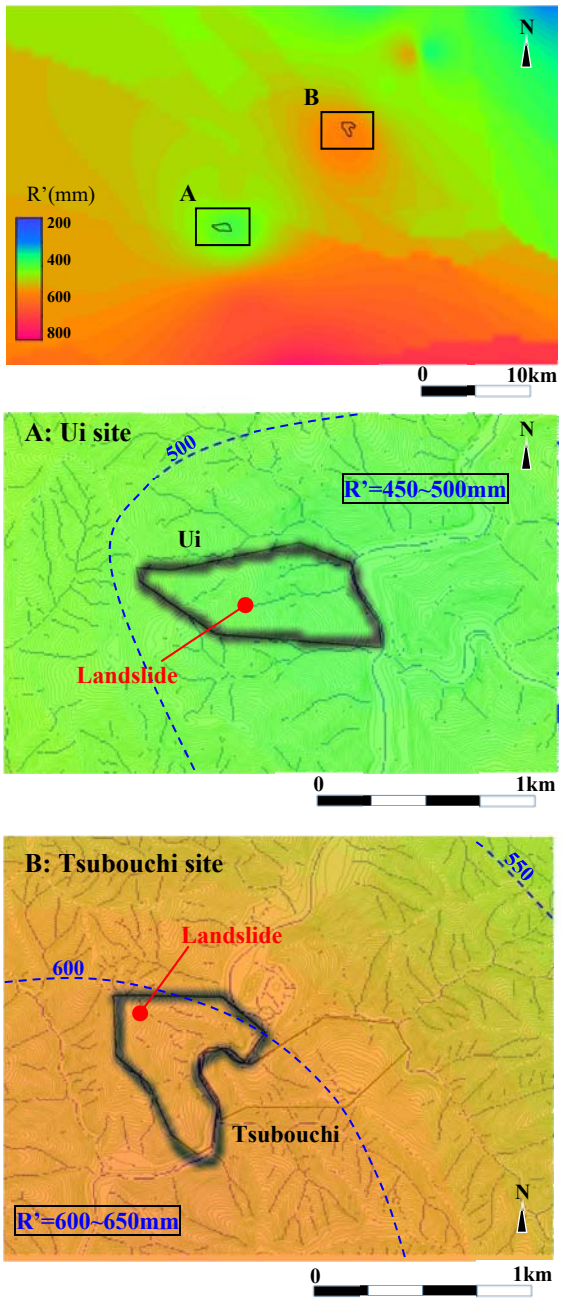

Fig. 7 Example of mapping R' distribution. Upper map: R' distribution around Yoshino country in Kii Mountains. A: Ui (R'= 488.6mm), B: Tsubouchi (R'= 598.4mm).

Both sites are occurred landslide at R' range about 450 to 650mm. In Tsubouchi site, places where occurred landslides located along R'= 600mm contour line curve.

3.3 Relation between drainage density and slope failure density

Figure 8 shows relation between drainage density and rainfall index R'. Generally, the value of R' decrease, as drainage density increase. In this study, lower limit of R' is about 250mm, regardless of drainage density accretion. The frequency of slope failures converges in the extent which drainage density range from 5 to 10km^{-1}, R' value range from 250 to 550mm. This relationship indicates that drainage density will be a good susceptibility index for rainfall-induced landslides and debris flows in small catchment area.

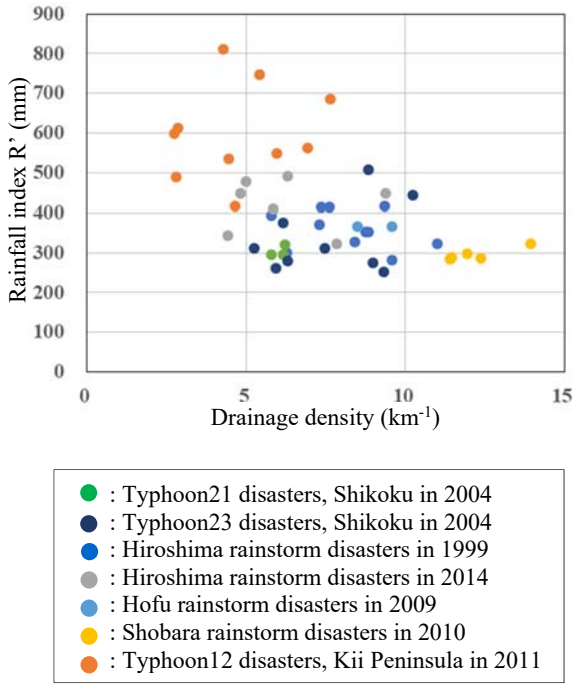

Fig. 8 Relation between drainage density and rainfall index R'.

4. DISCUSSION

4.1 Applicability to rainfall index for occurrence of slope failure

This paper presented the relationship between drainage density of small catchment area and rainfall index R'. Both values are roughly indicated inverse proportion. In the case of the rainfall index R' is nearly or equal, the frequency of slope failure increase, according to the drainage density increasing. Therefore, these two values are important parameter, for evaluation to susceptibility of slope failure and deduced occurrence time that estimated by rainfall index R' variation. However, there are points of remember. One is the area scale of measuring drainage density. In this study, calculation area of drainage basin established in small catchment area that range from 1 to 1.5km^2. If the area changed wider or smaller, affected to results of drainage density value, so may be appeared disagreement with the rainfall index R'. Another one, measuring of lowest drainage density basin. As previous statements, the drainage density of landslide block tend to smaller. Because, generally landslide block is comprised with debris, cracked rocks. These blocks become highly permeable. Therefore, the drainage density of landslide basin is extremely decrease. This low drainage density area that less than about 5km^{-1} needed to verification of measuring method, for example using 2 or 5-m high resolution DEM. Other attention, 2011 typhoon12 disasters in Kii Peninsula, occurred in the above R' = 400mm. And the distribution spread in the range which the drainage density is about 2 to 5km^{-1}. This showed apparently in case of Typhoon12 disasters, Kii Peninsula. It may be noticed that the difference of correlation is affected by base rock lithology. This area is mainly comprised by the bedrocks of accretionary complexes. Thus, plot on the data of divided by rock type (Fig.9). Generally, the area of distribute mainly Igneous rocks (Granite and Rhyolite group) located range of the drainage density over 5km^{-1} and the R' value less than 500 mm. While Other lithological area, for example Metamorphic rocks group, Lowest drainage density is about 2.5km^{-1}. In the other hand, Lowest R' value is about 250 mm through both base rocks. And the area of Lower drainage density, Higher R' value, tend to form Landslide (mass movement). For example, Kumano landslide induced by 201 Typhoon21, drainage density is 2.8km^{-1} and R' value is 612mm.

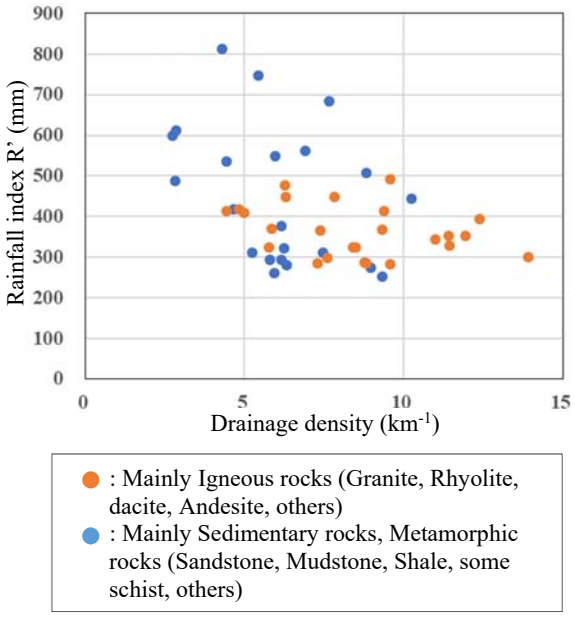

Fig. 9 Relation between drainage density and rainfall index R' divide two rock group.

