WATER HYACINTH FIBER FOR LIMITED-LIFE GEOSYNTHETIC GEONET AS SUBGRADE REINFORCEMENT OF RURAL ROADS

Mary Ann Adajar[1], Patricia Gwenn Ang[1], Judith Dungca[1], Julia Dominic Espinola[1], and Nicole Gabrielle Tan[1]

[1]Department of Civil Engineering, De La Salle University, Philippines

ABSTRACT

The increasing demand for urban development has led to the neglect of rural road maintenance, compromising structural integrity due to weak subgrade soils. This study investigates the potential of water hyacinth fiber geonets (WHFG) as eco-friendly, limited-life geosynthetic alternatives for reinforcing subgrades in rural roads. While geonets are commonly used for drainage, their application in subgrade reinforcement remains limited. Two WHFG types with different apertures, 16 mm × 16 mm (16WHFG) and 22 mm × 22 mm (22WHFG), were fabricated and assessed for tensile strength performance in comparison to commercial synthetic geonets. Water hyacinth, an invasive aquatic plant known for its rapid growth and ecological impact, was repurposed for sustainable engineering use. Fibers were extracted from dried stems, treated with sodium hydroxide, and woven into geonet structures. Tensile tests were conducted according to ASTM D4595 standards. Results show that although WHFGs have lower tensile strength than high-density polyethylene (HDPE) geonets, the 16WHFG meets the minimum strength requirements for slope protection and erosion control set by the Department of Public Works and Highways (DPWH). Its improved performance over 22WHFG is attributed to stronger fiber interlocking provided by smaller apertures. This research demonstrates the viability of WHFG as a sustainable reinforcement solution for rural subgrade soils. It offers the dual advantage of addressing geotechnical challenges and mitigating the environmental impact of water hyacinths. Further research is recommended to enhance the durability and large-scale implementation of natural fiber geonets in geotechnical applications.

Keywords: Water hyacinth fiber geonet, Limited-life geosynthetics, Natural fiber geonet, Subgrade reinforcement

INTRODUCTION

Rural road networks are essential in ensuring equitable access to basic services and economic opportunities. However, in many developing regions, these roads suffer from insufficient design and weak subgrade conditions, often leading to rapid deterioration under heavy vehicular loads. The structural integrity of these roads relies heavily on the subgrade's ability to distribute loads effectively, and any compromise in this layer can result in rutting, settlement, and premature failure.

To address these challenges, designers have turned to various materials and technologies that enhance subgrade performance, one of the most significant being geosynthetics [1]. Geosynthetics, including geotextiles, geogrids, and geonets, have been widely adopted in engineering projects to enhance the mechanical behavior of soil. Geosynthetics are synthetic materials that provide sustainable engineering solutions for geotechnical and geoenvironmental issues [2]. Accordingly, this material has a variety of purposes, which include drainage, separation, reinforcement, filtration, protection, and fluid barrier. According to Shukla [3], geosynthetics refers to a broad category of products with varying densities, thicknesses, structures, and other parameters, namely geotextiles, geogrids, geocells, geofoams, geomembranes, and geocomposites. These products are all produced under controlled conditions primarily from polymeric materials such as polypropylene, polyvinyl chloride, polyester, polyamide, polystyrene, and polyethylene. They are used in contact with soil, rock, or other construction-related materials to support civil engineering projects, a structure, or a system [4]. Fluid containment, environmental protection, stabilization, slope stability, and erosion control are some of the most common uses of geosynthetics. Some of its engineering applications are typically found in landfills, lagoons, dams, mining, roads, railways, slopes, walls, embankments, pond spillways, riverbanks, and channels [5-7].

While these conventional geosynthetics made from polymeric materials have demonstrated significant benefits in improving subgrade stability and load-bearing capacity, their widespread use has raised environmental concerns. Their resistance to degradation, although advantageous for long-term applications, poses a challenge regarding post-use disposal and environmental persistence. In response, the civil engineering community has begun to explore more sustainable alternatives that maintain performance while reducing environmental impact.

This shift in focus has led to a growing interest in limited-life geosynthetics (LLGs), materials specifically designed to provide temporary reinforcement and degrade after serving their purpose.

In recent years, biodegradable or limited-life geosynthetics have gained traction, especially in projects where long-term structural support is unnecessary. These materials are designed to deliver critical reinforcement during the early stages of soil consolidation and road service life, after which they naturally break down, minimizing their ecological footprint. This approach aligns particularly well with the needs of rural infrastructure, where cost-efficiency, sustainability, and context-specific engineering solutions are crucial. LLGs can provide effective short-term support during construction, promote long-term natural stabilization, and even assist in revegetation efforts, making them ideal for rural road applications with moderate traffic volumes and limited maintenance resources.

In the search for suitable LLGs, natural fibers have been investigated for their biodegradability, availability, and mechanical performance. Natural fibers such as jute, coir, and vetiver have been studied as alternatives to synthetic geosynthetics. However, one underutilized fiber source is water hyacinth, an invasive aquatic plant that poses a significant environmental challenge in many waterways. Water hyacinth (*Eichhornia crassipes*), an invasive aquatic plant abundant in many waterways, presents a viable source of natural fiber. In the Philippines, water hyacinths can proliferate at an alarming rate. These plants can cover up to 600 sqm. in just a year, threatening the aquatic biodiversity in the area by rapidly reducing the water's oxygen level as they grow. In a recent cleanup of the Pateros River, 420 bags' worth of water hyacinths were hauled out [8]. Its rapid proliferation clogs rivers, threatens biodiversity, and imposes high maintenance costs for removal. While the reuse of water hyacinth in handicrafts and animal feed has been explored, its potential in civil engineering applications remains largely untapped. With its abundant availability and high fiber yield, water hyacinth offers an untapped opportunity to create woven geonets that are locally sourced, biodegradable, and environmentally restorative.

The study by Patel, M. & Patel, A. [9] assesses the effectiveness of coir geotextiles in enhancing subgrade performance, noting improvements in strength and durability. Another paper [10] promoted green engineering by utilizing nonwoven coir geotextiles as an alternative material for slope stabilization. An article by Nguyen et al. [11] reviews the use of various natural fibers in geotechnical engineering, discussing their properties, benefits, and challenges. Kumar et al. [12] investigate using coir and jute fibers as sustainable alternatives to synthetic materials in rural road construction, highlighting their environmental benefits and mechanical properties. The research of Arifin et al. [13] assesses the tensile strength and durability of oil palm empty fruit bunch fibers in soft soil, providing insights into the performance of biodegradable fibers in geotechnical applications. Natural materials like bamboo were used as reinforcement to improve peat soil, demonstrating the effectiveness of natural materials in enhancing soil stability [14]. All of these reviewed studies collectively highlight the growing interest in sustainable, biodegradable materials for geotechnical applications, particularly in rural infrastructure. However, they also reveal a gap in research concerning the use of invasive species like water hyacinth as reinforcement materials.

This study aims to capitalize on this opportunity by developing a water hyacinth fiber geonet (WHFG), a biodegradable, woven reinforcement mesh intended to support rural subgrade soils during early loading stages. This study aims to evaluate the tensile strength performance of water hyacinth fiber geonets (WHFG) fabricated with two aperture configurations (16×16 mm and 22×22 mm) and to assess their suitability as subgrade reinforcement for rural roads. The performance of WHFG is compared against commercial high-density polyethylene (HDPE) geonets and benchmarked against existing standards from the Department of Public Works and Highways (DPWH) in the Philippines. This study introduces a novel use of water hyacinth fiber geonets (WHFG) as a limited-life geosynthetic for subgrade reinforcement. The study also highlights the effect of aperture size on geonet tensile strength, reinforcing the importance of fiber interlocking in improving performance. By analyzing the influence of aperture size on tensile strength and interlocking behavior, the study seeks to provide insight into the design optimization of natural geonets for engineering use.

RESEARCH SIGNIFICANCE

The adoption of WHFG provides an opportunity to transition toward bio-based, low-cost geosynthetics that are locally sourced, biodegradable, and potentially community-manufactured. It offers an innovative dual solution: addressing the structural weakness of rural road subgrades while simultaneously mitigating the environmental impact of invasive water hyacinths. Through this investigation, the study contributes to the growing body of knowledge on limited-life geosynthetics, demonstrating how biodegradable, locally sourced materials can be engineered to meet the mechanical and functional requirements of civil infrastructure. The research supports the advancement of sustainable rural development, ecological resource management, and climate-conscious engineering practices.

MATERIALS AND METHODS

The materials for this research were water hyacinth fibers and sodium hydroxide for the treatment of fibers. Dried water hyacinth stems were

sourced from local suppliers. The researchers constructed a large wooden loom with varying apertures for the manual weaving process of the WHFG.

Water Hyacinth Fiber Extraction and Treatment

The fibers were extracted from the water hyacinth stems after they were sun-dried. Though the fiber can also be extracted from the leaves and roots, water hyacinth stems have the highest fiber concentration and the longest fiber length. The dried water hyacinth stems had a thin external layer encasing the fibers, which are long individual strands clumped together by spongy material. To extract the fibers, the dried skin of the water hyacinth was hand-peeled carefully until the cluster of fibers was entirely exposed, as seen in Fig. 1. Afterwards, the peeled stems were soaked in water for at least three days to soften. After soaking in water, the peeled water hyacinth stems were transferred to a sodium hydroxide (NaOH) bath following the procedure described by Nguyen and Nguyen [15]. The NaOH bath should have a concentration of 10% solution, which was achieved by dissolving 4 grams of NaOH powder per liter of water. The stems were treated for 3 hours in the bath while maintaining a temperature between 40°C to 50°C. The treated stems were then rinsed in clean water several times until the water turned clear. The spongy material covering the fibers was scraped off, leaving only the fiber to have a thinner strand for the rope making. Thinner strands were expected to have higher fiber density and would yield higher strength properties [15].

(a) (b)

Fig.1 (a) Peeling of the outer layer of the stem, (b) Peeled water hyacinth stem

While the fibers were still wet, the braiding of strands to form ropes was performed (Fig. 2). Maintaining the damp condition of the strands while braiding produced better interlocking between the fibers. The rope-making procedure was performed following a simple cordage technique. A single rope was made of 2 entwined strands with a thickness of around 20mm. After braiding, the ropes were left out to sun-dry for at least 24 hours, during which their total thickness was reduced to about 4 to 5 mm.

Fig.2 Braided strands in wet condition

Weaving of Geonet

A plain weave pattern was used to achieve high tensile strength, as recommended by Artidteang et al. [16]. The weave was oriented to form a diamond-shaped aperture relative to the wooden loom, a configuration characteristic of geonets. Two different aperture sizes were employed in weaving the water hyacinth fiber geonet (WHFG), 16×16 mm and 22×22 mm. These sizes were selected based on standard aperture dimensions commonly found in commercially available synthetic geonets. For reference throughout this paper, a WHFG with a 16×16 mm aperture is denoted as 16WHFG, while that with a 22×22 mm aperture is denoted as 22WHFG.

The large wooden looms used for weaving, illustrated in Figs. 3 and 4, each measured 1.5 × 1.5 meters.

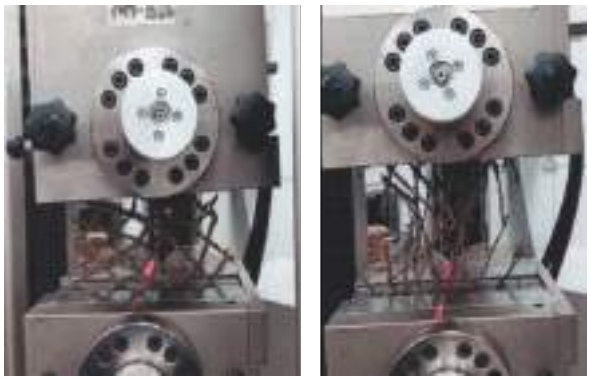
Fig. 3 Loom for 22WHFG geonet.

Fig.4 Loom for 16WHFG geonet.

A separate loom was designated for each aperture size to accommodate the required number of samples for all experimental tests. Evenly spaced nails along the wooden frame allowed the woven ropes to be secured tightly, helping to maintain consistent tension during the weaving process.

TEST METHOD

ASTM D 4595, Standard Test Method for Tensile Properties of Geotextiles by the Wide-Width Strip Method, was used to determine the tensile strength and elongation wherein a continually increasing longitudinal load was applied to the sample until rupture (Figs. 5a and 5b).



(a) (b)

Fig.5 Tensile test on (a) 22WFHG and (b) 16WFHG

The determination of wide-width strip force–elongation properties of geotextiles provides essential design parameters for reinforcement applications, such as subgrade stabilization. The specimen sizes were 200×300 mm in the shape of a rectangle. The tensile tests were done in two principal orientations, the machine direction (MD) and the cross-machine direction (CMD). In the machine direction, the tensile load is applied parallel to the production of the weaving flow, essentially along the length of the material as it is formed on the loom. The result of the tensile strength in the MD orientation assesses the material's strength along the primary alignment of the fibers or ropes. In the cross-machine direction, the tensile load is applied across the width of the material. Tensile testing in the CMD evaluates the strength across the woven structure, typically involving interlaced or supportive fibers. A total of 12 samples were prepared, wherein six samples were prepared per aperture size for each test orientation.

TEST RESULTS

The tensile strength of the fabricated water hyacinth fiber geonets (WHFG) was evaluated to assess their mechanical performance and suitability for potential geotechnical applications. Table 1 presents the average tensile strengths of the water hyacinth fiber geonets (WHFG) in both the machine direction (MD) and cross-machine direction (CMD). The 16WHFG exhibited notably higher tensile strength values, recording 3.4 KN/m (MD) and 2.9 KN/m (CMD), compared to 1.5 KN/m (MD) and 1.8 KN/m (CMD) for the 22WHFG. This difference in tensile performance is primarily attributed to the smaller aperture size (16×16 mm) of the 16WHFG, which results in a denser weave and greater rope overlap, enhancing load distribution and resistance to tensile deformation. In contrast, the 22WHFG's larger apertures offer less resistance under load due to increased spacing between the woven strands.

Table 1 Average Tensile Strengths of WHFG

	Tensile Strength MD (KN/m)	Tensile Strength CMD (KN/m)	CMD to MD ratio
22WHFG	1.5	1.8	1.2
16WHFG	3.4	2.9	0.85

This trend is consistent with findings from Gaviola et al. [17], who investigated geotextiles made from coconut fiber and vetiver grass. Their study observed that geotextiles with smaller aperture sizes exhibited higher tensile strength, leading to better performance in erosion control applications. They concluded that the increased number of mesh junctions due to the smaller aperture size enhanced the structural integrity of the geotextile, making it more effective for slope reinforcement. Similarly, in the present study, the 16WHFG's superior tensile strength can be attributed to its smaller aperture, which allows more junction points where ropes interlock. This denser interweaving contributes to a stronger load-bearing network across the geonet. Further support is found in the work of Sakleshpur et al. [18], who examined the relationship between tensile strength and junction strength in woven geosynthetics. Their study defined junction strength

as the force required to separate interwoven points and found that higher tensile strength correlated with stronger junctions, which in turn were linked to greater interlocking within the weave. This implies that the interlocking effect, reinforced by the tighter mesh of the 16WHFG, likely plays a critical role in its enhanced tensile behavior.

The CMD-to-MD strength ratios, 1.2 for 22WHFG and 0.85 for 16WHFG, indicate a relatively balanced biaxial performance, especially for the 16WHFG, suggesting its suitability in applications where tensile forces may not be strictly uniaxial. A balanced MD and CMD strength ensures the geonet can resist stretching and deformation, regardless of the load direction, improving durability and effectiveness in real-world use.

To assess the variability and reliability of the tensile strength measurements, standard deviation values were calculated for both the machine direction (MD) and cross-machine direction (CMD) tests. The results show that for 22WHFG, the standard deviations were 0.53 KN/m (MD) and 0.47 KN/m (CMD), while for 16WHFG, the values were 0.97 KN/m (MD) and 1.02 KN/m (CMD). These values indicate a moderate level of variation within the samples, which is expected in natural fiber-based materials due to inherent inconsistencies in fiber composition and alignment.

When compared to the Department of Public Works and Highways (DPWH) standard specifications for coco coir geonets in the Philippines, as outlined in Department Order No. 29, Series of 2008 [19], the 16WHFG meets the lower performance threshold required for slope stabilization and erosion control. Meanwhile, the 22WHFG falls below this range, suggesting limited structural reliability for primary reinforcement applications. A comparison with DPWH Department Order No. 54, Series of 1998 [20], which prescribes tensile strength values for synthetic geotextiles, reveals that both WHFG variants fall below the minimum requirements for high-performance erosion control materials. Specifically, geotextiles for Class B erosion control must exhibit minimum grab tensile strengths of 800 N (MD) and 510 N (CMD), equivalent to approximately 8.0 KN/m and 5.1 KN/m. Consequently, WHFGs are unsuitable for critical structural roles but remain viable for temporary or biodegradable reinforcement applications.

In comparison to commercial synthetic geonets of the same aperture size, which exhibit tensile strengths of 6.4 KN/m for HDPE with 22 x 22 mm aperture and 5.4 KN/m for HDPE with 16 x 16mm aperture, WHFGs represent a lower strength but environmentally sustainable alternative. Their value lies not in outperforming synthetic counterparts, but in offering a biodegradable, low-cost, and sustainable alternative. In regions with abundant water hyacinth biomass, the utilization of WHFGs can contribute to invasive species management while promoting green engineering practices. Their biodegradability and reliance on invasive biomass make them particularly attractive in eco-engineering contexts where long-term persistence is not required.

Despite their relatively lower strength, the WHFGs, particularly the 16WHFG, demonstrate sufficient tensile capacity for light-duty applications, such as rural road subgrade reinforcement, temporary slope stabilization, and low-volume erosion control systems. Additionally, their environmental biodegradability positions them as viable candidates for limited-life geosynthetic (LLG) solutions, where natural degradation is preferred post-construction.

CONCLUSIONS

This study explored the tensile performance of water hyacinth fiber geonets (WHFG) woven using two aperture configurations (16×16 mm and 22×22 mm) and assessed their suitability for geotechnical applications. Results revealed that the 16WHFG exhibited higher tensile strength, with values reaching 3.4 KN/m in the machine direction and 2.9 KN/m in the cross-machine direction, surpassing the 22WHFG in both orientations. These findings demonstrate the critical role of weave density and aperture size in enhancing mechanical properties.

In comparison with the Department of Public Works and Highways (DPWH) standards for natural geonets and geotextiles, the 16WHFG meets the lower threshold of performance for coco coir geonets but falls below the required specifications for synthetic geotextiles. When compared to commercial synthetic geonets, WHFGs exhibit lower tensile strength but provide considerable environmental and economic advantages due to their biodegradability and local material sourcing.

The WHFG's performance, especially the 16WHFG, is suitable for temporary and low-stress applications, such as rural slope stabilization, subgrade reinforcement in low-traffic areas, and eco-engineering projects focused on sustainable infrastructure. Their use contributes to waste valorization, particularly in regions heavily infested with water hyacinths, and supports circular engineering solutions.

To enhance the performance and practical adoption of WHFGs as sustainable geosynthetics, future work should consider conducting long-term field testing to evaluate the biodegradation rate and mechanical stability of WHFGs under real environmental conditions such as rainfall, UV exposure, and soil interaction. Performing a life-cycle assessment comparing WHFG with conventional synthetic geonets will quantify the environmental benefits in terms of carbon footprint, waste reduction, and end-of-life impacts.

DEVELOPMENT OF SOLIDIFIED CULTIVATING SOIL BLENDED WITH WASTE WOODY BIOMASS PREPARED BY THE EICP METHOD

Daiki Kawamura[1, 2] and Satoru Kawasaki[3]

[1] Kumagai Gumi Co., Ltd., Japan; [2]1Graduate School of Engineering, Hokkaido University, Sapporo, Japan; [3]Faculty of Engineering, Hokkaido University, Sapporo, Japan

ABSTRACT

Bio-cementation is well known as an environmentally friendly technique. It is studied for mitigating liquefaction, reducing dust, and increasing ground strength. This technique has been considered for use in the ground, but it is important to reduce ammonia (NH_3) and ammonium ions (NH_4^+) generation. On the other hand, these by-products have the potential to act as beneficial nutrient sources in agricultural applications. We aim to develop a solidified cultivating soil using generated ammonium ions (NH_4^+). Additionally, the importation of peat moss, a principal material of solidified cultivating soil, has declined due to the depletion of natural resources, prompting the search for environmentally sustainable alternative substrate materials. In this study, we conducted solidification and germination tests using EICP as a solidification method, which, unlike other bio-cementation techniques, does not require microbial cultivation, and using waste woody biomass such as bamboo powder and coco peat. Additionally, we investigated the degree of collapse of solidified cultivating soil, as well as the effects of ammonium nitrogen on solidification and germination. The results show that the solidification strength, represented by the degree of collapse, was enhanced with increased injection frequency at lower cementation concentrations (0.1 M and 0.25 M). At a concentration of 0.5 M, the solidification was sufficiently strong even with four injections. The germination rate increased as the molar concentration of cementation solution decreased. These results suggest that $CaCO_3$ cementation, when optimized in terms of concentration, holds promise for developing sustainable solidified cultivating soil.

Keywords: Bio-cementation, EICP, NH_4^+, Bamboo powder, solidified cultivating soil

INTRODUCTION

The labor force in Japanese agriculture continues to decline due to an aging population and decreasing birthrate. In response, smart agriculture has emerged, with the aim of enhancing efficiency and productivity through the integration of advanced technologies [1, 2]. These innovations include hydroponic systems and mechanized transplanting, which use growth substrates such as solidified cultivating soil and rock wool. These substrates exhibit three characteristics: high water permeability and retention capacity, ease of handling and transportation, and low weight. Solidified cultivating soil is produced by applying heat treatment to a soil-fiber mixture [3]. Conversely, rock wool is synthesized by melting materials such as blast furnace slag and basalt at high temperatures (approximately 1,500–1,600°C) [4]. This process raises environmental concerns due to substantial CO_2 emissions. Additionally, peat moss, a principal material of solidified cultivating soil, is imported in smaller quantities due to limited natural resources, prompting the need for environmentally sustainable alternative substrate materials.

In our research, we aim to develop a sustainable form of solidified cultivation soil with minimal environmental impact. Specifically, we focus on a cementation method that utilizes calcium carbonate ($CaCO_3$) and incorporates waste woody biomass. The cementation process relies on microbially induced carbonate precipitation (MICP) and enzyme-induced carbonate precipitation (EICP), which are established techniques used in applications such as erosion control [5], liquefaction mitigation [6], and slope stabilization [7]. These processes employ microbial or enzymatic activity to promote $CaCO_3$ precipitation through the following biochemical reactions [8]:

$$CO(NH_2)_2+H_2O\rightarrow 2NH_3+CO_2 \quad (1)$$

$$NH_3+H_2O\rightarrow NH_4^++OH^- \quad (2)$$

$$CO_2+H_2O\rightarrow HCO_3^-+H^+ \quad (3)$$

$$HCO_3^-\rightarrow H^++CO_3^{2-} \quad (4)$$

$$Ca^{2+}+CO_3^{2-}\rightarrow CaCO_3 \quad (5)$$

One concern associated with this technique is the production of ammonia (NH_3) and ammonium ions (NH_4^+), which can lead to nitrogen pollution. However, these byproducts can also serve as beneficial nutrients for vegetable cultivation. Previous studies have investigated the interaction among MICP/EICP, plant growth, and soil [9, 10], but the relation with woody biomass has received limited attention.

In this study, we conducted solidification and germination tests using EICP as a solidification

method, which, unlike other bio-cementation techniques, does not require microbial cultivation. We also used waste woody biomass such as bamboo powder and coco peat. Additionally, we investigated the degree of collapse of solidified cultivating soil, as well as the effects of ammonium nitrogen on solidification and germination.

MATERIALS AND METHODS

EICP

This study selected EICP as a solidification method, which is a cementation technique based on enzyme reactions, for two reasons: it does not require cultivation, and it can utilize waste. Urease is generally extracted from beans such as jack beans and soybeans [11]. Recently, researchers have studied extracting urease from waste materials such as watermelon seed [12]. In the future, we aim to reduce costs by using EICP with urease derived from waste materials.

Waste Woody Biomass

This study used two types of waste woody biomass materials: coco peat sourced from Sri Lanka and bamboo powder (Phyllostachys edulis) obtained from Gifu, Japan. Table 1 summarizes their physical properties. Bulk density was measured as the mass of biomass filling 100 mL in a graduated cylinder. Ignition loss was measured in accordance with JIS A1226:2020. The pH and electrical conductivity (EC) were measured using a compact meter (LAQUAtwin, HORIBA, Ltd.). Coco peat is generally produced through processes such as crushing, rinsing, and screening. It is widely used in hydroponic cultivation and for soil conditioning. Bamboo powder is produced through processes such as crushing and fermentation. Recently, bamboo powder has been considered for use in soil cultivation as awareness of abandoned bamboo forests has been increasing [13].

Table 1 Characteristics of wood materials

	Bamboo powder	Coco peat
Bulk density (g/cm^3)	0.195	0.154
Ignition loss (%)	88.5	90.9
pH	5.3	5.4
EC (dS/m)	1.83	4.8

Solidification Test

The solidification test was conducted to evaluate the relationship among the degree of collapse of the substrate, the amount of rinse water, and the frequency of solidification solution injections. The procedure is outlined as follows:

Sample preparation: Coco peat and bamboo powder were air-dried for 24 hours, sieved through a 2 mm screen, and mixed in a 1:1 volumetric ratio. The mixture was homogenized using a high-speed mixer (Braun MultiQuick9, De'Longhi Japan Corp.) operating at 1500 rpm.

Solution preparation: A urease solution (0.1 g/L, 2.1 U/mL) was prepared using urease reagent (Fujifilm Holdings Corp.). Urea and calcium nitrate [$Ca(NO_3)_2$] solutions with concentrations of 0.1 M, 0.25 M, and 0.5 M were prepared using urea reagent and calcium nitrate reagent (Fujifilm Holdings Corp.). The urease solution and the urea–calcium nitrate solutions were mixed in a 1:1 volumetric ratio to form the solidification solution.

Cultivating Soil Preparation: A 200 mL sample of the biomass mixture was combined with 160 mL of the solidification solution and packed into a commercial cell tray (Meiwa Co., Ltd.) with a filling density of approximately 0.17 g/cm^3 (see Fig. 1 for dimensions). In addition, number of cell was twelve.

Injection and rinsing: Solidification solution (10 mL) was injected at 3-hour intervals, either 3 or 7 times. The reason for setting this interval at three hours is that the decrease in calcium ions plateaus three hours after the solution is injected, and no further precipitation of calcium carbonate is expected thereafter. Subsequently, the samples were rinsed with 50 mL or 250 mL of deionized water. Control samples received only deionized water. The experimental variables were: i) concentration of the solidification solution, ii) number of solution injections, and iii) rinsing volume. The test was repeated twice.

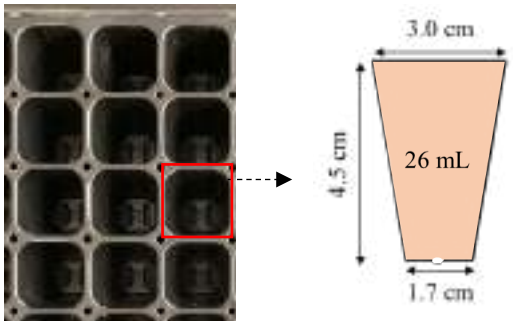

Fig. 1 Size of cell tray

Germination Test

The germination test was conducted to evaluate the relationship between seed germination rate, degree of collapse, and solidification solution concentration. The samples used for the germination test were prepared using the same method as those used for the collapse measurement, but they were different samples. Seeds of Japanese mustard spinach

were placed in 3 mm-deep holes at the center of each substrate surface (see Table 2 for test conditions). Germination was defined as the emergence of cotyledons. The germination rate was calculated as:

$$\text{Germination Rate (\%)} = (\text{Number of Germinated Seeds} / \text{Total Seeds}) \times 100 \quad (6)$$

In this experiment, total seeds was twelve, the test was repeated twice.

Table 2 Conditions of germination test

condition	
Temperature (℃)	25
Term (day)	7

Measurement of Substrate Collapse

Previous bio-cementation studies have typically used a needle penetrometer to assess physical strength [14]. However, due to the fragile nature of the solidified substrates in this study, an alternative collapse measurement method (illustrated in Fig. 2) was employed, as proposed in [3]. The collapse index shows how strong the solidified soil is, and it also shows how easily it breaks when taken out of the cell tray.

Chemical Analysis

After the germination tests, the pH and EC of the substrates were measured using the compact meter (LAQUAtwin, HORIBA, Ltd.). Ammonium nitrogen concentrations were measured in accordance with the indophenol blue absorptiometry method. Note that ammonium nitrogen was measured only once during the two trials, using a combined sample from all twelve cells.

RESULTS AND DISCUSSION

Table 3 presents a summary of the experimental results. In this experiment, Case 1 represents the control group. The number of injections refers to the frequency of solidification solution application, while rinse indicates the amount of deionized water used. The detailed findings from the solidification and germination tests are discussed below. The value of the degree of collapse shows the average of the 12 cells.

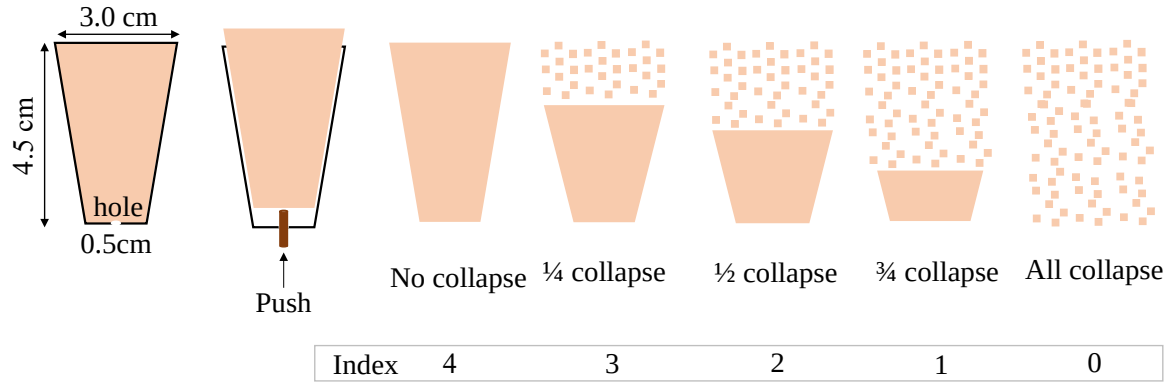

Fig. 2 Evaluation of degree of collapse [3]

Table 3 Summary of experiments results

	Urease (g/L)	Urea (mol/L)	$Ca(NO_3)_2$ (mol/L)	Injections (times)	Rinse (mL)	Germination rate (%)	pH	EC (mS/cm)	Ammonium Nitrogen (mg/kg)	Degree of collapse

Solidification Test

Fig. 3 shows the relationship between the degree of collapse and the concentration of the solidification solution. It is evident that Case 2 (0.1 M, 4 injections) exhibited insufficient strength. This is attributed to both the low concentration of the cementation solution and the limited number of injections. Additionally, Case 6 (0.25 M, 8 injections) exhibited less collapse than Case 3 (0.25 M, 4 injections), and Case 4 (0.5 M, 4 injections) showed similar strength to Case 7 (0.5 M, 8 injections). These results suggest that, at concentrations of 0.1 M and 0.25 M, a minimum of 8 injections is necessary to achieve sufficient strength. On the other hand, at a

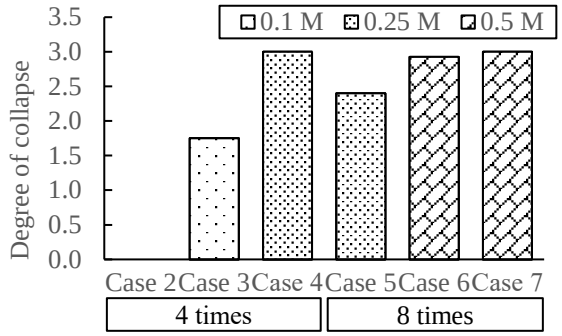

Fig. 3 Relation of degree of collapse and concentration of solidification solution

concentration of 0.5 M, the number of injections (4 or 8) did not significantly influence the degree of collapse, indicating that regardless of the number of injections, sufficient solidification can be achieved.

Fig. 4 shows the relationship between the degree of collapse and the amount of rinsing. This result is consistent with the chemical properties of $CaCO_3$, which is relatively insoluble in water. Thus, $CaCO_3$ maintains its solidification role even after rinsing.

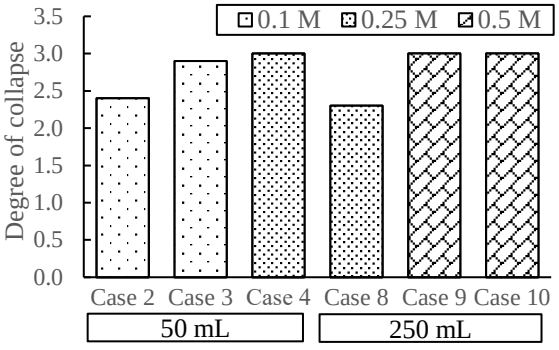

Fig. 4 Relation of degree of collapse and rinse amount

Fig. 5 and 6 present visual comparisons of the solidified cultivating soil. It is evident that Case 10 exhibited a lower degree of collapse (i.e., greater strength) than Case 8, supporting the numerical results.

Fig. 5 Photograph of solidified cultivating soil (Case 8, degree of collapse 2.3)

Fig. 6 Photograph of solidified cultivating soil (Case 10, degree of collapse 3)

Germination Test

Fig. 7 shows the inverse relationship between germination rate and the concentration of the solidification solution. Specifically, higher germination rates were observed in substrates treated with lower concentrations. This phenomenon is likely due to increased osmotic pressure in substrates solidified with higher concentrations, which may hinder seed water uptake and thus suppress germination. Also, past studies showed that root size gets smaller as the soil gets harder. When the concentration of solidification solution is higher, the collapse index becomes higher. This may mean that germination and strength are related.

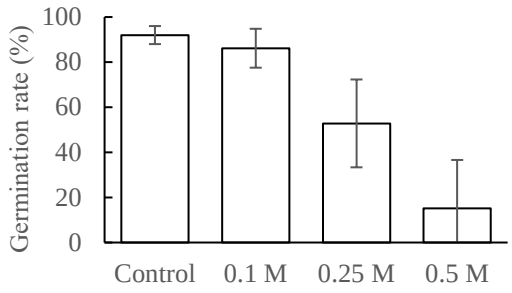

Fig. 7 Relation of Germination rate and concentration of solidification solution

Fig. 8 shows the relationship between germination rate and ammonium nitrogen concentration. A higher germination rate was associated with lower ammonium nitrogen levels. In Cases 8 through 10, the solidified substrates were rinsed to remove excess ammonium nitrogen. Although the initial

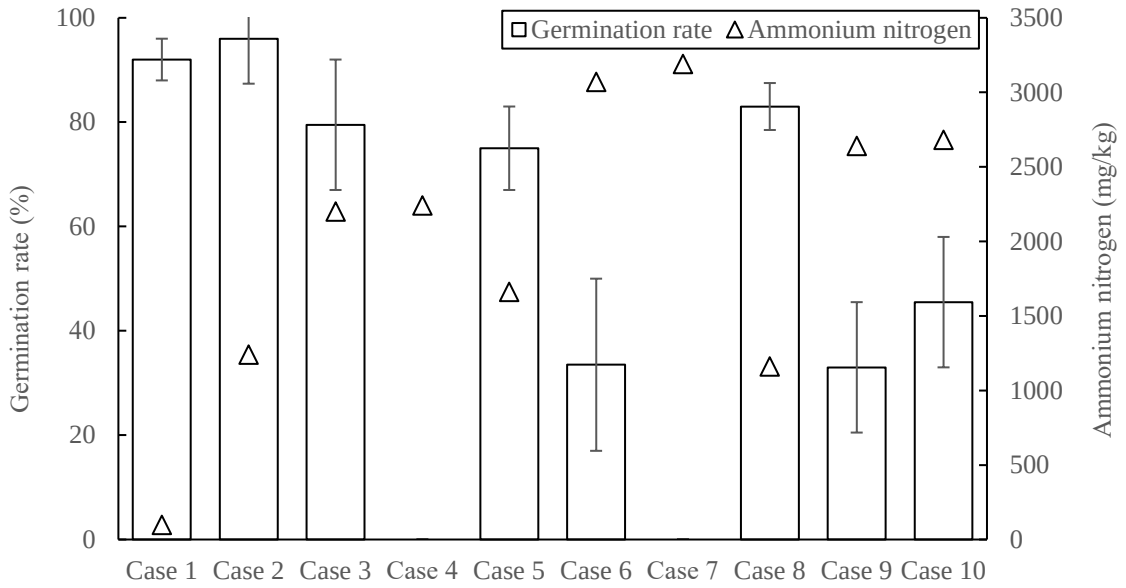

Fig. 8 Relation of Germination rate and ammonium nitrogen

concentration of ammonium nitrogen was reduced by approximately 15–30%, high residual concentrations still appeared to negatively affect plant growth. These findings are consistent with earlier studies indicating the phytotoxic effects of excessive ammonium nitrogen [15]. However, after germination, nitrogen becomes an essential element for plant growth. In particular, if nitrogen is deficient during the transition from cotyledon to true leaf, the leaves may turn yellow and wither. Future research will investigate the amount of ammonium nitrogen that does not inhibit germination and can serve as a nutrient afterward.

Woody biomass materials, such as coco peat and bamboo powder, can adsorb ammonium ions through ion exchange and micropore interactions. This experiment confirmed that rinsing alone was insufficient to reduce nitrogen concentrations to safe levels. Therefore, additional mitigation strategies such as the use of nitrifying bacteria may be required to minimize nitrogen-related stress during germination.

CONCLUSIONS

In this study, we aimed to develop a sustainable form of solidified cultivation soil with minimal environmental impact. We conducted solidification and germination tests using EICP as a solidification method, which, unlike other bio-cementation techniques, does not require microbial cultivation. We also used as substrate waste woody biomass such as bamboo powder and coco peat. Additionally, we investigated the degree of collapse of solidified cultivating soil, as well as the effects of ammonium nitrogen on germination. The findings aresummarized as follows:

- Degree of collapse, represented as the solidification strength, increased with more frequent injections, especially at lower cementationconcentrations (0.1 M and 0.25 M).At 0.5 M, sufficient strength was achieved even withfewer injections. Rinsing with deionized water did not have a significant impact on strength, as $CaCO_3$ is minimally soluble in water.

- Germination rate was inversely related to the concentration of the solidification solution. Solidified cultivation soil treated with 0.1 M solution showed the highest germination rates. This phenomenon is likely due to increased osmotic pressure in substrates solidified with higher concentrations, which may hinder seed water uptake and thus suppress germination.

- High concentrations of ammonium nitrogen negatively affected germination. Although insing reduced ammonium levels by 15–30%, it was not sufficient to eliminate phytotoxic effects. Additional methods, such as biological nitrification, may be necessary to improve the substrate’s growing conditions.

These results suggest that $CaCO_3$ cementation, when optimized in terms of concentration and injection frequency, holds promise for developing sustainable cultivation substrates using waste woody biomass.