4.2 Deploy to index of risk for rainfall-induced slope failure disasters.

The prediction of occurrence place, scale and type of slope failures, time of occurrence are important for risk management of rainfall-induced slope failure disasters. Relationship between drainage and rainfall index R' is avail to approximately indication for warning and evacuation. For example, indicate the slope failure risk according to frequency and limit of rainfall intensity (Fig.10).

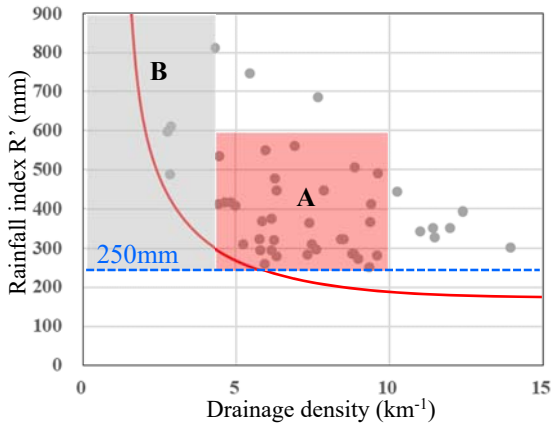

Fig. 10 Example of evaluate of disaster risk based on drainage density and rainfall index R'.

The red line in Fig.10, show change of R' values during a prospective hourly rainfall, this is generally equal to lower limit line of occurrence of slope failure. And the lower limit of R' value is about 250mm (blue line). Region A is a range that the drainage density is from 4 to 10km^{-1} and the R' value is from 250 to 600mm. In this region, frequency of slope failure occurrence is comparatively higher. And the range that the drainage density is larger than 10km^{-1}, the slope failure is mainly debris flow. On the other hand, the drainage density is less than about 4km^{-1}, the occurrence of landslide become dominant and increase the value of R' (region B). It suggested that the resistance for rainfall intensity is higher with the decrease of drainage density. However, the low drainage density area is needed more review, as above discussion that measuring drainage density of landslide character of channel distribution.

5. CONCLUSION

In this study, examined relationship between drainage density and rainfall index R' in small catchment area (1 to 1.5 km^2), through the past disasters data. Drainage density of the basin which occurrence of disaster, the value of including debris flow is higher than including landslide. The former is in range of about 6 to 12km^{-1} and the latter is in range of about 3 to 6km^{-1}. The relationship to rainfall index R', both values are roughly indicated inverse proportion. The value of R' decrease, as drainage density increase. Therefore, drainage density would be an effective index for evaluation the susceptibility of slope failures. In this study case, the lowest limit of rainfall index R' was about 250mm. It suggested that the possibility of rainfall-induced every slope failure are very unlikely during the value of R' is in less than 200 to 250mm. Particular, the frequency of slope failure is very rare at the condition that drainage density is less than about 5km^{-1}. Drainage density is easy to measure without field survey, and drainage basin scale is moderately small, therefore, drainage density is beneficial to warning and estimating of evacuation for regional disasters risk management.

ACKNOWLEDGMENTS

The authors thank to the undergraduate and master of Kagawa University for their help in measuring drainage density and rainfall index R'. And express sincere gratitude to all Agencies who have provided rainfall data during disasters, which was useful to estimating rainfall intensity along with change over time.

ABSTRACT

The main building (Headworks) in an irrigation network building can be defined as a building complex along the river where buildings can divert water to an irrigation channel so that the water can be used for irrigation purposes. If a weir is built, a water jump will occur downstream of the weir. The speed in the area is still high so that a construction of energy absorbers is made. Energy reducer is a hydraulic building which built to reduce energy of water that caused from the runoff of the top of the dam lighthouse. The construction of energy absorbers has several types including the type of Vlughter, Schoklitsch, Bucket, USBR, and The SAF Stilling Basin. In this study, the type of USBR II energy reducer is used, which is an energy reducer which has sharp channel blocks (dispersing teeth) at the upstream end and near the end of the downstream (end sill) and this type is suitable for flow with hydrostatic pressure greater than 60 m. The purpose of this study is to efficiently the model of energy absorbers by modifying the reduction the elevation in the energy absorbing floor type USBR II. This research was conducted at the Laboratory of River and Swamp, Water Resources Engineering, Faculty of Engineering, University of Brawijaya Indonesia by testing the physical model in accordance with the design work of South Borneo Kambat Dam, with a physical model of open channels with a width of 40 cm, fixed base, scalatic and using clean water.

Keywords: Irrigation, energy reducer, USBR II, ground floor reduction

INTRODUCTION

Main building (headworks) in an irrigation network can be defined as a building complex on or along a river where the building as a whole can divert water to an irrigation channel so that the water can be used for irrigation purposes. The main building consists of a complex of buildings, among others: (i) Building a dodger that is part of the main building that functions to divert the direction of the flow of the river into the channel (for example: weir) with energy absorbers; (ii) Energy dampening, which is part of the evacuation building which functions to reduce the flow of water when passing dam (for example: olak pond); (iii) Mud bag, which is part of the main building that functions to deposit or contain sediment from the river so that it does not enter into the irrigation canal until during rinsing; (iv) Rinsing building, which is part of the main building that functions to rinse the sediment.

If a weir construction is built on the river flow both on the trough and on the line, then on the downstream of the weir there will be a water jump. The speed in the area is still high, this will cause local scouring. To reduce the high speed, an energy damper construction is made. The hydraulic form is a form of meeting between a sloping cross section, a curved cross section, and a straight cross section. In general, the construction of energy absorbers is divided into five types, namely: (1) Vlughter type ponds; (2) Schoklitsch type ponds; (3) Bucket type pool; (4) USBR type pool; (5) Natural swimming type The SAF Stilling Basin (SAF = Saint Anthony Falls).

The Vlughter type olak pool was specifically developed for the plunge building in the irrigation channel. The limits given for z / hc 0.5; 2.0 and 15.0 are associated with the Froude 1.0 number; 2.8 and 12.8. The Froude numbers are taken at z depth below the upstream energy level, not on the pool floor as for the water jumping pool. The Vlughter pool can be used up to z height difference of not more than 4.50 m and or in the olak to mercury room floor (D) no more than 8 meters and consideration of soil porosity conditions at the weir location in the context of drying.

The use of the type of USBR energy absorbers in Indonesia began in 1970 [1]. This type is usually used for head drop that is higher than 10 meters. This processed space has various variations and most importantly there are four types that are distinguished by the hydraulic regime of flow and construction. These types, namely the processing space type USBR I, USBR II, USBR III, and USBR

IV.

The use of energy absorbers for weirs based on graphs and published formulas will be over design, this is due to; (1) Sometimes there is no back jump on the floor and sometimes the flow that occurs is higher than the tail water; (2) There is a difference in the determination of the Froude number in full jump (Fr1) and reverse jump (Fr2) conditions where Fr2 <Fr1; (3) Types of energy absorbers can be used for weirs provided that the size needs to be adjusted to the results of the Physical Model Test.

Experiments to determine the hydraulic spring length are not easy due to the occurrence of strong turbulence and the presence of one-phase and two-phase currents which add to the difficulty in measuring flow depth, pressure distribution and hydraulic jump length. According to the Elevatorski (1959), the initial formulation for the hydraulic jump length was carried out by [2]. Then in 1927-1929, Safranez carried out a systematic study of the length of the roll (roller) on hydraulic leaps. Furthermore [3]-[4] define that the end of the hydraulic jump is a position where the free surface reaches the maximum height. Peterka (1984) [5] examines that the hydraulic spring end is assumed to be the position where the highest beam velocity starts to detach from the base and then glides downstream. The results of Peterka's research are one that is often used to calculate the length of the hydraulic jump in the olak pool.

This research tried to find out the flow behavior in a flat pool and to find out the energy attenuation in the basic olak pool.

METHOD

Research Variable

The research was conducted at the Laboratory of River and Swamp, Water Resources Engineering, Faculty of Engineering, University of Brawijaya Malang, Indonesia. The implementation of this hydraulic physical model test research uses laboratory facilities, including; (a) physical overflow model with open channel, spillway uses upright Ogee type as fixed parameter with slope of launcher channel is 1:4, fixed channel width is 40 cm; (b) three pieces of water pump to supply clean water flow to the model; (c) water reservoir to supply water to the model and equipped with a discharge measuring device; (d) rechbox discharge measurement tool; (e) point gauge, pitot tube, water pass, measuring rod, measuring cup, bucket, telemetry, and stopwatch.

In this study several variables were used to support the results of this study. The dependent variable consist of; (a) critical depth (Yc); (b) y_1, y_2, y_3; (c) Froude number (Fr); (d) Jump Length (Lj); (e) Jump height (YJ). Moreover, the independent variable consist of ; (a) discharge (Q); (b) ogee spill upright; (c) slope of the launch channel; (d) high damping; and (e) USBR olak pool type II.

Energy Dissipation

Specific energy is energy relative to the channel base. The amount of this energy as illustrated in Fig. 1 and Eq. (1).

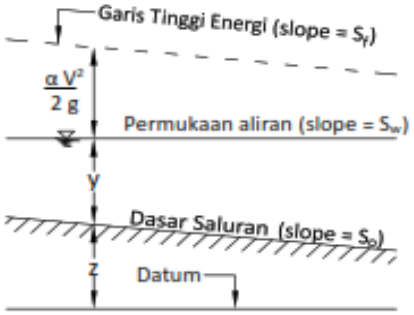

Fig. 1 Energy flow in open channel [6]-[7]

$$E = \frac{av^2}{2g} + y \qquad (1)$$

The velocity distribution coefficient (a) can be seen in Table 1.

Table 1. Velocity Distribution Coefficient (a) [8]

Channel	Minimum	Average	Maximum
Ordinary canals, overflow gutters	1.10	1.15	1.20
Natural rivers and heavy rivers	1.15	1.30	1.50
The river is covered by ice	1.20	1.50	2.00
River valleys are flooded	1.50	1.75	2.00

Froude Number (Fr) is defined as the average velocity *v* divided by the root of gravity *g* and the depth of water written as Eq. (2) [9].

$$Fr = \frac{v}{\sqrt{\frac{gy}{\alpha}}} \qquad (2)$$

Flow in open channels based on Froude numbers can be classified into three parts, namely sub-critical, critical and super critical flow, with the the criteria of; (a) sub-critical flow: when Fr<1; (b) critical flow: when Fr=1; (c) super critical flow: when Fr>1.

Hydraulic jumps are the fast transition from supercritical to subcritical flow. This is an extreme turbulence process, which is characterized by large-scale turbulence, surface waves and pounding, energy reduction and air entrainment. The nature of

the flow in the downstream and the energy lost in the hydraulic jump can be inferred from the momentum principle as a function of the Froude number upstream and the depth of the upstream flow.

For rectangular channels with horizontal flat shapes, the downstream flow depth is described as Eq (3).

$$\frac{y_2}{y_1} = \frac{1}{2}\left(\sqrt{1 + 8F_r{}^2} - 1\right) \quad (3)$$

The depth before hydraulic jump (y_1) and the depth after hydraulic jump (y_2) are also called the conjugation depth. Hydraulic jumps can be distinguished based on Froude numbers like the following Table 2.

Table 2. Classification of Hydraulic Jumps on Horizontal Square Channels [10]

Fr	Definition	Information
1	Critical flow	No jumps are formed
1.0 - 1.70	Choppy jumps	There are waves on the surface of the water
1.70 - 2.50	Weak jumps	Small energy loss
2.50 - 4.50	Oscillating leaps	Irregular oscillating bursts produce large waves towards the downstream, damaging and eroding the dikes.
4.50 - 9.00	Steady jumps	Energy reduction is 45–70%. Hydraulic jumps are very balanced. Not too affected by downstream conditions. The best economic planning
> 9.00	Strong jump	Strong jump. Energy reduction up to 85%. The risk of erosion at the bottom of the channel to watch out for.

Energy Loss

The loss of energy in jumping is the same as the specific energy difference before and after the jump. The amount of energy loss as defined in Eq (4).

$$\Delta E = E_{1-}E_1 = \frac{(y_2 - y_1)^2}{4y_1y_2} \quad (4)$$

An equation for energy loss in uniform flow and non-uniform flow in smooth launch channels as shown in Eq (5) [9].

$$\Delta E = y_w \cos\theta + \alpha \frac{{q_w}^2}{2g{y_w}^2} \quad (5)$$

Previous research was developed kinetic energy coefficients for sinking flows on launchers with values a is 1.1 - 1.6 [10]-[11]-[12]. The research step is described in the flow chart of the research on Fig. 2.

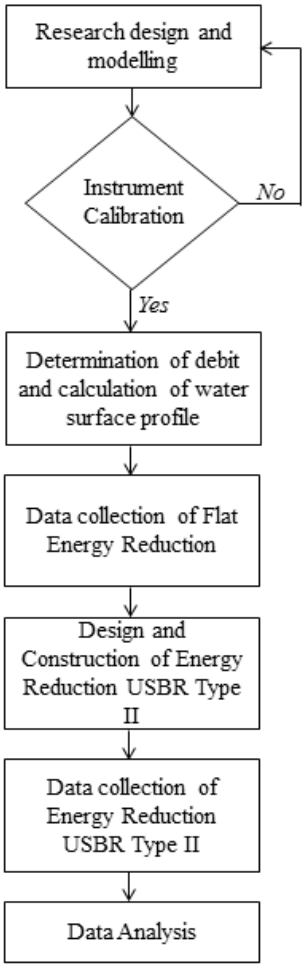

Fig. 2 Research flow chart

RESULT AND DISCUSSION

New Discharge Calculation between Thompson Discharge and Measure Discharge

The calculation of the new discharge is done by finding a relative error and correction discharge between the Thompson discharge and the measuring discharge. Then look for a new discharge value through the equation from the graph obtained from the correction discharge.

The steps to find a new discharge value are as follows:

Example of calculation (*h* thompson = 5.1cm);

1. Finding Relative Mistakes (Kr)

$$Kr = \frac{Qmeasure - Qthompson}{Qmeasure}$$
$$= \frac{0.850 - 0.842}{0.850} = \mathbf{0.010}$$

2. Finding the Correction Discharge Coefficient (K)

$$K = \frac{Qmeasure}{Qthompson}$$
$$= \frac{\mathbf{0.850}}{\mathbf{0.842}} = \mathbf{1.010}$$

From the calculation of the correction discharge coefficient it shown the smallest correction discharge coefficient value is 0.978 at h thompson 6.75 cm.