ANALYTICAL STUDY ON THE CONCRETE BREAKOUT STRENGTH OF HEADED REINFORCEMENT BAR EMBEDDED IN ROOF EXTERIOR BEAM-COLUMN JOINT

Zev Al Jauhari[1], and Tomoya Matsui[2]

[1]Graduate School of Engineering, Toyohashi University of Technology, Japan; [2] Toyohashi University of Technology, Japan

ABSTRACT

In recent years, headed reinforcement bars have been increasingly used as replacements for conventional anchoring in reinforced concrete beam-column joints (BCJ). This led to the development of headed bars, which are highly advocated by researchers, as their ultimate load-carrying capacity is influenced by many factors. The previous study investigated the pullout test of the headed reinforcement bar embedded in roof exterior BCJ specimens using such parameters. The use of supplementary bars significantly affected the anchorage capacity of the headed bars and contributed to the diagonal force of the concrete for resisting the applied load. In this study, the 3D nonlinear finite element (FE) model of the BCJ specimens is developed using FINAL software to analyze the headed bar's concrete breakout strength. The results obtained from FE analysis demonstrated good agreement with the test results, demonstrating that the FE model can accurately predict the behavior of the BCJ specimens in terms of pullout load capacity, failure mechanism, crack pattern, internal strain and stress distribution, and damage progress. The FE model developed can be utilized as a valuable tool for predicting the concrete breakout strength with various parameters, such as the diameter of the supplementary bar (d_s), the number of supplementary bars (n_s), and the spacing of the topmost supplementary bar from the headed bar (S_{p1}). None of the variables affected the failure mode of the FE model. Increasing the d_s and n_s led to higher anchorage capacity of the headed bar; otherwise, the presence of S_{p1} decreased the anchorage capacity.

Keywords: Finite element analysis, Headed reinforcement bar, Supplementary bar, Concrete breakout strength, Beam-column joint

INTRODUCTION

Reinforced concrete beam-column joints (BCJ) play a critical role in the structural integrity and load transfer mechanisms of reinforced concrete frames [1]. Traditionally, conventional anchoring methods such as bent bars and mechanical couplers have been employed to ensure adequate anchorage of reinforcement within these joints [2]. However, recent advancements have seen the increasing adoption of headed reinforcement bars as an alternative anchorage solution due to their potential to enhance load transfer efficiency and simplify construction [3]. Headed bars, characterized by enlarged ends, offer improved anchorage capacity, but their ultimate performance is influenced by multiple factors, including the presence and configuration of supplementary bar (transverse reinforcement bar near the head or along the headed bar) [4].

Numerous studies have explored the anchorage capacity of headed bars within concrete structural components. However, only few studies have been conducted regarding the anchorage capacity of headed bars embedded in L-shaped BCJ consider the supplementary bar. An experimental investigation involving pullout tests focused on the concrete breakout strength of headed bars specifically in L-shaped BCJ was carried out [5]. This research evaluated the performance of headed bars under various conditions, producing valuable findings that both validate and improve existing calculation models used in design codes. While experimental investigations provide valuable insights, the complexity of BCJ behavior necessitates robust numerical tools for detailed analysis and optimization [6,7]. Finite element (FE) modeling offers a powerful approach to simulate and predict the nonlinear behavior of BCJ, enabling a deeper understanding of failure mechanisms, crack propagation, and stress distribution.

In this study, FE analysis (FEA) was applied to the pullout test of mechanically anchored rebars conducted by Mohsuni et al. [5], aiming to assess the concrete breakout strength of headed bars embedded within roof exterior beam-column joints. To ensure the reliability of the numerical model, a comparative investigation was carried out by correlating the pullout capacity, failure modes, and the strain at reinforcement bars of the test specimens with the FEA results. Parametric studies were conducted to capture the influence of supplementary bar on the anchorage capacity in terms of diameter, quantity, and spacing relative to the headed bar.

RESEARCH SIGNIFICANCE

This study presents a 3D nonlinear FEA of headed bars embedded in L-shaped BCJs to validate their anchorage capacity and failure mechanisms based on the test results. It also conducts a parametric analysis of the role of supplementary bars in influencing the concrete breakout strength of headed bars. By varying parameters such as the number, diameter, and spacing of the supplementary bars, the research identifies how each factor affects the load-carrying capacity of headed bar. Understanding these relationships is crucial for the design of BCJs using headed bars to prevent brittle failures and enhance overall structural resilience, especially in seismic regions.

MATERIAL AND METHODS

Experimental Study

The previous research [5] conducted pullout tests on 70% of full-scale roof exterior BCJs to evaluate the anchorage capacity of headed bars. Typical specimens, named LE25-M and LE25-Ma, were experimentally tested to measure their pullout forces. The only difference between LE25-Ma and LE25-M was the diameter of the supplementary bar: LE25-Ma used a 6 mm bar, while LE25-M used a 13 mm bar. Fig. 1 shows the standard cross-section of the LE25-M specimen and detail of plate nut.

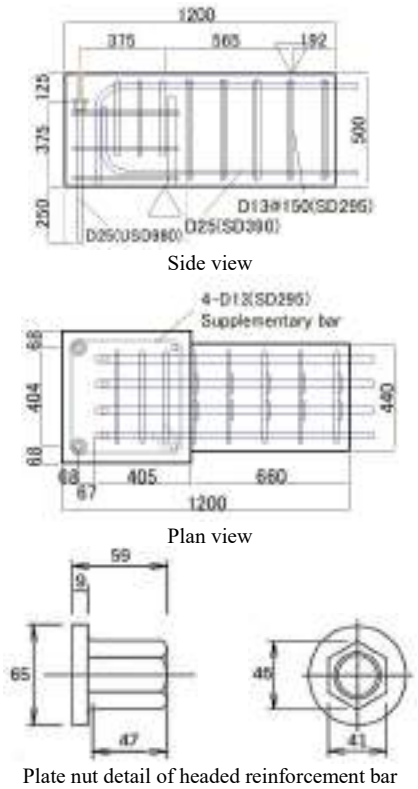

Fig.1 Cross-section and plate nut detail of LE25-M Specimen (unit: mm)

D25 (USD980)	1095	194000	Headed bar

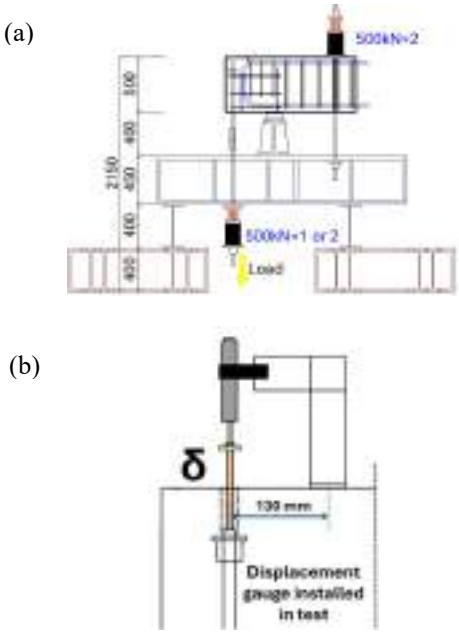

Fig.2 (a) Schematic illustration of test setup; (b) Pullout displacement calculated for test

The specimens were designed to exhibit failure modes such as concrete cones or side blowout. The concrete compressive strengths were 33.2 MPa and 32.6 MPa for LE25-M and LE25-Ma, respectively. Table 1 presents the mechanical properties of the steel reinforcing bars obtained from tensile testing. Fig. 2(a) depicts the loading setup employed during the test. The reaction force was transmitted to the force application beam, while each headed reinforcing bar was subjected to axial tensile loading applied directly through a centrally aligned hydraulic jack with a capacity of 500 kN. Linear displacement gauges were mounted on the upper surface of the plate nut to record the withdrawal displacement of the headed bars. The pullout displacement was determined by measuring the difference between the gauge position and the anchorage bar displacement, as illustrated in Fig. 2(b).

Test results demonstrated that the anchorage capacity of the headed bars was significantly influenced by the presence of supplementary bars. These supplementary bars enhanced the diagonal compressive stress distribution within the concrete matrix, thereby increasing its resistance against the

applied pullout forces. Therefore, ensuring enough supplementary bars is critical to optimize anchorage performance.

Numerical Study

Elements used

The nonlinear FEA was conducted using FINAL v11 [8] software. The geometric and structural configuration of the BCJ model is illustrated in Fig. 3. The analysis was performed in a fully three-dimensional framework, incorporating a triaxial stress state assumption. Concrete was designed using 8-node hexahedral solid elements, whereas reinforcing bars were idealized as one-dimensional beam elements. Headed reinforcing bars were represented by 4-node quadrilateral shell elements. To capture the slip behavior between the main-headed reinforcement and the surrounding concrete, a 4-node line element was introduced at the interface. This element facilitates discrete contact interaction by providing nodal linkage points between independently defined concrete and reinforcement element meshes. For the interface modeling between the plate nut and concrete, the nodes on the upper plate nut surface remain unconnected (independent) from the concrete nodes at the corresponding interface, while the nodes on the lower plate nut surface are constrained to share coincident nodes with the underlying concrete mesh, ensuring direct connectivity.

Material constitutive model

The modified Ahmad model was implemented to define the concrete compressive stress–strain behavior within the FE framework [9]. For the post-peak stress softening region, the Nakamura-Higai model [10] was employed as illustrated in Fig. 4. The model was designed so that only the area corresponding to the beam-column joint panel cover was brittle since the model was developed to break due to concrete failure only (cone or side blowout mode). The Ottosen four-parameter model is used for fracture conditions under triaxial stress. The crack-softened area on the tension side was assumed to bear almost no tensile stress after cracking, and strain reduction after cracking was not considered. The tension stiffening characteristic by the Izumo et al. [11] model was used, and the coefficient C was set to 1.0, assuming that almost no tensile stress is sustained after cracking. The shear transfer model after cracking on the beam was based on the Naganuma model [9], while the BCJ panel was assumed to have no shear transfer (zero shear stiffness). The factor for reducing compressive strength after cracking is based on the formulas proposed by Collins et al. [12] for LE25-M and by Naganuma [13] for LE25-Ma, respectively. This approach differs because the LE25-Ma model exhibits an unstable pullout capacity curve after reaching the peak pullout load due to solution divergence. In contrast, applying Naganuma's formula to the LE25-M model leads to an underestimation of the anchorage capacity.

C : a factor of tension stiffening phenomenon

Fig.4 Principal stress equivalent uniaxial strain relation of concrete

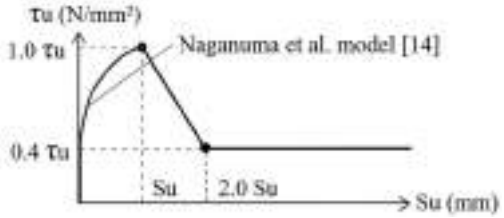

Fig.5 Bond stress-slip relationship

The stress-strain relationship adopted to represent reinforcement bar behavior was the modified Menegotto-Pinto model. The anchor plate was modeled as perfect elastic bodies with Young's modulus of 2.05 x 10^5 N/mm^2. The bond characteristics between headed reinforcing bars and concrete were based on the model by Naganuma et al. [14], and the slip at the maximum bond stress (S_u) was

assumed to be 1.0 mm. Then, peak stress was calculated based on fib Model Code 2010 (τ_u = $2.5\sqrt{f_{cm}}$) [15]. Fig. 5 shows the bond stress and slip relationship between reinforcing bars and concrete. The bond between the transverse reinforcement and concrete is assumed to be perfectly bonded.

Boundary conditions and loading

To accurately replicate the test setup within the FE model, specific boundary conditions were imposed on the model. In this study, the pin support at point A in Fig. 3 was constrained exclusively in the z direction, while the support at point B was fixed in both the x and z directions. The load was applied at the lowest node of the headed reinforcement (point C) in a displacement-controlled manner, directed downward until a displacement of 50 mm was achieved. The analysis was concluded once this displacement target was reached.

RESULTS AND DISCUSSIONS

Validation of FE model with test results

Pullout load vs displacement response

The pullout displacement (δ) in the FEA was calculated as the difference between the displacements at nodal points A and B ($\delta = \delta_A - \delta_B$), as illustrated in Fig. 6. The comparison of the pullout load and displacement curves obtained from both the FEA and the tests for LE25-M and LE25-Ma is presented in Fig. 7.

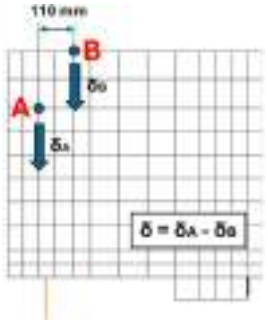

Fig.6 Pullout displacement calculated for FEA

Both models exhibit an increase in strength as pullout displacement progresses, with the LE25-Ma model demonstrating a particularly close match between the numerical prediction and test results. The LE25-M model, which has a larger hoop diameter, displayed a higher anchorage capacity compared to LE25-Ma. Notably, even after the appearance of diagonal cracks, LE25-M continued to show an increase in pullout load due to its greater anchorage strength. In contrast, LE25-Ma, having a lower anchorage capacity, experienced a significant drop in pullout load following the formation of diagonal cracks. Overall, the FE models align very well with the experimental data, particularly in terms of initial stiffness and the development of pullout load, up to displacements of 1.5 mm for LE25-M and 4 mm for LE25-Ma.

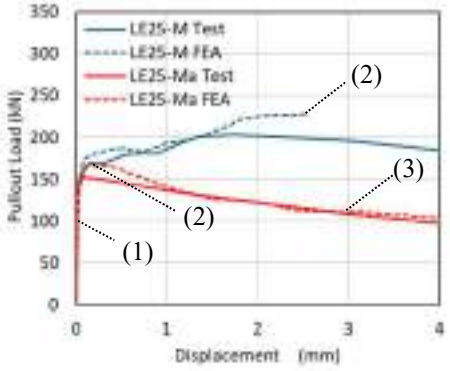

Fig.7 Pullout load-displacement relationship of LE25-M and LE25-Ma

Failure mechanism and crack pattern

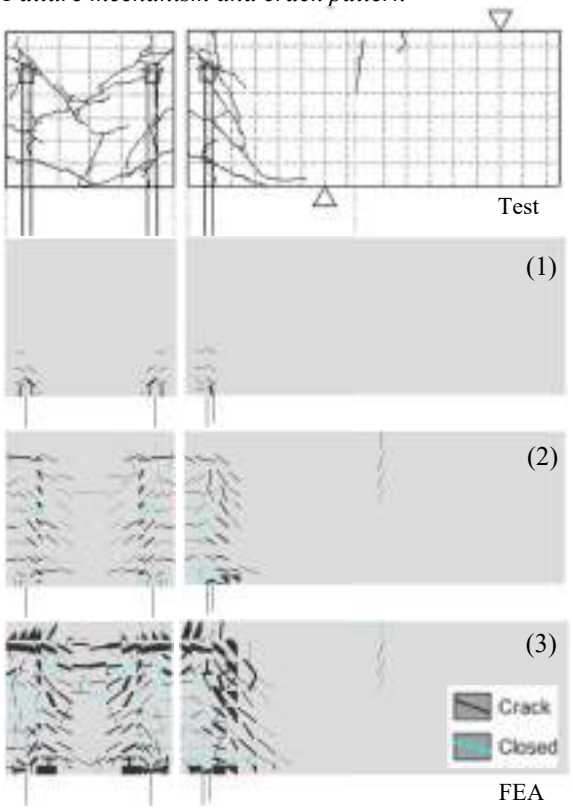

Fig.8 Crack patterns of LE25-Ma specimen and the FE model

Validating the crack pattern on the concrete is essential to confirm the potential impact of undesirable tensile stresses caused by the rapid formation of cracks due to headed bar pullout. Fig. 8 illustrates a comparison of the crack patterns observed in the LE25-Ma specimen between the test

and FEA. The number symbols in Fig. 8 correspond to those in Fig. 7.

The failure mechanism observed in both test and FEA followed a similar sequence: (1) initially, a vertical crack appeared at the bottom of the beam-column joint region, developing along the headed bar; (2) as the load increased toward its peak, diagonal cracks started to form around the anchorage bar, with the FE model accurately replicating this crack progression seen in the test; (3) eventually, additional diagonal cracks developed within the BCJ panel, accompanied by pullout displacement of the headed bar. Once diagonal cracks also emerged near the anchor plate, the pullout load of the anchorage bar began to decline. Both the FEA and test results indicate that ultimate failure was caused by cone cracking in the concrete cover adjacent to the anchorage. Notably, the failure mechanism observed in the LE25-M model closely mirrors that of the LE25-Ma model.

Strain of reinforcing bar

Fig. 9 shows the locations of the strain gauges on specimens where strain measurements were taken for comparison with the FEA. In Fig. 10, the relationship between pullout load and strain is displayed for both supplementary and main beam bars in the LE25-Ma model. Notably, the supplementary bars exhibit higher strain readings at points a3 and a5 than the test results. The strain at a5 (topmost supplementary bar) in the FEA exceeds the yield strain limit (μ = 2087). The strain at point a1 suggests compression of the supplementary bar under the pullout load for both the test and FEA. In the main bar, both the test and FEA show that the strain at point b1 is higher than at b2, while the results from FEA underestimate the test results. This proves that the strain in the supplementary bars is influenced by the shape of the concrete cone. These observations confirm the FE model's ability to replicate the strains observed experimentally in the reinforcing bars.

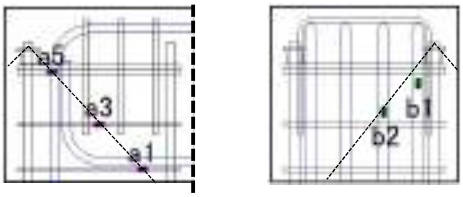

Fig.9 Location of strain gauges of the specimens

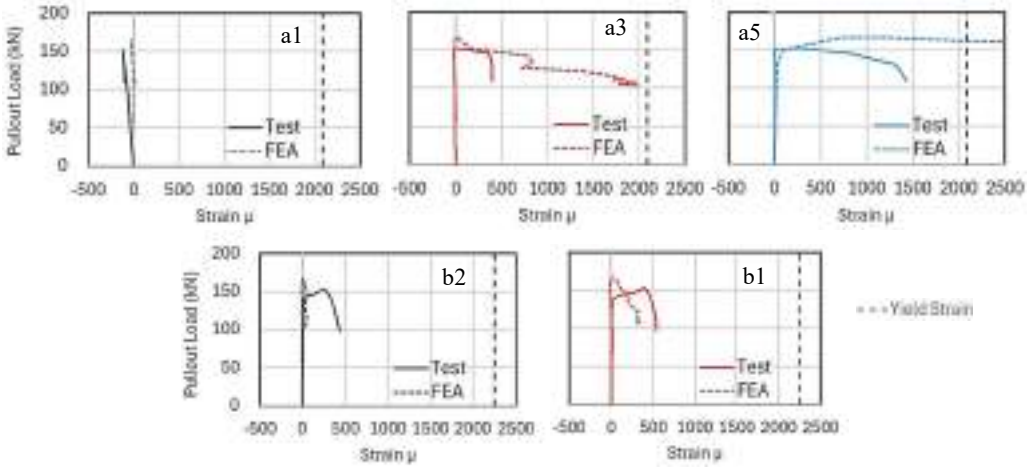

Fig.10 Relationship between load and strain of supplementary and main beam bars of LE25-Ma

Minimum principal stress

The minimum principal stress from the FEA is compared with the test results in Fig. 11 for LE25-M and LE25-Ma. Fig. 12 illustrates a cutaway diagram highlighting the positions of the headed and supplementary rebars. The stress contour shown in the figure is observed at the pullout load indicated as (2) in Fig. 7. The initial cracks in the analysis tend to be inclined, concentrating at the base of the headed reinforcing bar, where cracking first occurs. The stress then propagates at a 45-degree angle from the anchorage rebar. This concentration of stress can lead to crack initiation at the anchorage region of the headed bars. The stress was concentrated in the first supplementary bar (from the top), indicating that the presence of supplementary bars is important to bearing the pullout load and increasing the concrete breakout capacity. The FE models indicate that stress is focused on the near plate nut at the maximum pullout load. These findings confirm the stress state at the time of fracture, with the concentrated stress in the FE model aligning well with the observed specimen failures.

Parametric Study

The numerical results showed that the proposed FE model adequately describes the behavior of the

headed bar under pullout load. Additionally, a parametric numerical study was developed to investigate the influence of supplementary bars parameters on concrete cone failure and the pullout capacity of the anchors, including diameter and number of supplementary bars, and the distance of the topmost supplementary bar from the headed bar.

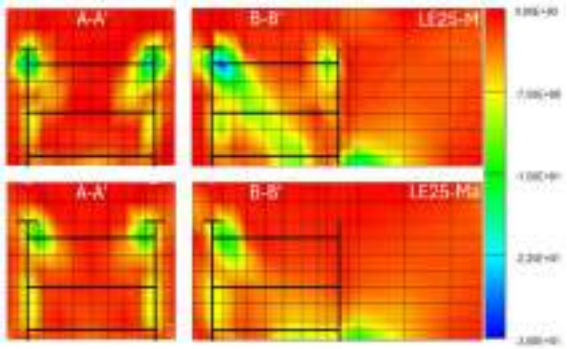

Fig.11 Minimum principal stress of the models

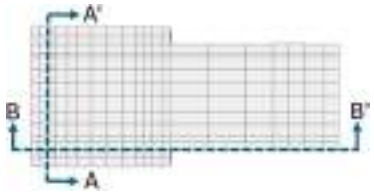

Fig.12 Cutaway of the models

The effect of supplementary bar diameter (d_s) on the concrete breakout strength of headed bars embedded in BCJ is investigated by modeling E4-10, E4-16, and E4-19 with d_s values of 10 mm, 16 mm, and 19 mm, respectively. It is notable that these models are designed based on the specimen LE25-M. Models with larger diameter bars provided better resistance to the applied pullout load, but the difference was not significant. As seen in Fig. 14(a), increasing the diameter to 16 mm and 19 mm resulted in higher ultimate capacities for the concrete breakout strength, by 9.8% and 11.4%, respectively, compared to the capacity of LE25-M model. The E4-10 model showed a decrease in anchorage capacity of around 7.4%, as shown in Table 2. The crack pattern and failure mode of E4-10, E4-16, and E4-19 are the same as those of LE25-M.

Varying the number of supplementary bars (n_s) was considered to study their effect on the concrete breakout strength capacity of headed bars in the LE25-M model. The arrangement of supplementary bars in this parametric model is shown in Fig. 13. The measured ultimate pullout capacity is plotted against varying n_s of the headed bar (4, 5, and 6) in Fig. 14(b). It is evident from the curve that a higher n_s leads to an enhancement in pullout capacity across all the models. There was a 12.6% increase in the pullout capacity of headed bars for E5-13, and a 21.8% increase was observed for E6-13, compared to LE25-M, respectively.

Another parametric study presents the effect of the topmost supplementary bar distance (S_{p1}) on the pullout load–displacement curve. Two variables of bar distance were considered and compared with the LE25-M (S_{p1} = 0) model. The pullout load–displacement curve for the E4-13a (S_{p1} = 30 mm) and E4-13b (S_{p1} = 60 mm) models is presented in Fig. 14(c). E4-13a model does not changing the anchorage capacity of the headed bar, whereas E4-13b model results reduct the capacity approximately 5.5%.

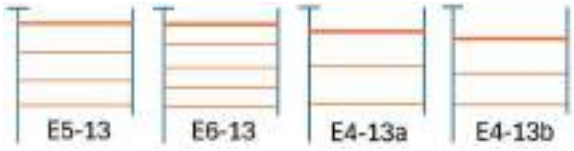

Fig.13 Configuration of supplementary bar in parametric study

Table 2 Results of parametric study

Model in Parametric Study	Variable	Max. Pullout Capacity (kN) (b)	Percentage of Increase (%) [[(b)-(a)]/(a)] x 100%
LE25-Ma	d_s = 6 mm	166.5	-27.1
E4-10	d_s = 10 mm	211.4	-7.4
E4-16	d_s = 16 mm	250.7	9.8
E4-19	d_s = 19 mm	254.3	11.4
E5-13	n_s = 5	257.2	12.6
E6-13	n_s = 6	278.1	21.8
E4-13a	S_{p1} = 30 mm	236.4	3.5
E4-13b	S_{p1} = 60 mm	215.7	-5.5

(a) is the maximum pullout capacity of LE25-M (228.3 kN), used as the benchmark model with d_s = 13 mm; n_s = 4 mm; S_{p1} = 0 mm.

CONCLUSION

The nonlinear finite element (FE) model developed in this study successfully predicted the concrete breakout strength of headed reinforcement bars in roof exterior BCJ specimens that were tested experimentally. This model simulated key behaviors such as the pullout load-displacement relationship, crack patterns, strain at reinforcement bars, and distributions of stress in the specimens analyzed theoretically. Both the experimental tests and FEA indicated that the anchorage capacity of the headed bars was affected by the configuration of the supplementary bars.

Additionally, the diameter, number, and spacing of the supplementary bars were found to significantly impact anchorage capacity. The diameter of the supplementary bars had a minor effect on the anchorage capacity, with a variation of approximately

7-11% increase or decrease in the capacity of LE25-M. Increasing the number of supplementary bars had a more substantial effect, enhancing anchorage capacity by 12.6% to 21.8% for 5 and 6 supplementary bars, respectively. The addition of the topmost supplementary bar's distance from the plate nut was observed to reduce the anchorage capacity of the headed bar.

ABSTRACT

Incorporating coal bottom ash (CBA) into construction materials offers an environmentally sustainable strategy for tackling waste management challenges. This study investigates the potential of CBA as an additive in fired clay bricks by evaluating its impact on key physical and mechanical properties. Clay bricks were produced with 0, 10, 20, 30, and 40 wt.% CBA, followed by firing at temperatures ranging from 900 to 1100 °C. The results show that higher CBA content resulted in a decrease in bulk density (from 2.26 to 1.70 g/cm³) and an increase in porosity, water absorption, and firing shrinkage. However, bricks containing 10–30 wt.% CBA, fired between 900 and 1100 °C, exhibited compressive strength exceeding ASTM C62-13a standards. The optimal incorporation of CBA at 900 °C was identified to be between 10–30 wt.%, underlining its potential as a sustainable alternative for enhancing the properties of fired clay bricks while promoting waste utilization.

.

Keywords: Coal bottom ash; Strength; Durability; Fired clay bricks; Porosity

INTRODUCTION

The construction materials sector is critical in addressing solid waste challenges by integrating industrial by-products and post-consumer waste into manufacturing processes. Among the well-established methods for reusing such waste is its incorporation into fired clay bricks, reducing the demand for virgin raw materials and enhancing environmental sustainability [1, 2]. This approach contributes to minimizing landfill waste and lowering overall production costs in the construction industry [3, 4]. The increasing focus on sustainable building practices has further accelerated the adoption of waste-derived materials in brick manufacturing, enabling compliance with industry standards while mitigating environmental impact [5, 6].

However, conventional brick production remains a major source of environmental pollution due to its significant greenhouse gas (GHG) emissions, contributing to smog, acid rain, and global warming [7]. In response, researchers have been exploring alternative raw materials to partially replace natural clay, thereby reducing the ecological footprint associated with its extraction and processing [8, 9]. Fired clay bricks are typically sintered at temperatures ranging from 900 to 1100 °C, and their physical and mechanical properties are highly influenced by the composition of raw materials and firing conditions [10]. In line with sustainability goals, various industrial by-products—including coal dust, gangue, fly ash, and coal slurry—have been investigated as partial clay replacements [11].

Among these, coal bottom ash (CBA), a coarse residue generated during coal combustion in power plants and industrial boilers, has emerged as a promising candidate. Produced in large volumes annually, CBA poses a serious disposal challenge and contributes to environmental degradation if not properly managed [3]. Nonetheless, its potential for recycling has been demonstrated in applications such as road subbase, backfill, cementitious binders, aggregates, and notably, fired clay bricks. Owing to its cost-effectiveness and compatibility with sustainability objectives, CBA is considered an attractive alternative material for brick production [12].

Recent studies have evaluated the feasibility of incorporating CBA into clay brick formulations. Adediran et al. reported that bottom ash improved apparent density and compressive strength in illitic clay-based bricks while reducing crack formation, mass loss, and water absorption. These improvements were attributed to the higher alkali oxide content (K_2O and Na_2O) in illitic clay, which enhances sintering reactions and mineral phase development. Specifically, at elevated sintering temperatures, alkali oxides act as fluxing agents, which lower the melting point of the system and promote the formation of a transient liquid phase. This temporary liquid phase enhances particle rearrangement, fills micro-pores, and facilitates vitrification, thereby increasing the densification of the brick matrix and reducing the open porosity. As a result, water absorption is

significantly decreased. Reported water absorption values ranged from 4% to 25%, and compressive strengths varied from 12 to 19 MPa depending on ash content and clay type [13]. Similarly, Kizinievič et al. (2022) found that adding 15% CBA decreased drying shrinkage by 21%, although it increased porosity, reducing mechanical strength [14]. Sutcu et al. (2019) further observed that bricks fired at 1050 °C exhibited lower porosity, water absorption, and higher density and thermal conductivity than those fired at 950 °C. While increased fly ash content typically led to higher porosity and water uptake, bottom ash had relatively minor impacts. Notably, bricks with 5–10% bottom ash demonstrated comparable compressive strength to conventional clay bricks [15].

These findings underscore the potential of coal bottom ash (CBA) as a viable partial substitute for natural clay in fired clay brick production, contingent upon the appropriate optimization of its incorporation ratio and firing parameters. Accordingly, the present study aims to systematically evaluate the influence of CBA incorporation at levels ranging from 10 to 40 wt.% under varying sintering temperatures (900–1100 °C) on fired bricks' fundamental physical and mechanical properties. This investigation seeks to establish a technically sound and environmentally sustainable alternative to conventional brick manufacturing while simultaneously addressing the pressing issue of coal combustion by-product management.

MATERIALS AND METHODS

Materials

The raw materials used in this study included natural clay sourced from a local brick factory in Kamala Sai, Kala Sin Province, Thailand (Fig. 1 (a)) and coal bottom ash (CBA) obtained from a coal power plant in Mae Moh, Lampang, Thailand (Fig. 1 (b)).

Fig. 1 Raw materials: (a) raw clay and (b) CBA.

The chemical composition of both clay and CBA was analyzed using X-ray fluorescence (XRF) (Horiba, Japan), with the results presented in Table 1. The crystalline structure of the materials was examined using X-ray diffraction (XRD: X' Pert Pro MPD, Philips, Netherlands). Particle size distribution was determined with a particle size analyzer (Mastersizer 2000+ Hydro 2000 MU), while microstructural characteristics were assessed using a scanning electron microscope (SEM) (LEO 1460 VP, Zeiss).

Clay bricks processing procedure

Clay bricks were fabricated by blending raw clay with coal bottom ash (CBA), both of which were pre-dried to achieve a stable moisture content. The materials were homogenized under ambient conditions, with water added at a ratio of 10–15% by weight to facilitate workability (Fig. 2). The resulting mixtures were molded into brick specimens with dimensions of 50 × 95 × 30 mm. These specimens were initially air-dried at room temperature for seven days, followed by oven drying at 110 °C for 48 hours to ensure complete moisture removal. The fully dried bricks were then subjected to firing at 900, 1000, and 1100 °C, employing a heating rate of 5 °C/min and a soaking duration of 30 minutes at the target temperature.

Fig. 2 Manual mixing of raw materials for clay bricks.

Fired clay bricks characterization

Firing shrinkage was measured following the ASTM C362-09 (2018) standard [16], which provides a framework for assessing the thermal behavior of ceramic materials during the firing process. Apparent porosity, water absorption, and bulk density were evaluated according to ASTM C373-18 (2018) [17], ensuring precise characterization of the material properties.

The mechanical properties of the fired clay bricks, essential for assessing their suitability in construction applications, were tested using a Universal Testing Machine (Chun Yen Testing Machines Co.). These tests followed the guidelines outlined in ASTM C773-88 (2020) [18], ensuring the reliability and reproducibility of the results. This standardized approach guarantees accurate material characterization, contributing valuable insights to material science and engineering. The reported results are the average of ten samples with the standard deviation shown as an error bar in the graphs.

Table 1 Chemical oxides composition of clay and CBA used in the experiments.

Oxide (wt.%)	Clay	CBA
SiO_2	50.49	56.22
Al_2O_3	29.84	15.76
Fe_2O_3	5.90	6.00
CaO	0.30	11.00
K_2O	1.20	1.53
Na_2O	-	-
SO_3	-	3.32
TiO_2	0.80	0.45
MnO	1.20	0.10
MgO	-	5.56
LOI.	9.34	0.07

RESULTS AND DISCUSSION

Characterization of raw materials

Table 1 presents the chemical composition of the raw materials as determined by X-ray fluorescence (XRF) analysis. The clay sample was primarily composed of SiO_2 (50.49%) and Al_2O_3 (29.84%), along with minor constituents such as K_2O, Fe_2O_3, CaO, MnO, and TiO_2. In comparison, the coal bottom ash (CBA) exhibited a higher SiO_2 content (56.22%), with Al_2O_3 (15.76%) and CaO (11.00%) as principal oxides, accompanied by MgO, K_2O, SO_3, Fe_2O_3, and TiO_2. The substantial presence of silica and alumina in CBA underscores its potential as a viable supplementary material in fired clay brick production.

Particle size distribution analysis conducted by ASTM D422-63 (2007) [19] indicated a mean particle diameter of 42.38 microns for raw clay, whereas CBA particles averaged 100 microns, signifying a coarser texture (Fig. 3).

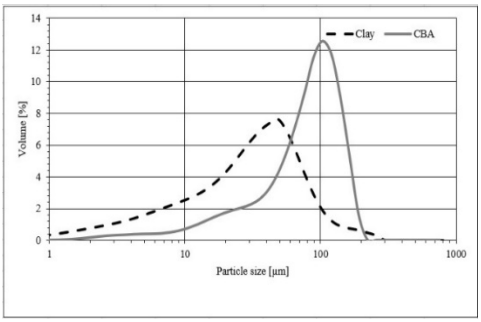

Fig. 3 Particle size distribution of the raw materials.

X-ray diffraction (XRD) analysis was performed to identify the crystalline phases present in clay and CBA (Fig. 4). The predominant minerals in raw clay included quartz (SiO_2; pdf. 01-085-1045), kaolinite ($Al_2(Si_2O_5)(OH)_4$; pdf. 01-080-0855), orthoclase ($KAlSi_3O_8$; pdf. 00-031-0966), hematite (Fe_2O_3; pdf. 01-089-8103), and muscovite ($KAl_2Si_3AlO_{10}(OH)_2$; 00-007-0025). In contrast, CBA contained mullite ($3Al_2O_3 \cdot 2SiO_2$; pdf. 79-1455), anorthite ($CaO \cdot Al_2O_3 \cdot 2SiO_2$; pdf. 02-0523), calcite ($CaCO_3$; pdf. 01-0837), hematite, and quartz.

Scanning Electron Microscopy (SEM) analysis (Fig. 5) revealed differences in surface morphology between the materials. Raw clay exhibited irregular particle shapes and noticeable agglomeration, whereas CBA particles appeared coarser, angular, and heterogeneous, reflecting their nature as a by-product of bottom combustion.

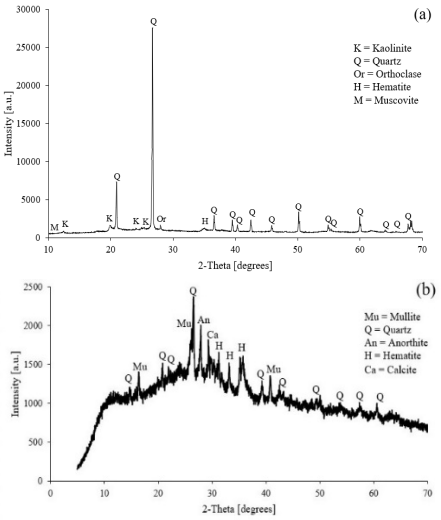

Fig. 4 XRD patterns of (a) raw clay and (b) CBA.

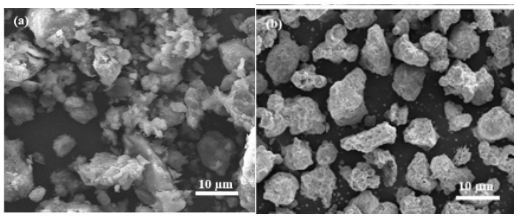

Fig. 5 SEM images of (a) raw clay and (b) CBA.

Technical properties of fired clay bricks

Physical and mechanical properties

Bulk density

The bulk density of fired clay bricks is primarily affected by the specific gravity of the constituent materials, processing methods, and firing temperatures [20]. As illustrated in Fig. 6, bulk density decreased with increasing CBA content and was positively correlated with firing temperature. Bricks without CBA exhibited densities ranging from 2.14 g/cm³ at 900 °C to 2.33 g/cm³ at 1100 °C. The addition of 10 wt.% CBA reduced these values to 1.93 g/cm³ and 2.26 g/cm³, respectively. Further increases in CBA content to 40 wt.% resulted in bulk densities of 1.70 g/cm³ (900 °C) and 1.98 g/cm³ (1100 °C). This reduction is attributed to the lower specific gravity and increased porosity induced by CBA incorporation.

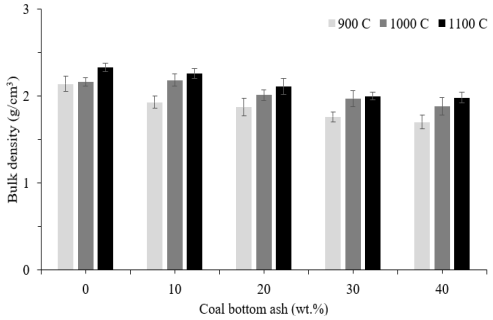

Fig. 6 Bulk density of fired clay brick samples.

Water absorption

Water absorption in fired clay bricks is governed by porosity, particle size distribution, and the microstructural arrangement of raw materials, all of which critically influence durability and long-term performance [21]. A dense and compact microstructure is essential to minimize water ingress and improve resistance to environmental degradation [22].

As shown in Fig. 7, bricks without CBA exhibited water absorption values of 13.44%, 10.51%, and 8.36% at firing temperatures of 900, 1000, and 1100 °C, respectively. In comparison, bricks containing 10–40 wt.% CBA demonstrated higher water absorption, ranging from 11.20% to 19.33%, depending on firing conditions. Increasing the sintering temperature consistently reduced water absorption across all CBA levels. This behavior is attributed to enhanced vitrification and a transient liquid phase formation during firing, which improves densification and decreases open porosity [13]. According to ASTM C62-23 standards, water absorption limits are ≤17% for severe weathering and ≤22% for moderate weathering conditions [23]. The findings confirm that bricks incorporating up to 30 wt.% CBA, when fired at temperatures ≥1000 °C, comply with these thresholds, supporting their suitability for structural applications.

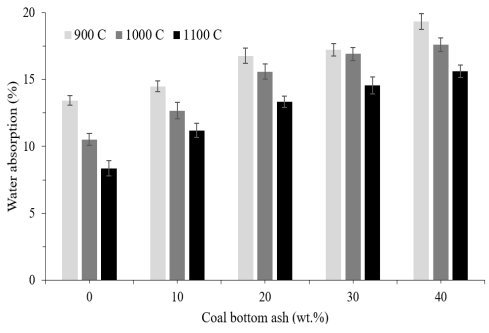

Fig. 7 Water absorption of fired clay brick samples.