3. Finding Corrected Discharge

$Q_{correction} = Q_{measure} \; x \; K$

= 0.850 x 0.978 = 0.831 l/s

4. Finding the relative error of Correction Discharge

$$Kr = \frac{Qmeasure - Qcorrection}{Qmeasure}$$
$$= \frac{0.850 - 0.831}{0.850} = \mathbf{0.022\ l/s}$$

5. Finding New Discharge

The calculation is obtained from the graph of the relationship between h thompson and correction discharge. The graphs as shown on Fig. 4.

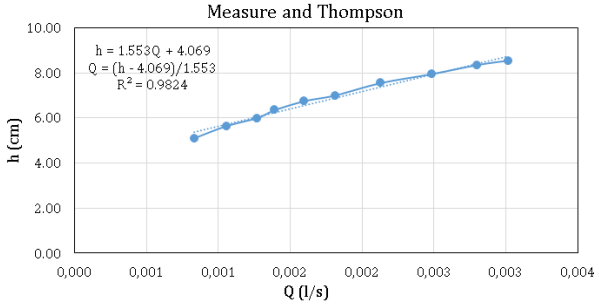

Fig. 4 Graph of the relationship between Q and h

From the graph above, statistics are used to calculate Thompson's new discharge. Calculation as follows;

Example of calculation (h thompson = 5.1 cm)

$$\boldsymbol{h = 1.553Q + 4.069}$$

from above algoritm, $\boldsymbol{a = 1.553}$ and $\boldsymbol{b = 4.069}$, so:

$$h = aQ + b$$
$$Q = \frac{h - b}{a}$$
$$= \frac{5.1 - 4.069}{1.553} = \mathbf{0.664\ l/s}$$

Discharge value at h thompson 5.1cm is 0.664 l/s.

Calculation of Flat Energy Reduction

The measured data is critical depth (*yc*), y_1, y_2, *Lj*. Measurement data as shown in Table 2.

Table 2. Calculation and Measurement Results of Flat Energy Reduction

h Rechbox (cm)	Q (l/s)	Theoretical		
		Yc (cm)	y_1 *(cm)*	y_2 *(cm)*
7.00	11.004	4.257	1.392	9.855
8.00	13.019	4.762	1.544	11.080
9.00	15.102	5.257	1.692	12.287
10.00	17.246	5.744	1.836	13.478
11.00	19.446	6.222	1.981	14.636

Measurement of Flat Energy Reduction				
Yc (cm)	y_1 *(cm)*	y_2 *(cm)*	*Kr* y_2 *(%)*	*Lj (cm)*
4.300	1.400	10.650	8.071	154
4.750	2.550	11.500	3.787	159
5.250	1.700	12.300	0.103	162
5.750	1.850	13.150	2.431	181
6.300	2.000	14.700	0.435	87

From the data above, it can be seen that the critical depth (*yc*) and y_1 between the theoretical results and the measurement results have relatively the same value, whereas for the value of y_2 it has a relative error of less than 10%.

Calculation of Energy Reduction Buildings (USBR Type II)

The energy absorbers used in this study are USBR Type II energy absorbers. The calculation of the USBR Type II energy absorbing building uses data from a 9 cm rechbox h discharge. The calculation steps are as follows:

Known data;

Discharge (Q) = 15.102 l/s

Y_1 = 1.692cm

Y_2 = 12.287cm

1. Calculation of Olak Pool Length (*L*)

   L = 4.16 x y_2 = 4.16 x 12.287 = 51,115cm

2. Chute Block Design

   a. Chute Block high (h_1)

   $h_1 = y_1$ = 1.692cm

   b. Chute Block width (W_1)

   $W_1 = y_1$ = 1.692cm

   c. Distance between Chute Block (S_1)

$S_1 - y_1$ = 1692cm

d. Chute Block distance with the wall
0.5 x y_1 = *0.846cm*

3. Block Edge Design
   a. Block Edge high (h_2)
   h_2 = 0.2 x y_2 = 0.2 x 12.287 = 2.457cm
   b. Block Edge width (W_2)
   W_2 = 0.15 x y_2 = 0.15 x 12.287 = 1.843cm
   c. Distance between Block Edge (S_2)
   S_2 = 0.15 x y_2 = 0.15 x 12.287 = 1.843cm
   d. Upper End Block Thickness
   0.02 x y_2 = 0.02 x 12.287 = 0.246cm

Result of Launcher Slope 1:4 Measurement without Decreasing Energy Reduction Using Type USBR II

The measurements are made by measuring water level and the velocity. The following are the results of measurements carried out on 5 variations of discharge.

Table 3 Data on Water Level, Jump Length and Velocity on h Rechbox 7 cm

CONCLUSIONS

It can be concluded that the value of the discharge has a value that is relatively the same as the discharge value using the rechbox and thompson discharge equations, but with the rechbox discharge equation the relative error value is 0.013 compared to the relative error with the Thompson discharge equation which is 0.022, so that the calculation of new discharges is based on the value of the discharge rate and the value with the rechbox discharge equation. In the measurement of flat energy absorbers, the value of *Lj* (jump length) has a greater value at each increase in discharge, namely 154cm, 159cm, 162cm, 181cm. However, at the largest discharge, the value of *Lj* is smaller than 4 other discharges, due to the limited channel length of 87cm. In the measurement of energy absorbers USBR type II, the value of *LJ* (Leap Length) has a greater value at each increase in discharge, namely 54cm, 70cm, 114cm, 124cm, 152cm. The *Lj* value of the USBR type II energy reducer measurement has a smaller value than the measurement of flat energy absorbers because there is a type II USBR energy reducer. For the value of the water level and velocity in each section it has a greater value at each increase in discharge, and the Froude value at critical depth is 1, the flow is critical, whereas in *y2* the Froude value is less than 1 (Froude <1), ie the flow is subcritical.

ABSTRACT

Assessment of aquatic environmental impacts, nutrient transfer and the clarification of contaminated sites were conducted based on water quality analysis of the Mae Klong River. Twelve sampling stations were surveyed between April 2015 and April 2016 covering Kanchanaburi, Ratchaburi and Samut Songkhram Provinces. Results showed that aquatic environmental factors varied seasonally. A mathematical model developed using the box modeling method showed that middle (Ratchaburi Province) and lower (Samut Songkhram Province) riverine zones were point source areas. Highest DIN and PO_4^{3-}-P loads were found in Samut Songkhram Province. Results implied that PO_4^{3-}-P levels were higher than the standard criterion for aquaculture (< 1.45 μmol L^{-1}). Levels of PO_4^{3-}-P continued to increase, downriver, particularly in the estuary. Recent PO_4^{3-}-P levels suggest that the number of agroindustry plants discharging waste effluent into the river should be reduced. Monitoring to assess the aquatic status of the Mae Klong River and estuary using the PO_4^{3-}-P database is urgently required to control water quality and reduce contamination levels.

Keywords: Pollution, Carrying Capacity, Environmental impact, Mae Klong River

INTRODUCTION

The Mae Klong at approximately 140 km long with a catchment area of 22,075 km^2, is the most important river in Western Thailand. The Mae Klong diversion dam is located in the upper zone, about 10 km from the river basin and forms the headworks of the Greater Mae Klong Irrigation Project which divert and distribute water to about 3.0 million rai (1 ha = 6.25 rai) of the cultivated area in 10 irrigation subprojects [1]. The river flows across the lower plain and passes through Ratchaburi Province, before discharging into the Gulf of Thailand in Samut Songkhram Province, where the important estuarine ecosystem supports a residential population as well as various industries [2]. More than 100 industrial factories are located along the banks of the Mae Klong River. Apart from industry and fisheries, other activities supported by the river include intensive agriculture [3].