Apparent porosity

Apparent porosity is critical in determining the durability and performance of fired clay bricks, as it is closely associated with increased water absorption, reduced compressive strength, and enhanced thermal insulation [20–23]. Fig. 8 illustrates the variation in apparent porosity as a function of CBA content and firing temperature.

Across all sintering temperatures, a general trend of increasing porosity with higher CBA incorporation was observed. The highest porosity (34.95%) occurred in samples with 40 wt.% CBA fired at 900 °C, while the lowest value (23.43%) was found in bricks with 10 wt.% CBA fired at 1100 °C. Bricks without CBA showed porosity values ranging from 19.87% to 21.57%, depending on firing temperature. These results confirm that CBA content has a pronounced influence on the microstructural characteristics of the bricks, particularly in terms of porosity, which in turn affects bulk density and water absorption.

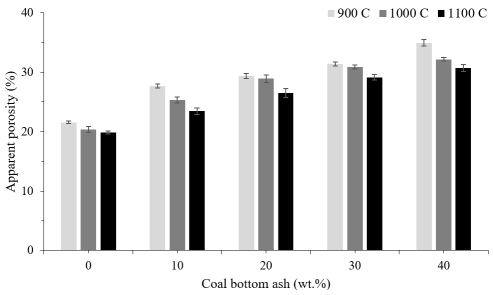

Fig. 8 Apparent porosity of fired clay brick samples.

Firing shrinkage

Firing shrinkage is a fundamental property influencing fired clay bricks' dimensional stability and structural integrity. Accurate linear shrinkage and weight loss assessment is essential to ensure that products meet design and quality specifications [24–25]. As shown in Fig. 9, variations in shrinkage behavior were observed across different CBA contents and sintering temperatures, reflecting the materials' thermal expansion and contraction characteristics [20, 23].

The linear firing shrinkage of all specimens ranged from 4.55% to 6.83% after sintering at 900–1100 °C, remaining well within the ASTM C62-23 (2023) limit of 8% [26]. The results indicate that increased firing temperature promotes densification and corresponds with a shrinkage pattern typical of ceramic materials undergoing partial liquid-phase sintering [20]. These findings confirm the dimensional reliability of CBA-modified bricks under standard thermal processing conditions.

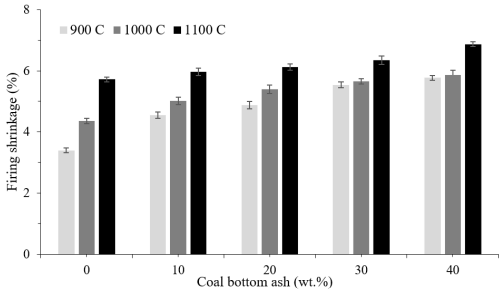

Fig. 9 Firing shrinkage of fired clay brick samples.

Compressive strength

Compressive strength is a key performance indicator for assessing the structural suitability of fired clay bricks, reflecting both material quality and load-bearing capacity. According to ASTM C62-23, fired clay bricks must achieve a minimum compressive strength of 17.2 MPa to meet standard construction requirements.

As shown in Fig. 10, compressive strength generally decreased with increasing CBA content across all firing temperatures. The values ranged from 16.75 MPa to 27.46 MPa, with the highest strength observed in control samples fired at 1100 °C (28.1 MPa) and the lowest in bricks containing 40 wt.% CBA fired at 900 °C (16.75 MPa). Despite this decline, bricks with 10–30 wt.% CBA fired at 900 °C and up to 40 wt.% CBA fired at ≥1000 °C exceeded the ASTM threshold.

Elevated firing temperatures enhanced sintering, crystallization and densification, reduced porosity, and strengthened the brick matrix. Conversely, excessive CBA content introduced a more porous microstructure, increasing water absorption and lowering density and strength [3, 15]. These results are consistent with previous studies indicating that high bottom ash content adversely affects mechanical performance due to increased porosity [14–15]. Thus, carefully optimizing CBA dosage and firing conditions is critical to achieving structurally sound and sustainable bricks.

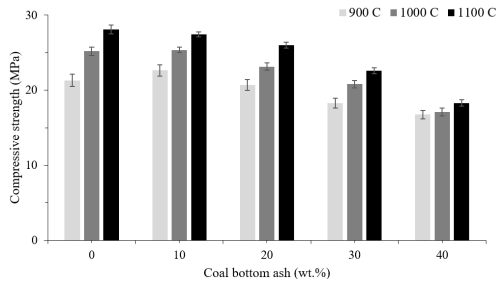

Fig. 10 Compressive strength of fired clay brick samples.

CONCLUSIONS

This study comprehensively evaluates coal bottom ash (CBA) as a sustainable supplementary material in producing fired clay bricks. Through systematic experimentation involving varying CBA contents (0–40 wt.%) and firing temperatures (900–1100 °C), the research demonstrates that CBA can partially replace natural clay without compromising key physical and mechanical properties. The high flux content of CBA, including K_2O, CaO, and MgO, facilitates improved sintering and reduced energy consumption.

Optimal performance was observed in bricks incorporating 10–30 wt.% coal bottom ash (CBA) and fired at temperatures of 1000 °C or higher, where the compressive strength exceeded the minimum requirement of 17.2 MPa specified by ASTM C62-23. Although increased CBA content resulted in higher porosity and water absorption, these adverse effects were effectively mitigated at elevated temperatures due to enhanced sintering and vitrification, which facilitated improved densification and mechanical integrity. Within this optimal range, the produced bricks exhibited acceptable physical properties and enabled partial replacement of natural clay, thereby aligning with both performance criteria and sustainability goals.

ABSTRACT

Alkali-activated material (AAM) is a cement-free concrete binder and can significantly reduce CO_2 emissions compared to conventional cement. Although large amount of powder causes high viscosity and poor handling of AAM concrete, the high viscosity can be utilized to increase segregation resistance required for high fluidity concrete. This paper presents an investigation on performance of AAM high fluidity concrete which had a mixture conditions determined based on mortar experiments. As a result of mortar experiments, the flow of AAM mortar with mole ratio of silicon to alkali (Si/A) of 0.4 decreased as the blast furnace slag (BFS) substitution ratio increased while one with Si/A ratios of 0.6 and 0.8 increased with BFS substitution ratio rise. AAM mortar with 20% of BFS replacement ratio had little increase in compressive strength by Si/A increase. AAM high fluidity concrete, which had mortar phase with 181 mm of flow value, resulted in more than 600 mm of slump flow. In addition, the 0.4% decrease in W/B caused 10% greater compressive strength at the age of 28 days, however, significant longer 500 mm slump flow time.

Keywords: Alkali-activated material, Compressive strength, Slump flow, 500 mm slump flow time

INTRODUCTION

Cement is widely used as concrete binder in the world, and huge amount of carbon dioxide is emitted in its production process. The carbon dioxide emission is one of major factors causing global warming, and is regarded as an international issue. Therefore, the concern with developing cement-free concrete binder has been growing, and the typical example is alkali-activated material (AAM), such as geopolymer. AAM is a general term for solidified materials produced by condensation polymerization reaction between activator and powders containing large amount of Si, Al and Ca components. Fly ash (FA) and blast furnace slag powder (BFS) are general component materials of AAM. A typical activator is a mixture of Sodium silicate solution (Water glass, WG) and sodium hydroxide solution (Caustic soda solution, CS).

AAM has no requirement of cement and can utilize by-products from other industries, so AAM can contribute to resource-recycling and low environmental impact. However, it has been found that AAM with sufficient compressive strength for required performance has high viscosity. The high viscosity of AAM is caused by water glass with high viscosity and higher unit content of powders (FA, BFS, etc.) than general cement concrete [1]. Mimura has reported that AAM mortar, which produced with the activator without water glass, had lower viscosity than that with water glass [2]. However, it is also mentioned that containing no water glass significantly decreased in compressive strength of AAM mortar. Therefore, high viscosity of AAM should be utilized while ensuring appropriate strength with activator containing water glass. For example, high viscosity of AAM can have effect on increasing segregation resistance in high fluidity concrete [3].

In this study, effects of several mixture conditions on fresh properties and compressive strength were evaluated by using AAM mortar. Slump flow test and compressive strength test were also performed on AAM high fluidity concrete with the mixture proportion determined based on the mortar results.

RESEARCH SIGNIFICANCE

Performance of AAM is affected by diverse constituent materials and mixture conditions. Many researchers investigate these effects by mortar experiments [4]. However, little discussion focuses on performance of AAM concrete based on results of mortar experiments. In this study, compressive strength, slump flow and 500 mm slump flow time were examined in order to investigate application of AAM to high fluidity concrete with the mixture proportion determined based on the mortar results. Achievement of AAM high fluidity concrete might contribute to not only resource-recycling and low environmental impact but also labor saving and cost reduction in construction.

EXPERIMENTS OF AAM MORTAR

Materials

The materials used for AAM mortar in the present study are listed in Table 1. FA and BFS were used for binder of AAM mortar in this study. FA was in accordance with Class II of Japanese Industrial Standards (JIS A 6201) and is easily available in Japan. BFS in accordance with JIS A 6206 had specific surface area of 4000 cm^2/g and was mixed in order to increase strength of AAM mortar.

Activator in this study was a mixture of WG and CS. WG had a mole ratio of Na_2O to SiO_2 of 2.5. In Japan, water glass was specified by the former JIS K 1408, which have now been regulated by standard of Japan Inorganic Chemical Industry Association. The mole concentration of CS was set to 7 mol/L. When the water component of CS and WG was unsatisfied with unit water content of a mixture condition, additional tap water (Wad) was mixed to the activator. Crushed sand from Kure City (density: 2.62 g/cm^3) was used as fine aggregate (S). Chemical admixtures in this study were high-performance water reducing admixture (Ad1) and retarder (Ad2). Ad1 and Ad2 were mainly composed of naphthalenesulfonic acid and oxycarboxylic acid, respectively. Both admixtures were commercially available for cement concrete. Ad2 was used to ensure enough time for casting AAM mortar because AAM with BFS generally has short setting time.

Mixture conditions and proportions

The mixture conditions and proportions of AAM mortar in the present study are given at Table 2. Mole ratios of silicon to sodium in the activator (Si/A) were 0.4, 0.6 and 0.8. BFS substitution rates, which represent BFS volume substitution fraction to FA, were 20%, 30% and 50%. The effect of Si/A and BFS substitution rate was investigated with AAM mortar from M1 to M9.

Ad1 rate (Ad2 rate) was a mass rate of Ad1 (Ad2) to FA and BFS, and was 0% or 2%. The previous study [3] has reported that a high-performance water-reducing agent with main component of Naphthalene sulfonic acid increased in compressive strength of AAM mortar using activator consisting of only caustic soda solution and had little increase effect on compressive strength of AAM mortar with water glass of mole ratio 2.0. In this study, the effect of Ad1 and Ad2 on compressive strength of AAM mortar with WG of mole ratio of 2.5 was evaluated by comparison with results from M10 to M15.

The following mixture conditions of AAM mortar were set constant in 15 mixture proportions of this study. A mole ratio of sodium to water in activator (A/W) was set to 0.1. Water-binder ratio (W/B, binder in this study presents FA and BFS) was determined to be 0.4. A unit water content (W) was 240 kg/m^3,

Table 1 Materials of AAM mortar

Materials	Properties
Fly ash (FA)	Class II
Blast furnace slag (BFS)	Specific surface area: 4000 cm^2/g
Caustic Soda Solution (CS)	Mole concentration of NaOH: 7 mol/L
Water glass (WG)	Mole ratio of SiO_2/Na_2O: 2.5
Water (Wad)	Tap water
Fine aggregate (S)	Crushed sand
Admixture 1 (Ad1)	High-performance water-reducing agent, Naphthalenesulfonic acid
Admixture 2 (Ad2)	Retarder, Oxycarboxylic acid

Table 2 Mixture conditions and proportions of AAM mortar

I.D.	Si/A	BFS rate (vol%)	Ad1 (%)	Ad2 (%)	Mixture proportions (kg/m^3)								
					FA	BFS	WG1	WG2	CS	Wad	S	Ad1	Ad2
M1	0.4	20	2	2	452	148	---	112	166	47	1327	12	12

M13	0.6	30	2	0	385	215	---	168	127	46	1345	12	0
M14	0.6	30	0	2	385	215	---	168	127	46	1345	0	12
M15	0.6	30	0	0	385	215	---	168	127	46	1345	0	0

Note: BFS rate represents BFS substitution rate. The other mixture conditions are as follows:
A/W = 0.1, W/B = 0.4, W = 240 kg/m³, B = FA+BFS, Ad1 = B×2%, Ad2 = 2%

which included water component of caustic soda solution and water glass.

Experimental procedure

AAM mortar in the present study was mixed with a mortar mixer which had the maximum capacity of 2 liters. FA, BFS and fine aggregate were mixed for 30 seconds, and then the activator was added and mixed for 1 minute.

Just after mixing, a mortar flow test was conducted by using a flow table and mold with a truncated cone shaped. The mold placing AAM mortar was lifted vertically, and the flow table made 15 strokes with once a second. The diameters of AAM mortar ware measured at the most spread and at right angle to it, and the mortar flow was evaluated by the average of the measurements.

In this study, the compressive strength test of AAM mortar was performed by using a cylindrical specimen with a diameter of 50 mm and a height of 100 mm. After placing, the top surface of specimen was sealed with double plastic wrap. All specimens with a mold and plastic wrap were cured under sealed condition at room temperature of 20 degree Celsius. The specimen was demolded just before the compressive strength test.

For the compressive strength test, the cylindrical specimen was loaded at a loading rate of 0.2 N/mm^2 per second. The compressive strength of AAM mortar was evaluated with the average of 3 specimens. The compressive strength test in accordance with JIS A 1108 was conducted at the age of 7 days and 28 days.

Results and discussion

Fig. 1 shows the result of the mortar flow test. When AAM mortar had the mixture condition of Si/A of 0.4, the flow value was decreased as BFS substitution rate increased. This decrease in flow might be caused by BFS replacement of FA, which has spherical particle. However, the flow value of AAM mortar with Si/A of 0.6 and 0.8 was increased with BFS substitution rate. In addition, the amount of AAM mortar adhering to the flow mold was increased, and higher viscosity was visually observed. Fluidity and viscosity of AAM mortar were affected by various mixture conditions, so, further investigation and discussion might be required in order to achieve appropriate fresh properties for high fluidity concrete.

Fig. 2 shows the relationship between Si/A and compressive strength for each BFS substitution rate. Increase in BFS substitution rate caused higher compressive strength of AAM mortar regardless of Si/A as shown in Fig. 2, so development of compressive strength of AAM mortar at early age in the present study might be dominated by BFS, and might be almost independent to Si/A. Because the reaction of activator with FA which has main component of amorphous silica and alumina could be much slower than that of BFS containing large amount of Ca under room temperature curing condition of 20 degree Celsius in this study.

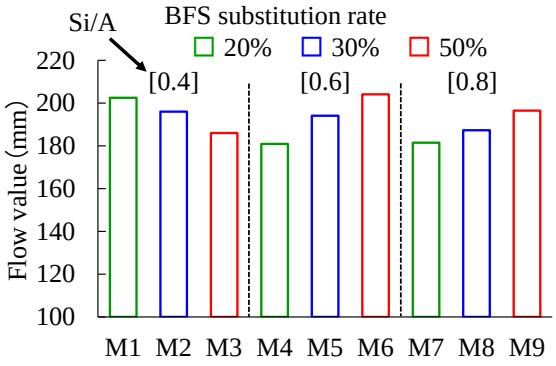

Fig.1 Flow value of AAM mortar

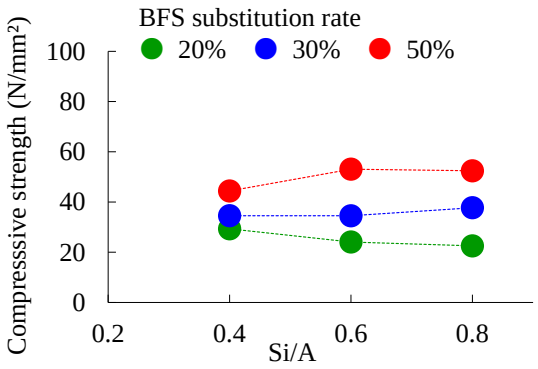

Fig. 2 Compressive strength of AAM mortar at the age of 7 days

Fig. 3 shows the compressive strength of AAM mortar at the age of 28 days. The compressive strength at the age of 28 days also increased as BFS substitution rate rise. This result indicates that contribution of FA to strength development was smaller than BFS at the age of 28 days under room temperature curing condition. In order to appropriately evaluate strength development by FA, compressive strength test at long term age such as 91 days is required. At the lowest BFS substitution rate of 20% in the present study, Si/A had little effect on the compressive strength at the age of 28 days, while AAM mortar with 30% and 50% of BFS substitution rate had higher compressive strength as Si/A rise. Uehara [5] has reported that low alkali concentration and small BFS substitution rate are caused relatively small compressive strength of AAM mortar with silica fume added instead of water glass as source of silica. According to this paper, this might be because the low alkali concentration and small BFS substitution rate cause less dissolution of silica fume as small BFS substitution rate prevents from consumption of Si component which is required in

hardening process of BFS. In this study, the alkali concentration which was 0.1 of A/W was the same as the previous study [4], and the low concentration might cause lower dissolution of FA. In addition, component of Si in the activator at low BFS substitution rate could be consumed little in hardening process, so the compressive strength of AAM mortar with 20% of BFS substitution rate was almost independent to Si/A. However, it is noted that source of silica in the previous study was silica fume instead of water glass and constituent materials and mixture conditions were different from those of this study.

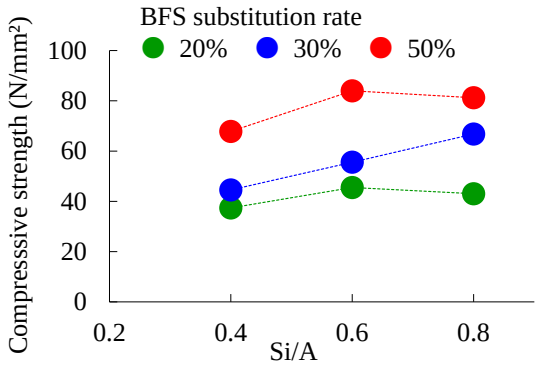

Fig. 3 Compressive strength of AAM mortar at the age of 28 days

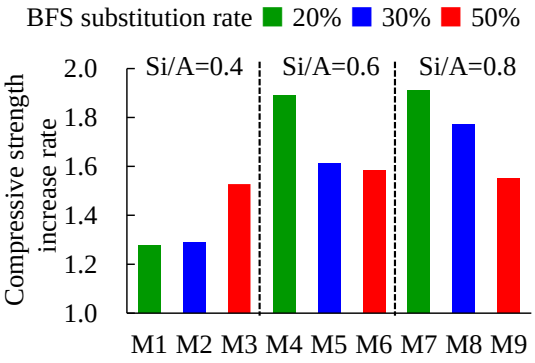

Fig.4 Compressive strength increase rate

Fig. 4 shows the increase ratio of the compressive strength at the age of 28 days to that at the age of 7 days. When Si/A was 0.6 and 0.8, the compressive strength increase rate was decreased as BFS substitution rate increased. This is because the compressive strength at the age of 7 days was higher with higher BFS substitution rate due to the effect of BFS on early strength development. In addition, the decrease in unit content of FA due to BFS substitution rate rise could also cause less effect of FA on strength development at long term age. On the other hand, the compressive strength increase ratio was increased by higher BFS substitution rate at 0.4 of Si/A. In this case, less silicon was supplied from water glass than the other cases. AAM mortar at the age of 28 days could contain insufficient component of silicon for FA due to consumption for hardening reaction of BFS at early age, so BFS substitution rate had higher contribution to the compressive strength at the age of 28 days.

Fig. 5 demonstrates that the effect of the chemical admixtures on the compressive strength of AAM mortar. At the age of 7 days, AAM mortar without the chemical admixtures which were high-performance water-reducing agent (Ad1) and retarder (Ad2) for cement concrete had the highest compressive strength. The maximum difference in the compressive strength was 7.6 N/mm^2 at 0.4 of Si/A.

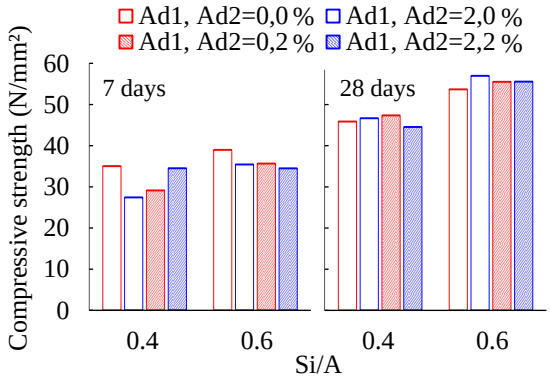

Fig.5 Effect of chemical admixtures on compressive strength

Although the compressive strength of AAM mortar with the chemical admixtures was lower than that without the chemical admixtures at the age of 7 days as shown in Fig. 5, the compressive strength of AAM mortar at the age of 28 days was equivalent regardless of the chemical admixtures and the maximum difference in the compressive strength was only 2.8 N/mm^2. This difference at 0.6 of Si/A was correspond to less than 5% of the averaged compressive strength. These results indicate that Ad1 and Ad2 used in the present study had little effect on the compressive strength. Especially, although the retarder (Ad2) which had main component of Oxycarboxylic acid restrained hardening reaction and decreased in the compressive strength at early age (except for the mixture condition of Si/A of 0.4 and Ad1 addition), such effect could diminish with age. Therefore, AAM mortar with Ad1 and Ad2 could have equivalent compressive strength at the age of 28 days shown in Fig. 5.

EXPERIMENTS OF AAM CONCRETE

Materials

AAM concrete used the same materials as AAM mortar. Crushed stone with a density of 2.67 g/m^3 was used in AAM concrete as coarse aggregate (G).

Table 3. Mixture conditions and proportions of AAM concrete

I.D.	W/B	BFS rate (vol%)	Mixture proportions (kg/m^3)								
			FA	BFS	WG	CS	Wad	S	G	Ad1	Ad2
C1	0.4	10	360	52	116	87	32	624	954	8.25	0.825
C2	0.4	20	311	101	116	87	32	630	963	8.25	0.825
C3	0.36	20	346	113	116	87	32	609	932	9.17	0.917

Note: BFS rate represents BFS substitution rate. The other mixture conditions are as follows:
A/W = 0.1, Si/A = 0.6, W = 165 kg/m^3, B = FA+BFS, Ad1 = B×2%, Ad2 = B×0.2%, s/a = 0.4

Mixture conditions and proportions

The mixture conditions for AAM concrete in this study are shown in Table 3. The mixture conditions determined for AAM concrete in this study were A/W, Si/A, W (kg/m^3), W/B, BFS substitution rate (vol%), sand-total aggregate ratio (*s/a*, vol%), Ad1rate (%) and Ad2 rate (%).

The base mixture of AAM concrete in this study was C2 given at Table 3. Its mixture conditions for AAM concrete were set to reference to the AAM mortar experimental results. BFS substitution rate was 20% in order to ensure enough setting time for flow test and casting AAM concrete. Si/A was determined as 0.6, because AAM mortar with Si/A of 0.6 had the highest compressive strength with 20% of BFS substitution rate at the age of 28 days shown in Fig. 3. Therefore, the mortar phase in AAM concrete with C2 mixture was correspond to AAM mortar of M4. In addition, *s/a* and Ad2 rate were set to 0.4 and 0.2%, respectively. AAM mortar with BFS substitution rate of 20% had enough setting time for casting in a laboratory and required little effect of Ad2, so Ad2 rate for AAM concrete was set to lower than that for AAM mortar. A unit water content of AAM concrete was determined as 165 kg/m^3, which was evaluated from unit water content of 240 kg/m^3 of AAM mortar and approximate volume fraction of mortar phase in AAM concrete. The others of mixture conditions were the same as AAM mortar. That is, A/W was 0.1 and Ad1 was 2%.

In this study, AAM concrete with a mixture condition of BFS substitution rate of 10% (C1) and a mixture condition of W/B of 0.36 (C3) were also prepared in order to investigate fresh properties and compressive strength.

Experimental procedure

FA, BFS and fine aggregate were mixed for 30 seconds by a bi-axial forced mixing type mixer. Coarse aggregate was then added and mixed for another 30 seconds, after which the alkaline solution was added and mixed for 60 seconds. A slump flow test in accordance with JIS A 1150 was performed just after mixing.

A cylindrical specimen for compressive strength test had 100 mm in diameter and 200 mm in height. After casting, all specimens were sealed with double plastic wrap and cured in the same condition as AAM mortar. The procedure from curing to compressive strength test was the same as AAM mortar. Compressive strength test was conducted at the age of 7 days and 28 days.

Results and discussion

Fig.6 shows the relationship between slump flow and 500 mm slump flow time. In this study, the mixture conditions of AAM concrete was determined with reference to AAM mortar of M4. Although M4 had the lowest flow value of 181 mm in this study, 600 mm slump flow was achieved by AAM concrete of 3 mixtures, as shown in Fig.6. In addition, AAM concrete of this study was observed no segregation, so viscosity of AAM was effective to increase in segregation resistance.

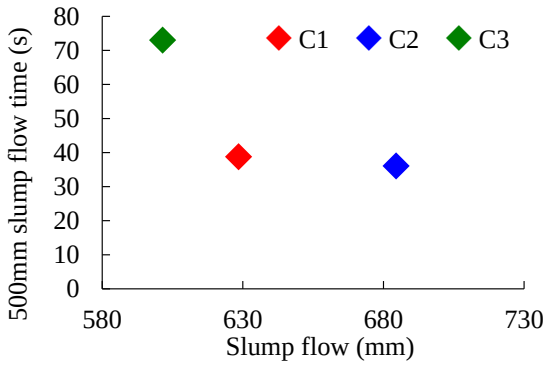

Fig.6 500mm slump flow time and slump flow

AAM concrete of C2, which had 10% higher BFS substitution rate than C1, had 685 mm of slump flow. Slump flow of C2 was 55 mm greater than that of C1. 500 mm slump flow time was only 3 seconds shorter than that of C1, and C2 had equivalent 500 mm slump flow time to C1. This result indicates that C2 had equivalent viscosity and higher fluidity compared with C1. It is well known that BFS unit content increase causes lower fluidity and slump flow become smaller. However, slump flow of AAM concrete in this study was increased with BFS increase, so effects of BFS on slump flow of AAM concrete are needed further experiments and discussion.

Compared with result in C2, the slump flow of C3 was reduced by 83 mm due to decrease in W/B of 4% and C3 had approximately 12% lower fluidity. 500 mm slump flow time of C3 was extended by 37

seconds. This flow time was equivalent to twice flow time of C2 and shows that C3 had higher viscosity. The higher viscosity of C3 was also visually observed. These results indicate 4% decrease in W/B has greater effect on 500 mm slump flow time than 10% reduction in BFS substitution rate.

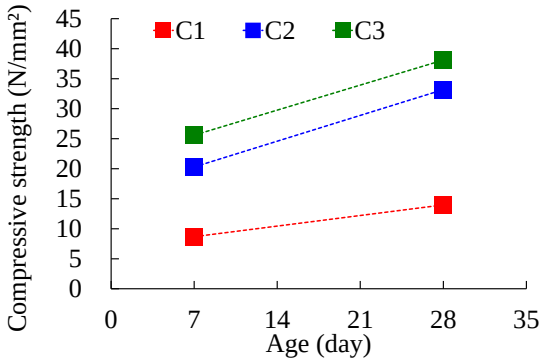

Fig.7 compressive strength of AAM concrete

The compressive strength of AAM concrete at the age of 7 days and 28 days is shown in Fig.7. C1 with BFS substitution rate of 10% had the lowest compressive strength of 14 N/mm² at the age of 28 days. Compared with the compressive strength of C2, the compressive strength of C1 with BFS substitution rate of 10% was less than half, it was approximately 40% at the age of 7 days and 28 days. The compressive strength of C3, which had 4% lower W/B in order to increase in compressive strength, was 1.3 times and 1.1 times at the age of 7 days and 28 days compared C2, respectively. This result indicates that the BFS substitution rate had greater effect on compressive strength of AAM concrete than W/B.

Compared with a result of the previous study [4], AAM concrete in this study had the equivalent compressive strength and slump flow, however, 500 mm slump flow time was much longer. This might be because that mixture conditions such as a unit content and the maximum size of coarse aggregate were different. In addition, the maximum compressive strength in this study was only 38.1 N/mm^2. In order to expand usage of AAM concrete as alternative of cement concrete, it is necessary to satisfy various strength property requirements. Some mixture conditions such as A/W, W/B and BFS substitution rate affect strength development, however, increasing compressive strength of AAM concrete often causes shorter setting time. Therefore, further investigation are required on effect of various materials and mixture conditions on performance of AAM concrete.

CONCLUSIONS

In this study, fresh and strength properties of AAM mortar and AAM concrete with various mixture conditions are experimentally investigated in order to evaluate application of AAM to high fluidity concrete. The conclusions of this study are as follow:

(1) The flow test results of AAM mortar shows that when the Si/A ratio is 0.4, the flow value decreases with increasing BFS substitution rate. However, when the Si/A ratio is 0.6 or 0.8, the flow value shows the opposite behavior.
(2) The compressive strength of AAM mortar with 20% of BFS substitution rate might be almost independent to Si/A.
(3) High-performance water-reducing agent with main component of Naphthalenesulfonic acid and retarder with main component of Oxycarboxylic acid have little effect on compressive strength of AAM mortar at the age of 28 days.
(4) AAM concrete, which has mortar phase with 181 mm of mortar flow, achieves 600 mm slump flow, and reduction in W/B by 4% causes 12% lower fluidity based on slump flow and twice 500 mm slump flow time due to higher viscosity.
(5) In AAM concrete, BFS substitution rate has greater effect on compressive strength than W/B.

INFLUENCE OF BIOCHAR WATER HYACINTH ON THE SHEAR STRENGTH OF ULTISOLS

Erica Elice S. Uy[1], Jeann Patrick B. Barcelona[2], Juan Angelo V. Malaca[2], Lance Matthew R. Santiago[2], Jose Gabriel R. Zamora[2] and Angelo B. Edora[3]

[1,2]De La Salle University, Philippines; [3]Nagoya University, Japan

ABSTRACT

Ultisols are reddish, acidic, and clayey soils that are abundant in the Philippines. It is commonly found in upland areas and approximately covers 41.5% of the land area. However, this material is underutilized due to its high plasticity, which can have an adverse effect on its shear strength. In order to explore ultisol's potential, soil stabilization is essential. A promising material that can be blended to ultisol is water hyacinth biochar. This type of material has hydrophobic qualities which can be beneficial to high plastic material since it can repel water. Water hyacinth was used since it is an invasive species that disrupts the bodies of water that it grows on. In this study, biochar water hyacinth was blended to ultisols having 0%, 5% and 10% proportions. To investigate on the influence of this material to ultisols the relative density was varied. The samples were prepared having a relative density of 32.5%, 60% and 92.5%. The shear strength parameters were established by performing a direct shear test under undrained condition. Based on the results, biochar water hyacinth had a significant effect on the cohesion of the soil.

Keywords: Water hyacinth Biochar, Ultisols, Shear strength, Undrained condition

INTRODUCTION

According to the Bureau of Soils and Water Management (BSWM), one of the most common lowland soil in the Philippines is Ultisols or Alisols. The area covered by Ultisols in the Philippines is approximately 41.5% [1]. They are formed as a result of very extensive weathering and leaching processes that produce a subsurface that is clay-enriched and predominantly composed of minerals including quartz, kaolinite and iron oxides. Ultisols are usually composed of sand, silt and clay [2-5]. The percentage varies due to the lithology and morphology on where it is located and formed. In the Philippine setting, it was found that some Ultisols in the Visayas group of island was observed to have high clay content and high plasticity [5]. Although this soil is abundant in the Philippines, it is not being utilized as a construction material. A possible reason is the high fines content which can have a negative impact to the shear strength. With this, there is a need to explore soil stabilization techniques that will lessen the plasticity and increase the shear strength.

Soil stabilization in general are techniques to improve the index properties, shear strength and compressibility of a soil. It can be categorized into mechanical, physical and chemical stabilization [6, 7]. In mechanical stabilization, it physically alters the soil properties to improve the strength. One way is by adding and blending industrial waste materials such as silica fume, rice husk ash and ground granulated blast furnace slag [8, 9]. These waste materials may improve the gradation of the soil and can also contribute to an increase in shear strength. Mechanical stabilization also involves changing the density of the soil by means of compaction [6, Rivera-7]. In this manner, the void spaces become smaller making the relative density higher. Physical stabilization improves soil's properties by introducing reinforcements such as geotextiles [10, 11]. Chemical stabilization alters the soil's properties by introducing additives such as lime, fly ash and cement. This results to the chemical reactions that enhances the bonding and interlocking in the soil matrix [12]. Also, in this technique the purpose of the additives is to develop pozzolanic reaction which improves the shear strength of a weak soil. The additives are also known as binders which also frequently adopted in the enhancement of particle bonds and interaction. Binders such as lime and cement are very common. However, these materials usually have negative impact to the environment. For lime binders, are calcium-based and undergoes calcination process. This process needs high energy which leads to an increase in carbon dioxide emission [10, 13, 14].

An emerging material for soil stabilization is the use of biochar. This material is a form of charcoal that is both environmentally safe and a stable, carbon-rich form of charcoal that can be added to the soil. This is produced using a process called pyrolysis, where biomass is heated at temperatures starting at 250 Degrees Celsius with almost no oxygen [15]. Waste materials such as agricultural waste, forestry waste, sewage waste and municipal waste are some of the commonly used raw materials [16].

Several studies explored the potential of biochar as an additive to improve the shear strength of soil. In a

study by Reddy [17], they used wood biochar in assessing the shear strength of the clay soil mixed with the sample. The biochar proportion used in the study is 5%, 10% and 20%. Based on the results, shear strength increased as the amount of biochar was increased. The study by Xu [18] used what straw as the raw material for biochar. In this study, 0, 2.5, 5, 10, and 20% of biochar by weight was added to the clay. It was observed that the shear strength increased for 2.5 and 5% biochar while 10% and 20% decreased. The largest shear strength was observed at 5% biochar content**.** Li [19] investigated the effect of the bagasse biochar and rice platycodon biochar to the shear strength of red loam. The proportions of the two biochar were 0%, 2%, 4%, 6%, and 8%. They were added to the loam mass with respect to the dry mass. In their results, the biochar content of 2%, 4% and 6% showed an increase. The largest shear strength was observed at 6% and decrease was observed at 8%. It can be observed that although adding biochar can increase the shear strength at 5% and 6% showed the largest improvement. Also, when the amount of biochar was increased larger than 5% or 6% shear strength decreased. However, comparing it to 0% biochar, there was still an improvement observed.

A potential biochar raw material is water hyacinth. According to Dersseh [20], water hyacinths are invasive tracheophyte plant. Several countries experienced disruption due to its abundance. In the Philippines, thick water hyacinth beds cover the rivers which can obstruct the passageway of barges and ferry services [21]. The potential of water hyacinth as an additive was explored by numerous studies. A study by Sathya [22] assessed the influence of water hyacinth extract from Thanjavur District, India as a Bio-admixture in cement and concrete. It was found that there is a progressive increase of compressive strength whenever there is an increase in the replacement of water hyacinth extract. In the study of Okwadha & Makomele [23], the water hyacinth extract served as an admixture in concrete cube production. The ratios of water hyacinth used were 0%, 10%, 15%, 20%, and 25%. Slump tests and compressive tests of various concrete cubes were performed to evaluate the workability of the concrete after 7, 14 and 28 days. After all the laboratory tests, the researchers concluded that the water hyacinth in the form of liquid extract increased the workability of concrete with an increase in percentage replacement of concentration of the solution. The enhancement of workability in concrete may be caused by the small fragments of lignocellulose and hemicellulose dissolved in water hyacinth extract.

Accordingly, this study aims to explore the potential and effect of water hyacinth biochar (WHBC) to the shear strength of Ultisols. Biochar was added by weight and the proportions were 0%, 5%, 10%, 15%, and 20%. The relative density of the soil sample was varied to further assess the effectiveness of the water hyacinth biochar in increasing the shear strength of soil. The relative densities used were 32.5% (Loose), 60% (Medium Dense), and 92.5% (Very Dense). Direct shear test was performed simulating an undrained condition.

RESEARCH SIGNIFICANCE

This study investigated the effect of water hyacinth biochar's on the shear strength of Ultisols. The significance of the study is in the potential of treated Ultisols as a construction material. The results of the study highlight the contribution of water hyacinth biochar to the shear strength of Ultisols and the potential of WHBC as an additive for soil amendment. Lastly, the study introduces another beneficial use of water hyacinth. This can lessen its negative impact to the water ways by processing it into a potential additive for soil stabilization.

ULTISOL

The samples were obtained from the mountainous are of Zamboanga Peninsula region in Mindanao. Based on visual inspection in accordance with Standard Practice for Description and Identification of Soils, the sample has a reddish color and has a flat particle shape. When the cementation was observed, it is considered moderate since the particles crumbled with a considerable amount of pressure. For its structure, it is deemed homogeneous. It was observed that it has the same color and appearance throughout.

Figure 1. Ultisols Soil

Sieve and Hydrometer Analysis and Index properties such as specific gravity (G_s), liquid limit (LL), plastic limit (PL), plasticity index (PI), maximum dry unit weight (γ_{dmax}), optimum moisture content (OMC), minimum void ratio (e_{min}) and maximum void ratio (e_{max}) were established. Soil classification was established considering the Unified Soil Classification System (USCS). The experiments were performed in accordance to American Society for Testing and Materials (ASTM) Standards. The results are tabulated in Table 1.

Table 1 Index Properties of Ultisols

Index Properties	
G_s	2.78
LL	51
PL	39
PI	12
γ_{dmax} (kN/m^3)	12.66
OMC	36.64%
e_{min}	1.537
e_{max}	1.930

The Grain Size Distribution Curve (GSDC) is shown in Figure 2. Based on the trend of the GSDC, it shows a poorly graded sample and its soil classification is SC (clayey sands, sand-clay mixtures).

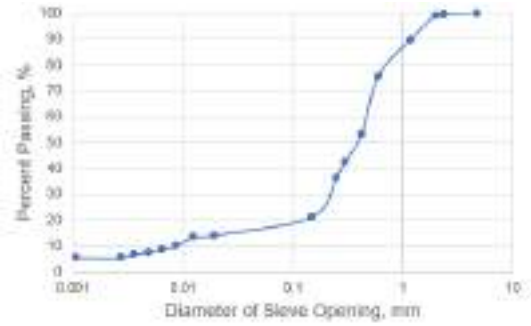

Figure 2. GSDC of Ultisol

Scanning electron microscopy (SEM) of the Ultisols is shown in Figure 3. It can be observed that the texture is rough with fine particle sized. It can also be observed that the particles also contain micro-pores. The Energy-dispersive X-ray spectroscopy (EDX) of Ultisol is tabulated in Table 2. Based on the results, the soil predominantly composed of Carbon and Oxygen. Traces of Aluminum, Silicon and Iron were observed. The EDX was determined to investigate the elements that can have a reaction with the water hyacinth biochar.

Table 2 EDX of Ultisol

Element Symbol	Element Name	Atomic Conc.	Atomic Weight
C	Carbon	49.06	43.42
O	Oxygen	37.68	25.04
Al	Aluminum	4.78	7.13
Si	Silicon	3.98	6.18
Fe	Iron	2.17	6.71
Nb	Niobium	1.83	9.40

WATER HYACINTH BIOCHAR

The water hycinth was sourced in the National Capital Region. Shown in Figure 4 is the biochar process implemented in the study. Before the biocharing process, the plant was first sun dried to remove moisture. Once dried, it was cut into smaller pieces in order to fit the furnace. For the biochar process, a furnace was fabricated as shown to accommodate the target temperature conditions.

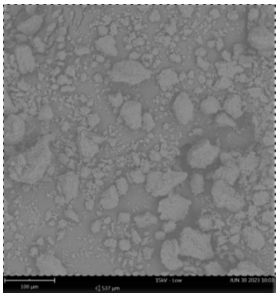

Figure 3. SEM of Ultisols

According to Masto [24], the optimal temperature and time for water hyacinth biochar process is 300 to 350 Celsius for 30 – 40 minutes, respectively. This condition was chosen since it yielded the optimal temperature for the biochar process while minimizing the increase in pore structure and size of particles. This may decrease the shear strength of amended soil samples in addition to preserving biochar yield.

Figure 4 Biochar Process

SEM-EDX of water hyacinth biochar was also obtained. This is to verify the quality of biochar process performed. Based on the results of SEM in Figure 5, it can be seen that the texture is smooth and flaky. It is noticeable that its particle size is not uniform. Shown in Table 3 is the summary of results of EDX. Based on the results, Carbon is the predominant material which is an indication of an effective biochar process.

Table 3 EDX of WHBC

Element Symbol	Element Name	Atomic Conc.	Atomic Weight
C	Carbon	72.35	57.60
O	Oxygen	22.20	23.55
Cl	Chlorine	1.46	3.44
K	Potassium	1.40	3.62
Nb	Niobium	1.17	7.18
Ca	Calcium	0.61	1.62

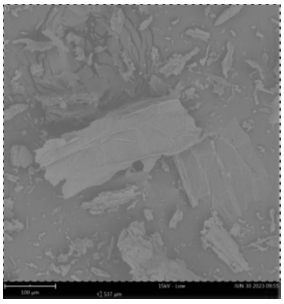

Figure 5. SEM of the WHBC

SHEAR STRENGTH TEST AND RESULTS

Sample Preparation

Reconstituted samples were tested in this study. The target amount of soil and water for 0% water hyacinth biochar was based on γ_{dmax} and OMC of the Ultisols. The target amount of soil, water and water hyacinth was based also on the γ_{dmax} and OMC of Ultisols mixed with WHBC. To achieve this, a separate standard proctor test was performed considering the target proportions of WHBC. The summary of results is tabulated in Table 4.

Table 4 Percentage of WHBC Amended in relation to the soil's Optimum Moisture Content and Maximum Dry Unit Weight

WHBC Proportions (%)	Optimum Moisture Content (%)	Maximum Dry Unit Weight (kN/m^3)
0	36.64	12.66
5	41.6	6.2
10	47.67	5.63
15	54.41	4.77
20	56.76	2.51

Three relative densities, 32.5%, 60%, and 92.5%, were prepared to know the effect of WHBC to the shear strength of Ultisols. These values were chosen due to being the median value for the ranges of loose, medium dense, and dense conditions. Once the target amount of soil, water and water hyacinth is established, these were mixed and soaked for at least 16 hours. To create reconstituted samples, moist tamping was performed. Moist tamping was done to ensure uniform density within the sample [25]. The samples were tamped for a minimum of 10 times per layer for a minimum of 3 layers.

Direct Shear Test Experimental Design

To evaluate the effectiveness of the WHBC in increasing a soil's shear strength, the shear strength of the soil samples mixed with 0%, 5%, and 10% biochar were determined using a direct shear test based on the ASTM D3080. The test was conducted under drained conditions. The rate of shearing used was 0.12 mm/min as suggested by Dafalla [26]. This rate of shearing was chosen since it is low enough for the pore water pressure to dissipate without further affecting the results of the test. The normal stresses used in the test were 22.5 kPa, 45 kPa, and 90 kPa. These normal stresses simulate a fill with a height of at most 6 m.

Shear Strength Results

For the direct shear test, typical results of the stress-strain and volumetric strain-shear strain curves are shown in Figures 6-10. For Ultisols, it was observed that strain hardening was experienced. For samples prepared at 60% relative density peak was observed for 22.5kPa normal stress. For samples with water hyacinth biochar, strain hardening was observed for all samples. For the volumetric strain-shear strain curves samples exhibit contractive behavior during shearing. Samples tested in general showed ductile behavior as the mode of failure.

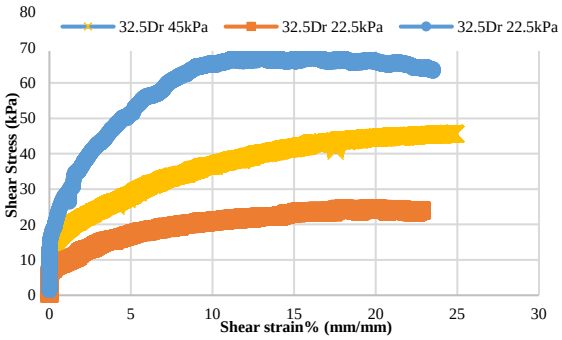

Figure 7. Stress-strain Curve for 32.5 Dr with 5% WHBC

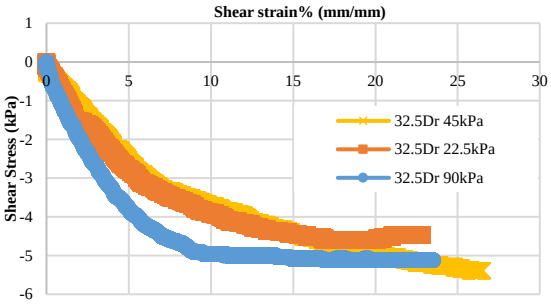

Figure 8. Volumetric strain-shear strain Curve for 32.5 Dr with 5% WHBC

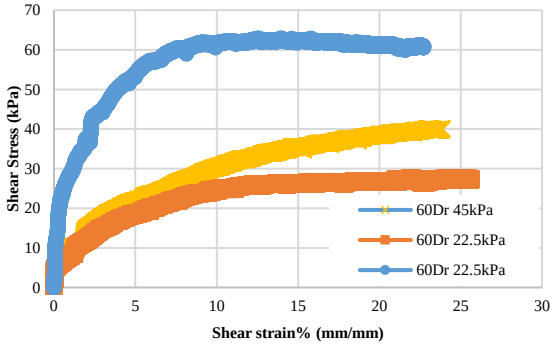

Figure 9. Stress-strain Curve for 60 Dr with 5% WHBC

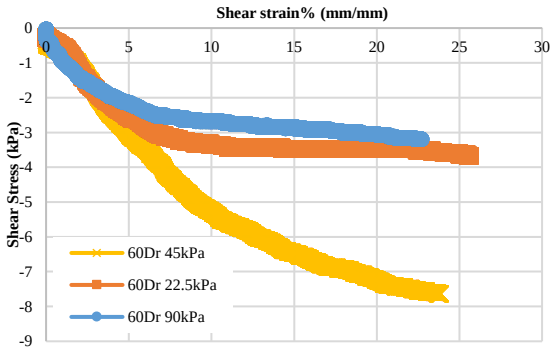

Figure 10. Volumetric strain-shear strain Curve for 60 Dr with 5% WHBC

The Mohr-Coulomb Failure Envelope of each relative density was plotted as shown in Figure 11 and 13. The Failure Envelope is shown to generally increase the denser the soil sample gets, and decrease the more biochar is amended. This increase in shear strength can be seen in Figure 11. When comparing between different groups of biochar amendments, Figure 12 verifies that increasing the amount of biochar present decreases the cohesion of the soil. This decrease in cohesion confirms that WHBC may not be suitable for increasing the shear strength parameters of the soil sample.

The shear strength parameters of the soil sample were obtained and compared with one another as tabulated in Tables 5 and 6. As seen, there is a decrease in cohesion once an additional amount of biochar was amended. This is true for majority of the cases, however, there are a few outliers present. The most prominent outlier is the increase in cohesion in the medium dense condition from 5% WHBC to 10%. For the angle of internal friction, there is no consistent trend that was observed. The addition of WHBC did not enhance the bonding and interlocking of the Ultisols' soil particles. This is can be attributed to the flaky texture of WHBC, which acted similar to fine particles, thereby reducing particle contact. In addition, the hydrophobic nature of WHBC limited the development of cohesion which also contributed to the reduction in shear strength.

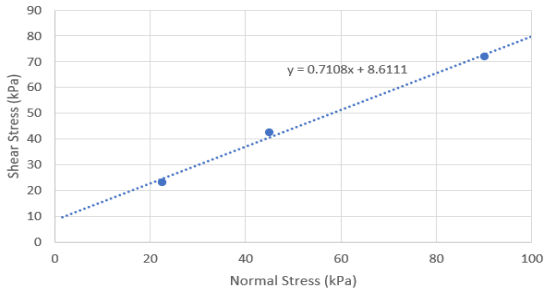

Figure 11. Mohr-Coulomb Failure Envelope of 0% BC at 32.5% Relative Density

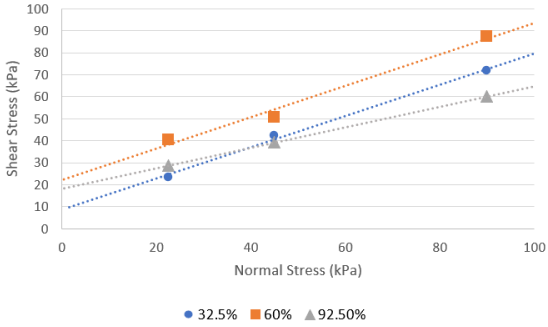

Figure 12. Mohr-Coulomb Failure Envelopes of 0% BC at Different Relative Densities

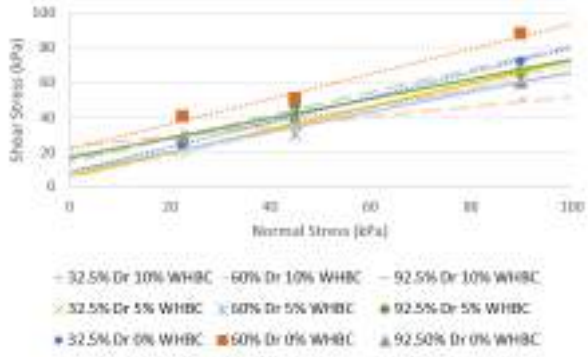

Figure 13. Mohr-Coulomb Failure Envelopes of 0%, 5%, & 10% BC at Different Relative Densities

Table 5. Percentage of WHBC Amended in Relation to the Soil's Cohesion at Different Relative Densities

	Relative Density (%)		
WHBC (%)	32.5	60	92.5
0	8.611111	22.08333	18.19444
5	6.388889	0.568783	16.80556
10	5.555556	23.47222	14.44444

Table 6. Percentage of WHBC Amended in Relation to the Soil's Angle of Internal Friction at Different Relative Densities

	Relative Density (%)		
WHBC (%)	32.5	60	92.5
0	35.40363	35.50421	24.92555
5	33.40932	29.63049	29.1703
10	32.62784	15.80516	33.47968

An Analysis of Variance (ANOVA) was carried out to determine whether the effects of the percentage of the WHBC and its relative density were significant on both the cohesion and angle of internal friction of the soil. In the analysis, the cohesion values of the 60% Dr sample were disregarded due to its low R-squared value from the regression analysis. For the sample's cohesion, the percentage of WHBC and relative density yielded a p-value of 0.02 and 0.002 respectively, which was less than the level of significance of 5%. As such, it can be said that both the amount of biochar and its relative density may have a significant effect on the cohesion of the sample. As for the friction angle, a p-value of 0.38 and 0.25 was obtained for the percentage of WHBC and relative density. This implies that both the relative density and the percentage of biochar may not have a significant effect on this.

CONCLUSIONS

The study explored the potential of Ultisols as construction material. However, due to its high fines content the soil was improved by adding WHBC. It can be observed that the cohesion decreased as the presence of biochar increased. For the angle of internal friction, no consistent pattern was observed. This is because of the flaky texture of WHBC which behaved similar to a fine grained material. Instead of causing an increase in the cohesion, a reduction was observed since WHBC is a hydrophobic material. Due to the texture of WHBC, it is recommended to use it as an additive for the purpose of improving its permeability.

ABSTRACT

This research evaluates enhanced concrete formulations incorporating Portland Slag Cement (PSC), Portland Pozzolana Cement (PPC), and High-Volume Fly Ash (HVFA) against conventional Ordinary Portland Cement (OPC) mixtures across grades M15 to M30. Key parameters—compressive strength, workability, and water-cement ratio—were assessed over 7-day and 28-day curing periods. The study explores how Supplementary Cementitious Materials (SCMs) enhance durability and sustainability while reducing environmental impact. Results indicate PSC and PPC mixes outperform OPC, with PPC achieving 67.01 MPa for M30 (10.5% above OPC), alongside improved resistance to degradation and cost savings. HVFA mixes, despite lower early strength (e.g., 38.9% below OPC at 7 days for M20), offer exceptional workability (up to 240 mm slump) and sustainability benefits by minimizing OPC use. These findings demonstrate that optimized designs reduce carbon emissions and reliance on virgin materials, supporting eco-friendly construction. PSC and PPC are recommended for strength-driven projects, while HVFA suits workable, large-scale applications.

Keywords: Italic Concrete Mix Optimization, Alternative Cement, PPC, PSC, HVFA, Sustainability

INTRODUCTION

Concrete remains the cornerstone of modern construction, with its performance largely dictated by the type of cement and mix design. Traditional Ordinary Portland Cement (OPC) mixes, while reliable, contribute significantly to carbon emissions due to their high clinker content. In response, optimized mixes incorporating Supplementary Cementitious Materials (SCMs) such as slag (in PSC), pozzolana (in PPC), and fly ash (in HVFA) have emerged as sustainable alternatives. These materials not only reduce environmental impact but also enhance mechanical properties and durability.

This study compares the performance of PSC, PPC, and HVFA mixes against standard OPC mixes for concrete grades M15, M20, M25, and M30. The focus is on evaluating compressive strength, workability, and sustainability, with the aim of identifying optimal alternatives to OPC for various construction applications.

1. Enhancing cost efficiency by reducing reliance on OPC.
2. Increasing durability by improving resistance to chemicals and environmental degradation.
3. Developing sustainable concrete with lower carbon footprints.
4. Reducing the heat of hydration to prevent thermal cracking.
5. Achieving better workability and surface finish.

The adoption of PPC, PSC, and HVFA as alternatives to OPC brings several advantages to the construction industry. These materials contribute to the circular economy by utilizing industrial by-products such as fly ash and slag, reducing dependency on virgin raw materials and minimizing waste disposal issues. Additionally, the performance characteristics of concrete improve significantly when blended cements are used, leading to enhanced mechanical properties and improved resistance to aggressive environmental conditions.

Recent advances in materials science and environmental engineering have intensified the search for sustainable, high-performance alternatives in construction. With rising concerns over climate change and resource depletion, the industry is increasingly shifting toward eco-friendly materials that reduce energy consumption and lower carbon emissions. By integrating industrial by-products such as slag and fly ash,

concrete mixes can significantly decrease reliance on energy-intensive OPC, yielding both economic and environmental benefits. This study not only investigates the mechanical and durability aspects of alternative mixes but also explores their potential to transform traditional construction practices, thereby contributing to a greener future in civil engineering. The use of fly ash as a partial replacement for cement has gained traction due to its potential to reduce embodied carbon, the extensively documented the mechanical and environmental performance of HVFA concrete, showing that it could meet structural requirements while offering superior durability [1].

Further emphasized the sustainable benefits of HVFA concrete, noting a significant reduction in CO_2 emissions alongside adequate compressive strength for M20–M30 grade mixes [2&3].The genetic algorithms also served to optimize HVFA concrete mixes, finding that up to 50% replacement levels could be achieved without significantly compromising strength or workability [4]. These findings align) work on self-compacting concrete, where fly ash improved both flowability and long-term performance [5].From a sustainability perspective, multiple studies have evaluated the ecological advantages of blended cements. Replacing OPC with supplementary cementitious materials like fly ash and slag could drastically reduce energy consumption and greenhouse gas emissions [6 & 7]. The Central Pollution Control Board (2020) also highlights the importance of fly ash utilization in achieving India's waste management and decarbonization goals [8].Kumar and Nanda (2017) showed that Combining fly ash with Ground Granulated Blast Furnace Slag (GGBS) enhances strength and durability, further supporting the move away from pure OPC use [9]. Papadakis (2000) found that Such materials also improve resistance to carbonation and chloride ingress, thus extending the service life of concrete structures[10,11 &12].Shetty and Rao (2019) and Neville (2011) provide foundational insights into concrete behavior, confirming the viability of blended cements in practical applications.

BIS guidelines (IS 10262:2019) now accommodate PPC and PSC in concrete mix designs, reflecting an institutional shift towards sustainable practices [13 & 14].The use of locally available industrial byproducts not only reduces environmental impact but also contributes to the circular economy. Studies like Kumar and Santhanam (2003) affirm that Class F fly ash can be effectively used in Indian construction contexts, further improving the case for regional adoption [15 &16].

RESEARCH SIGNIFICANCE

The environmental impact of cement production is a major concern in the construction industry, with Ordinary Portland Cement (OPC) accounting for approximately 7–8% of global CO_2 emissions. As the demand for concrete continues to grow—particularly in rapidly urbanizing regions—there is an urgent need to explore sustainable alternatives that reduce carbon emissions without compromising structural performance. This research is significant because it evaluates the sustainability and mechanical performance of optimized concrete mixes using Portland Slag Cement (PSC), Portland Pozzolana Cement (PPC), and High-Volume Fly Ash (HVFA), as compared to conventional OPC-based concrete in the commonly used grades M15 to M30. The following are the objectives of the study:

1. To Evaluate the Effectiveness of Different Concrete Mixtures
2. To Make Concrete Production More Sustainable
3. To identify the best cement substitutes for particular uses
4. To optimize mix designs for enhanced durability and reduced environmental impact.

METHODOLOGY

Coarse Aggregates Well-graded, angular particles ranging from 10mm to 20mm and Fine Aggregates preference for natural river sand; M-sand is considered an alternative for this study. Gradation analysis ensures optimal workability.

Coarse Portland Slag Cement (PSC) blends Ordinary Portland Cement (OPC) with ground granulated blast furnace slag, Portland Pozzolana Cement (PPC) incorporates pozzolanic fly ash, and High-Volume Fly Ash (HVFA) cement uses substantial fly ash as a partial cement replacement, while OPC, without supplementary cementitious materials (SCMs), serves as the baseline. Coarse aggregates, ranging from 10mm to 20mm, are well-graded and angular, and fine aggregates, preferably natural river sand with M-sand as an alternative, undergo gradation analysis to ensure optimal particle size distribution for enhanced workability and strength. Fineness tests are conducted on PPC, PSC, OPC, and fly ash to evaluate their surface area and uniformity, and moisture content in fine aggregates is assessed to adjust the water-cement ratio appropriately.

Fineness tests are conducted on PPC, PSC, OPC, and fly ash to evaluate their surface area and uniformity, while gradation analysis is performed on coarse and fine aggregates to ensure optimal

particle size distribution for enhanced workability and strength, and moisture content in fine aggregates is assessed to adjust the water-cement ratio appropriately.

The mix design process is followed as per IS 10262 2019. & IS 456 2000.

Exposure Condition Assumed mild to moderate as per IS 456 2000.

Target Mean Strength Computed for each grade e.g., M20 26.6 MPa, M25 31.6 MPa, M30 38.25 MPa.

Water-Cement (W/C) Ratio Selected based on strength and cement type, adjusted with admixtures e.g., 0.57 for M15-OPC, 0.31 for M30-PSC/PPC (conforming to IS 269 2015).Water Content Determined for high workability (~186 kg/m³), reduced by superplasticizers (e.g., 15% for OPC, 35% for PSC/PPC).Cement Content Calculated using W/C ratio and water content, meeting IS 456 2000 minimums (e.g., 280 kg/m³ for M15, 390 kg/m³ for M30-OPC).

Aggregate Proportioning Coarse aggregates (60/ 40 ratios of 20 mm to 10 mm) and M. Sand proportioned for optimal grading. The trial Mixes Conducted to adjust proportions, verifying workability and strength. Validation Workability Slump tests (IS 1199 1959) confirmed collapse slump.

Strength Compressive strength tested at 7 and 28 days (IS 516 1959) to ensure fckt) was met.

Compliance Verified against IS 456 2000 for cement content, W/C ratio, and durability.

This method ensured all mixes met strength, workability, and durability requirements while promoting sustainability through PSC, PPC, and HVFA use.

RESULTS

The experimental dataset includes 16 mixes four grades (M15, M20, M25, M30) for each cement type. Mix proportions are detailed in Table 1. Aggregates (20mm, 10mm, M. Sand) varied slightly but maintained consistency across grades.

The Compressive Strength Tests Cubes cast for each mix is evaluated for 7-day and 28-day strength. The comparative Analysis Strength performance is carried out across mixes compared to OPC benchmarks. SCMs in PSC and PPC were optimized for strength and sustainability, and HVFA utilized abundant fly ash. Mixes followed IS 10262 2019, with dry blending, water. Optimised mixes exhibited higher initial slump values (175-240 mm), with HVFA showing the highest workability (240 mm for M20, M25, M30).

Table 1 7-Day Compressive Strength (MPa) and Comparison

Grade	Mix Type	OPC 53 (kg/m³)	Fly Ash (kg/m³)	PSC/PPC (kg/m³)	Total Cementitious (kg/m³)	OPC Reduction (%)
M-15	OPC	280	0	0	280	0.00
	PSC	80	0	160 (PSC)	240	71.4%
	PPC	80	0	160 (PPC)	240	71.4%
	HVFA	145	145	0	290	48.2%
M-20	OPC	300	0	0	300	0.00
	PSC	100	0	200 (PSC)	300	66.7%
	PPC	100	0	200 (PPC)	300	66.7%
	HVFA	160	160	0	320	46.7%
M-25	OPC	340	0	0	340	0.00
	PSC	120	120	120 (PSC)	360	64.7%
	PPC	120	120	120 (PPC)	360	64.7%
	HVFA	170	170	0	340	50.0%
M-30	OPC	350	0	0	350	0.00
	PSC	130	130	130 (PSC)	390	62.9%
	PPC	130	130	130 (PPC)	390	62.9%
	HVFA	195	195	0	390	44.3%

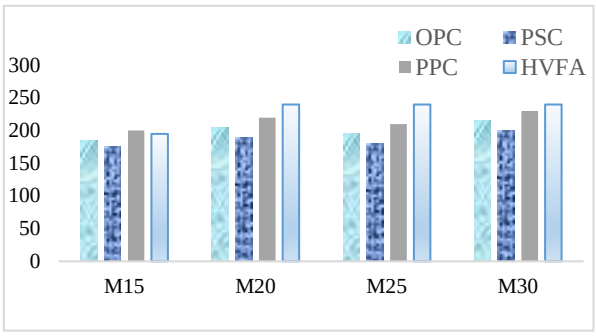

Fig.1 Slump values for different Mixes in mm

Lower slump the observations indicate that concrete mixes incorporating Portland Slag Cement (PSC) tend to have lower slump values, suggesting they may need additional water or the use of plasticizers to improve workability. On the other hand, mixes using High-Volume Fly Ash (HVFA) or Portland Pozzolana Cement (PPC) exhibit higher slump values, making them easier to handle, though care must be taken to control water content and prevent segregation. Among the mixes, the M30 grade shows the most variation in slump, highlighting the importance of careful mix design adjustments to ensure consistent workability. Overall, a clear trend emerges: as the grade of concrete increases from M15 to M30, slump values also rise. This suggests that higher-grade concretes demand greater workability to facilitate proper placement during construction.

Compressive strength at both 7 days and 28 days is essential for evaluating concrete performance. The 7-day strength provides insight into early strength gain, critical for construction schedules, while the 28-day strength reflects long-term performance. Below, Table 3a presents the 7-day compressive strength data extracted from the experimental results, and Table 3b presents the 28-day compressive strength data, both in MPa, with comparisons against OPC for each grade (M15, M20, M25, M30).

The table highlights distinct strength development trends for each binder type across different concrete grades. Portland Slag Cement (PSC) shows both early and sustained strength improvement due to its latent hydraulic properties, making it a strong alternative to Ordinary Portland Cement (OPC) in applications requiring early formwork removal or rapid construction. Portland Pozzolana Cement PPC), while slower in early strength development due to delayed pozzolanic reactions, demonstrates superior 28-day strength, especially in higher grades like M25 and M30. This makes PPC highly suitable for structural elements where long-term strength and durability are key. In contrast, High-Volume Fly Ash (HVFA) concrete exhibits lower early and 28-day strengths, limiting its use in high-strength or load-bearing structures. However, it offers excellent workability and sustainability, making it ideal for mass concrete, foundations, or non-structural elements where reduced carbon footprint is prioritized over early strength.

Overall, the results underscore the importance of selecting the appropriate binder based on project-specific requirements such as performance timeline, environmental goals, and structural demand to ensure both efficiency and sustainability in concrete design.

W/C Ratio Optimized mixes have lower ratios (0.31-0.50) than OPC (0.41-0.57), contributing to higher strength and durability (Fig.2).

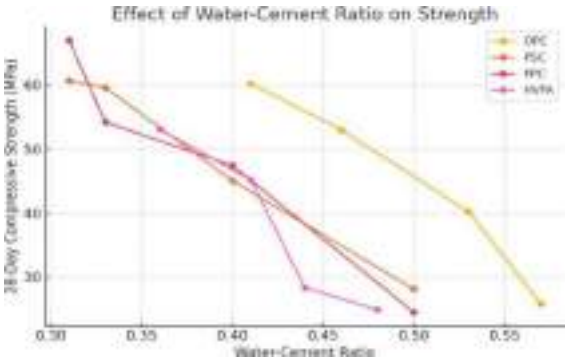

Fig.2 Effect of Water-Cement Ratio on 28-Day Compressive Strength

Optimized mixes reduce OPC content, cutting carbon emissions and costs due to SCM availability. Using SCMs like fly ash or slag lowers production costs and reduces concrete's carbon footprint, as OPC manufacturing is energy-intensive. A 50% fly ash substitution can cut emissions by 40%, supporting sustainability efforts. Additionally, SCMs enhance durability, extending structure lifespan and reducing maintenance costs.

Table 2 7-Day Compressive Strength (MPa) and Comparison

Grade	OPC (MPa)	PSC (MPa)	PPC (MPa)	HVFA (MPa)	PSC vs OPC (%)	PPC vs OPC (%)	HVFA vs OPC (%)
M15	16.90	18.49	15.53	16.69	+9.4%	-8.1%	-1.2%
M20	24.63	28.78	30.07	15.04	+16.8%	+22.1%	-38.9%
M25	34.93	37.93	33.12	33.58	+8.6%	-5.2%	-3.9%
M30	40.34	42.30	43.97	34.21	+4.9%	+9.0%	-15.2%

Table 3 Observation on 7- and 28-days strength

Grade	Binder	7-Day Highlights	28-Day Highlights
	OPC	Baseline early strength for low-grade concrete.	Standard long-term performance reference.
M15	PSC	Early gain due to slag hydration.	Sustains better strength with time.
	PPC	Slow early reaction limits strength.	Strength improves as pozzolanic activity matures.
	HVFA	Slightly behind OPC, limited early reactivity.	Modest strength due to delayed ash activation.
	OPC	Balanced early performance.	Reliable long-term strength.
M20	PSC	Improved early strength from slag activity.	Continues strength gain with extended hydration.
	PPC	Strong early response from blended pozzolans.	Outperforms OPC over time.
	HVFA	Weak early strength from diluted binder.	Lags due to slow fly ash reactivity.
	OPC	Good early performance benchmark.	Stable long-term strength.
M25	PSC	Strong start from slag effects.	Maintains advantage over OPC.
	PPC	Slightly delayed start.	Catches up and surpasses OPC.
	HVFA	Moderate early strength.	Lower strength suitability for structural use.
	OPC	High early strength, suitable for structural demand.	Long-term strength standard.
M30	PSC	Matches or slightly leads OPC early.	Retains comparable strength.
	PPC	Good early results.	Best strength outcome over time.
	HVFA	Poor early strength.	Not ideal for high-strength needs.

CONCLUSIONS

This study demonstrates that PSC and PPC offer superior compressive strength and workability, making them viable alternatives to OPC across all grades. HVFA excels in workability and sustainability but compromises early compressive strength, limiting its use in high-strength applications. Optimised mixes enhance performance whilst providing environmental benefits, reinforcing their adoption in sustainable construction practices.

This investigation has thoroughly assessed the efficacy of concrete mixes utilizing Portland Slag Cement (PSC), Portland Pozzolana Cement (PPC), and High-Volume Fly Ash (HVFA) against traditional Ordinary Portland Cement (OPC) for grades M15 to M30. The results underscore that PSC and PPC surpass OPC in compressive strength and workability, with PPC recording a 28-day strength of 67.01 MPa in M30, a 10.5% improvement over OPC. All optimized mixes showed enhanced workability, with HVFA leading due to its superior slump values.

Conversely, HVFA's early strength lagged significantly, dropping 38.9% below OPC at 7 days in M20, limiting its use in high-strength contexts, though its sustainability and flowability make it ideal for large-scale projects like foundations or dams. By reducing OPC reliance and incorporating by-products such as slag and fly ash, these mixes lower environmental impact and costs, promoting a greener, more economical construction sector. PSC and PPC are thus ideal for strength-driven projects, while HVFA suits applications valuing workability and eco-friendliness. Further studies should examine long-term resilience and ways to boost HVFA's initial strength to broaden its scope. This research supports adopting these mixes for sustainable, high-performing construction solutions.

ABSTRACT

This study investigates the effect of printing direction on the mechanical properties of 3D-printed cement mortar. The specimens were printed in both unidirectional and multidirectional (with orientations of 0°, ±45°, and ±90°) and tested for compressive and flexural strength in both directions, perpendicular and parallel to printing plane. Three types of mortar were tested: plain mortar, mortar mixed with nano-calcium carbonate, and mortar mixed with micro-polypropylene fibers. Notably, unidirectional printing showed higher strength perpendicular to the print plane but showed limitations in the parallel stress direction due to inefficient interlayer adhesion and delamination. In contrast, multidirectional printing significantly improves the uniformity of stress distribution and mechanical properties in both stress directions, thereby enhancing the overall stability of the printed structure. Additionally, incorporating nano-calcium carbonate and micro polypropylene fibers enhanced mechanical properties and reduced anisotropic behavior. These approaches contribute to improving the overall structural performance and mitigate direction dependency in 3D-printed cement mortar.

Keywords: 3D printing cement mortar, Printing direction, Unidirectional and Multidirectional printing, Nano-calcium carbonate mortar, Micro-polypropylene fibers reinforced mortar

INTRODUCTION

Due to several advantages, 3D printing of cement-based materials plays a crucial role in the construction industry sector [1]. These include the reduction of labor, minimization of material waste, particularly in formwork, and the ability to fabricate complex and customized geometries [2].

As a result, various aspects of 3D printing technology have been under continuous development. This includes efforts to design buildability mortars with low settlement [3], optimize mixture compositions for sustainability and environmental compatibility, and explore diverse printing techniques to tailor the printed cement mortar's mechanical and structural performance.

One of the primary challenges in 3D-printed cementitious components arises from the layer-by-layer deposition process, which inherently induces anisotropic mechanical behavior [4]. Unlike homogeneous materials with uniform properties in all directions, 3D-printed mortars exhibit directional dependence, with mechanical strength enhanced in specific orientations.

Furthermore, the interlayer bonding between printed layers is often mechanically weaker than the bulk material, leading to reduced lateral or parallel loading performance [5]. This structural discontinuity imposes significant limitations on the use of 3D-printed elements in load-bearing applications.

Previous studies have shown critical limitations in the mechanical performance of 3D-printed materials arising from the printing technique. For example, the infilling printing technique demonstrated that unidirectional printing, which involves stacking identical layer patterns, leads to increased internal voids, inefficient stress distribution, and mechanical weaknesses at the interlayer interfaces. Hence, the multidirectional printing pattern showed reduction in interlayer void [6].

Similarly, fiber-reinforced 3D-printed geopolymer composites show improvements in strength, but interlayer bonding remains a weak point. While fiber addition improved structural stability and mechanical properties [7-9], the fundamental issue of anisotropic behavior due to printing orientation was not directly addressed [10].

RESEARCH SIGNIFICANCE

This study aims to evaluate the influence of printing orientation on the mechanical performance of multilayer 3D-printed cement mortar, with a particular focus on compressive and flexural strength in both perpendicular and parallel loading directions. Previous research has studied fiber reinforcement and printing direction separately, but few have studied their combined effects. Additionally, this study

utilizes a partially quasi-isotropic printing pattern and includes nano-calcium carbonate and micro polypropylene fibers to investigate their roles in reducing the mechanical anisotropy of the 3D-printed cement mortar.

MATERIALS AND METHODS

Materials

The materials used in this study included hydraulic cement, with a fixed water-to-cement ratio (w/c) of 0.22. Two additive materials were also incorporated: nano-calcium carbonate (NC, 2% by cement weight) and micro polypropylene fibers (PP, 0.1% by volume). The detailed mix proportions for all mixtures are summarized in Table 1.

Printing Properties

The fresh and hardened properties of the 3D printable mortar mixtures are presented in Table 2. Incorporating nano-calcium carbonate and polypropylene fibers resulted in a shorter initial printing time. This also contributed to improved stability of the extruded filament, helping maintain the shape and settlement of the printed layers.

Table 2 Properties of mixture for 3D-printing

Specification	Detailed		
	OPC	NC 2%	PP 0.1%
Flow (%)	150.0	140.0	135.5
Printable time (min)	95	89	86
Time gap (min)	9	12	6
Filament width (mm)	28	26	25
Filament heigh (mm)	11	13	14
Density (kg/m^3)	2,123	2,174	2,106

Experimental Procedure

Printing procedure

The printing process began with preparing mortar mixtures according to the proportions specified in Table 1. After mixing, the fresh mortar was loaded into the concrete hopper of a customized 3D printer, as illustrated in Fig 1. The hopper was then sealed with a piston, preparing the extrusion material.

During the printing process, the mortar was extruded by a piston-driven pump, which forced the material through a plastic hose and out of a nozzle (a diameter of 20 mm). The nozzle was positioned 15 mm above the printable area and moved along a programmed path at 10 mm/s. The extrusion rate was kept constant at 2.5 ml/s.

After each layer was printed, the nozzle was moved to a starting point, lifted for another 15 mm, and waited for a period determined by the time gap specified in Table 2, depending on the mixture design, before proceeding to the next layer. This is to ensure adequate buildability for all tested mixtures.

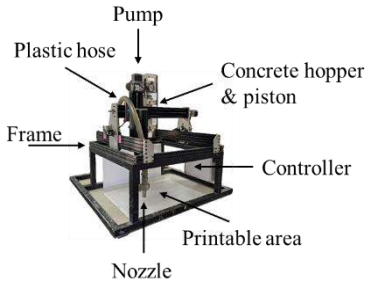

Fig. 1 Printing machine

The printing directions and filament patterns were pre-designed and programmed into the controller integrated with the 3D printing system. The printing direction employed in this study were categorized below.

Unidirectional printing refers to a deposition in which all layers are printed in the 0° direction, meaning that each layer is aligned identically and stacked in the same orientation. In this study, a total of six layers were printed using this approach. The top and side views of the printed specimen are illustrated in Fig 2.

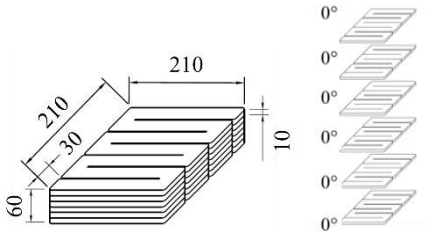

Fig. 2 Unidirectional printing pattern

Table 1 Mix proportions for 3D-printing

Name	Mix Proportions (kg/m^3)							
	Cement	Water	Fine Aggregate	Silica Fume	Polyethylene Glycol	Type G	NC	PP
OPC	879	213	1171	88	22	145	-	-
NC 2%							17.6	-
PP 0.1%							-	0.9

Multidirectional printing, also called the partially quasi-isotropic pattern, involves printing each layer in a different orientation to reduce anisotropy and improve structural uniformity. In this study, the layer orientations were arranged as follows: 0° (Layer 1), +90° (Layer 2), +45° (Layer 3), -45° (Layer 4), -90° (Layer 5), and 0° (Layer 6), as illustrated in Fig 3. This alternating sequence mimics quasi-isotropic behavior by balancing the layer directions around a central axis.

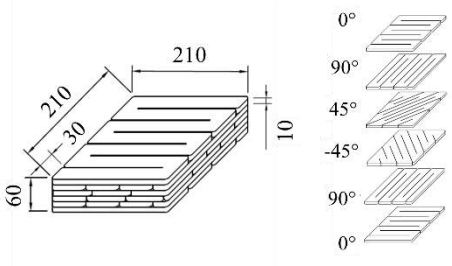

Fig. 3 Multidirectional printing pattern

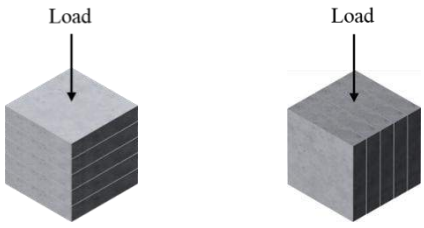
Sample preparation

For mechanical property evaluation, the printed specimens were cured under moisture-insulated conditions for 28 days before testing. The specimens were then cut into 50-mm cube for compressive strength testing conducted by ASTM C109-20 [11]. For flexural strength testing, specimens were cut into prisms with dimensions of 40 mm × 40 mm × 160 mm (width × height × length), following the ASTM C348-21 standard [12].

Mechanical Properties

Compressive strength

The compressive strength test was conducted to investigate the influence of the printing direction on the compressive strength of 3D-printed specimens. Two loading directions: perpendicular (Fig 4a) and parallel to printing plane (Fig 4b) were performed.

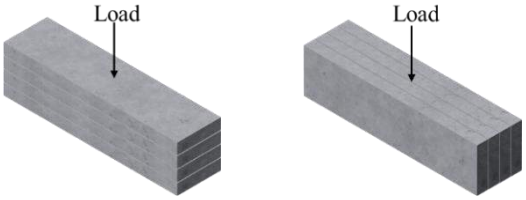


(a) (b)

Fig. 4 Compressive loading direction (a) perpendicular, (b) parallel to the printing filament orientation

Flexural strength

The flexural strength test was conducted to investigate the effects of layer orientation on the flexural behavior of the printed specimens. Two loading directions were considered: flexural loading perpendicular to the printed layers (Fig 5a) and flexural loading parallel to the printed layers (Fig 5b). Comparing the results from both directions highlights the influence of filament arrangement on the flexural strength of the 3D-printed specimens.