[4] reported that freshwater inputs to the river depend on rainfall, irrigation control systems, and natural tributaries that flow through agricultural areas. Paddy rice is cultivated in about two-thirds of the area with the other third under sugar cane cultivation [5]. The aquatic environmental parameters, particularly dissolved oxygen and ammonia nitrogen, have deteriorated to critical levels over the past decade [6]. Rapid urbanization and industrial and agricultural development, coupled with inadequate sewerage systems, contribute to elevated material inputs in the water resources, e.g. nitrogen (N) and phosphorus (P) [7].

The abundance of nitrogen and phosphorus compounds causes eutrophication problems [8]. Thus, this study aimed to describe the impacts of aquatic environmental parameter variations. Assessment of non-point source nutrient loads was a major focus, together with clarification of nutrient transfer patterns and a pollution carrying capacity assessment at the impacted sites using a mathematical model. Results will contribute to water quality conservation to maintain acceptable and sustainable utilization management of river ecosystems.

MATHEMATICAL MODEL

Sampling sites

Twelve localities along the Mae Klong River were selected as sampling stations (Fig. 1). They were clustered in an 'upper' zone in Kanchanaburi Province (stn. 1-2), a 'middle' zone in Ratchaburi Province (stn. 3-7), and an 'estuarine' zone in Samut Songkhram Province (stn. 8-12). Water sampling was conducted during two separate time periods to take account of the effects of seasonal variability on nutrient loadings as April 2015 (dry season) and September 2015 (rainy season). Under the influence of monsoon winds, Thailand has three seasons: rainy season (May-September), winter season (October-February) and dry season (March-April) [9].

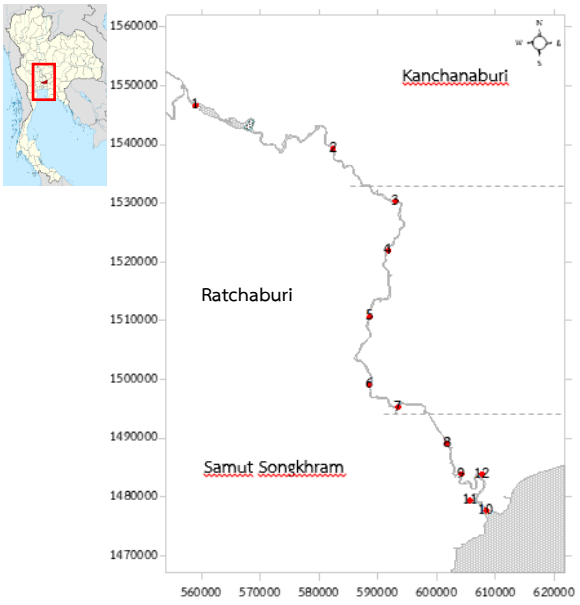

Fig. 1 Sampling stations (stn.1-12) of the Mae Klong River with the 'upper' zone in Kanchanaburi province (stn. 1-2), a 'middle' zone in Ratchaburi province (stn. 3-7), and an 'estuarine' zone in Samut Songkhram province (stn. 8–12).

Sample collection and analysis

Temperature, dissolved oxygen (DO), salinity and pH of the water samples were measured using a multi-parameter probe (YSI-6600 Sonde Instrument) at the sampling sites (stn.1-12). For nutrient analysis, water samples were pre-filtered through GF/F (Whatman) and then immediately stored at 4 °C before transportation to the laboratory where they were kept at -20 °C until required for analysis. Ammonium (NH_4^+), nitrite and nitrate (NO_2^- and NO_3^-), and orthophosphate (PO_4^{3-}) concentrations were determined using a Skalar segmented flow analyzer with corresponding detection limits of 0.70-57.14, 0.70-14.28 and 0.03-3.87 µmol L^{-1}. Specifically, the DIN and P loads were assessed at stn. 1-10 cross-sectional sites using a two-dimensional Surfer model. Nutrient loads were approximated by equation (1)

$$M_i = [Conc]A_iUh_i\Delta t_i \quad (1)$$

where M_i is the amount of nutrient load (ton/day), Conc is the nutrient concentration (µg L^{-1}), A_i is the cross-sectional area of section *i* (m^2), Uh_i is the flow velocity of section *i* (cm/s) and Δt_i is the length of time (i.e. 1 day) [2].

DIN and P loads were used for making decisions regarding the focus areas for pollution carrying capacity assessment using the mathematical model (Fig. 2). Pollution carrying capacity was conducted at two separate time periods: September 2015 and April 2016.

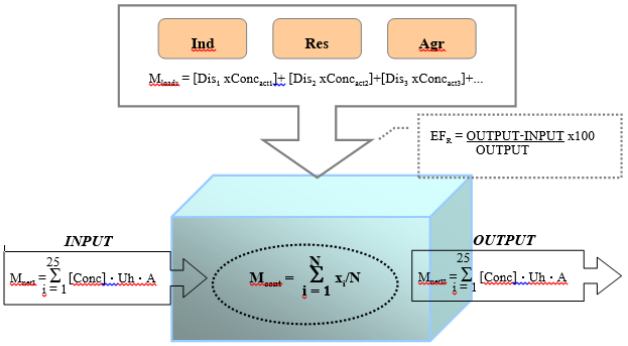

Fig. 2 Mathematical model for pollution carrying capacity assessment of the Mae Klong River.

In Fig. 2, M_{loads} is the amount of nutrient discharge (ton day^{-1}) from industrial (Ind.) residential (Res.) and agricultural (Agr.) activity, Dis_1 is the amount of discharge in each activity (l day^{-1}), $Conc_{act1}$ is the average concentration of DIN or PO_4^{3-}-P (µg L^{-1}) M_{cont} is the amount of nutrients within the box (ton/day), x_i is the concentration of DIN or PO_4^{3-}-P (µg L^{-1}) at the present time within the box, M_{net} is the amount of each nutrient load (ton/day), [Conc] is the concentration of DIN or PO_4^{3-}-P (µg L^{-1}) in the time focus (1-25 hrs). Uh is the flow velocity (cm s^{-1}) passing through the section in the time focus, and A is the cross-sectional area (m^2) of the section in focus.

Data analysis

Physicochemical properties of the water samples associated with both sampling periods (April 2015 and September 2015) were determined using descriptive statistics and presented as means ± standard deviations (SD). T-test was used to verify statistical differences between the two study periods, with $p \leq 0.05$.

RESULTS

Table 1 shows the physicochemical characteristics of the water samples for both study periods (rainy and dry seasons). Results revealed that water temperature and salinity varied minimally from season to season ($p \leq 0.05$) and were lower during the rainy season. Sampling locations (stn.1-12) and seasonal variability had no significant impact on pH levels which remained relatively constant throughout. The DO varied in response to seasonal variability ($p > 0.05$) at alarmingly higher than Thailand's minimum threshold of 4 mg L^{-1}. Average levels of NH_4^+ and NO_2^-+NO_3^- also varied significantly ($p \leq 0.05$) with the season. Minimum and maximum

concentrations of NH_4^+ and PO_4^{3-} associated with dry and rainy seasons were respectively 1.73 and 28.92 μmol L^{-1}, and 0.10 and 5.23 μmol L^{-1}. Observations also revealed that NH_4^+ and NO_2^-+NO_3^- were high during the dry season.