(a) (b)

Fig. 5 Flexural loading direction (a) perpendicular, (b) parallel to the printing filament orientation

RESULTS AND DISCUSSIONS

Compressive Strength

Unidirectional

Fig 6 indicates that OPC mixture exhibited the greatest anisotropy in compressive strength, with values of 15.7 MPa in the perpendicular direction and 10.7 MPa in the parallel direction, a 31.7% reduction in compressive strength. This significant variation shows the mechanical weakness along the printed layers when subjected to parallel loading, likely due to interlayer debonding.

Conversely, the NC 2% and PP 0.1% led to an overall increase in compressive strength in both loading directions, with a decrease of 23.0% and 22.0%, respectively. These results indicate that the additive materials adjust the matrix's mechanical and physical properties and diminish the directional dependence of the mechanical response in 3D-printed components.

The increase in compressive strength observed in the NC 2% mix can be attributed to the filler effect of nano-calcium carbonate within the mortar matrix. These mechanisms increase mortar density, enhancing compressive strength of 3D-printed specimens [13]. In the case of micro polypropylene fibers, the improvement in compressive strength is due to their function as microcrack-bridging elements, which not only inhibit crack propagation but also enhance the toughness of the printing filament mortar [14]. The influence of the printing direction on the compressive strength will be further discussed in the Influence of Printing Orientation section.

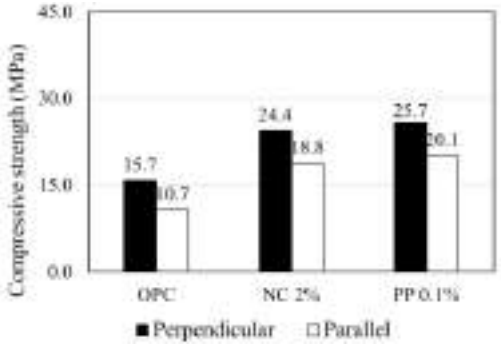


Fig. 6 Compressive strength of unidirectional printing

Multidirectional

In the case of multidirectional printing, Fig 7 presents the compressive strengths of mortar with various mix proportions under two loading directions. For the OPC mixture, a clear difference is observed between the compressive strength in the perpendicular direction (18.0 MPa) and the parallel direction (12.7 MPa), representing a 29.9% reduction in strength under parallel loading. This reduction is due to the debonding of the printing filament.

Upon the NC 2% and PP 0.1% mixtures, compressive strengths in both directions increased, and the anisotropy in mechanical response was significantly reduced to only 9.3% and 8.7%, respectively. These findings suggest that the printing orientation substantially affects the structural integrity and stability of 3D-printed components by mitigating interlayer weaknesses and promoting a more uniform stress distribution throughout the printed specimens.

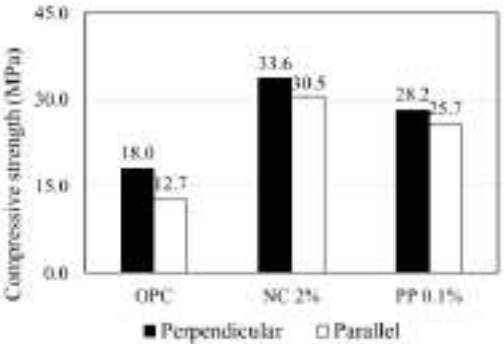

Fig. 7 Compressive strength of multidirectional printing

Flexural Strength

Unidirectional

Fig 8 presents the flexural strength test results of unidirectionally printed specimens. The OPC mixture exhibited the highest anisotropy, with flexural strengths of 8.6 MPa (perpendicular) and 6.0 MPa (parallel), corresponding to a 29.9% reduction. This significant reduction confirms that printing direction strongly influences flexural performance, as the layer-by-layer extrusion in 3D printing introduces planes of weakness when stress is applied along the filament direction.

Although the NC 2% mixture improved the flexural strength, the directional variation remained high at 29.4%. In contrast, the PP 0.1% mixture significantly enhanced the flexural strength beyond that of mixture OPC, and NC 2% substantially reduced the directional effect to 10.0%. This shows the role of fibers in bridging interlayer bonding and enhancing material toughness, resulting in more uniform flexural performance across different loading directions. The influence of the printing direction on the flexural strength will be further discussed in the Influence of Printing Orientation section.

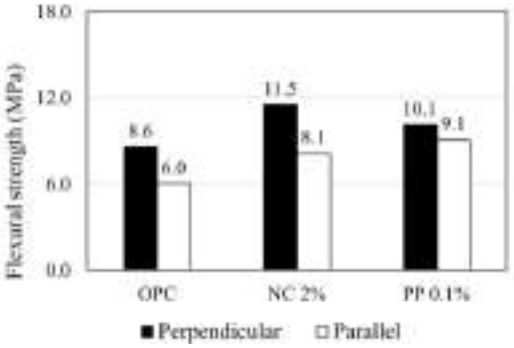

Fig. 8 Flexural strength of unidirectional printing

Multidirectional

In the case of multidirectional printing, Fig 9 presents the flexural strengths of printing specimens. It shows that all mixtures exhibited higher flexural strength when subjected to perpendicular bending direction than in the parallel direction. Among them, the OPC mixture demonstrated the highest directional disparity, with flexural strengths of 10.6 MPa (perpendicular) and 9.3 MPa (parallel), resulting in an 11.7% reduction in flexural strength.

In contrast, the NC 2% and PP 0.1% mixtures exhibited notably reduced differences between directions, 12.2% and 9.5%, respectively. According to Fig 8, it was found that the reduction in flexural strength decreased from 29.9% and 29.4% to 11.7% and 12.2% in the mixture of OPC and NC 2%, respectively. These results highlight the effectiveness of multidirectional printing structure integrity through the loading direction on mechanical performance.

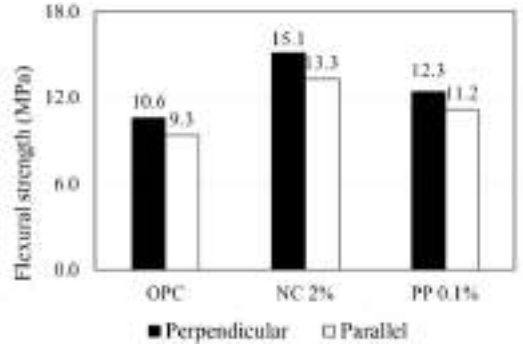

Fig. 9 Flexural strength of multidirectional printing

Influence of Printing Orientation

Compressive strength

Figure 10 shows the influences of printing orientation on the compressive strength of the printed cement mortar. According to the results, the multidirectional printing technique improves the structural integrity of the printed specimens for all mixtures. Enhanced structural integrity leads to a reduction in anisotropic behavior. In contrast, unidirectional printing exhibits limitations in loading direction, as the printed structures can effectively subject the compressive load only in the perpendicular direction to the print layers. Therefore, multidirectional printing may be crucial in future applications, as real-world 3D-printed structures are unlikely to experience loading in a single direction.

In the case of the perpendicular loading direction, the strength of 3D-printed specimens contributes to the printed material and interfilamentous void [4]. The mixture incorporated with NC and PP demonstrates higher compressive strength due to the NC's filler effect and the PP's microcrack-bridging [14-16]. Particularly, the compressive strength improvements were 14.6%, 37.8%, and 9.4% for the OPC, NC 2%, and PP 0.1% mixtures, respectively. However, the inter-filamentous void also plays a crucial role. The multidirectional printing technique serves the cross-ply and oblique patterns, reducing interfilamentous of the printed specimens. This leads to higher compressive strength than the unidirectional printing technique.

In the case of the parallel loading direction, the interlayer bonding plays a crucial role in the compressive strength of the 3D-printed specimens. The multidirectional printing technique tailors a diversity of printing orientations, leading to improved interlocking between the interlayers. This promotes uniform distribution of stress and consequently enhances the compressive strength of the 3D-printed specimens [17]. Unlike the unidirectional printing technique, which follows a single printing path and induces voids between interfilamentous surfaces and layers, the multidirectional approach mitigates such defects [6]. Therefore, the multidirectional printing led to a noticeable enhancement in strength compared to unidirectional printing, with increases of 18.4%, 62.5%, and 28.0%, for OPC, NC 2%, and PP 0.1% mixtures, respectively. It provides better mechanical performance under parallel loading conditions.

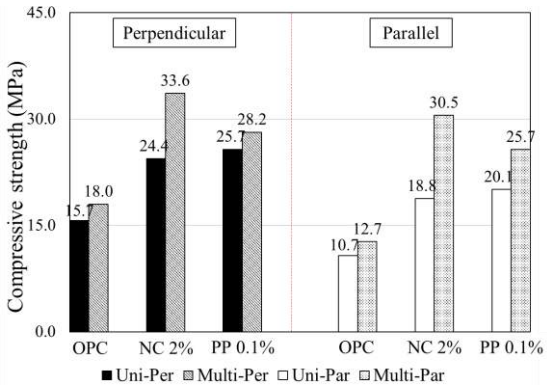

Fig. 10 Effect of printing orientation on compressive strength

Flexural strength

Fig 11 illustrates the influences of printing orientation on the flexural strength of 3D-printed mortar specimens. The perpendicular bending direction and the multidirectional printing technique demonstrate higher flexural strength than specimens printed with the unidirectional technique. Due to the multidirectional orientation utilizing the diverse interlocking between two adjacent layers increases flexural strength [12]. Particularly, the flexural strength improvements were 23.6%, 31.3%, and 22.3% for the OPC, NC 2%, and PP 0.1% mixtures, respectively. On the other hand, the unidirectional printing technique has only a single pattern, leading to a lack of diversity in interlocking between interlayers, resulting in lower flexural strength.

Moreover, lower flexural strength was observed in the parallel bending direction due to weak interlayer bonding and additional shear stress concentration. In contrast, the multidirectional printing orientation, which employs ±45° layer alignment, is more compatible with the direction of shear stresses generated during bending. This alignment enhances stress distribution and interlayer performance, resulting in improved flexural strength [18]. Specifically, the flexural strength of multidirectional printed mortar exceeded that of unidirectionally printed samples by 55.6%, 63.3%, and 23.1% for OPC, NC 2%, and PP 0.1% mixes, respectively. These findings demonstrate the mechanical advantage of the multidirectional printing technique over the unidirectional approach.

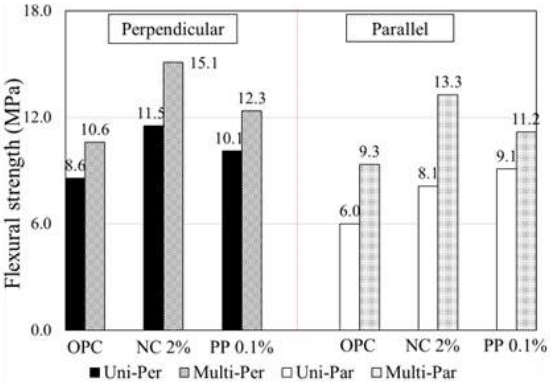

Fig. 11 Effect of printing orientation on flexural strength

CONCLUSIONS

Unidirectional printing provides satisfactory performance under perpendicular loading; however, it exhibits mechanical limitations under parallel loading due to weak interlayer bonding. To overcome this behavior, multidirectional printing techniques, including various printing orientations (0°, ±45°, and ±90°), have been utilized to mitigate anisotropy and enhance interlayer bonding. These approaches lead to significantly mitigated direction dependency in both compressive and flexural strengths.

Moreover, the incorporation of 2% nano-calcium carbonate and 0.1% micropolypropylene fibers contributes to additional enhancements in mechanical performance, demonstrating their effectiveness in mitigating the directional limitations of printed structures.

[3]Base Bahay Foundation, Incorporated, Philippines

ABSTRACT

Bamboo is a renewable resource, and its mechanical properties can support its adoption in the construction industry as an alternative structural member. Given the Philippines' exposure to earthquakes and winds, ensuring the reliability of members and their connections is important. However, bamboo connections remain insufficiently studied. This study focuses on the shear strength of a T-connection using fish-mouthed bamboo secured with a J bolt. The T-connection was tested with three variations of J-bolt diameters (8 mm, 10 mm, and 12 mm), and was also tested with mortar infill and clamp attachments. A T-test and regression analysis determined the significance of these variables on the joint's shear strength. Results showed that J-bolt size had no significant effect since the bamboo failed first. However, the thickness and density of the bamboo were found to significantly influence shear strength. Samples with both clamp attachments and mortar infill had higher strength than those without. The highest strength was the densest bamboo sample with both clamp and mortar. Furthermore, connections without mortar behaved like roller support, while those with mortar acted as fixed support, offering greater flexibility in structural design. Case studies were conducted to assess the performance of T-connections in a 49 m² bamboo structure located near a fault line, considering both seismic and wind loads. Results showed that the connection is not feasible for two-story and three-story buildings. However, a one-story building can withstand the applied forces.

Keywords: Bamboo, Shear Strength, T-connection, Clamp Attachment, Mortar Infill

INTRODUCTION

The UN-Habitat Philippines Country Report 2023 highlights a housing backlog of 6.5 million units [1]. To address this, Bambusa blumeana is emerging as a sustainable structural material, particularly in low-rise buildings and indigenous structures due to its affordability, superior mechanical strength, and fast harvest rate of up to 4.87 culms/clump per year [2,3]. Despite its potential, adoption remains limited due to concerns about structural integrity, as typical bamboo connections are prone to shear and tensile failures and lack uniform load distribution due to bamboo's natural irregular shape makes achieving joint uniformity challenging. [4].

Bamboo is a key component of Cement Bamboo Frame Technology by Base Bahay [5]. This system uses reinforced concrete foundations, while beams and columns are made entirely of bamboo, connected with steel joints. This study focuses on T-joints, where one bamboo culm is connected perpendicularly to another, enhancing resistance to dynamic loads and lateral forces like wind and seismic activity [6]. There are two bamboo parts in the connection. The tee is the vertical component of the connections and is one internode long. The stem is the horizontal portion and is two internodes long as seen in Fig.1. The stem is longer so that when the force is applied the majority of the reaction will be at the connection. To improve load distribution, fish mouths are carved at connection points, maximizing surface contact [7]. The study also explores J-bolts which serve as a cost-effective alternative to steel plates, utilizing hooked rods to secure bamboo culms effectively, thereby enhancing the stability and reliability of the joints.

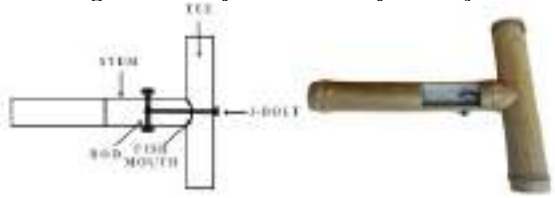

Fig.1 Steel bolted T-connection

The research focused on the shear capacity of the T connection since the Philippines is vulnerable to earthquakes and strong winds. The study is conducted to determine whether this type of connection is applicable to housing projects in the Philippines. Specifically, it will investigate how the geometric properties of bamboo, the dowel diameter, the presence of mortar, and the presence of clamps influence shear capacity. Additionally, the study seeks to predict the shear capacity of T-Joint Fish mouth J-Bolt connections under varying conditions using multilinear regression analysis, providing insights for optimizing bamboo connections in construction.

RESEARCH SIGNIFICANCE

The study will help promote the adaptation of bamboo engineering in the construction industry. The identification of the shear capacity of connection is important to ensure the safety of the bamboo structures so that the bamboo will be designed better to accommodate the correct loads. Furthermore, the development of the connection can lead to innovative construction techniques that enhance the performance and aesthetics of bamboo structures. The research on the shear strength of the connection is not limited to the construction of houses but can also be applicable in walk paths or where there is shear stress in bamboo connections.

METHODOLOGY

The experiment was conducted into three phases. The first phase was to determine the strength of the mortar used to fill the connections. The second phase was the testing of the shear capacity of the connection. The last phase was to determine the moisture content and density of the bamboo used in the connection.

Preparation For T-Connection

The bamboo that was used was already treated by Base Bahay. The bamboo was first cut into appropriate lengths, and their geometric properties were recorded. One end of the stem is then cut using a hole saw to produce a fish mouth. The fish mouth will allow the tee and the stem to properly connect to one another. The stem is then inserted with a plain rod. The tee is then inserted with a hook. The hook is then tightened to hook the plain rod

Preparation For J-bolt

The study utilized stainless steel rods in three distinct diameters: 8 mm, 10 mm, and 12 mm. These rods were then cut into 35- and 15-mm rods. The 35 mm rods were then bent and hammered into a J-bolt. The 15 mm rod is used as a lock for the J-bolt. The rod and the J-bolt always have the same size.

Testing Of Mortar

The mortar used in the study had a ratio of 1 Portland Cement to 3 Sand with a water of 0.5. The mortar was then placed in 50 mm cube specimens and was subjected to a compressive test. There were two batches made with 6 samples per batch. The averages of each batch were determined to be the strength of the mortar to be used in the connection.

Testing Of T-connection

A Universal Testing Machine (UTM) was used to determine the shear strength of the connection, it was set at 10 mm/min. A Linear Variable Differential Transformer (LVDT) was also used to determine the deformation of the connection during the application of the load. The bamboo was then tied to a steel plate to ensure that there were no movements during the testing. There were four different set ups for the connections throughout the study aside from having three different J-bolt sizes. The first set up was the connection had no mortar infill and was not held by a clamp. The second set up still had no mortar infill but was held by a clamp. The third setup had mortar infill but no clamp. The last set up had both mortar infill and clamp. Table 1 shows the code used throughout the experiment. For example, 8CM-1 refers to an 8mm J-bolt, “C” for with clamp, “M” for with mortar, and 1 for the first trial out of 5. If “C” or “M” is not present in the code, this means that the clamp or the mortar is not present. Each setup was repeated five times, resulting in a total of 60 samples.

Table 1 Codes for naming bamboo specimen

J-bolt Size	Presence of Clamps	Presence of Mortar Infill
8	“C”=Present	“M”=Present
10	“ ”=Absent	“ ”=Absent
12		

Testing Of Moisture Content and Density

Once the testing of the shear capacity is completed. Each sample is deconstructed and a piece in the shape of a rectangular prism is obtained. This piece is then measured for its length, width, height, and weight. The sample is then oven dried for 24 hours. After drying, the sample is then weighed again to obtain the moisture content of the bamboo and the density of the bamboo.

RESULTS AND DISCUSSION

The output of the study mainly studies the maximum strength of the connection. It also studies the effects of the properties of the bamboo, size of J-bolt, presence of mortar, and the presence of clamps.

Results of the Mortar

The first batch of mortar had an average strength of 9.025 MPa. On the other hand, the second batch had an average strength of 9.684 MPa. It is determined that the values of both batches are not significantly different from each other.

Initial Findings

Figure 2 illustrates four distinct peaks in the connection's strength as it progresses towards total failure for each setup, except for the configuration with both mortar and a clamp. Fig.2 also represents all other cases where mortar infill and clamps are absent, as they exhibit the same trend. The first peak represents the initial splitting of the bamboo, occurring at the fish mouth region. This split is caused by the moment generated by the shear force applied by the UTM. The second peak varies depending on the setup. For configurations without a clamp and mortar, it results from crack propagation beyond the internode. Table 2 shows the maximum strength of each type of bolt for this case.

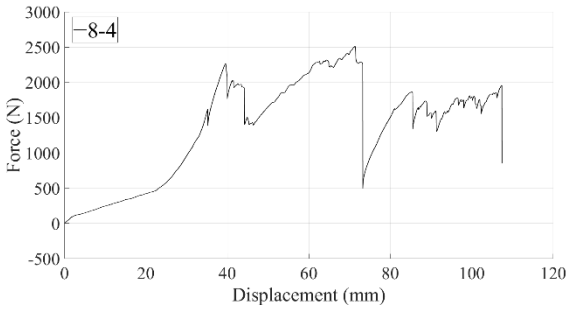

Fig.2 Shear strength of 8 mm J-bolt connections

Table 2 Maximum Strength without Mortar and without Clamp

Bolt Size (mm)	Strength (kN)
8	2.5130
10	2.9481
12	3.0241

Figure 3 represents all setups with clamps but without mortar infill. The second peak for this case is attributed to the clamp's strength as seen in Fig.3. The failure of the clamp leads to a significant crack in the bamboo. Table 3 presents the highest strength recorded for each bolt type in this case.

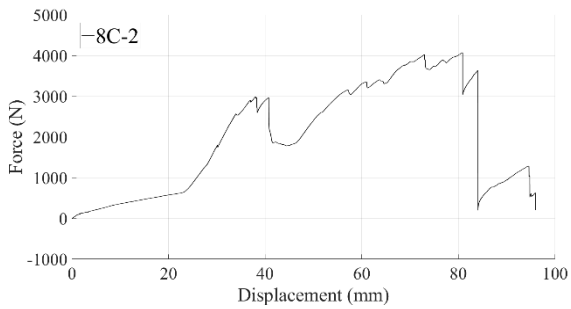

Fig.3 Shear strength of 8C connections

Table 3 Maximum Strength without Mortar and with Clamp

Bolt Size (mm)	Strength (kN)
8	4.9235
10	5.7190
12	5.6302

Figure 4 represents all cases that have mortar infill, but the clamp is absent. For the arrangement with this case, the second peak is related to the mortar's strength, with the connection weakening as cracks form in the mortar. The third peak is associated with the excessive cracking in setups without mortar. In configurations with mortar, this peak is linked to the strength at the internode. Once the crack extends through the internode, the strength diminishes. The final peak corresponds to the J-bolt, representing the highest strength achieved before complete failure. The peak strength of every bolt type for with mortar infill and without clamp is displayed in Table 4. For the 8 mm J-bolt, splitting of the steel rod was observed, which was not present in larger diameter rods.

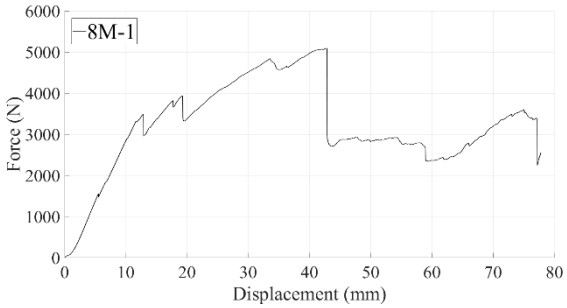

Fig.4 Shear strength of 8M connections

Table 4 Maximum Strength with Mortar and without Clamp

Bolt Size (mm)	Strength (kN)
8	5.2512
10	7.5335
12	5.4704

Figure 5 represents the case with mortar infill and clamp. It can be seen in Fig.5 that only two peaks were observed before total failure. The first peak corresponds to the initial bamboo split, while the second peak represents the combined strength at the second internode, clamp, and mortar, which all fail simultaneously. The assessment of connection strength also differs based on the configuration. In the setup without a clamp and mortar, the first peak is regarded as the connection's maximum strength, as

the initial crack is enough to signify failure. In the setup with a clamp but without mortar, the second peak is considered the maximum strength. The first peak produces only minor cracking due to the clamp's ability to prevent further splitting. However, once the clamp fails, significant damage follows. For the setup with mortar but without a clamp, the third peak is identified as the connection's strength, as considerable damage occurs at that stage. Finally, in the configuration with both mortar and a clamp, the second peak is regarded as the connection's maximum strength since the damage identified here is significant. Table 5 details the maximum strength achieved by each type of bolt in this instance.

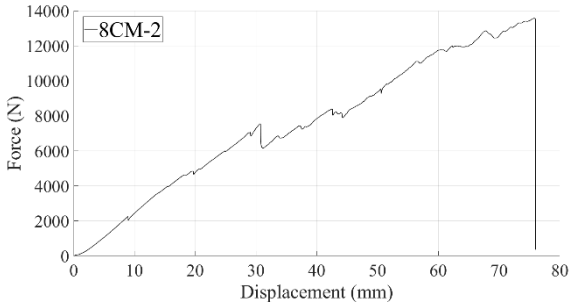

Fig.5 Compressive strength of 8CM connections

Table 5 Maximum Strength with Mortar and with Clamp

Bolt Size (mm)	Strength (kN)
8	13.5752
10	12.4944
12	17.3716

Different J-bolt Sizes

It was found in Figure 6 that the sizes of the J-bolt did not make a significant difference in the shear capacity of the connection. A T-test with a 95% confidence level was also used to determine whether there was a significant difference in the strength of connection. It was found that even when all the connections had mortar infill or clamps. If the variable that was changed was the J-bolt size, the shear capacity of the connection had no significant difference. This is because the bamboo fails first before the J-bolt.

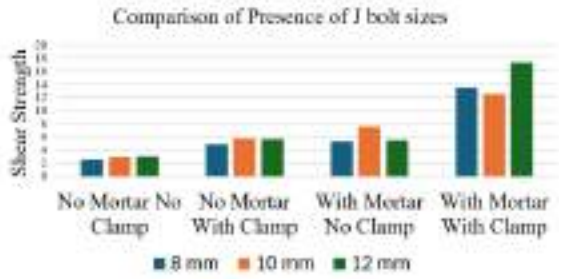

Figure 6. Comparison of Average Strength with Different J-bolt Sizes

Presence of Mortar Infill

Figure 7 indicates that connections with mortar infill exhibited significantly higher maximum strengths compared to those without mortar infill. A T-test with a 95% confidence level showed that the P value of the with mortar infill versus without mortar infill was less than 0.05%. Furthermore, the connection without the mortar had a higher amount of displacement before the first peak of strength of the setup. On the other hand, the setup with mortar infill displaced only by a minimal amount before the first peak. It can be said here that the setup without mortar infill can be designed as a hinged support since it is able to move a significant displacement before damage occurs. The setup with mortar infill can be designed as a fixed support since the displacement it can withstand before damage is minimal.

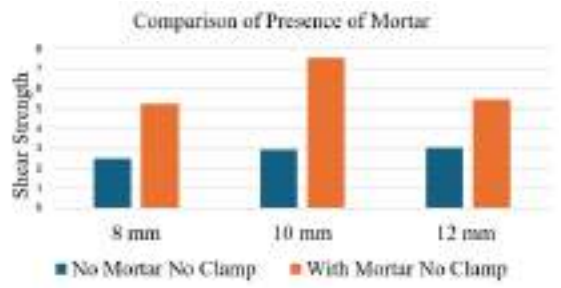

Figure 7. Comparison of Average Strength with Mortar and Without Mortar

Presence of Clamps

Figure 8 demonstrates a significant difference in connection strength between setups with and without clamps, with the clamped configuration exhibiting higher strength. A T-test with a 95% confidence level showed that the P value of the with clamp versus without clamp was less than 0.05%. This proves that the clamp increases the shear strength of the connection. In terms of displacement, there is no significant difference between the with and without clamp set ups.

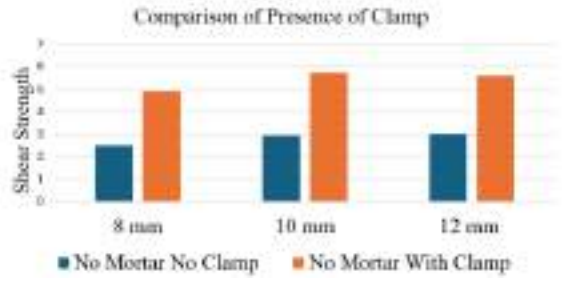

Figure 8. Comparison of Average Strength with Clamp and Without Clamp

Presence of Mortar Infill and Clamps

Figure 9 shows that the setup with clamp and mortar had a higher strength than both the setup with only mortar infill and only clamp. A t-test conducted at a 95% confidence level revealed that the p-value for the comparison between the with clamp and mortar setup, the with clamp setup, and the with mortar setup was less than 0.05, indicating a significant difference. This suggests that the set up with clamp and mortar is the best setup in terms of strength of the connection.

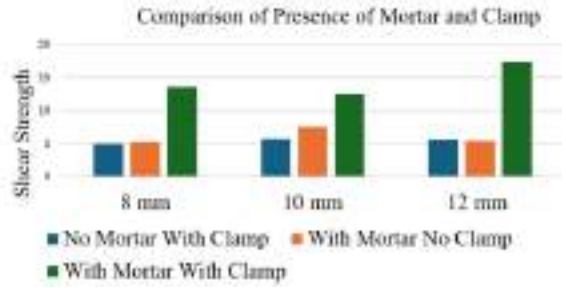

Figure 9. Comparison of Average Strength with Mortar and with Clamp

Regression Analysis

A multilinear regression analysis was performed to determine the significant factors that contributed to the strength of the connection. The properties of the bamboo, mortar, clamp, and the size of the J-bolt were all included in the study. The regression analysis was iterated twice since in the first iteration there were factors that had a p value higher than 0.05 which means they are not significant to the strength of the connection. In the second iteration, all factors exhibited a p-value of less than 0.05, indicating that each variable significantly influences the strength of the connection. These variables include stem thickness, stem bamboo density, mortar presence, and clamp presence. The regression also has an R square value of 0.798523 which means that 79.85% of the strength of the connection is contributed by the factors mentioned above. The equation that predicts the strength of the connection is given by Table 6.

Table 6 Coefficients of Variables

Intercept	Stem Thickness	Stem Density	Mortar Presence	Clamp Presence
-5557.20	463.85	4753270.4	4532.96	3428.63

These findings further demonstrate that the presence of mortar and clamps effectively enhances shear strength. Moreover, they indicate that the J-bolt has a minimal impact on joint strength, with the geometric properties of the bamboo playing a more significant role.

Case Study

A case study was conducted to determine the shear force that a building in the Philippines would experience and whether the connection can withstand such force. Three cases will be examined in this study: the first case involves a one-story structure, the second case focuses on a two-story structure, and the third case considers a three-story structure. It will be assumed that there are only earthquakes and wind forces that could affect the shear strength of the connection. Furthermore, the lot area is assumed to be 49 m², as data from the Philippines Statistics Authority (PSA) indicates that the majority of housing units occupy this size [8]. Lastly, it is assumed that the building is situated along a fault line, located in Zone 4 the highest seismic risk zone in the Philippines and positioned in the windiest area of the Philippines, with the soil condition classified as soft soil and wind speed of 340 kph. The values in Table 11 are calculated using the National Structural Code of the Philippines (NSCP). The maximum earthquake and wind force that the following buildings can experience are shown in Table 7.

Table 7 Maximum Earthquake and Wind Load

Building Type	Earthquake Load (kN)	Wind Load (kN)
3 Story	16.1	4.56
2 Story	11.1	4.56
1 Story	3.98	2.6

In all considered scenarios, seismic loading governs the structural design over wind loading. The regression analysis formula was used to estimate the shear strength of the connection, assuming the average of the thickness and density of the bamboo available is comparable to that used in the sample bamboo members. The values of the maximum shear strength can be observed in Table 8.

Table 8 Maximum Shear Strength Per Condition

Condition	Maximum Shear Strength (kN)
With Mortar and With Clamp	8.99
With Mortar and No Clamp	5.57
No Mortar and With Clamp	4.46
No Mortar and No Clamp	1.03

To ensure the structural integrity of connections in one-story building, elements of high density and substantial thickness must be employed, secured with clamps, and filled with mortar. It is not possible for the connection to be used in two- and three-story structures. Furthermore, setting up with clamps and without mortar is sufficient to withstand the force experienced in a one-story building. However, it should be noted that connections without mortar exhibit significant displacement. Therefore, using a mortar infill is still recommended for improved stability and performance.

CONCLUSION

The steel bolted T-connection can be used in housing especially since housing projects in the Philippines is 1 story only. The strength of the connection is reliant on the geometric properties of the bamboo. The selection of bamboo with high density and substantial thickness is crucial to ensure the integrity of the structure. The presence of mortar and clamps also had a positive influence on the maximum strength of the connection. Furthermore, the usage of the smallest J-bolt (8 mm) would be recommended since the size of the steel rod does not significantly impact the strength of the joint. The utilization of T-connections presents a practical advantage for industry applications. Connections without mortar exhibited behavior akin to roller supports, whereas mortar-filled connections approximated fixed supports, thereby providing enhanced flexibility in structural design considerations.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the faculty and staff of the Civil Engineering Department at De La Salle University (DLSU) for their invaluable assistance. Furthermore, they extend their appreciation to the Department of Science and Technology - Engineering Research and Development for Technology (DOST-ERDT) for providing the scholarship budget that enabled this experiment, and to Base Bahay for their contribution of materials and for essential support during the testing phase of the project.

CORRELATION BETWEEN INFILL DENSITY AND MECHANICAL PROPERTIES IN 3D PRINTING

Boonthum Wongchai

Faculty of Engineering at Sriracha, Kasetsart University, Thailand

ABSTRACT

Fused Deposition Modeling (FDM) 3D printing is widely used for part manufacturing. Infill density is a key factor that influences the mechanical properties of printed parts. This study investigates the correlation between infill density and the mechanical properties of enhanced polylactic acid (PLA+). Specimens were fabricated using an FDM 3D printer in accordance with ASTM D638-14 standards, employing a grid infill pattern. Infill densities were varied at 20%, 30%, 40%, 50%, 60%, 70%, 80%, 90%, and 100%. Regression analysis was used to examine the relationships between infill density and key mechanical properties, including Young's modulus, yield strength, ultimate tensile strength, tensile strength at break, and tensile strain at break. The results show that the relationships between infill density and both Young's modulus and yield strength are best described by linear equations, with coefficients of determination (R^2) of 0.99 and 0.98, respectively. A quadratic equation with an R^2 of 0.98 best fits the correlation between infill density and ultimate tensile strength. The relationships between infill density and both tensile strength at break and tensile strain at break yield R^2 values below 0.90, suggesting more variation in the data and a lower degree of model fit compared to the other properties.

Given the increasing use of 3D-printed PLA-based components in construction and geotechnical applications such as lightweight formworks, temporary structural elements, and erosion control systems. This study provides valuable insights into how infill density affects mechanical performance, which can guide material selection and structural design for sustainable engineering solutions.

Keywords: Infill density, 3-D printing, Enhanced polylactic acid (PLA+), mechanical properties

INTRODUCTION

In recent years, 3D printing has emerged as a key technology within the field of additive manufacturing (AM), offering the ability to fabricate complex geometries with minimal material waste and shorter production times compared to conventional methods. The AM process typically begins with a CAD-designed prototype exported as an STL file, which is then processed by slicing software to generate G-code for layer-by-layer fabrication. AM supports a wide range of materials, including polymers, metals, ceramics, and composite blends, making it suitable for applications across aerospace, automotive, robotics, and sensor technologies. Among various AM technologies such as stereolithography (SLA) and multi jet fusion (MJF). Fused deposition modeling (FDM) is the most widely adopted due to its low cost, ease of use, and material versatility [1-3].

Beyond industrial applications, FDM 3D printing has gained interest in construction and geotechnical engineering. PLA-based materials, including enhanced PLA+ filaments, are being explored for temporary or lightweight structural elements, such as formwork, soil-retaining structures, erosion control modules, and physical modeling in geotechnical testing. Their biodegradability and ease of fabrication make them particularly appealing for sustainable and low-impact environmental applications. Understanding how infill density influences the mechanical properties of these printed materials is therefore essential for optimizing performance and safety in such engineering contexts.

In 3D printing, various materials are selected based on desired properties such as strength, flexibility, and application requirements. PLA (Polylactic Acid) is one of the most popular filaments due to its ease of use, low printing temperature, and biodegradable nature, making it ideal for beginners and general-purpose printing. PLA+ is an enhanced version of PLA that includes additives to improve strength, durability, and surface finish while maintaining the same ease of use. ABS (Acrylonitrile Butadiene Styrene) is known for its toughness, impact resistance, and higher temperature tolerance but requires a heated bed and enclosed print area to prevent warping. PETG (Polyethylene Terephthalate Glycol) combines the ease of printing of PLA with the strength and temperature resistance of ABS, offering excellent durability, chemical resistance, and a glossy finish, making it a versatile choice for functional parts. Composite materials, such as PLA reinforced with recycled desized carbon fiber shells, have been shown to enhance tensile modulus and strength compared to pure PLA [4]. Conversely, PLA/TPU polymer blends improve ductility but reduce mechanical strength [5]. Sandwich printing techniques, such as PLA/wood with a PLA core and

PLA combined with carbon fiber-reinforced PLA, are employed to further enhance mechanical performance [6, 7].

Printing parameters—including infill pattern, infill density (ID), infill rate, build orientation, raster angle, nozzle temperature, bed temperature, extrusion speed, and nozzle diameter—significantly affect mechanical properties such as Young's modulus, yield strength, ultimate strength, strength at break, and strain at break [8-12]. For PLA, increasing the infill density has been shown to enhance Young's modulus, ultimate strength, and the maximum load-to-weight ratio [13, 14]. In the case of PEEK, higher nozzle temperatures and lower printing speeds contribute to improved mechanical properties, while annealing typically increases mechanical strength with rising annealing temperatures [15].

In this study, PLA+ filament is used to evaluate the mechanical performance of 3D-printed specimens fabricated with varying infill densities. A consistent grid infill pattern is applied to all samples to ensure uniform internal structure. The influence of infill density on mechanical properties such as tensile strength and stiffness is thoroughly examined, and statistical regression analysis is employed to quantify the correlation between these parameters.

MATERIALS AND METHODS

According to ASTM D638-14, the standard test method for tensile properties of plastics, a Type I specimen with a thickness of 3.2 mm is designed using SOLIDWORKS software (Fig.1) and exported as an STL file [16]. Creality Slicer software is used to generate the G-code files by varying the infill density at 20%, 30%, 40%, 50%, 60%, 70%, 80%, 90%, and 100%. A grid infill pattern with a raster angle of 45° is applied (Fig.2). All specimens are fabricated using a Creality CR-10 Smart 3D printer with eSUN PLA+ filament, which has a density of 1.23 g/cm³.

The nozzle diameter used in the printing process was 0.4 mm, and the layer height was maintained at 0.2 mm to ensure dimensional accuracy. The top and bottom layer thicknesses were set to 0.4 mm, with four layers applied for both the top and bottom surfaces, using 100% infill in these regions to provide solid shell layers. The nozzle temperature was set at 200 °C, and the heated bed temperature was maintained at 60 °C to enhance adhesion during printing. A print speed of 50 mm/s was selected to balance print quality and production time. Each specimen was printed in a horizontal orientation on the build plate to minimize warping and ensure flatness. After printing, specimens were conditioned at room temperature for 24 hours prior to mechanical testing. These printing parameters were selected based on standard practices and prior research that demonstrated their effectiveness in producing dimensionally accurate and mechanically consistent PLA-based parts [17].

Fig.2 Infill density settings in Creality Slicer software: (a) 20% infill, (b) 80% infill.

(a) (b)

Fig.3 (a) Tensile testing setup, and (b) fractured specimens after testing.

Three specimens for each infill density are tested using an Instron 5982 universal testing machine, equipped with a 100 kN load cell and operated at a crosshead speed of 5 mm/min, as shown in Fig.3. The test is conducted using Bluehill software to control and monitor the testing process. Stress-strain curves are generated for each test, as illustrated in Fig.4. The Mechanical properties evaluated include Young's modulus (E), yield strength (σ_Y) determined using a 0.2% offset, ultimate tensile strength (σ_U), tensile strength at break (σ_B), and tensile strain at break (ε_B). These parameters provide a comprehensive understanding of the material's tensile behavior under varying internal structures. The results are used to assess the influence of infill density on the overall mechanical performance of the printed specimens.

Regression analysis is used to describe the relationship between mechanical properties and infill

density. This relationship can be represented by a polynomial equation as follows:

$$y = a_n ID^n + a_{n-1} ID^{n-1} + \ldots + a_2 ID^2 + a_1 ID + a_0 \quad (1)$$

where y is the dependent mechanical property, ID is the infill density, a_n are the polynomial coefficients, and n is the degree of the polynomial (e.g., n = 1 for linear, n = 2 for quadratic, n = 3 for cubic, etc.).

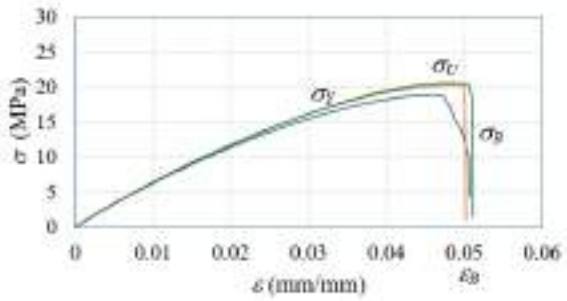

Fig.4 Stress-strain curve at 30% infill

RESULTS AND DISCUSSION

Young's Modulus

Fig.5 presents the plot of Young's modulus versus infill density. The results indicate a linear relationship between Young's modulus and infill density. Through regression analysis, this relationship can be expressed as:

$$E = 4.0151\ ID + 346.58 \quad (2)$$

Eq. (2) has an R^2 value of 0.99, indicating a high degree of accuracy. This suggests that infill density is a strong predictor of the material's stiffness. Therefore, by adjusting the infill density, the mechanical properties of the printed part can be effectively tailored.

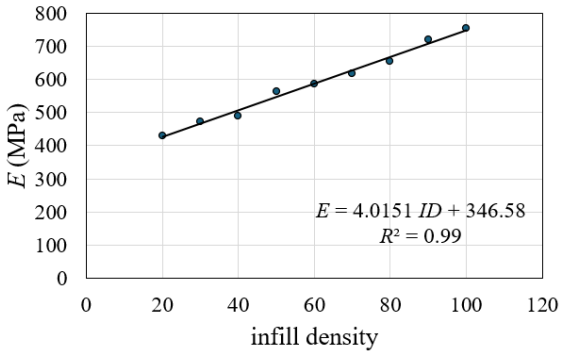

Fig.5 Young's modulus vs infill density with n = 1

Yield Strength

Similar to the plot of Young's modulus versus infill density, the relationship between yield stress and infill density also exhibits a linear trend, as shown in Fig.6. The regression analysis reveals a strong linear correlation with a high R^2 value of 0.98, indicating excellent accuracy. This relationship can be expressed as:

$$\sigma_Y = 0.091\ ID + 14.793 \quad (3)$$

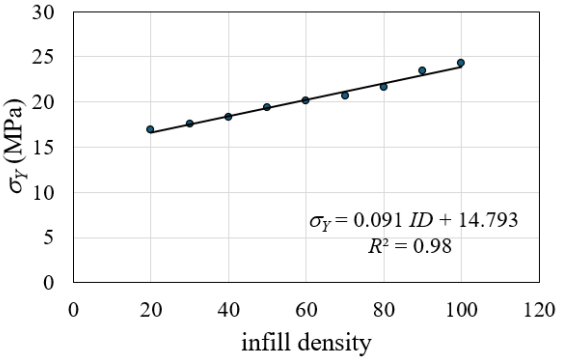

Fig.6 Yield strength vs infill density with n = 1

This result suggests that infill density is a strong predictor of the material's yield strength, allowing for precise control of mechanical properties through infill adjustments. Such control is critical for designing parts that meet specific strength requirements without unnecessary material use.

Ultimate Tensile Strength

For ultimate tensile strength, a linear regression can be plotted with an R^2 value of 0.9218, as shown in Fig.7. The relationship between ultimate tensile strength and infill density can initially be expressed as:

$$\sigma_U = 0.1264\ ID + 15.608 \quad (4)$$

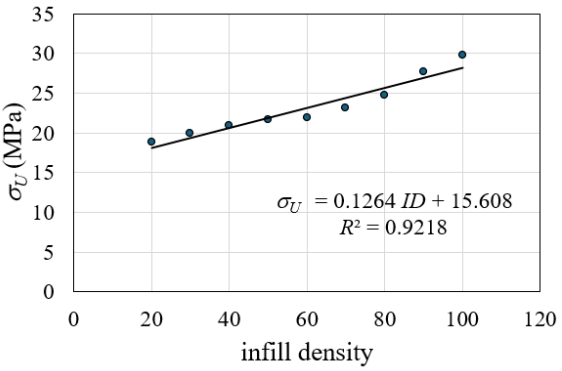

Fig.7 Ultimate tensile strength vs infill density with n = 1

Although Eq. (4) demonstrates a reasonably strong correlation, the stress-strain curve at 30% infill in Fig.4 and similarly at other infill levels reveals a nonlinear behavior in the plastic deformation region.

This suggests that a nonlinear model may better represent the relationship. Consequently, a quadratic regression with n = 2 was applied, also shown in Fig.8, resulting in an improved fit with an R^2 value of 0.98:

$$\sigma_U = 0.0014\ ID^2 - 0.044\ ID + 19.774 \quad (5)$$

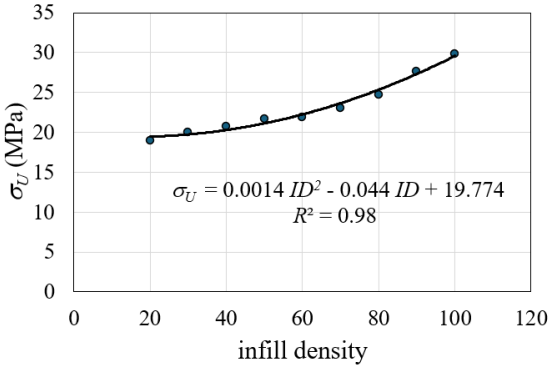

Fig.8 Ultimate tensile strength vs infill density with n = 2

This result confirms that infill density is a strong predictor of the material's ultimate tensile strength, and that quadratic regression provides a more accurate model for capturing the mechanical behavior, particularly in the plastic region.

The nonlinear model was found to better represent the relationship between infill density and ultimate tensile strength, as indicated by the improved R^2 value of 0.98 compared to the linear model. This is consistent with the behavior observed in the stress–strain curves (e.g., Fig. 4), where the material exhibits nonlinear plastic deformation, especially at lower infill densities. Linear models tend to oversimplify this behavior by failing to account for the gradual transition from elastic to plastic deformation and the complex internal stress distribution in FDM-printed structures.

Previous studies have also reported similar findings. The mechanical properties of FDM-printed components are influenced by a combination of process parameters, such as infill density, due to factors like layer adhesion, void content, and anisotropic material behavior, all of which contribute to nonlinear performance trends. The ultimate tensile strength does not increase linearly with infill density, owing to the irregular stress distribution and fracture mechanisms introduced by internal porosity and layer geometry [18, 19]. These insights support the use of a quadratic model, which more accurately captures the mechanical response of printed specimens across different infill levels.

Tensile Strength at Break

Fig.9 presents the plot of tensile strength at break versus infill density. A quadratic regression provides the fit for the data, with an R^2 value of 0.6737, and can be expressed as:

$$\sigma_B = 0.0006\ ID^2 + 0.0664\ ID + 13.079 \quad (6)$$

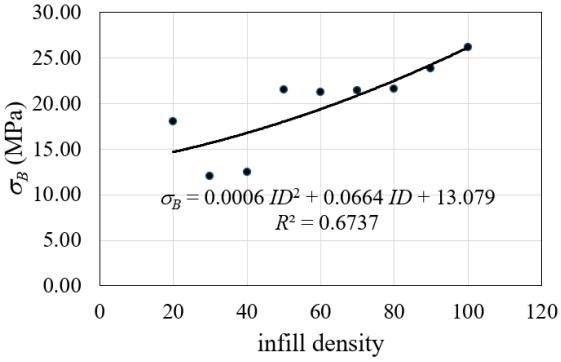

Fig.9 Tensile strength at break vs infill density with n = 2

Understanding tensile strength and strain at break is essential for assessing the mechanical performance and failure resistance of 3D-printed parts. These properties indicate how much stress and deformation a material can withstand before breaking, which is critical for load-bearing applications or safety-critical components.

The relatively low R^2 value (67.37%) reflects the variability and complexity of fracture behavior during tensile testing. The apparent scattering of data points in Fig.9 may partially result from human factors such as inconsistencies in specimen preparation, printing parameters, or testing alignment. To overcome these issues, more rigorous control of experimental conditions is recommended such as using automated calibration of tensile test machines, maintaining uniform environmental conditions (e.g., temperature and humidity), and increasing the number of replicates to minimize outlier influence and improve statistical reliability.

Tensile Strain at Break

Similar to the tensile strength at break, the relationship between infill density and tensile strain at break is best represented by a quadratic regression, as shown in Fig.10. The equation is expressed as:

$$\varepsilon_B = 9\times10^{-6}\ ID^2 - 0.0012\ ID + 0.0833 \quad (7)$$

This model yields an R^2 value of 0.7795, indicating an accuracy of 77.95% in predicting the strain at break. The relatively moderate accuracy is attributed to the complex and inconsistent nature of fracture behavior during tensile testing.

As shown in Fig. 10, the tensile strain at break initially decreases with increasing infill density up to approximately 60%, after which it begins to increase. This trend can be explained by the interplay between

structural stiffness and material deformability. At lower infill densities, the internal structure is more compliant, allowing greater elongation before failure. As the infill density increases, the structure becomes stiffer and more constrained, reducing the strain at break. However, beyond 60%, the higher material continuity and internal support may enhance energy dissipation and delay crack propagation, leading to an increase in tensile strain at break.

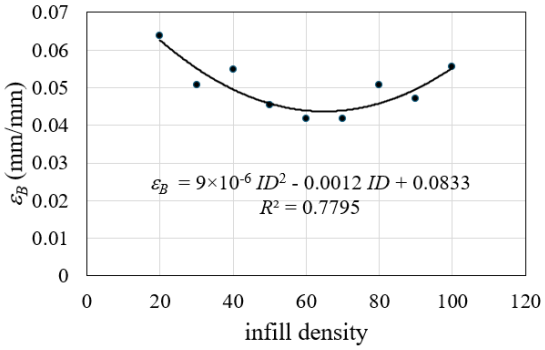

Fig.10 Tensile strain at break vs infill density with $n = 2$

Although increasing the polynomial degree to n = 6 improves the R^2 value to above 0.95 for both tensile strength and tensile strain at break, such high-degree polynomial models tend to overfit the data. While they may fit the experimental points closely, they lack physical interpretability and are not suitable for reliably predicting real-world mechanical behavior.

CONCLUSIONS

This study examined the influence of infill density on the mechanical properties of enhanced PLA+ specimens fabricated using FDM 3D printing. Specimens were printed according to ASTM D638-14 standards with a grid infill pattern, and infill densities ranged from 20% to 100%. Based on the experimental results and regression analysis, it was found that both Young's modulus and yield strength show a strong linear relationship with infill density, with high accuracy reflected in R^2 values of 0.99 and 0.98, respectively. The ultimate tensile strength was best modeled using a quadratic equation, achieving an R^2 of 0.98. In contrast, the relationships between infill density and tensile strength at break as well as tensile strain at break were less consistent, with R^2 values below 0.90, indicating weaker correlations. Overall, the findings confirm that infill density is a significant factor in determining certain mechanical properties of PLA+ parts and can be effectively used to tailor stiffness and strength in FDM-printed components.

TWO-AXIS VIBRATION RESPONSE ATTENUATION OF BUILDING STRUCTURE USING ROLLING CYLINDER DYNAMIC VIBRATION ABSORBER

Lovely Son[1], Mulyadi Bur[1], Bima Anugrah Saputra[1] and Zeki Midi[1]

[1]Mechanical Engineering Department, Engineering Faculty, Andalas University, Indonesia

ABSTRACT

This study proposes a novel two-axis dynamic vibration absorber designed to mitigate building vibrations in two axes of motion. The dynamic vibration absorber comprises two cylinders rolling along a circular curved track, each aligned orthogonally to reduce vibration responses along separate axes. Both absorbers are placed on the upper floor of the building and the natural frequencies of the cylinders are tuned to match the two lowest natural frequencies of the building's bending modes. Several simulation studies in frequency and time domains are performed to evaluate the damper performance in reducing the building structural response under seismic excitation. The simulation data shows that the proposed dynamics vibration absorber can effectively reduce the seismic response of the building structure. Additionally, an experimental set-up is built and tested to validate the simulation outcomes. Experimental findings reveal a 70% reduction in structural vibration, with close agreement between empirical and simulation results, confirming the DVA's efficacy.

Keywords: Vibration, Dynamics, Building, Absorber, Structure

INTRODUCTION

Vibrations of building structures due to earthquakes have become the focus of attention of researchers in recent decades. This is because earthquakes are natural phenomena that are difficult to predict accurately both in terms of time and place of occurrence [1,2]. Besides that, earthquakes with large energy can cause damage and even collapse of building structures. Therefore, anticipating the effects of earthquakes on building structures is very important in designing earthquake-resistant building structures.

Dynamic vibration absorbers (DVAs) are proven passive solutions for mitigating structural vibration. Many researches have been conducted to investigate diverse DVA configurations for structural application such as pendulum absorbers [3], U-shaped water tanks [4], and tuned mass dampers TMDs [5]. DVA can be tuned to minimize vibration amplitudes and even harness energy from structural oscillations, offering dual-functional benefits [6]. Design of multiple DVAs that simultaneously absorbs vibration energy from a high-speed train that enabling streamlined performance assessment have been established [7]. Recent studies investigate the application of Genetic Algorithm (GA) to optimize vibration suppression in a Two-DOF structure model subjected to seismic load [8]. For high-rise structures, advanced numerical models are essential to accurately evaluate DVA effectiveness, as oversimplified two-degree-of-freedom models fail to capture real-world complexities. Research related to the application of DVA for multidirectional vibrations has been carried out by several researchers. Qin et al. [9] apply multiple DVA in reducing a floor-like lightweight joist structure vibration. Yin et al. [10] propose a technique to control multi-directional vibration of marine pipe system using mistuned cyclic symmetric structure as DVA.

RESEARCH SIGNIFICANCE

Although various concepts and models of DVAs have been developed for single and multi-degree-of-freedom vibration systems [11], their application to spatial structures, which more closely resemble real-world conditions, remains quite limited. This research presents a vibration control strategy for spatial structures utilizing DVA based on a rolling cylinder mechanism. A two-story building model serves as a case study to illustrate the proposed damper application. Two rolling cylinders, set to move perpendicularly along a circular track, are mounted on the upper floor of the building. This configuration enables the dampers to effectively suppress bending-mode vibrations along both the -x and -y axes.

One Degree of Freedom System with a Rolling Cylinder DVA

A single-degree-of-freedom (One-DOF) vibration system integrated with a rolling cylinder dynamic vibration absorber (DVA) is shown in Fig.1. The primary system is defined by mass M, stiffness k, and damping coefficient c. The DVA consists of a cylinder with mass m and radius r, which rolls along a circular track of radius R

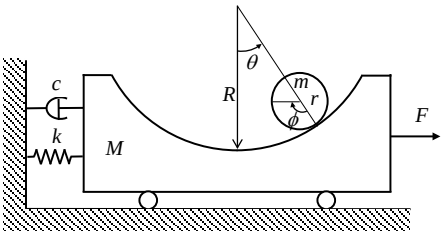

Fig.1 One degree of freedom system with rolling cylinder DVA

The moment balance on the cylinder at the contact point between the cylinder and the pad results in:

$$J_G\left(\ddot{\phi}-\ddot{\theta}\right)+mr\left(R-r\right)\ddot{\theta}+m\ddot{x}r\cos\theta+mgr\sin\theta +C_r\dot{\theta}=0 \quad (1)$$

In the case of without slip $\phi=\frac{R}{r}\theta$ and $\ddot{\phi}=\frac{R}{r}\ddot{\theta}$, therefore Eq. (1) can be simplified by:

$$L\left(\frac{J_G}{r^2}+m\right)\ddot{\theta}+m\ddot{x}\cos\theta+mg\sin\theta+\frac{C_r}{r}\dot{\theta}=0 \quad (2)$$

Where $L=R-r$ and L denotes the pendulum length. Applying a force balance to the main mass yields:

$$M\ddot{x}+c\dot{x}+kx+m\ddot{x}+mL\ddot{\theta}\cos\theta-mL\dot{\theta}^2\sin\theta=F \quad (3)$$

Eq. (2) and (3) are the governing equations of 1-DOF vibration system with rolling cylinder DVA.

Building Structure Model with Two Rolling Cylinder DVA

A building structure model incorporating two rolling cylinder dynamic vibration absorbers (DVAs) as shown in Fig.2 is utilized to evaluate the damper performance. The structure represents a two-story building model, comprising a basement floor, a first floor, and a second floor. Each floor is supported by six vertical columns, as illustrated in Fig.2. Two rolling cylinder DVAs are positioned atop the second floor. These absorbers are designed to mitigate the two lowest bending mode vibrations of the structure in the x- and y-directions

Governing equation

To derive the governing equations for the space structure equipped with absorbers, the system is modeled using the finite element method (FEM). The coupled differential equations governing the absorber and the structure are formulated as:

$$L_i\left(\frac{J_{Gi}}{r_i^2}+m_{di}\right)\ddot{\theta}_i+m_{di}\ddot{x}_{di}\cos\theta_i+m_{di}g\sin\theta_i +\frac{C_{ri}}{r_i}\dot{\theta}_i=0\ ,i=1,2 \quad (4)$$

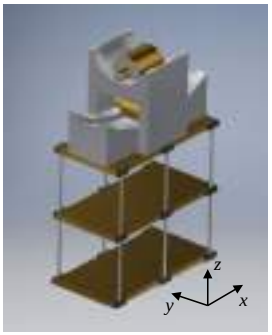

Fig.2 Building structure model with two rolling cylinder DVA

$$\left[\mathbf{M}\right]\{\ddot{\mathbf{x}}\}+\left[\mathbf{C}\right]\{\dot{\mathbf{x}}\}+\left[\mathbf{K}\right]\{\mathbf{x}\}=\{\mathbf{B_u}\}\,f_{ext} +\{\mathbf{B_v}\}\,f_{in} \quad (5)$$

where

[**M**], [**C**] and [**K**] are the structural mass, damping and stiffness matrix calculated by FEM, respectively. {$\mathbf{B_u}$} and {$\mathbf{B_v}$} in Eq. (5) are the row matrices that contain delta functions $\delta_{i,j}$ as follows :

$$\{\mathbf{B_u}\}=\begin{Bmatrix}\delta_{u,1} & \delta_{u,2} & \cdots & \delta_{u,j} & \cdots & \delta_{u,NDOF}\end{Bmatrix} \quad (6)$$

$$\{\mathbf{B_v}\}=\begin{Bmatrix}\delta_{v,1} & \delta_{v,2} & \cdots & \delta_{v,j} & \cdots & \delta_{v,NDOF}\end{Bmatrix} \quad (7)$$

In Eq. (6) and (7), subscript *u* and *v* denote position of the external forces and the interaction forces between DVA and structure. $\delta_{i,j}$ denotes delta function that can be expressed by:

$$\delta_{i,j}=\begin{cases}1, & \text{if } i=j\\ 0, & \text{if } i\neq j\end{cases} \quad (8)$$

The external and interaction force between structure and DVA are expressed as:

$$f_{ext}=F \quad (9)$$

$$f_{in}=mL\dot{\theta}^2\sin\theta-mL\ddot{\theta}\cos\theta-m\ddot{x} \quad (10)$$

Eq. (5) can be expressed in modal coordinates as follows:

$$\ddot{q}_i+2\zeta_i\omega_i q_i+\omega_i^2 q_i=\mathbf{\Psi_i}\left[\{\mathbf{B_u}\}\,f_{ext}+\{\mathbf{B_v}\}\,f_{in}\right], \quad i=1,2,\cdots,\infty \quad (11)$$

Frequency response function (FRF)

The frequency response function (FRF) of the space structure model integrated with two cylindrical DVAs is calculated under the assumption of linear system behavior. For small cylinder displacements, linear approximations are applied to the cylinder's rotational motion and translational dynamics. Using this assumption, the governing equations of the system (Eqs. (4) and (5)) are linearized as follows:

$$\left[\mathbf{M}\right]_{\mathbf{lin}}\{\ddot{\mathbf{x}}\}+\left[\mathbf{C}\right]_{\mathbf{lin}}\{\dot{\mathbf{x}}\}+\left[\mathbf{K}\right]_{\mathbf{lin}}\{\mathbf{x}\}=\{\mathbf{B}\}_{\mathbf{lin}}F \quad (12)$$

Where

$$[\mathbf{M}]_{\mathbf{lin}} = \begin{bmatrix} m_{11} & \cdots & m_{1p} & \cdots & m_{1q} & \cdots & m_{1n} & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ m_{p1} & \cdots & m_{pp}+m_{d1} & \cdots & m_{pq} & \cdots & m_{pn} & m_{d1}L_1 & 0 \\ \vdots & \vdots & \vdots & \cdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ m_{q1} & \cdots & m_{qp} & \cdots & m_{qq}+m_{d2} & \cdots & m_{qn} & 0 & m_{d2}L_2 \\ \vdots & \vdots & \vdots & \cdots & \vdots & \cdots & \vdots & \vdots & \vdots \\ m_{n1} & \cdots & m_{np} & \cdots & m_{nq} & \cdots & m_{nn} & 0 & 0 \\ 0 & \cdots & m_{d1} & \cdots & 0 & \cdots & 0 & L_1\left(\frac{J_{G1}}{r_1^2}+m_{d1}\right) & 0 \\ 0 & \cdots & 0 & \cdots & m_{d2} & \cdots & 0 & 0 & L_2\left(\frac{J_{G2}}{r_2^2}+m_{d2}\right) \end{bmatrix}$$

$$[\mathbf{C}]_{\mathbf{lin}} = \begin{bmatrix} c_{11} & \cdots & c_{1p} & \cdots & c_{1q} & \cdots & c_{1n} & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ c_{p1} & \cdots & c_{pp} & \cdots & c_{pq} & \cdots & c_{pn} & 0 & 0 \\ \vdots & \vdots & \vdots & \cdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ c_{q1} & \cdots & c_{qp} & \cdots & c_{qq} & \cdots & c_{qn} & 0 & 0 \\ \vdots & \vdots & \vdots & \cdots & \vdots & \cdots & \vdots & \vdots & \vdots \\ c_{n1} & \cdots & c_{np} & \cdots & c_{nq} & \cdots & c_{nn} & 0 & 0 \\ 0 & \cdots & 0 & \cdots & 0 & \cdots & 0 & \frac{C_{r1}}{r_1} & 0 \\ 0 & \cdots & 0 & \cdots & 0 & \cdots & 0 & 0 & \frac{C_{r2}}{r_2} \end{bmatrix} \quad [\mathbf{K}]_{\mathbf{lin}} = \begin{bmatrix} k_{11} & \cdots & k_{1p} & \cdots & k_{1q} & \cdots & k_{1n} & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ k_{p1} & \cdots & k_{pp} & \cdots & k_{pq} & \cdots & k_{pn} & 0 & 0 \\ \vdots & \vdots & \vdots & \cdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ k_{q1} & \cdots & k_{qp} & \cdots & k_{qq} & \cdots & k_{qn} & 0 & 0 \\ \vdots & \vdots & \vdots & \cdots & \vdots & \cdots & \vdots & \vdots & \vdots \\ k_{n1} & \cdots & k_{np} & \cdots & k_{nq} & \cdots & k_{nn} & 0 & 0 \\ 0 & \cdots & 0 & \cdots & 0 & \cdots & 0 & m_{d1}g & 0 \\ 0 & \cdots & 0 & \cdots & 0 & \cdots & 0 & 0 & m_{d2}g \end{bmatrix}$$

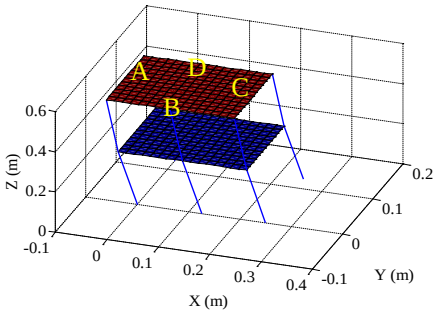
RESULTS AND DISCUSSION

The vibration attenuation performance of the building structure model equipped with two rolling cylinder dynamic vibration absorbers (DVAs) is numerically evaluated using the nominal simulation parameters listed in Table 1. In the simulation study, the DVAs are positioned at the center of the second floor.

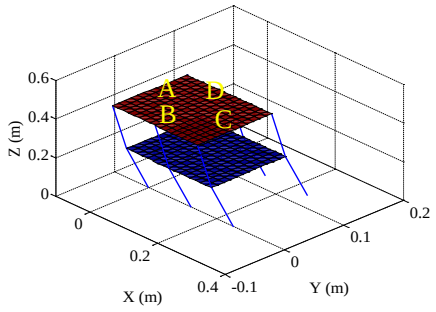
Table 1 Nominal simulation parameters

No	Parameters	Value
1	1st floor dimensions	(250 × 125× 8) mm
2	2nd floor dimensions	(250 × 125 × 8) mm
3	Columns dimensions	(2 × 3 × 125) mm
4	Columns modulus (E_c)	69×10^9 N/m^2
5	Plate modulus (E_c)	120×10^9 N/m^2
6	1st pendulum mass (m_{d1})	0.35 kg
7	2nd pendulum mass (m_{d2})	0.09 kg
8	1st pendulum inertia (J_{G1})	3.5×10^{-5} kg m^2
9	2nd pendulum inertia(J_{G2})	3.7×10^{-6} kg m^2
10	Structural damping ratio (ζ)	1×10^{-3} Ns/m
11	1st pendulum length (L_1)	0.08 m
12	2nd pendulum length (L_2)	0.033 m
13	1st cylinder radius (r_1)	0.01 m
14	2nd cylinder radius (r_2)	0.005 m
15	Damping (C_{r1} and C_{r2})	1×10^{-4} Nms

The two lowest natural frequencies of the structure and their corresponding mode shapes, derived from numerical simulations is depicted in Fig.3. As illustrated, the first and second mode shapes represent the structure's lowest bending modes in the x- and y-directions, with natural frequencies of 1.77 Hz and 2.65 Hz, respectively. Two cylindrical DVAs are tuned to these two natural frequencies to target vibration mitigation in these critical modes.



f_1 = 1.77 Hz



f_2 = 2.65 Hz

Fig.3 Two Lowest natural frequencies and mode shapes of the structure model

Two rolling-cylinder dynamic vibration absorbers (DVAs) are designed to suppress vibrations in the building structure along two orthogonal axes (x and y directions). Both devices are mounted on the top floor of the building, as shown in Fig. 2. Their effectiveness is assessed through the structure's frequency response functions (FRFs), evaluated in the x–z and y–z planes. The FRF in the x–z plane is obtained using excitation at point A and response measurements at point C, whereas the FRF in the y–z plane is determined from excitation and measurements taken at points B and D (see Fig. 3).

Variation of Pendulums İnertia (J_{G1}, J_{G2})

The effect of varying J_{G1} on the frequency response function (FRF) in the x-z plane is shown in Fig.4(a). The results demonstrate that reducing J_{G1} from its nominal value enhances the damper's effectiveness in suppressing vibrations near the natural frequency of the first bending mode in the x-z plane. Conversely, as shown in Fig.4(b), variations in J_{G1} exhibit negligible impact on the FRF in the y-z plane.

The impact of J_{G2} variations on the FRF in the x-z and y-z planes (Fig.5) reveal that the x-z plane FRF exhibits little to no sensitivity to J_{G2} adjustments. In contrast, deviations in J_{G2} affect the y-z plane FRF, though the effect remains relatively minor.

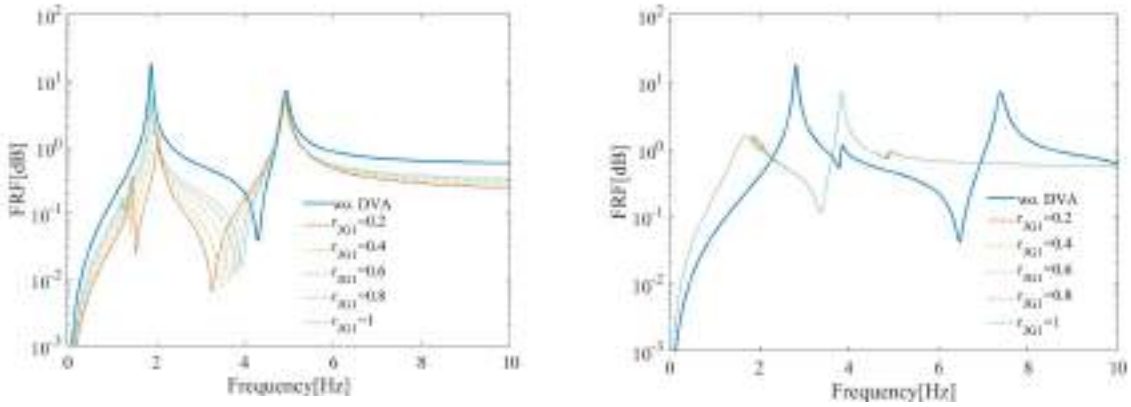


Fig. 4 Variation of FRF vs J_{G1} (a) x-z plane (b) y-z plane

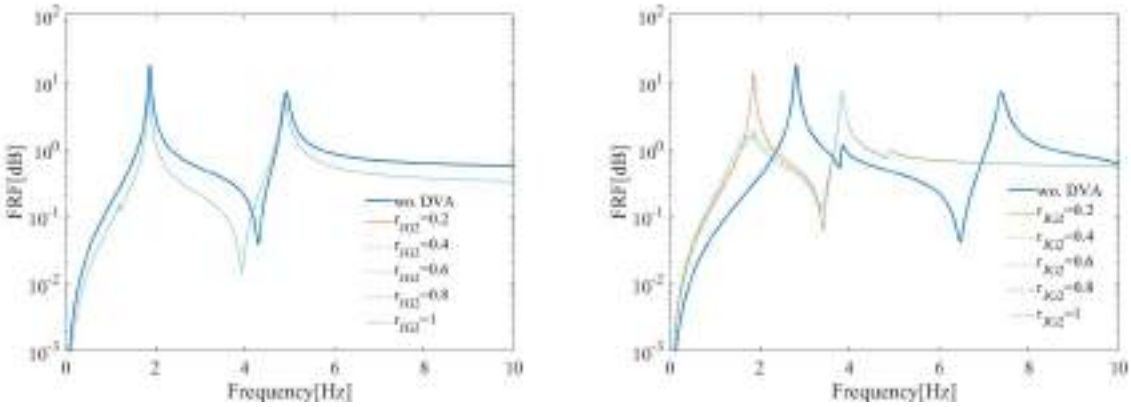

Fig. 5 Variation of FRF vs J_{G2} (a) x-z plane (b) y-z plane

Variation of Circular Track Radius (L_1, L_2)

The effect of increasing L_1 on the FRF of the structure in the x-z and y-z planes is shown in Fig.6. It is shown that variations in L_1 markedly influence the FRF in the x-z plane. Notably, reducing L_1 below its nominal value enhances the DVA's effectiveness in mitigating structural vibrations in this plane. In contrast, the y-z plane FRF exhibits negligible sensitivity to changes in L_1.

Relationship between L_2 adjustments and the FRF of the structure in the x-z and y-z planes is evaluated by varying the ratio between L_2 to its nominal value as shown in Fig.7. The results reveal that increasing L_2 has negligible impact on the x-z plane FRF. Conversely, elevating L_2 introduces a slight but measurable effect on the y-z plane FRF.

Variation of Cylinder Radius (r_1, r_2)

Fig.8 demonstrates the influence of the first cylinder radius (r_1) on the FRF of the structure in the x-z and y-z planes. Enlarging r_1 enhances the dynamic absorber's vibration mitigation performance in the x-z plane. Conversely, increasing r_1 exerts minimal influence on the y-z plane FRF.

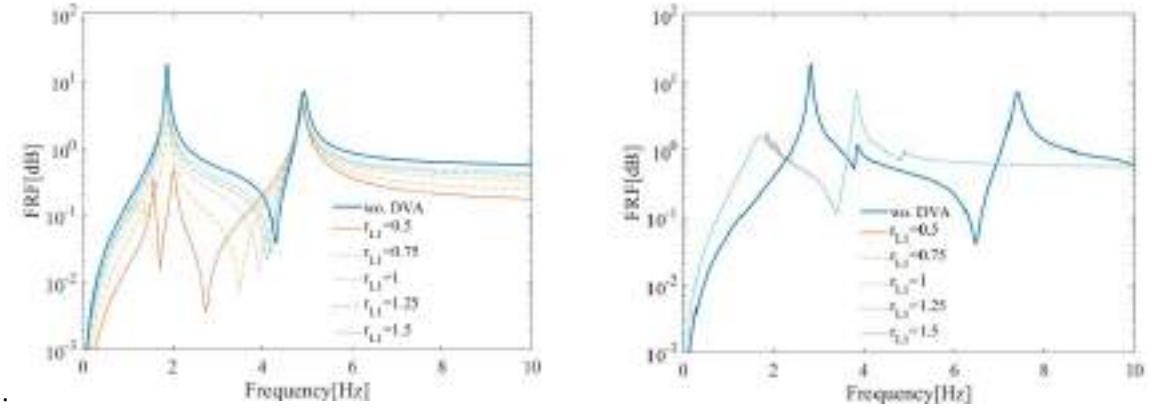

Fig. 6 Variation of FRF vs L_1 (a) x-z plane (b) y-z plane

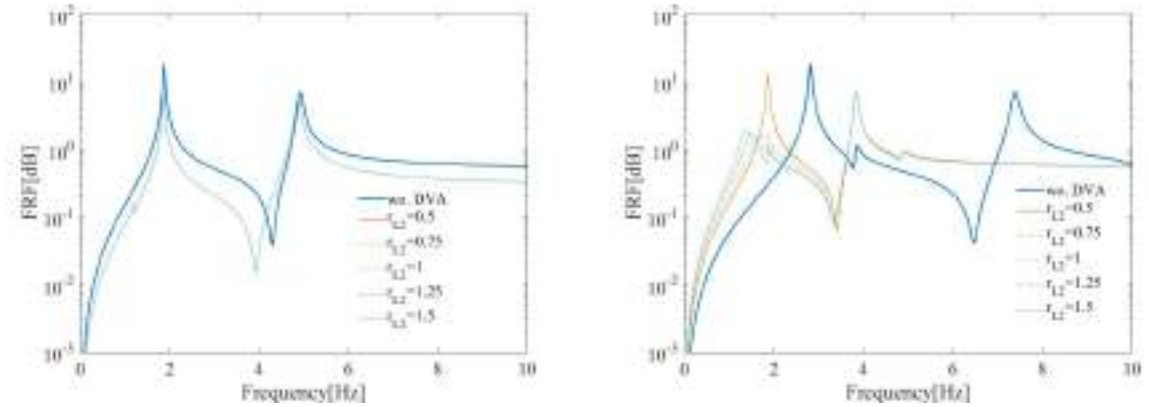

Fig.7 Variation of FRF vs L_2 (a) x-z plane (b) y-z plane

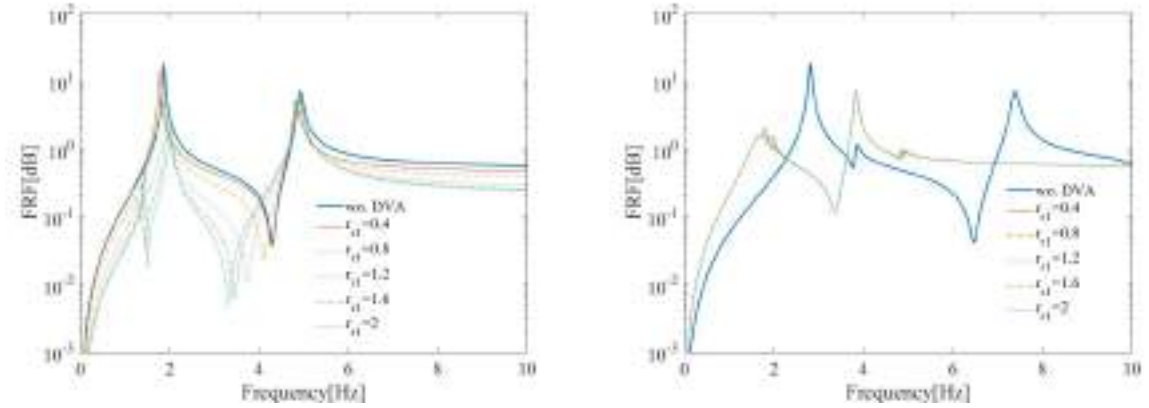

Fig. 8 Variation of FRF vs r_1 (a) x-z plane (b) y-z plane

Time-domain responses simulation of the structure in x-z plane and y-z plane at two distinct measurement points are shown in Fig.9. The external excitations are applied at points A (x-direction) and B (y-direction), with the Kobe earthquake signal serving as the disturbance input. The structural response is measured at points C and D. It is shown that both dynamic absorbers significantly mitigate structural vibrations in the x-z and y-z axis. Compared to conventional DVA which is only able to reduce vibrations in one axis [9], rolling cylinder DVA developed in this study has the ability to dampen vibrations in both directions of the vibration axis.

EXPERIMENTAL VALIDATION

The excitation force is applied using an impact hammer and the acceleration data are collected using B&K accelerometer type 4507. Fig.10 shows the

comparison of the experimental FRF and the simulated FRF in the y-z planes. Experimental data can validate simulation results. The difference in the peak FRF is likely arise from uncertainties in modeling parameters, particularly the moment of inertia and damping coefficient.

CONCLUSIONS

This study proposes a concept for space building structural vibration attenuation using two cylinder dynamic vibration absorber. Both absorbers are placed on the top floor of the building and are used to dampen vibrations in the x-z and y-z planes. The simulation results show that there are a number of parameters that significantly affect the performance of the dampers. Furthermore, employing optimal DVA parameters can reduce the structural response by as much as 70%. Experimental studies show that the simulation results can be validated experimentally.