Table 1 Physicochemical properties of water samples (mean±SD)

Parameters	Study period	
	April 2015 (dry)	September 2015 (rainy)
Temp (°C)	31.85±0.71[a]	29.19±0.72[b]
DO (mg L^{-1})	5.62±2.26[a]	5.47±1.11[a]
Salinity (psu)	2.79±5.19[a]	0.39±0.62[a]
pH	7.63±0.22[a]	7.18±0.19[a]
NH_4^+ (μmol L^{-1})	8.57±8.41[a]	5.13±2.08[a]
NO_2^-+NO_3^- (μmol L^{-1})	26.83±13.34[a]	11.55±3.76[b]
PO_4^{3-} (μmol L^{-1})	1.31±1.90[a]	1.77±1.18[a]

Table 2 shows the cross-sectional area, water volume and current velocity associated with the 10 cross-sectional sites (stn. 1-10). During the dry season (April), stn. 10 exhibited the highest volume and velocity of 78.49 x 10^6 ton day^{-1} and 39.7 cm s^{-1}, respectively. Meanwhile, stn. 2 recorded the lowest volume (3.09 x 10^6 ton day^{-1}) and stn. 7 had the lowest velocity (12.5 cm s^{-1}).

Table 2 Water volume and velocity of the 10 cross-sectional sites during the dry (April 2015) season

Zone	Stn.	Section area (m^2)	Volume (10^6 ton day^{-1})	Velocity (cm s^{-1})
Upper	1	1,217.05	31.34	29.8
	2	196.58	3.09	18.2
Middle	3	253.98	4.37	19.9
	4	536.14	10.84	23.4
	5	531.77	10.93	23.8
	6	564.10	9.07	18.6
	7	732.09	7.91	12.5
Lower	8	747.91	10.15	15.7
	9	1,213.72	26.95	25.7
	10	2,288.23	78.49	39.7

Nutrient loads (DIN and P) associated with stn. 1-10 were estimated using (1). Results indicated that the DIN and P loads were respectively in the range of 2.09-31.00, and 0.03-5.25 ton day^{-1}. The highest DIN and P loads were registered at stn. 10, 31.00 ton day^{-1} and 5.25 in the dry season (Table 3). Results of nutrients loads indicated that the lower zone (Samut Songkhram Province) should focus on a point source area in the Mae Klong River.

Table 3 DIN and P transport (ton day^{-1}) at three cross-sectional sites during the dry season (April 2015)

Zone	Sectioned codes	DIN (ton day^{-1})	PO_4^{3-}-P (ton day^{-1})
Upper	St1	9.80	0.13
	St2	2.09	0.03
Middle	St3	3.22	0.04
	St4	3.36	0.10
	St5	3.35	0.11
	St6	4.71	0.12
	St7	4.54	0.11
Lower	St8	5.97	0.13
	St9	12.64	0.44
	St10	31.00	5.25

DIN and P transport for pollution carrying capacity were calculated using the equation shown in Fig. 2, with primary and secondary data collected from government officials (Table 4).

Table 4 Parameters for calculating the mathematical model in the lower area (Samut Songkhram Province) of the Mae Klong River

Type of waste water	Waste water volume	No.	Levels of concentration (μg/l)	
			DIN	PO_4^{3-}-P
Industry*	5 $x10^5$ $Lday^{-1}$	80 factory	23.6 $x10^3$	4.45 $x10^3$
Domestic	342 $Lcap.^{-1}day^{-1}$	194,069 cap.	10.9 $x10^3$	1.4 $x10^3$
Shrimp pond	1.9 $x10^4$ $LRai^{-1}day^{-1}$	1,613 Rai	2.7 $x10^3$	43.1
Rice field	2.3 $x10^3$ $LRai^{-1}day^{-1}$	-	3.6 $x10^3$	49.6

Results revealed that DIN and P transport during the rainy season were higher than levels in the dry season. However, output levels of DIN and P loads in both seasons were lower than input levels (Fig.3). To improve self-remediation of the river, especially during the dry season, high DIN and P levels in the box require larger recharge from the Mae Klong River in the dry season and imposition of restrictions on the discharge of wastewater into the river.

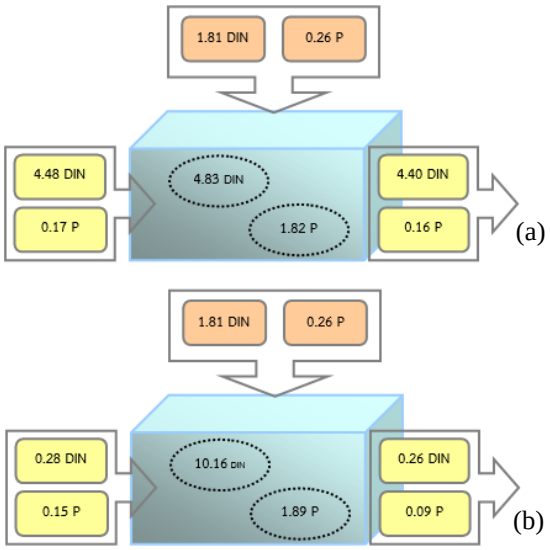

Fig. 3 DIN and P transport (ton day^{-1}) for pollution carrying capacity assessment using the mathematical model in the rainy (September 2015) and dry (April 2016) seasons in the lower part of the Mae Klong River.

DISCUSSION

Research results indicated that temperature and salinity of the river water varied minimally with seasons, while pH levels also remained relatively constant throughout. According to [2], freshwater inflow and precipitation-induced drainage influence the salinity level. Findings also revealed that dissolved oxygen (DO) was higher than Thailand's minimum threshold of 4 mg L^{-1}, rendering the water unfit for aquatic animals [10].

Furthermore, high DIN and P nutrient concentrations suggested anthropogenic contamination from the high population density along and near both sides of the river. Nutrient loads from the major areas revealed the impact of anthropogenic activity, while water flow characteristics influenced water quality in those areas [2]. Generally, nutrient loadings in a river are linked to natural and anthropogenic sources, e.g. runoff from urban areas and plantations, and inflow through organic-rich ground [11]. In addition, non-point sources e.g. storm water runoff and runoff from agricultural and urban areas contribute significantly to riverine biogeochemistry [12].

In water quality assessment, NH_4^+ is an important determinant [13]. The NH_4^+ levels in water bodies should be below 1 mg L^{-1} (or 71.4 µmol L^{-1}) [14], and the PO_4^{3-} levels below 1 µmol L^{-1} to avert eutrophication [2]. The PO_4^{3-} levels in the Mae Klong River were in excess of the limit.

Anthropogenic activity and water mass transfer direction of the Mae Klong River, especially in the lower zone (Samut Songkhram Province), contributed to high DIN and P loads. Nutrient input-outputs were high in the dry season when nutrient loads were excessive. [11] reported that nutrients in water could be diluted or enhanced in response to areas that the water flows through, and that nutrient concentrations influence the self-remediation of the waterways. In addition, land use contributes to nitrogen enrichment in the river [15], while phosphorus emission from wastewater is prevalent in highly populated areas [16].

The mathematical model for pollution carrying capacity of the area (lower zone) was positive, indicating adequate self-remediation and nutrient input-output balance. However, nutrient loads should be monitored, especially during the dry season.

CONCLUSIONS

Effects of seasonal variability (rainy and dry seasons) and nutrient transfer patterns on the anthropogenic nutrient loads (DIN and P) and the self-remediation of the Mae Klong River in Thailand were investigated. Findings revealed maximum DIN and P loads of 31.0 ton day^{-1} and 5.25 ton day^{-1}, respectively during the dry season in the lower part of the river. The predominantly positive nutrient transport for DIN and P indicated adequate self-remediation with subsequent nutrient input-output still in balance. To address self-remediation in the area requires enhanced recharge from the Mae Klong River during the dry season. Observations also indicated that water mass transfer direction influenced drainage, nutrient dilution and nutrient accumulation in the area.