CRITICAL ANALYSIS OF OLIVINE PERFORMANCE AND POTENTIAL FOR CARBON SEQUESTRATION IN SUSTAINABLE CONSTRUCTION

Roohollah Kalatehjari [1], Sara Bayandor[1] and Yousef Adeeb Chamachaei[1]

[1] Built Environment Engineering Department, School of Future Environments, Auckland University of Technology, Auckland 1010, New Zealand

ABSTRACT

Global efforts to reduce CO_2 emissions have increased research interest in olivine due to its significant carbon sequestration potential. However, the broad variability in mineralogical characteristics, carbonation mechanisms, and environmental impacts of olivine poses challenges to its practical use, highlighting a need for systematic evaluation. A systematic literature review was conducted on 102 scholarly sources published since 2000, adhering to PRISMA guidelines. The review comprehensively analysed olivine grain size, mineral composition, carbonation mechanisms, chemical treatments, CO_2 absorption efficiency, and environmental impacts. Statistical analyses were performed on keyword frequencies, regional focus, and publication trends to establish research themes and identify knowledge gaps. The analysis revealed a marked increase in olivine research in recent years (from 2021 to 2024), comprising 52.4% of total studies. The primary focus across 79% of reviewed publications was CO_2 sequestration efficacy, frequently involving grain sizes below 180 µm and high-purity forsterite (>80% Mg_2SiO_4), a magnesium-rich silicate mineral. Key thematic areas identified were carbon dioxide (33 mentions), carbonation (18 mentions), and mineral carbonation (11 mentions). Geographically, research predominantly originated from Europe (19.3%), the USA (15.9%), and Malaysia (10.2%). Critically, fewer than 30% of studies included comprehensive life-cycle analyses or economic feasibility evaluations, and only 18% reported durability and porosity data. While recent research has expanded significantly, substantial gaps remain regarding long-term durability, economic analysis, and regional-specific adaptations. Future research must prioritise comprehensive environmental impact assessments, economic evaluations, and field-scale durability testing to facilitate the practical application of olivine in sustainable construction.

Keywords: Olivine, Carbonation, CO_2 sequestration, Systematic literature review, Sustainable construction

INTRODUCTION

Global warming, driven primarily by the emission of greenhouse gases (GHGs), continues to exacerbate environmental challenges. Carbon dioxide (CO_2) is the dominant contributor to these shifts, responsible for approximately 76% of global GHG emissions and playing a central role in the global climate crisis [1]. The Paris Climate Agreement, ratified by numerous countries, sets a target to limit global temperature rise to below 2°, with a concerted effort to reduce CO_2 emissions through sustainable practices [2]. The construction industry, a significant emitter of CO_2, accounts for 33% of global emissions, with cement production alone contributing around 8% of the total carbon footprint [3]. Given the increasing demand for concrete due to population growth and infrastructure development, alternative approaches to mitigate CO_2 emissions in construction are urgently needed. As such, the search for effective methods to capture and store atmospheric CO_2 has intensified, with a growing interest in olivine, a naturally occurring mineral with potential for carbon sequestration.

Olivine is an abundant silicate mineral found in mafic and ultramafic rocks, making up a significant portion of the Earth's mantle [4]. Olivine's unique ability to absorb CO_2 through mineral carbonation reactions, which convert CO_2 into stable magnesium or iron carbonates, has positioned it as a promising candidate for both environmental and construction applications [5]. Studies indicate that olivine can effectively capture CO_2 on a large scale, with the potential to neutralise emissions generated by industries like cement production [6]. Additionally, olivine's high magnesium content makes it suitable for producing alkali-activated materials (AAMs), replacing traditional binders in soil stabilisation and construction materials [7]. While the potential for CO_2 sequestration is well-documented, the practical application of olivine in sustainable construction remains underexplored. The literature surrounding olivine's role in both carbon sequestration and construction materials is expanding, but gaps remain regarding its long-term durability, environmental impact, and economic feasibility [8, 9]. As depicted in Figure 1 (Geographic Distribution of Studies), the analysis reveals that among the 102 papers reviewed, 88 provided specific regional information. It shows relevant research to be most concentrated in Europe (19.3%), followed by the United States (15.9%) and Malaysia (10.2%). The "Others" category, representing countries with less than 2% of total

publications each, constitutes a significant portion (25.0%) of region-specific research. This geographic imbalance underscores the need for more diverse regional investigations to adapt olivine applications to local conditions, resources, and environmental challenges.

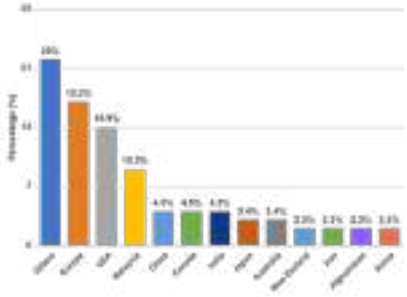

Fig. 1 Geographic Distribution of Olivine Research

Fig. 2 (Research Trends) illustrates the evolving focus in olivine research from 2000 to 2024, revealing a significant acceleration in research activity. Analysis of publication trends shows that 52.0% of all studies were published between 2021 and 2024, compared to 37.2% during 2011-2020 and only 10.8% from 2000-2010. This dramatic increase reflects growing recognition of olivine's potential for carbon sequestration and sustainable construction applications.

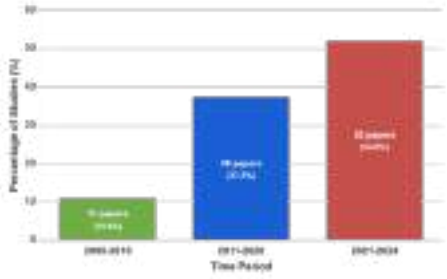

Fig. 2 Olivine Research Publication Trends (2000-2024)

This paper aims to provide a critical analysis of olivine's performance, examining its CO_2 sequestration efficiency and exploring its potential for use in sustainable construction applications.

RESEARCH SIGNIFICANCE

The significance of this study lies in the growing need to mitigate global CO_2 emissions, particularly in the construction industry, which is a major contributor to greenhouse gas emissions. By exploring olivine's role in carbon capture and its integration into construction materials, this research offers valuable insights into environmental technologies and sustainable building practices, contributing to climate change mitigation and enhancing the sustainability of construction processes globally.

METHODOLOGY

A systematic literature review (SLR) was conducted to achieve the goal of this study. The review followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines to ensure a transparent and replicable process. The initial search was conducted across reputable academic databases, including Google Scholar and Scopus, targeting global sources published from 2000 to 2024. A total of 102 scholarly articles were identified, with selection based on strict inclusion and exclusion criteria. The inclusion criteria were: (1) articles published from 2000 onward, (2) written in English, and (3) open access or fully retrievable. Exclusion criteria involved non-English articles, conference papers, newsletters, and review articles. The PRISMA-based identification, screening, and selection process is visually summarised in Fig. 3. Characteristics of Olivine

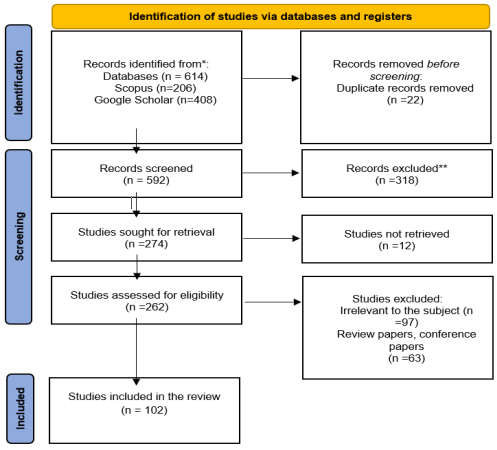

Fig. 3 Systematic literature review process (based on PRISMA guidelines)

Mineralogy and Carbonation Stability

Olivine ($(Mg,Fe)_2SiO_4$) exhibits significant variability in its mineralogical characteristics, with forsterite (Mg_2SiO_4) and fayalite (Fe_2SiO_4) representing the end members of this solid solution series. Analysis of 102 studies providing compositional data reveals that high-purity forsterite (>80% Mg_2SiO_4) demonstrates superior carbonation potential and stability compared to iron-rich varieties, enhancing carbonation efficiency and stability over extended periods [10]. Table 1 summarises the typical mineralogical composition ranges of olivine observed across the reviewed studies.

Table 1 Typical mineralogical composition ranges of olivine and optimal values for CO_2 sequestration

Component	Typical Range (%)	Optimal Range for CO_2 Sequestration (%)
Forsterite (Mg_2SiO_4)	70-92	>80
Fayalite (Fe_2SiO_4)	5-30	<15
Accessory minerals (pyroxenes, amphiboles)	0-10	<5
Serpentine content	0-15	<5

The carbonation stability of olivine primarily depends on its mineral composition and the environmental conditions of application. Magnesium-rich olivine exhibits higher carbonation reactivity, with studies reporting sustained CO_2 sequestration capacity over extended periods. The dominant carbonation reaction involves the conversion of magnesium silicates to magnesium carbonates, as shown in Equation (1) [11].

$$Mg_2SiO_4 + 2CO_2 + 2H_2O \rightarrow 2MgCO_3 + H_4SiO_4 \quad (1)$$

This reaction forms stable magnesium carbonate (magnesite) and orthosilicic acid (H_4SiO_4), effectively locking carbon dioxide in solid form. These carbonation products are highly stable, with estimated retention times extending to geological timescales (>1000 years), making olivine a promising material for long-term carbon sequestration.

An alternative pathway involves bicarbonate-mediated carbonation [12]. In this system, the solution is buffered to a moderately alkaline pH (~7.9), allowing simultaneous silicate dissolution and carbonate precipitation. This modification significantly reduces reaction time and likely involves the direct reaction of forsterite with bicarbonate ions (Equation 2) and continuous regeneration of bicarbonate through the reaction of CO_2 with hydroxide ions (Equation 3).

$$Mg_2SiO_4 + 2HCO_3^- \rightarrow 2MgCO_3 + SiO_2 + 2OH^- \quad (2)$$
$$OH^- + CO_2 \rightarrow HCO_3^- \quad (3)$$

Grain Size and Specific Surface Area

Grain size is a critical factor affecting olivine's carbonation efficiency and practical applications. Analysis of the database (Fig. 4) reveals that 85 out of 102 studies report on grain size information, with the majority (64.7%) investigating multiple grain size ranges rather than a single size fraction. Among the studies focusing on a single grain size category, fine-grained olivine (<100 μm) was the most frequently studied, followed by coarse-grained (>500 μm), and medium-grained (100-500 μm) olivine.

The most frequently studied specific particle sizes were 75 μm (14 mentions), 100 μm (11 mentions), and 5-10 μm (10 mentions each). The focus on using smaller particle sizes aligns with the proven impact of fine-grained olivine particles to achieve significantly higher carbonation rates compared to coarser fractions [13].

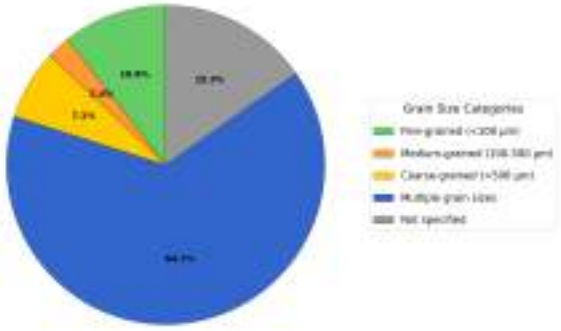

Fig. 4 Distribution of Olivine Grain Sizes in Research Studies

The Specific Surface Area (SSA) of olivine particles directly correlates with carbonation kinetics and efficiency **[10]**. 34 out of 102 studies report SSA values, with measurements ranging widely from 0.36 to 670.8 m^2/g, depending on particle size, processing methods, and measurement techniques. Mechanical activation through processes like high-energy milling can significantly increase SSA, hence improving olivine's reactivity [14]. However, the energy requirements for such processing must be balanced against the carbon sequestration benefits in practical applications.

For sustainable construction applications, multiple grain size distributions are typically employed to balance carbonation potential with functional properties such as workability and strength development. This approach provides a practical compromise between competing requirements for optimal performance [10].

ENVIRONMENTAL IMPACTS AND CHEMICAL TREATMENTS

Durability and Porosity Considerations

The durability of olivine-containing materials emerges as a critical consideration for sustainable construction applications. Analysis of the database indicates the importance of porosity characteristics as one of the key studied parameters in 100 out of 102

studies. Porosity measurements across these studies indicate a significantly wide range of values from 1% to 98%, depending on olivine content, grain size, and processing methods. The most frequently reported porosity ranges are 10-15%, 5-20%, and 10-40%, with varied distributions across different material compositions. Higher values of porosity (>30%) significantly influence carbonation behaviour by facilitating CO_2 diffusion while affecting structural integrity [10].

Durability aspects of olivine have also been considered in the majority of studies, 92 out of 102. Durability aspects include permeability (16 papers), mechanical strength (4 studies), freeze-thaw performance (3 papers), and enhanced acid attack resistance compared to Portland cement [15], and potential self-healing properties through ongoing carbonation [16].

Carbon Sequestration Mechanisms

The carbon sequestration potential of olivine operates through several interconnected mechanisms, with its efficiency strongly influenced by grain size. Analysis of the database reveals that 100 out of 102 studies focused on CO_2 sequestration, with direct mineral carbonation being the most frequently discussed pathway (68 papers), followed by enhanced weathering (31 papers) and passive sequestration (1 paper). Aligned with previous discussions, fine-grained olivine (<180 μm) demonstrates significantly high CO_2 absorption rates, with sequestration capacities ranging from 0.25 to 0.8 tons of CO_2 per ton of olivine [10, 11]. Primary sequestration involves the following three mechanisms:

1. **Direct mineral carbonation**: The conversion of olivine to magnesium or iron carbonates through reaction with CO_2 in the presence of water (eq. 1) [11].
2. **Enhanced weathering**: Accelerated natural weathering processes that increase alkalinity in marine or soil environments, promoting CO_2 dissolution and subsequent carbonate formation. This mechanism is investigated by assessing the potential of soil carbonation and enhanced weathering through Life Cycle Assessment (LCA) [17].
3. **Passive sequestration**: Slow and ongoing carbonation of olivine in applications such as construction materials or landscaping aggregates [18].

Table 2 illustrates the relationship between grain size and carbon dioxide sequestration efficiency based on the analysed literature. While the data points are derived from a limited number of papers explicitly reporting quantitative sequestration rates (8 papers) and completion times (2 papers), they represent the best available estimates from the current literature.

Table 2 Relationship between olivine grain size and carbon dioxide sequestration efficiency

Grain Size (μm)	CO_2 Sequestration Rate (kg CO_2/ton olivine/year)	Time to 50% Completion (year)	Dominant Mechanisms
<63	200-800	1-3	Direct carbonation
63-125	100-350	3-7	Direct carbonation & Enhanced weathering
125-250	50-200	5-15	Enhanced weathering
250-500	25-100	10-25	Enhanced weathering & Passive sequestration
>500	10-50	>25	Passive sequestration

Treatment Approaches and Contamination

Various treatment methods have been identified for enhancing olivine's carbon sequestration potential. Among the 102 studies analysed, using multiple-treatment approach was reported in 30 studies, followed by thermal treatment in 24 studies, physical treatment in 22 studies, chemical treatment in 18 studies, 4 studies discussing other treatment approaches including biological catalysis, electrochemical enhancement, and ultrasonic treatments, and 4 other studies not specifying their applied treatment methods (Fig. 5). Most Common commonly used treatment approaches include: thermal treatment **[11]**, physical treatment **[10]**, chemical treatment and multiple treatment **[11]**.

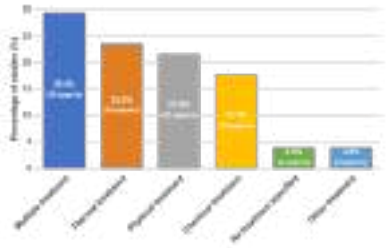

Fig. 5 Distribution of Treatment Methods for Enhancing Olivine Reactivity

30 papers in the database address contamination concerns and potential environmental impacts, with particular focus on heavy metal leaching. While element release remains within acceptable

environmental limits in most controlled construction applications [15], site-specific assessments are essential for large-scale implementations.

Life Cycle Assessment and Economic Feasibility

Despite olivine's promising carbon sequestration potential, comprehensive LCA and economic analyses remain limited in the literature. Only 28 out of 102 studies discuss LCA methodologies, with just 6 incorporating comprehensive assessments. Almost half of the studies (50 out of 102) meaningfully address economic and commercialisation aspects. It is critical to assess the environmental benefits of olivine against the emissions and energy consumption associated with its mining, processing, transportation, and implementation **[10]**. Table 3 presents a comparative assessment of different olivine applications based on life cycle and economic considerations.

Table 3 Life cycle assessment and economic feasibility of olivine applications

Application	Net CO_2 Sequestration Potential (tons CO_2/ton olivine)	Economic Feasibility	Key Challenges
Coastal Application	High (0.6-0.8 tons)	Medium-Low	Transport emissions, ecological impacts
Agricultural Soil Amendment	Medium (0.3-0.5)	Medium	Heavy metal accumulation, variable efficiency
Construction Materials	Low-Medium (0.2-0.4)	High	Slow carbonation rates, durability concerns
Industrial Direct Carbonation	Medium-High (0.5-0.7)	Low	High energy requirements, process complexity

Economic analyses, such as those conducted by Cheeseman et al. [10], indicate cost ranges of 20-120$ per ton of CO_2 sequestered, depending on application method and scale.

Olivine Applications in Sustainable Construction

The integration of olivine into sustainable construction practices represents a promising avenue for both carbon sequestration and enhanced material performance. Analysis of the database reveals multiple potential applications that capitalise on olivine's unique properties. In soil stabilisation applications, olivine-treated soils exhibit enhanced strength characteristics while simultaneously sequestering CO_2, with unconfined compressive strength improvements of 20-45% reported in several studies [7]. These properties make olivine particularly valuable for ground improvement in construction projects, providing dual benefits of enhanced soil bearing capacity and carbon reduction.

In concrete and cementitious applications, olivine demonstrates potential as a supplementary cementitious material (SCM) or aggregate replacement. Eleven studies, including research by Cheeseman, Shanks [10], investigated olivine's integration into concrete mixtures, reporting that partial replacement (5-15% by weight) of traditional Portland cement with olivine-derived materials can reduce the carbon footprint by 8-20% while maintaining comparable mechanical properties. For road construction applications, identified in 7 papers, olivine aggregates in asphalt mixtures demonstrated adequate mechanical performance coupled with ongoing passive carbonation potential. Landscape applications, such as olivine-enriched soils in urban green spaces and olivine sand for walkways, were addressed in 4 studies, showing potential for widespread deployment with minimal technical barriers.

CURRENT CHALLENGES AND FUTURE DIRECTIONS IN OLIVINE RESEARCH

The durability and long-term performance of olivine-based materials remain insufficiently investigated. This represents a significant knowledge gap in understanding how olivine-containing materials withstand environmental stressors over extended periods. Current literature predominantly focuses on short-term laboratory investigations (typically < 1 year), which fail to capture the complex degradation mechanisms that may emerge over decades of service life. This stark disparity represents a critical research gap, with fewer than 10% of studies incorporating field-scale testing (Fig. 6). This laboratory-to-field scaling challenge has severely limited the translation of promising research findings into practical applications.

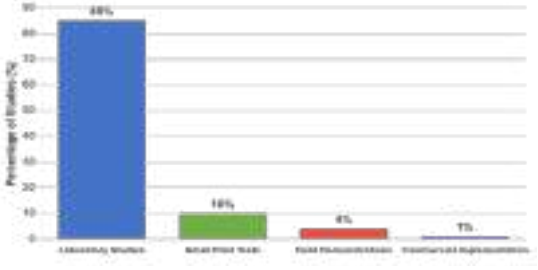

Fig. 6 Distribution of Olivine Research Across Implementation Stages

CONCLUSION

This systematic review of 102 scholarly sources demonstrates olivine's significant potential for carbon sequestration and sustainable construction

applications. The research landscape shows geographic disparities, with studies predominantly from Europe (19.3%), the USA (15.9%), and Malaysia (10.2%), collectively accounting for 45.4% of all studies with regional information. Recent years have seen accelerated research interest, with 53% of all studies published since 2021.

Three main carbonation mechanisms were identified in the literature. The effectiveness of these mechanisms was found to be strongly influenced by treatment methods and environmental conditions.

The analysis revealed that high-purity forsterite (>80% Mg_2SiO_4) with fine grain sizes (<180 μm) achieves optimal CO_2 sequestration rates (0.25-0.8 tons CO_2/ton olivine). Medium-grained olivine (100-250 μm) offers an optimal balance between carbonation potential and functional properties, with porosity ideally maintained between 15-25% to facilitate CO_2 diffusion while ensuring structural integrity.

Olivine demonstrates promise for sustainable construction applications, as a supplementary cementitious material with enhanced acid resistance and potential self-healing properties. However, significant knowledge gaps persist, with fewer than 30% of studies including comprehensive life cycle assessment (LCA) or economic feasibility evaluations, and only 18% reporting on critical durability data.

Future research must prioritise long-term field demonstrations, regional adaptation strategies, standardised assessment protocols, and integrated LCA.

A STUDY ON THE CORRELATION BETWEEN THE COEFFICIENT OF AIR PERMEABILITY AND AIR INFLOW AS AN INDEX OF PCM MATERIAL PERMEABILITY

Arisa Nakamura [1], Barchinoyhon Sayfullaeva [2], Yuki Sakoda [3] and Shushi Sato [4]

[1] The Graduate School Integrated Arts, Sciences, Agriculture and Marine Science, Kochi University, Japan;
[2] The Graduate School Integrated Arts, Sciences, Agriculture and Marine Science, Kochi University, Japan;
[3] The United Graduate School of Agricultural Sciences, Ehime University, Japan; [4] Kochi University, Japan

Abstract

In reinforced concrete structures, the penetration of degradation factors into the interior cause neutralization and salt attack. Therefore, the quality of concrete layer and PCM requires low material permeability. Two types of air permeability test methods, double chamber method and cylinder method, are applied to evaluate non-destructively. However, there are few examples of their application research results concern to PCM, and verification of the relationship between these two tests is insufficient. Based on the above background, the objective of this study was to clarify the relationship between the coefficient of air permeability and the air inflow. Surface air permeability tests using the cylinder and double chamber methods were conducted on the repaired surface of RC open canal with PCM. The result suggests that the test results of the double chamber method and the cylinder method do not correspond accurately. On the other hand, a positive correlation between the coefficient of air permeability and the air inflow was confirmed up to a certain period of time. Air permeability of the concrete and PCM was found that the criteria for quality evaluation based on the cylinder method did not correspond to the criteria for quality evaluation in the double chamber method. In the future, it is necessary to clarify the limits of applicability of the cylinder method, and to consider new evaluation criteria based on the air inflow.

Keywords: Material permeability, Double chamber method, Cylinder method, Inorganic Surface Coatings

INTRODUCTION

The durability of concrete structures cannot be adequately evaluated based on only strength. A comprehensive assessment of durability requires the prediction of deterioration processes over time.

In reinforced concrete (RC) structures, deterioration primarily results from the penetration of degradation factors into the interior. When neutralization and salt attack occur, it induces corrosion of internal reinforcing bars and cracking, ultimately leading to a decline in the durability of the reinforced concrete. To inhibit the penetration of degradation factors, the quality of concrete layer requires low material permeability. This requirement also applies to polymer cement mortar (PCM), which is commonly used for the repair and strengthening of concrete structures.

Two types of material permeability test methods, double chamber method and cylinder method, are applied to evaluate permeability non-destructively. Omoya et al. confirmed a strong correlation between air inflow and the coefficient of air permeability through tests conducted on five types of concrete and two types of mortar [1]. However, this evaluation combined concrete and mortar, and there are few studies that have focused exclusively on PCM. Consequently, the relationship between these two air permeability tests remains insufficiently verified for PCM.

Based on the above background, the objective of this study is to clarify the relationship between the coefficient of air permeability and air inflow as material permeability indicators, focusing specifically on PCM. Surface air permeability tests using the double chamber and cylinder methods were conducted on PCM-repaired surfaces of RC open canal. This research offers a new perspective for understanding the permeability behavior of mortar in the field of repair engineering.

RESEARCH SIGNIFICANCE

In Japan, the maintenance and management of existing infrastructure are essential, even in the face of a growing shortage of skilled labor. As labor-saving strategies in infrastructure maintenance become increasingly important, the cylinder method offers a more straightforward approach to evaluating material permeability. Clarifying the relationship between the cylinder method and the double chamber method will facilitate the broader application of the cylinder method and the development of a standardized evaluation procedure.

OVERVIEW OF THE SURFACE AIR PERMEABILITY TEST

Double Chamber Method

A schematic diagram of the double chamber method is presented in Fig.1. In this method, the coefficient of air permeability (kT) is calculated based on the time-dependent recovery of pressure within the vacuumed inner cell. The double-chamber apparatus consists of an inner chamber and an outer chamber, with both chambers being pressure-controlled to maintain equal pressure and to physically prevent the inflow of external air [2]. However, for in situ measurements, external equipment such as a power generator and vacuum pump is required in addition to the surface air permeability tester, resulting in increased operational costs.

Cylinder Method

A schematic diagram of the cylinder method is presented in Fig.2. In this method, the volume of air inflow into the cylinder is measured following the release of negative pressure. Unlike the double chamber method, the testing apparatus consists of a single chamber. Consequently, it is significantly influenced by the surface fragile layer, which can lead to an overestimation of the actual permeability [3].

OVERVIEW OF THE EXPERIMENT

Repair Method Applied in the Experiment

This study was conducted on concrete surfaces repaired using a combined method of inorganic coating and a silicate-based surface impregnation material. Inorganic coating methods refer to techniques applied to the surfaces of open canals with the objective of mitigating the ingress of deterioration agents such as carbon dioxide and chloride ions, preventing water leakage, and improving water tightness [4]. The silicate-based surface impregnation method involves the penetration of silicate materials into the concrete surface layer to modify and densify its microstructure, thereby aiming to restore or enhance durability by reducing the permeability to harmful agents [5]. If the impregnated material remains in the form of dry solid residues, it can re-dissolve upon exposure to moisture and continue to exhibit its pore-filling effect [6]. By combining these methods, it is possible to suppress crack width propagation and facilitate the filling of cracks.

The experiment was conducted on a RC open canal located within the field of the Monobe Campus, Kochi University. The west wall of the canal, where the surface coating was applied in 2016, and the east wall, treated in 2023, were selected as test areas. A summary of the test sections is provided in Table 1. Both sides of the RC channel were repaired using either standard PCM or Fast-Hardening PCM, with

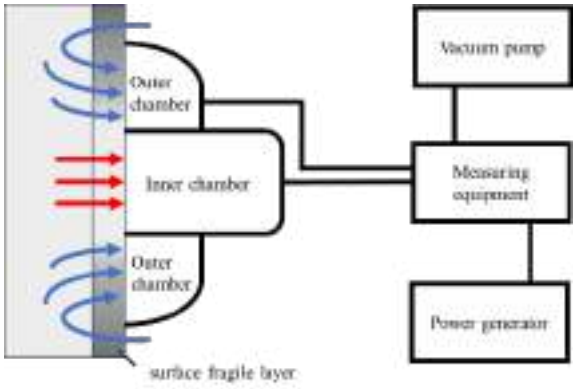

Fig.1 Schematic diagram of the double chamber method

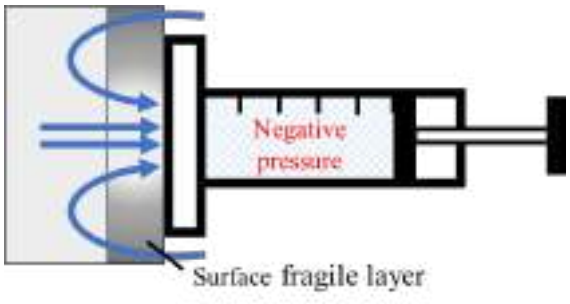

Fig.2 Schematic diagram of the cylinder method

Table 1 A summary of the test sections

Year of Repair	Type of PCM	Impregnation Coating Condition	Number of Test Sections
2016	Standard／Fast-Hardening	8 coated ／ 6 uncoated	14
2023	Standard／Fast-Hardening	2 coated ／ 2 uncoated	4

and without application of the impregnation material, for follow-up investigation.

Overview of the Test Method

In this study, the relationship between the coefficient of air permeability and the air inflow volume as performance indicators was examined by comparing two types of material permeability data obtained from actual measurements.

To obtain the material permeability data, surface air permeability tests were conducted using both the double chamber method and the cylinder method. The double chamber method was performed using the “Permea-TORR” air permeability tester (manufactured by FTS Co., Ltd.), with reference to JSCE-K572: *Guidelines for the Design and Construction of Silicate-Based Surface Impregnation Materials (Draft)* (in Japanese) [7]. The cylinder method was performed using the “ACROS” air

permeability cylinder (manufactured by MARUI Co., Ltd.).

For the west wall of the open canal, which was repaired in 2016, five measurement points were established in each section, while for the east wall, repaired in 2023, three measurement points were established in each section.

RESULTS AND DISCUSSION

Comparison of Permeability Indicators in a Composite Method Combining Inorganic Coating and Silicate-Based Surface Impregnation

First, we compared two permeability indicators: the coefficient of air permeability measured by the double chamber method and air inflow measured by the cylinder method. Fig.3 shows the time-dependent changes in the coefficient of air permeability, and Fig.4 presents those in the air inflow for mortar specimens with a service life of less than one year.

Both the air permeability coefficient and the air inflow rate were found to decrease over time. This trend is considered to result from the use of a composite method combining an inorganic surface coating and a silicate-based surface impregnation, which likely contributed to the filling of surface cracks.

However, while both the air permeability coefficient and air inflow rate decreased over time, the rate of reduction differed between the two indicators. A comparison of test results across different sections revealed that the numerical trends of the air permeability coefficient and air inflow rate did not consistently align. In other words, the outcomes of the cylinder method and the double-chamber method do not necessarily correspond.

Analysis of the Relationship between the coefficient of air permeability and Air Inflow

Next, the relationship between the coefficient of air permeability (kT), as calculated by the double chamber method, and air inflow, as measured by the cylinder method, was examined. Scatter plots of the test results obtained using both methods are shown in Fig.5 for the 2023 repair site and in Fig.6 for the 2016 repair site. Table 2 summarizes the regression equations, slope, intercept, and coefficient of determination (R^2) corresponding to Fig.5 and 6.

In Fig.5, a positive correlation was observed between the permeability and air inflow, with a correlation coefficient of 0.53. On the other hand, the correlation coefficient of the results shown in Fig.6 was 0.14, showing no such correlation. These results suggest that although permeability and air inflow are used as indicators of material permeability of concrete and mortar, they do not necessarily coincide. In addition, the test results shown in Fig.5 are less

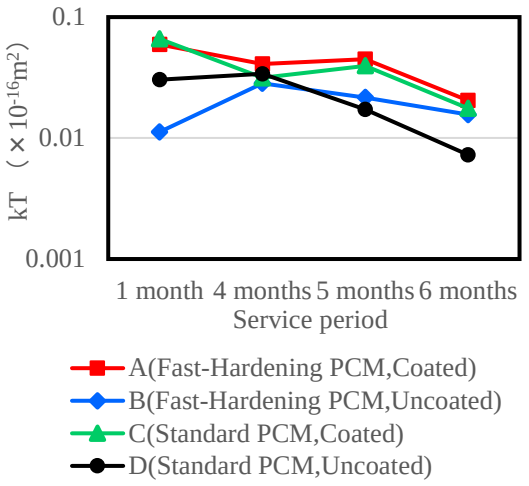

Fig.3 Time-dependent changes in the coefficient of air permeability

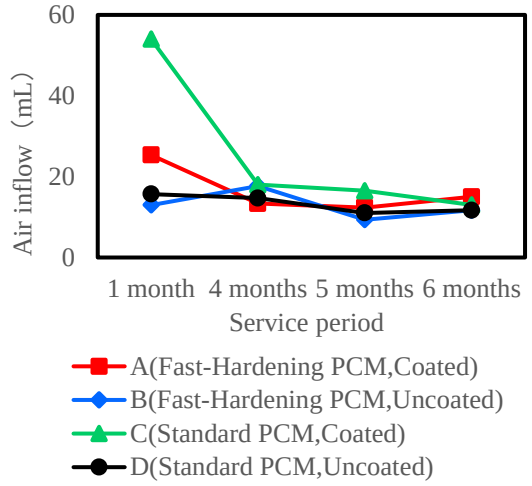

Fig.4 Time-dependent changes in the air inflow

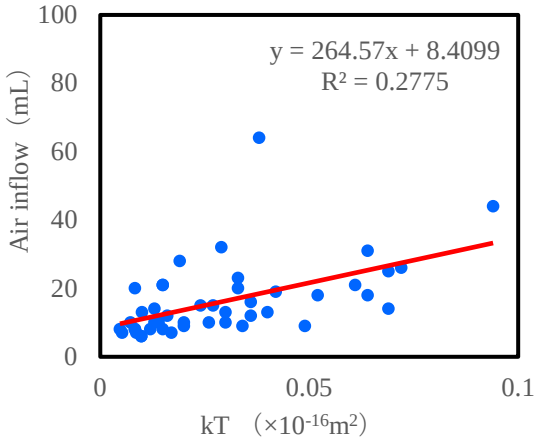

Fig. 5 Relationship between the coefficient of air permeability and air inflow for mortar with less than one year of service

than one year after service, while Fig.6 is seven years after service. Thus, the correlation between the two appears to decrease after a certain period of service.

This discrepancy is believed to stem from differences in the testing principles of the double chamber and cylinder methods. In the double chamber method, a vacuum pump is used to create negative pressure within a sealed chamber, and the coefficient of air permeability is calculated based on the time required for the internal pressure to return to equilibrium. In contrast, the cylinder method generates negative pressure by pulling a piston, and the amount of air that flows into the cylinder is measured directly. These differences in how negative pressure is applied—as well as the potential influence of the surface fragile layer—may contribute to the inconsistency observed between the results of the two methods.

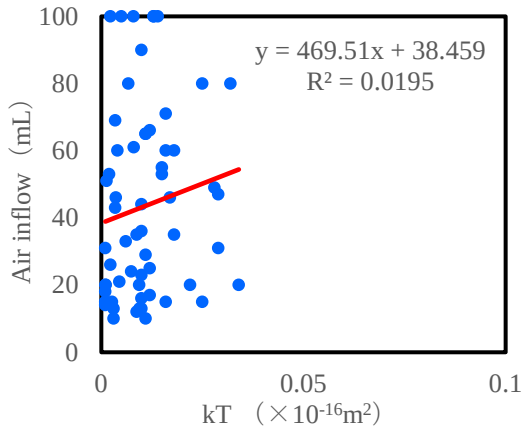

Fig. 6 Relationship between the coefficient of air permeability and air inflow rate for mortar with seven years of service

Table 2 Regression results for Fig.5 and 6

Figure Number	Regression Equation	Slope (a)	Intercept (b)	R^2
Fig.5	y = 264.57x + 8.4099	264.57	8.4099	0.2775
Fig.6	y = 469.51x + 38.459	469.51	38.459	0.0195

Analysis of Grading Based on Mortar Material Permeability

Finally, the grading of material permeability was examined using test results obtained from the double-chamber and cylinder methods applied to PCM-Repaired surfaces.

For the evaluation based on the coefficient of air permeability, the classification criteria established by R.J. Torrent et al., who developed the double chamber method, were employed [8]. In addition, for performance evaluation based on air inflow, Watanabe et al., who proposed the cylinder method, developed a conceptual grading chart for material permeability. This chart categorizes air inflow into four levels based on actual measurements, using the coefficient of air permeability as a reference [9].

Using these two sets of criteria — one based on the coefficient of air permeability and the other on air inflow — the test results from the 2023 construction site, where a positive correlation between the two indicators was confirmed, were classified. The criteria applied in this study and the corresponding grading results are presented in Table 3.

The results of surface air permeability tests conducted using the double-chamber method at the 2023 construction site were evaluated and classified between “very good” to “normal.” In contrast, the results from the cylinder method were classified between “normal” and “very bad.” These differences indicate a discrepancy in surface quality evaluations depending on the testing method used. In other words, for mortar, the performance evaluation criteria based on the coefficient of air permeability proposed by R.J. Torrent et al. and those based on the air inflow suggested by Watanabe et al. are not consistent. Therefore, it is necessary to consider developing unified performance evaluation criteria for mortar that incorporate both the coefficient of air permeability and the air inflow.

CONCLUSION

In this study, surface air permeability tests using the double chamber and cylinder methods were conducted on the repaired surface of RC open canal with PCM to clarify the relationship between the coefficient of air permeability and air inflow.

Table 3 Performance evaluation criteria based on material permeability and the corresponding test results

		Very good	Good	Normal	Bad	Very bad
The coefficient of air permeability	Criteria	0.001~0.01	0.01~0.1	0.1~1	1~10	10~
	Number of data	9	37	2	0	0
Air inflow	criteria	0～5		5～15	15～35	35～
	Number of data	0		26	19	3

Since the decreasing trends of the coefficient of air permeability and the air inflow differ, it is suggested that the test results obtained from the double chamber method and the cylinder method are not necessarily consistent. In addition, for concrete and PCM, a positive correlation of r = 0.53 was confirmed within the first year of service. However, after seven years of service, the correlation decreased to r = 0.14, indicating that no significant correlation remained. These results suggest that the correlation between the two indicators diminishes after a certain period of use.

Furthermore, when applying the evaluation method based on the coefficient of air permeability obtained using the double chamber method and that based on the air inflow measured using the cylinder method, the results showed that the coefficient of air permeability was classified between “very good” to “normal,” while the air inflow was classified between “normal” and “very bad.” These differences revealed a clear discrepancy in performance evaluation. Therefore, it is suggested that new evaluation criteria should be established for assessing the performance of mortar using material permeability indicators.

FUTURE WORK

This study revealed that there is a positive correlation between the coefficient of air permeability and the air inflow within a certain period of service. To clarify the applicability limits of the cylinder method, it is considered necessary to conduct follow-up investigations and correlation analyses at the same site and at other sites constructed under similar conditions.

In addition, it was found that the performance evaluation of mortar based on the coefficient of air permeability and air inflow lacks consistency, indicating the need for re-evaluation. Moving forward, tests such as accelerated carbonation and freeze-thaw cycles, which are closely related to material permeability, will be conducted to better understand the long-term deterioration behavior of mortar. Moreover, tests will be carried out at multiple locations with varying PCM application methods and environmental conditions to validate the generalizability of the observed correlation. Through these efforts, we aim to establish practical in-situ evaluation criteria based on both the coefficient of air permeability and air inflow.

EFFECT OF FLY ASH AND SILICA FUME AS PARTIAL REPLACEMENTS OF CEMENT ON THE MECHANICAL PROPERTIES OF SELF-COMPACTING CONCRETE

Fauzan[1], Suci Andini[2], Suci Meilita[3], and Muhammad Johafis[4]

[1 ,2,3,4]Department of Civil Engineering, Faculty of Civil Engineering, University Andalas, Indonesia;

ABSTRACT

Self-compacting concrete (SCC) is a type of concrete that can flow and fill molds without mechanical compaction, improving construction efficiency. The use of fly ash and silica fume in SCC can enhance its mechanical properties. Therefore, this study investigates the effects of partially substituting cement with fly ash and silica fume in SCC and their contribution to advanced construction materials. The objective was to determine the effect of adding 15% fly ash and 10% silica fume (by weight of cement) on the mechanical strength of SCC. The research was conducted experimentally in the laboratory. Specimens were cylinders 150 mm in diameter and 300 mm high; a total of 24 specimens were prepared for compressive tests and 24 for tensile tests. Fresh concrete was evaluated according to ACI 237R-07 using the slump-flow test and segregation resistance using the V-funnel test. Hardened concrete was tested for compressive and tensile strength at 7 and 28 days. The results showed that adding 15% fly ash increased slump flow, whereas 10% silica fume reduced slump flow due to higher water demand. At 28 days, compressive strength increased by up to 20.11% compared with the control SCC, while tensile strength increased by 34.88%.

Keywords: SCC, Fly Ash, Silica fume, Slump Flow, Mechanical Properties

INTRODUCTION

Self compacting concrete (SCC), which was first introduced in Japan, is a very special type of concrete that can flow and fill every corner of the formwork, even when there is solid reinforcement, purely because of its weight and without the need for vibration or compaction equipment [1-3]. SCC concrete is particularly suitable for structures that are very difficult to perform manual compaction, for example, due to very tight reinforcement or due to formwork shapes that do not allow concrete to withstand the segregation usually found in building construction with conventional concrete [4-5]. Segregation in concrete building structures can pose high risks, such as building collapse at the time of an earthquake, as the quality of concrete has declined from planned [6-9]. The application of SCC concrete in construction is generally used in tunnels, bridge pillars, high-rise buildings, and precast concrete. SCC concrete can be classified as an advanced construction material [10-12].

Currently, a lot of research has been done on SCC concrete. The use of Flyash and Silica fume in SCC can improve the mechanical properties of concrete. Thus the addition of flyash and silica fume as substitutes for Partial cement in SCC to contribute to the development and application of advanced construction materials has been investigated. This study focuses on investigating the influence of flyash and silica fume as a substitute for some cement in the SCC concrete mixture, which can later minimize the use of cement and also increase the mechanical strength of concrete.

RESEARCH SIGNIFICANCE

This study aims to determine the effect of the addition of fly ash and silica fume as a substitute for part of the total weight of cement on the strength of SCC concrete in increasing its mechanical strength, especially its compressive and tensile strength. This study examines the fresh and hardened properties of Self-compacting concrete with fly ash and silica fume by considering the impact of waste by reducing waste flying ash. The results of this research can be used as a new invention in the world of concrete technology that has high workability, durability and strength advantages, so that it can be applied well in high-rise buildings and precast concrete structures around the world.

MATERIAL AND MIX DESIGN

Material

Cement

Ordinary Portland Cement (OPC), which is produced by the cement factory in Padang (PT. Semen Padang), Indonesia, used in this study.

Coarse aggregate

Coarse aggregates are obtained from locally available aggregates with a maximum size of 19 mm

in accordance with ASTM C33/C33M [13]. The properties of coarse aggregates are shown in Table 1.

Table 1. Properties of coarse aggregate

Property	Value
Specific Gravity	2.41
Absorption	5.93 %
Fine Modulus (FM)	3.4
Water Content	1.99 %

Fine aggregate

Locally available fine aggregates were used in this study, with a maximum size of 4.75 mm. Table 2 shows the properties of fine aggregates [14].

Table 2. Properties of fine aggregate

Property	Value
Specific Gravity	2.54
Absorption	3 %
Fine Modulus (FM)	2.85
Water Content	1.83 %

Water

Drinking water, which is free of acids or organic substances, was used for concrete mixing and treatment in this study.

Admixture

SCC concrete is a concrete that flows easily, so it requires a superplasticizer material such as a high-range water reducing admixture (HRWRA). In this study, ViscoCrete 3115, a third-generation superplasticizer for concrete and mortar manufactured by Sika, was used. It is specially developed to produce high-flow concrete with outstanding flow retention properties.

Fly ash

Fig.1 Fly Ash class C

Fly Ash is waste from burning coal in power plants, which is used as a substitute for some cement to improve the durability of concrete. In this study, FlyAsh class C was used (Fig. 1), which according to ACI this type contains pozzolan and hydrolysis properties, has a high CaO content that can harden itself when reacting with water such as cement, and has the benefit of increasing the compressive strength of concrete. Classification of Fly Ash in accordance with ASTM C 618–05 shown in Table 3 [15].

Table 3. Classification of Flying Ash

Flying Ash	Class
	C
SiO2 + A12O3 + Fe2O3,min,%	50.0
SO3,max, %	5.0
Moisture Content, max, %	3.0
Loss on ignition, max, %	6.0

Silica fume

Silica Fume is a microscopic material used to improve the strength and resistance of concrete to corrosion and chemical reactions. According to the American Concrete Institute (ACI), silica fume is a very fine concrete additive that has a particle size of about 1/100th the size of a cement particle as shown in Fig. 2. Fume silica is rich in high silicon dioxide (SiO2), more than 85%, and behaves as a reactive pozzolan material. Physical properties of Silica Fume can be seen in Table 4.

Fig.2 Silica Fume

Table 4. Physical Properties of Silica Fume

Sifat fisik	Value
Ukuran Pertikel	< 1µm
Warna	Dark gray
Bulk Density (kg/m^3)	200 - 300
Specific Gravity	2.2
Kehalusan (kg/m^2)	15.000 – 30.000

Mix Design Proportion

The design of an SCC concrete mixture with a target compressive strength of 79.73 MPa (11000 psi) was calculated based on ACI 211.4R-08 [16]. The water/cement ratio is maintained constant in all mixtures with a value of 0.27 Percentage of Fly ash 15% and silica fume 10% of the total weight of cement. The control mixture is set as 0% Flyash and silica fume. Details of the proportions of the concrete mixture are listed in Table 5.

Table 5. Mix proportions of SCC-Flyash-Silica Fume

Material	FA+SF 0%	FA 15%	SF 10%	FA+SF 15+10%
Cement (kg/m^3)	512.5	512.5	512.5	512.5
Fine Aggregate (kg/m^3)	877.5	864.8	852.3	839.6
Coarse Agg (kg/m^3)	668.9	668.79	668.79	668.79
Water (kg/m^3)	205	205	205	205
FA+SF (kg/m^3)	0.0	15	10	15+10
Viscocrete-3115 (L/m^3)	2.44	2.44	2.44	2.44

Test Specimen

A total of 48 cylindrical test pieces were prepared, consisting of 24 cylinders for compressive strength testing, and 24 cylinders for tensile strength testing.

Testing is divided into fresh concrete testing and hard concrete testing. The properties of concrete are measured based on the diameter of the slump flow using a slump tool (Fig.3) and the resistance of segregation using a v-funnel (Fig.4) according to ACI237R-07 [17]. The targeted slump diameter is 550-650 mm, which allows the concrete to flow through the solid reinforcement. The hardened properties of the SCC were tested on the cylindrical test pieces on the 7th and 28th days (Fig. 5-6), in compressive strength [18], and tensile strength [19].

Fig. 3 Slump test

Fig. 4 V funnel test

Fig.5 Compression Test on cylindrical specimens

Fig.6 Tensile Test on Cylindrical Specimen

RESULT AND DISCUSSION

Properties of Fresh Concrete

The results of the tests on fresh concrete conducted in the slump test and the v funnel flow test show that the effect of fly ash can increase the slump flow because the fine fly ash particles can fill the space between the cement particles and can flow more easily, after adding 15% the slump value increases or it can be said that the concrete is thinner as shown in Fig. 7. and the flow time is faster. The addition of 10% silica fume shows a decrease in the slump value because it absorbs more water, the mixture is thicker therefore the slump value decreases as shown in Fig. 8. and the flow time of concrete becomes slower compared to normal concrete.

The test results after normal concrete is added fly ash and silica fume give a complex effect, fly ash can increase slump while silica fume can decrease slump due to increased water requirements. This results in an equilibrium in the concrete mixture. The period it takes for concrete to expand to a diameter of 500 mm during the slump flow test reflects the viscosity and stability of the concrete. The T500 slump test along the distribution boundary took place in the range of 4.0-5.0 seconds and the slump flow rate width was 500-750 mm. As a result, all concrete mixtures were within the SCC limits as predicted. The v-funnel test results for all mixtures show that the SCC has met the required time, as shown in Fig. 9.

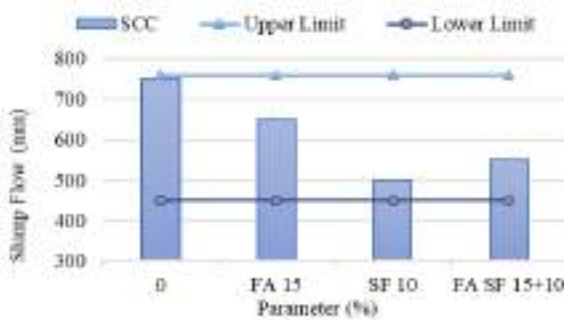

Fig.7 Slump flow result

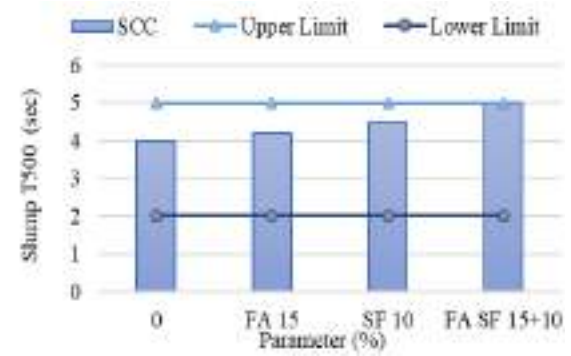

Fig.8 Result of Slump T500

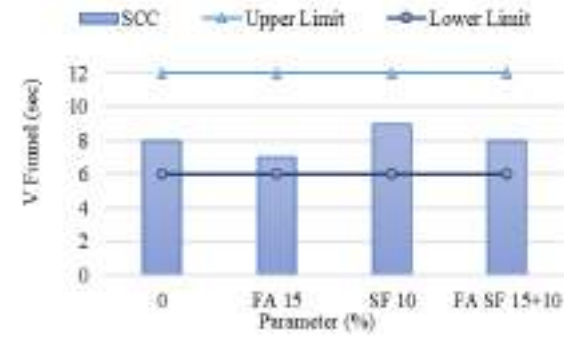

Fig.9 Result of V Funnel

Properties of Hard Concrete

Compressive strength test

The compressive strength of all mixtures is tested after 7 and 28 days of casting[9]. The results of the compressive test conducted on SCC concrete with a percentage of 15% fly ash and 10% silica fume are shown in Fig. 10 .As seen in Table 6, the compressive strength results of the SCC test specimen on day 7 (after the test) show that the compressive strength of SCC using fly ash and silica fume is stronger than that of SCC silica fume and SCC fly ash. Concrete at the age of 7 days, without the addition of fly ash and silica fume is 9.5 Mpa.

The compressive strength of SCC concrete with the addition of 15% fly ash, 10% silica fume, 15% fly ash and 10% silica fume is 8.9 Mpa, 8.7 Mpa, and 9.2 Mpa, respectively. When the compressive strength of all mixtures is tested after 28 times of casting, SCC concrete has a higher compressive strength, as shown in Table 6. and Fig. 10. The percentage increase in maximum compressive strength in SCC at 28 days of age was 20.11%.

Table 6. Percentage of Increase in Compressive strength

No	Parameter SCC (%)	Day-7 Percentage of Increase (%)	Day-28 Percentage of Increase (%)
1	0.0	-	-
2	FA 15	-6.32	2.55
3	SF 10	-8.42	10.15
4	FA SF 15+10	-3.16	20.11

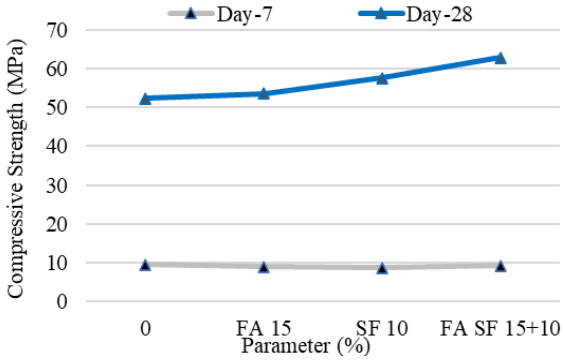

Fig.10 Compressive test results

Tensile strength test

Self-compaction concrete (SCC) testing with the addition of fly ash and silica fume at 28 days of age. Overall, the strength of the SCC tensile was significantly increased compared to at 7 days of age, as fly ash and silica fume slowed down the initial hydration and in the long term the hydration reaction was more perfect to strengthen the bonds and reduce pores in the SCC. Strong yield Pull at 28 days increased 1.5 times compared to 7 days age, as shown in Fig. 11.

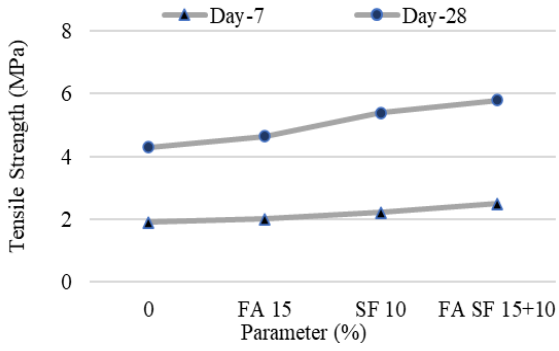

Fig.11 Tensile strength test results

The percentage increase in maximum strength at the day-age SCC was 34.88% and 31.58% respectively (Table 7). Compared to the control SCC at 28 days of age, the increase with the addition of 15% fly ash additives, 10% silica fume, 15% fly ash and 10% silica fume resulted in a strong increase in tensile strength of 7.48%, 25.59%, and 34.88% at 28 days of age, respectively.

Table 7. Percentage of increase in tensile strength

No	Parameter SCC (%)	Day-7	Day-28
		Percentage of Increase (%)	Percentage of Increase (%)
1	0.0	-	-
2	FA 15	5.26	7.48
3	SF 10	16.32	25.59
4	FA SF 15+10	31.58	34.88

CONCLUSIONS

Based on experimental findings examining the properties of SCC with added fly ash and silica fume, the following conclusions were drawn:

1. The addition of 15% fly ash increased slump flow because its fine particles fill the voids between cement grains, improving workability. In contrast, 10% silica fume reduced slump flow due to its higher water demand. Combining both produced a balanced mix that met SCC requirements.
2. Compressive strength tests showed up to a 20.11% improvement at 28 days compared with the control mixture. This significant gain is attributed to the continued pozzolanic activity and long-term densification of the matrix.
3. Splitting tensile strength increased by up to 34.88% at 28 days. Fly ash and silica fume delayed early hydration but promoted stronger bonding and reduced porosity over time.
4. Overall, partially replacing cement with fly ash and silica fume reduced cement consumption while enhancing the mechanical performance of SCC, making it a promising sustainable and durable construction material.

ABSTRACT

Indonesia is one of the most earthquake-prone countries in the world, where many reinforced masonry (RM) houses are built without complying with seismic-resistant building standards. These non-standard RM houses are highly vulnerable to severe damage or sudden collapse during strong earthquakes. This study presents a numerical analysis of a retrofitting method for non-standard RM houses using a ferrocement layer with a cross reinforcement system on the walls. The research involved modeling a 1:4 scaled specimen of an actual damaged RM house in West Pasaman, using ETABS V.22 software, and applying time-history earthquake loads at acceleration levels of 0.3 g, 0.6 g, 1.0 g, and 1.5 g. The results show that retrofitted RM houses experience smaller maximum tensile stresses compared to non-retrofitted ones under all earthquake acceleration levels. The reduction in tensile stress indicates that the crossed ferrocement layer effectively improves wall stability and prevents severe damage. This strengthening method can be implemented without demolishing existing structures, making it a cost-effective and practical solution for reducing seismic risks in vulnerable housing.

Keywords: Earthquake, Reinforced Masonry, Retrofitting, Ferrocement Layer, Tensile Stress

INTRODUCTION

Indonesia is a country prone to earthquakes due to several geographical and geological factors. Geologically, the structure of the earth's crust in Indonesia lies at the confluence of tectonic plates, which results in the Indonesian region having a high risk of earthquake disasters [1]. Several earthquake incidents occurred in Indonesia, causing many material losses and fatalities, including the West Sumatra earthquake (2009), the Lombok and Palu earthquakes (2018), the West Pasaman earthquake (2022) [2], and the East Java earthquake (2024). During the 25 February 2022 West Pasaman earthquake, at least 2,025 houses were reported damaged, including 1,111 units verified as heavily damaged after BNPB/BPBD verification in West Pasaman Regency. Similarly, the 22 March 2024 East Java (Bawean–Tuban) earthquake sequence caused 4,679 damaged houses across the province (774 heavy, 1,332 moderate, 2,573 light), indicating widespread vulnerability of non-standard RM housing to strong shaking [3]. These figures underscore the need for practical retrofitting strategies for Indonesia's RM dwellings to reduce seismic risk.

In general, RM houses are built using reinforcement on concrete column elements and beam, as shown in Fig. 1. The building of this house is usually strong against earthquake loads, but if the construction of the RM house has structural elements such as beams and columns that are not in accordance with building standards, then it does not have strength against earthquake loads [4-7]. When an earthquake occurs, this house can suffer minor to severe damage, and it can even collapse suddenly.

To avoid the sudden collapse of RM houses that do not meet standards when an earthquake occurs, research on the numerical analysis of RM house reinforcement that does not meet standards and is damaged after an earthquake needs to be carried out. One of the reinforcement methods developed is to use a ferrocement layer with a cross system on the building wall [8-11]. This method is effective, the cost is relatively cheap, the materials are easy to obtain, and the work can be done by the community or local craftsmen. This research aims to fill the gap by developing research on RM house reinforcement that is not in accordance with standards, which is strengthened using a cross-system ferrocement layer.

Fig.1 Reinforce masonry (RM) house

This study focuses on a numerical analysis study of the reinforcement of RM reinforcement houses that

are not in accordance with standards by making a test specimen based on the original house in West Pasaman that was damaged after the 2022 West Pasaman earthquake. By conducting this study, it is hoped that all RM houses that do not meet the standards can be strengthened with this method, so that they can reduce the risk of damage due to earthquakes in the future.

RESEARCH SIGNIFICANCE

In this analytical study, an element analysis was carried out to determine the seismic behavior of the original RM house compared to the RM house reinforced with a ferrocement layer. This research is very important because the results can be used as a reference for building earthquake-resistant houses in earthquake-prone areas, both in disaster mitigation efforts and in the post-earthquake reconstruction stage. In addition, the reinforcement method using a ferrocement layer is an effective method and is easy to apply by the community independently.

ANALYTICAL WORK

Specimen Design

The specimen used is a design of a house specimen image of the RM model horn, which is scaled 1:4 from its original size due to the limited area of the vibrating table test equipment. The specimens made amounted to 1 (one) piece, where the RM model house specimen was reinforced with a ferrocement layer with a cross system. The layout of the specimen design is in accordance with the shape of the existing houses in the community and the need for rehabilitation and reconstruction in earthquake areas in Indonesia. The research procedure at the design stage of the RM model house is as follows:

Specimen plan drawings

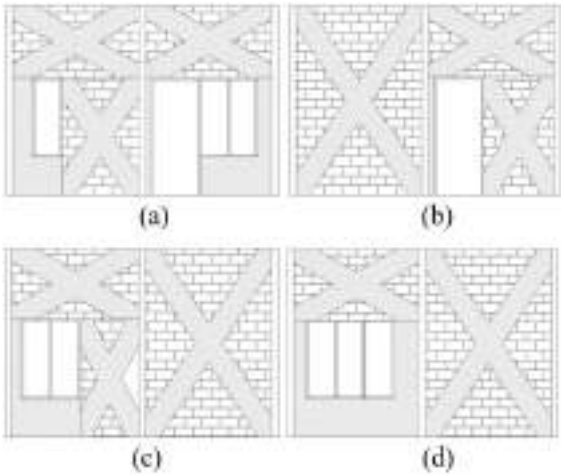

Fig.2 Model house with retrofitting; a) front view, b) back view, c) left side view, and d) right side.

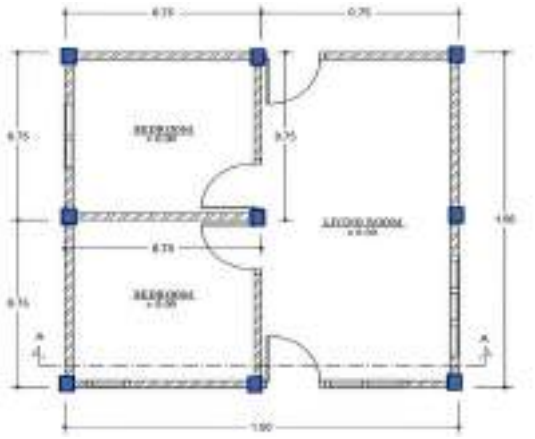

Fig.3 Specimen plan

The specimen plan image of the RM model house was taken to adjust the existing one with a type 36 house with a size of 6 m x 6 m x 4 m. After being scaled 1:4 from the original house size, the size for a simple model house becomes 150 cm x 150 cm x 100 cm. Specimens without reinforcement and specimens with ferrocement layer reinforcement of the cross system can be seen in Figs. 2-3.

Specimen detail drawings

Detailed drawing of the wall with a species thickness of ± 0.5 cm. Fig. 4 is a detailed drawing of the wall of a model house or specimen that is reinforced with woven wire with a cross system on the wall of the specimen, given plaster with a thickness of ± 0.5 cm. Plasters and specimen species are made with a mixture of cement and sand in a ratio of 1:4.

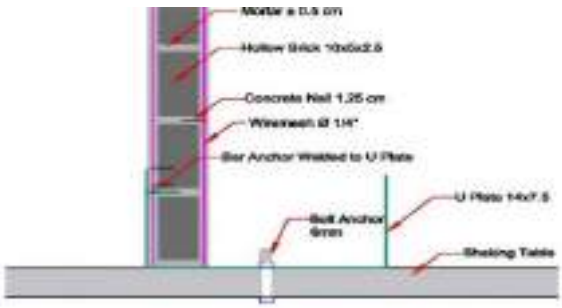

Fig.4 Details of wall of the house model, and Installation of the ferrocement layer with crossed system on the wall of the house

Material Properties

This numerical analysis study uses five main materials, namely bricks, plaster, concrete, reinforcement, and woven wire, which is defined as steel.

The hollow brick has a compressive strength (fc') of 3.3 MPa, a shear modulus of 3096 MPa, an elasticity modulus of 7431.35 MPa, and a specific

gravity of 1600 kg/m^3. Plastering with compressive strength (fc') of 9.9 MPa, shear modulus of 6161.75 MPa, elastic modulus 14788.2 MPa, and specific gravity of 1600 kg/m^3. The woven wire has a yield strength (fy) of 275 MPa, the highest tensile strength (fu) of 620 MPa, a shear modulus of 187500 MPa, and a specific gravity of 8.0 g/cm^3. The reinforced concrete has a comprehensive strength (fc') of 15 MPa, and the reinforcement has a yield strength of 280 MPa, and the highest tensile strength (fu) of 0,420 MPa [12].

Modeling

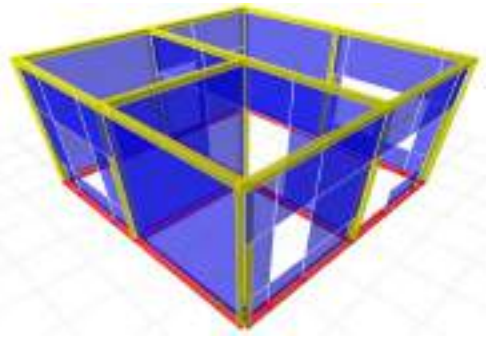

Fig. 5 Modeling of non-standard RM houses without retrofitting

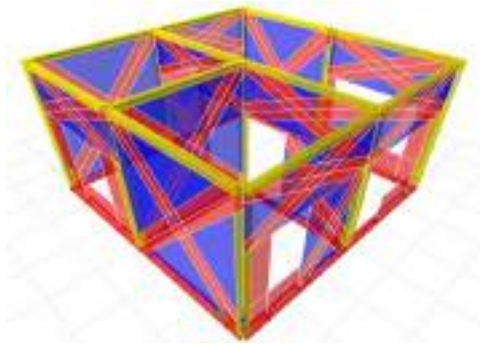

Fig. 6 Modeling of non-standard RM houses retrofitted with ferrocement layer with crossed system

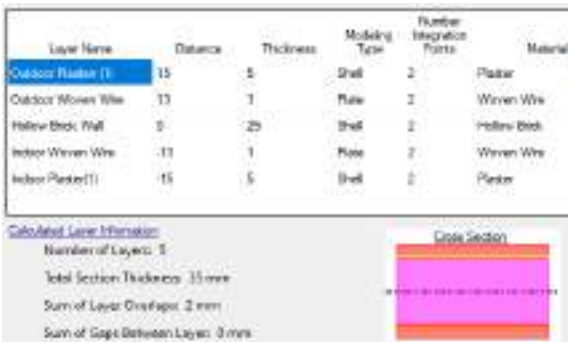

Fig. 7 Section properties of walls with ferrocement layer

The modeling of the URM brick house in this study is shown in Fig. 5. Meanwhile, Fig. 6 shows the modeling of the house with a retrofitting crossed ferrocement layer, where blue is the area of a wall without retrofitting, defined as a brick. At the same time, red is the area of the wall that is given retrofitting, which is defined as a wall consisting of 5 (five) layer properties as shown in Fig. 7.

Loading

The house model weighs 471 kg, as shown in Table 1. A real house without scale weighs 430 kg/m ^{2} (Table 2). Then the weight of the model house should be based on the following broad scale (equation 1):

$$Ls \times qa = qs \quad (1)$$

where,

Ls: Specimen Area (m^2)
Q: Original Weight House (kg/m^2)
qs: Specimen Weight (kg)

So,

$$2{,}25\ m^2 \times 430\ kg/m^2 = 968\ kg$$

Therefore, the model house is given an additional load of 500 kg. The additional load is divided into nine sections, which are inserted in each corner of the model house.

Table 1 Model house weight

Material	kg
Hollow brick weight	157
Mortar weight	246
Weight of the roof frame and the roof	68
Total weight of Specimen	471

Table 2 Weight of the original house

Material	kg
Hollow brick weight	10606
Mortar weight	4172
Weight of the roof frame and the roof	718
Total weight of Specimen	15496
qa: Dead load weight of the original house	430kg/m^2

Numerical Analysis with Time History Analysis

Numerical analysis was carried out in the study using the time history of the earthquake load. There are four variations of the given earthquake acceleration load, namely 0.3 g, 0.6 g, 1.0 g, and 1.5 g, with a duration of 10 seconds for each acceleration variation.

RESULTS AND DISCUSSION

Behavior of House Models with 0.3 g Earthquake

Acceleration

Based on the analysis results from ETABS V.22 software with a 0.3 g earthquake acceleration, the tensile stress on the walls of both the unretrofitted and retrofitted houses is primarily shown in yellow and green in Figs. 8-9, respectively.

For the unretrofitted house, the maximum tensile stress reaches 0.07 MPa, which is below the tensile strength of the brick (0.264 MPa). The tensile strength of the brick is calculated as 8% of its compressive strength, which is 3.3 MPa, resulting in 0.264 MPa. Although the stress is below the tensile capacity, any tensile stress on unreinforced brick walls is considered a high-risk category that could lead to cracks and collapse.

In contrast, the house retrofitted with a ferrocement layer shows a significantly lower maximum tensile stress of 0.03 MPa. Even if the tensile stress were to exceed the hollow brick's tensile capacity, the wall would remain safe due to the high tensile resistance provided by the woven wire reinforcement. The woven wire serves to maintain wall stability and prevent damage.

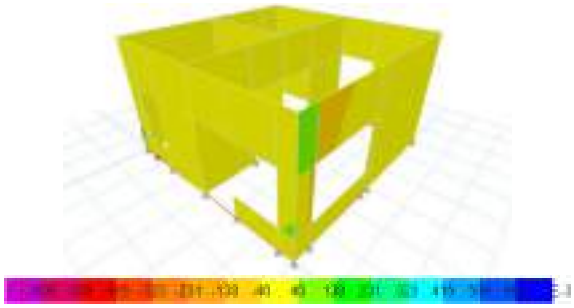

Fig. 8 Wall tension pattern on non-standard RM wall due to 0.3 g earthquake acceleration

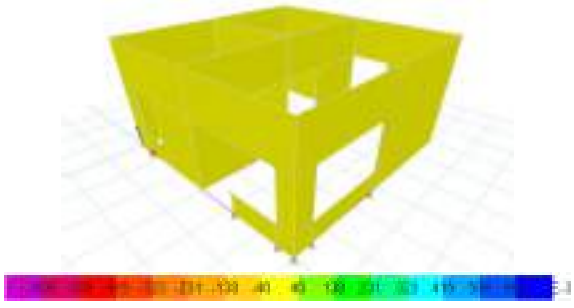

Fig. 9 Wall tension pattern on retrofitted non-standard RM wall due to 0.3 g earthquake acceleration

Behavior of House Models at 0.6 g Earthquake Acceleration

The analysis results for the 0.6 g earthquake acceleration, shown in Fig. 10 (unretrofitted) and Fig. 11 (retrofitted), indicate that the highest tensile stress occurs in areas with large openings, such as the living room.

In the unretrofitted house, the maximum tensile stress reaches 0.12 MPa. While this value is still below the tensile strength of the brick walls (0.264 MPa), it represents a significant increase from the 0.3 g acceleration. The stress distribution is more widespread and intense, particularly around windows and doors, which are typically points of weakness. This increased stress level suggests a higher risk of cracking and damage, which could compromise the structural integrity of the wall during a prolonged seismic event.

Conversely, the retrofitted house shows a much smaller maximum tensile stress of only 0.09 MPa. This demonstrates the effectiveness of the ferrocement layer with a cross reinforcement system in absorbing and distributing seismic forces. Even though the stress value is still present, the wall's ability to withstand these forces is significantly enhanced by the woven wire. The wire, with its high tensile strength, acts as a secondary reinforcement system, preventing the brick from failing catastrophically even if the stress were to exceed its own tensile capacity. The overall behavior of the retrofitted model remains stable and secure, indicating its good performance under moderate earthquake loads.

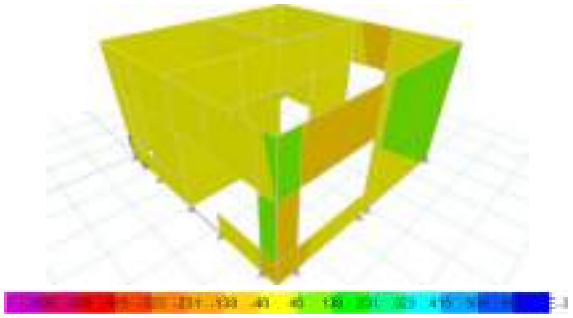

Fig. 10 Wall tension pattern on non-standard RM wall due to 0.6 g earthquake acceleration

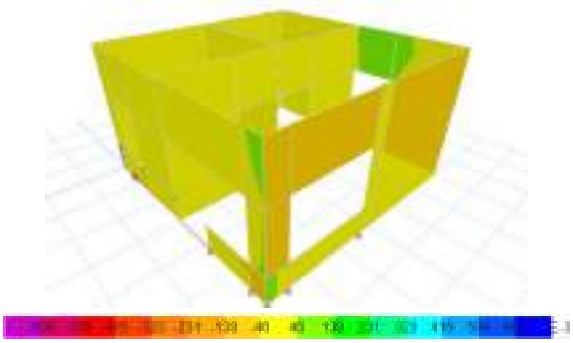

Fig. 11 Wall tension pattern on retrofitted non-standard RM wall due to 0.6 g earthquake acceleration

Model House Behavior at 1.0 g Earthquake Acceleration

The analysis results for the 1.0 g earthquake acceleration show a more significant difference between the two models. In the unretrofitted house, as seen in Fig. 12, higher tensile stresses begin to appear, marked by blue areas. These areas indicate stress values between 0.231 MPa and 0.323 MPa. Overall, the maximum tensile stress value in this model is 0.26 MPa. This indicates that the brick walls are approaching a critical point where severe damage may occur.

In contrast, in the retrofitted house (Fig. 13), the tensile stresses are still dominated by yellow and green areas. This indicates that the stresses are much lower and more evenly distributed. The maximum tensile stress value in this model is only 0.18 MPa. This striking difference proves that the ferrocement layer with the cross reinforcement system effectively dampens and distributes earthquake energy, preventing dangerous stress concentrations. These results show that in addition to increasing the strength of the walls, houses reinforced with a ferrocement layer can also reduce the pressure that occurs on the walls.

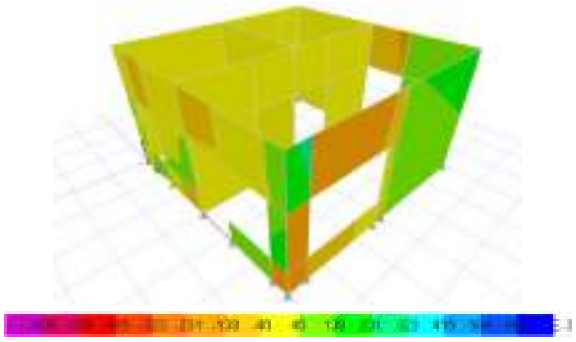

Fig. 12 Wall tension pattern on non-standard RM wall due to 1.0 g earthquake acceleration

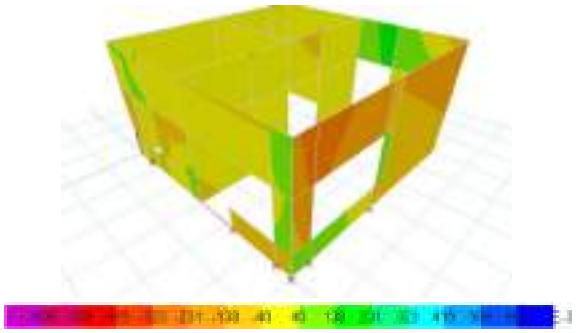

Fig. 13 Wall tension pattern on retrofitted non-standard RM wall due to 1.0 g earthquake acceleration

Model House Behavior at 1.5 g Earthquake Acceleration

The analysis results for the 1.5 g earthquake acceleration, shown in Fig. 14 (unretrofitted) and Fig. 15 (retrofitted), demonstrate an even more striking difference in the behavior of the two models. At this very high acceleration level, the unretrofitted house experiences a maximum wall pressure of 0.21 MPa. This value is dangerously close to the critical resistance limit of the brick walls, indicating that the structure is highly vulnerable and at serious risk of severe cracking or even partial collapse if subjected to prolonged shaking.

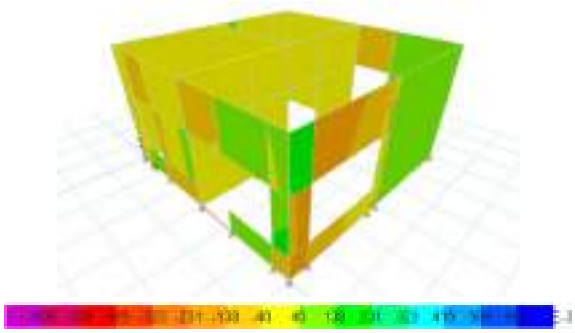

Fig. 14 Wall tension pattern on non-standard RM wall due to 1.5 g earthquake acceleration

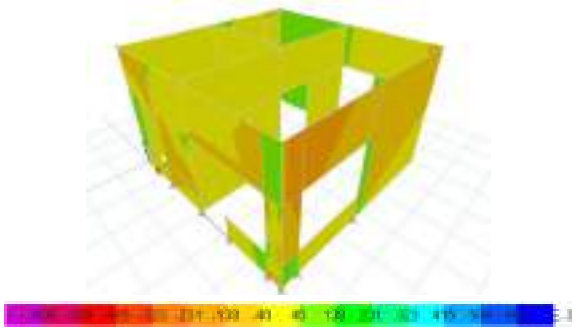

Fig. 15 Wall tension pattern on retrofitted non-standard RM wall due to 1.5 g earthquake acceleration

In contrast, the house retrofitted with a ferrocement layer shows a much superior performance. The maximum pressure on its walls reaches only 0.11 MPa. These results prove that this retrofitting method not only increases the wall's strength but also effectively reduces the pressure caused by seismic loads. With a significantly lower stress value, the walls of the retrofitted house remain stable and secure, preventing severe damage or collapse even under very high earthquake acceleration.

It should be noted that the numerical analysis using ETABS is subject to several limitations. The model is based on a 1:4 scaled specimen, which may introduce scale effects that do not fully capture the behavior of full-scale masonry houses. In addition,

the wall composition was simplified into representative material layers, while in reality the construction quality, workmanship, and irregularities in mortar joints may vary significantly. These assumptions, although necessary for computational feasibility, can introduce uncertainties in predicting the actual seismic response of non-standard RM houses.

CONCLUSION

Based on the results of the analysis, it can be concluded that reinforced masonry (RM) houses built without meeting seismic-resistant standards are highly vulnerable to severe damage or collapse during strong earthquakes. The hollow brick walls in these houses do not have adequate resistance to seismic loads. To address this vulnerability, one of the most effective retrofitting methods is the use of a ferrocement layer with a cross-reinforcement system on the walls. This method is not only effective but also practical, as the materials are easy to obtain and the application can be done by local communities or craftsmen without demolishing the existing structures.

The numerical analysis demonstrates that retrofitted houses experience smaller maximum tensile stress values at every level of earthquake acceleration. This proves that the reinforcement system is highly effective in maintaining the stability of the walls and preventing damage such as cracks or collapse. The analysis results show that the tensile stress on the retrofitted house never exceeds the tensile capacity of the hollow brick. The presence of the woven wire, which has a high tensile resistance, ensures that the walls remain safe and stable.

Overall, this strengthening method is a cost-effective and practical solution for seismic risk reduction in vulnerable housing, both as part of disaster mitigation efforts and in the post-earthquake reconstruction phase.

Despite the promising results, the findings of this study should be interpreted with caution due to the inherent limitations of the numerical modeling. Scale effects, simplification of wall composition, and the exclusion of construction irregularities may influence the accuracy of the simulated response. Future work is recommended to validate the numerical results with experimental shaking table tests on larger-scale specimens and to incorporate more detailed modeling of material.

SEISMIC ASSESSMENT AND RETROFITTING OF THE WEST SUMATRA BPBD OFFICE BUILDING USING SHEAR WALLS

*Fauzan[1], Abdul Hakam[2], Muhammad Ridho Zainadi[3], Arifin Shaleh[4], and Muhamad Rezki[5]

[1,2,3,4,5]Department of Civil Engineering, Andalas University, West Sumatra, Indonesia

ABSTRACT

The structural reliability of public buildings in seismic-prone areas is crucial to ensure safety and functionality. The BPBD office building in Padang, West Sumatra, was assessed due to various deficiencies in its current condition, including cracks, material degradation, and insufficient lateral resistance based on Indonesian standards (SNI 1726:2019, SNI 2847:2019, and SNI 1727:2020). Structural modeling and analysis using ETABS indicated that the existing structure does not meet inter-story drift requirements, with the second floor exceeding the permissible limit. Additionally, several beams failed in shear, compromising seismic performance. To address these weaknesses, a global retrofitting approach was implemented by strategically adding reinforced concrete shear walls along the weak axis. Re-analysis of the retrofitted model demonstrated significant improvements: inter-story drift values complied with code requirements, column internal forces decreased by up to 88% in both moment and shear, and beam internal forces were reduced by approximately 75% in moment and 65% in shear. Furthermore, floor slab analysis revealed inadequate flexural capacity under seismic loads. Strengthening with Fiber Reinforced Polymer (FRP) sheets successfully increased the slab capacity from 0.89 t.m to 2.62 t.m, exceeding the external moment requirement of 2.51 t.m. These results confirm that a combined retrofitting strategy using shear walls to enhance global stiffness and FRP to