ABSTRACT

In decision making, linguistic variables tend to be complex to handle but they make more sense than classical fuzzy numbers. Fuzziness is not sufficient enough to deal with information and degree of reliability of information is critical. Z-numbers is proposed to model the uncertainty produced by human judgment when eliciting information. Therefore, the implementation of z-numbers is taken into consideration, where it has more authority to describe the knowledge of human being and extensively used in the uncertain information development. This issue has motivated the authors to propose fuzzy multi criteria decision making methodology using z-numbers. The proposed methodology is demonstrated the capability to handle knowledge of human being and uncertain information for risk assessment in oil and gas industry. This assessment is due to periodic basis, which will give insights from the operational until the strategic level of decision making process that is capable of dealing with uncertainty in human judgment. The consistent fuzzy preference relations is developed to calculate the preference-weights of the criteria related based on the derived network structure and to resolve conflicts arising from differences in information and opinions provided by the decision makers. The proposed methodology is constructed without losing the generality of the consistent fuzzy preference relations under fuzzy environment.

Keywords: Multi criteria decision making, Consistent fuzzy preference relations, Z-numbers, Reliability, Risk assessment, Oil and gas industry

INTRODUCTION

Risk assessment is an evaluation process for identified hazards or undesirable events. It is a process of categorizing and measuring the risk related outcomes from a specific incident in a particular scenario [1]. It can cause individual wounds of workers, environmental damages, degradation and damage of the assets which have high effects on the reputation of the industry. In the human decision making process, the risk is present because of uncertainty and imprecision [2]. Commonly, uncertainty and imprecision exist due to the lack of information, incompatible evidence, vague information and individual information. In oil and gas industries, risk assessment and decision making have been considered as crucial aspects. The investigation on risk assessment factors assists the decision makers to minimize the risk related and take the appropriate decisions about risk level [3].

Multiple criteria decision making (MCDM) approach has become a discipline of operations research which has been widely explored by experts or practitioners [4]. It is the process of making decision in the appearance of multiple criteria or objectives. Nowadays, uncertainty affected strongly in the world where much of the information on which decisions are based is uncertain [5] [6]. Thus, consistency is crucial for achieving correct solutions in decision process.

Consistent fuzzy preference relations was proposed by [7] for constructing the decision matrices of pairwise comparisons based on additive transitivity property. Due to each positive reciprocal matrix is described by fuzzy numbers in fuzzy linguistic terms, so to satisfy the consistency is very difficult [8]. Besides, establishing a fuzzy positive reciprocal matrix requires $\frac{n\times(n-1)}{2}$ judgments to be made for a level with n criteria. Hence, the number of comparison increase with the number of criteria, so inconsistent conditions are likely to occur. To solve the consistency problem, the consistent fuzzy preference relations technique is adopted in order to construct fuzzy decision matrix instead of fuzzy positive reciprocal matrix. The utilisation of consistent fuzzy preference relations in this phase yields decision matrices for making pairwise comparison matrices using additive transitivity. There are only *n-1* comparisons judgments are

required to ensure the consistency on a level that contains *n* criteria.

In the literature of fuzzy set, Zadeh [9] introduced fuzzy set theory in representing vagueness or imprecision in a mathematical approach. In order to do so, the main motivation of using fuzzy sets shows its ability in appropriately dealing with imprecise numerical quantities and subjective preferences of decision makers [10]. Zadeh [11] proposed a notion of z-number, which is an order pair of fuzzy numbers $(\tilde{A},\tilde{B})$. The $\tilde{A}$ component plays the role of a fuzzy restriction and represent the information about an uncertain variable, while the $\tilde{B}$ component is a reliability of $\tilde{A}$ component and enable to represent an idea of certainty or probability [12] [13]. The idea of z-numbers is to provide a basis for computation with numbers which are not completely reliable and more intelligent to describe the knowledge of human being and capable to cater uncertain information.

In real world decision making problems, linguistic variables tend to be very complex to handle but makes more sense than classical fuzzy numbers. Rather than use classical fuzzy numbers, the linguistic scales are expressed in a more details and flexible way by z-numbers. The membership functions of type-1 and type-2 fuzzy sets have no information regarding knowledge of human being. This issue motivates us to propose consistent fuzzy preference relation that has capability to handle knowledge of human being and uncertain information properly using z-numbers. Then, apply for risk assessment in oil and gas industry problem.

The rest of this paper is organized as follows: Section II introduces the concept of z-numbers. Section III presents the proposed methodology of consistent fuzzy preference relation using z-numbers. In Section VI, a case study for risk assessment in oil and gas industry. Section V summarises the conclusion.

PRELIMINARIES

In this section, the authors briefly review basic concept and definition of z-number that are illustrated as follows.

Z-numbers

A z-number is an ordered pair of fuzzy numbers

$$\mu_{\tilde{A}}(x)=(a_1,a_2,a_3,a_4)=\begin{cases}\dfrac{(x-a_1)}{(a_2-a_1)} & if \quad a_1\le x\le a_2\\ 1, & a_2\le x\le a_3\\ \dfrac{(a_4-x)}{(a_4-a_3)} & if \quad a_3\le x\le a_4\\ 0 & otherwise\end{cases}$$

$$\mu_{\tilde{B}}(x)=(b_1,b_2,b_3,b_4)=\begin{cases}\dfrac{(x-b_1)}{(b_2-b_1)} & if \quad b_1\le x\le b_2\\ 1, & b_2\le x\le b_3\\ \dfrac{(b_4-x)}{(b_4-b_3)} & if \quad b_3\le x\le b_4\\ 0 & otherwise\end{cases} \quad (1)$$

denoted as $Z=(\tilde{A},\tilde{B})$. First component, $\tilde{A}$ is known as restriction component whereby it is a real-valued uncertain on X while second component, $\tilde{B}$ is a measure of reliability for $\tilde{A}$ [11]. The illustration for z-number is depicted in Fig. 1 [12].

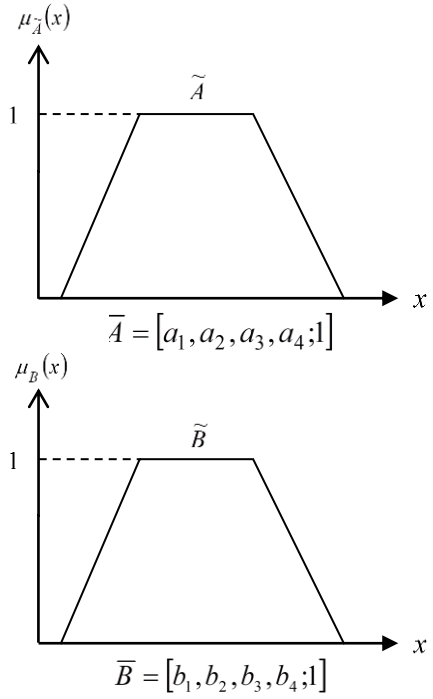

Fig. 1: Z-number, $Z=(\tilde{A},\tilde{B})$

PROPOSED METHODOLOGY

This section focuses on the development of integrated fuzzy risk assessment using z-numbers. It is worth mentioning that the structure of the proposed methodology is depicted as Figure 2.

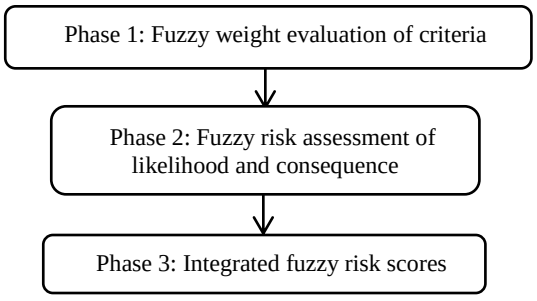

Fig. 2: Structure of fuzzy risk assessment in the presence of z-numbers.

Phase 1: Fuzzy Weights Evaluation of Criteria

Stage 1: Construct a pair-wise comparison matrices
The pairwise comparison matrices are constructed among all preferences elicited that comprise all criteria in z-numbers form as following matrix *A*:

$$A=\begin{bmatrix} 1 & \tilde{a}_{12} & \cdots & \tilde{a}_{1n} \\ \tilde{a}_{21} & 1 & \cdots & \tilde{a}_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ \tilde{a}_{n1} & \tilde{a}_{n2} & \cdots & 1 \end{bmatrix}=\begin{bmatrix} 1 & \tilde{a}_{12} & \cdots & \tilde{a}_{1n} \\ 1/\tilde{a}_{12} & 1 & \cdots & \tilde{a}_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ 1/\tilde{a}_{1n} & 1/\tilde{a}_{2n} & \cdots & 1 \end{bmatrix} \quad (2)$$

The risk analystss use the linguistic terms as depicted in Table 1 to present the weights and Table to present relibilility.

Stage 2: Convert the z-numbers into type-1 fuzzy numbers and aggregate them.
All z-numbers in fuzzy decision matrices are converted into type-1 fuzzy numbers by reduction process using intuitive vectorial centroid. The intuitive vectorial centroid is an extension of the classical vectorial centroid methods for fuzzy numbers that proposed by [14]. Compare to other centroid methods in the literature, the way to get the centroid value is more intelligent manner, easy to compute, more balance, and consider all feasible cases of fuzzy numbers. Intuitive vectorial centroid can be computed as

$$IVC(\tilde{x}_{\tilde{A}},\tilde{y}_{\tilde{A}})=\left(\frac{2(a_1+a_4)+7(a_2+a_3)}{18},\frac{7h_{\tilde{A}}}{18}\right) \quad (3)$$

where

$\tilde{x}$: the centroid point on the horizontal *x*-axis

$\tilde{y}$: the centroid point on the vertical *y*-axis

$(\tilde{x},\tilde{y})$: the centroid coordinate of fuzzy number $\tilde{A}$

The reduction process of z-numbers into type-1 fuzzy sets using intuitive vectorial centroid can be computed using [15].

Then, aggregate fuzzy decision matrix from risk analysts' evaluation.

$$\tilde{x}_{ij}=(\tilde{x}_{ij}^1\times\tilde{x}_{ij}^2\times\ldots\times\tilde{x}_{ij}^n)^{1/k} \quad (4)$$

where $\tilde{x}_{ij}$ is the performance rating of criteria, A_i with respect to criterion C_j evaluated by *kth* experts and $\tilde{x}_{ij}=(a_1^k,a_2^k,a_3^k,a_4^k;h^k)$.

Stage 3: Compute the criteria evaluations using consistent fuzzy preference relations.

Step 1: Construct a hierarchy structure.
The construction of hierarchy model needs judgment matrix filled by risk analysts about the evaluation of all criteria.

Step 2: Construct a pair-wise comparison matrices.
Consistent fuzzy preference relations is adopted to evaluate the weights of difference criteria for the performance of alternatives. The pairwise comparison matrices are constructed among all criteria in the dimension of the hierarchy systems based on the risk analysts preferences in stage 1 as following matrix *A*:

$$A=\begin{bmatrix} 1 & \tilde{a}_{12} & \cdots & \tilde{a}_{1n} \\ \tilde{a}_{21} & 1 & \cdots & \tilde{a}_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ \tilde{a}_{n1} & \tilde{a}_{n2} & \cdots & 1 \end{bmatrix}=\begin{bmatrix} 1 & \tilde{a}_{12} & \cdots & \tilde{a}_{1n} \\ 1/\tilde{a}_{12} & 1 & \cdots & \tilde{a}_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ 1/\tilde{a}_{1n} & 1/\tilde{a}_{2n} & \cdots & 1 \end{bmatrix} \quad (5)$$

Step 3: Convert risk analysts' preferences from z-numbers into regular fuzzy numbers.
Conversion process is computed by using [15] .

Step 4: Aggregate the risk analysts' preferences.
The pairwise comparison matrices of risk analysts' preferences are aggregated using equation below:

$$\tilde{a}_{ij}=(\tilde{a}_{ij}^1\times\tilde{a}_{ij}^2\times\ldots\times\tilde{a}_{ij}^n)^{1/k} \quad (6)$$

where *k* is the number of risk analysts and *i=1,2,…m; j=1,2,…n*.

Table 1 Trapezoidal fuzzy numbers preference scale [16]

Linguistic variables	Scale of relative important crisp numbers	Trapezoidal fuzzy numbers	Reciprocal trapezoidal fuzzy number
Equally important (EI)	1	(1, 1, 1, 1; 1)	(1, 1, 1, 1; 1)
Intermediate value (IV)	2	(1, 3/2, 5/2, 3; 1)	(1/3, 2/5, 2/3, 1; 1)
Moderately more important (MMI)	3	(2, 5/2, 7/2, 4; 1)	(1/4, 2/9, 2/5, 1/2; 1)
Intermediate value (IV)	4	(3, 7/2, 9/2, 5; 1)	(1/5, 2/9, 2/7, 1/3; 1)
Strongly more important (SMI)	5	(4, 9/2, 11/2, 6; 1)	(1/6, 2/11, 2/9, 1/4; 1)
Intermediate value (IV)	6	(5, 11/2, 13/2, 7; 1)	(1/7, 2/13, 2/11, 1/5; 1)
Very strong more important (VSMI)	7	(6, 13/2, 15/2, 8; 1)	(1/8, 2/15, 2/13, 1/6; 1)
Intermediate value (IV)	8	(7, 15/2, 17/2, 9; 1)	(1/9, 2/17, 2/15, 1/7; 1)
Extremely more important (EMI)	9	(8, 17/2, 9, 9; 1)	(1/9, 1/9, 2/17, 1/8; 1)

Table 2 Reliability linguistic terms and their corresponding z-numbers [17]

Linguistic Terms	Generalised fuzzy numbers
Very-low (VL)	(0,0,0,0.25;1)
Low (L)	(0,25,0.25,0.5;1)
Medium (M)	(0.25,0.5,0.5,0.75;1)
High (H)	(0.5,0.75,0.75,1;1)
Very-high (VH)	(0.75,1,1,1;1)

Step 5: Defuzzify the fuzzy numbers of aggregation's result of risk analysts' preferences.
Intuitive vectorial centroid for z-numbers is used for conversion process using [15].

Step 6: Compute the criteria values as weightage/ fuzzy weight, *FW* for alternatives' evaluation using consistent fuzzy preference relations.
Consistent fuzzy preference relations was proposed by [7] for constructing the decision matrices of pairwise comparisons based on additive transitivity property. Referring to [18], a fuzzy preference relation R on the set of the criteria or alternatives A is a fuzzy set stated on the Cartesian product set $A \times A$ with the membership function $\mu_R : A \times A \to [0,1]$. The preference relation is denoted by $n \times n$ matrix $R = (r_{ij})$ where $r_{ij} = \mu_R(a_i, a_j) \quad \forall i, \ j \in \{1,...,n\}$. The preference ratio, r_{ij} of the alternative a_i to a_j is determined by:
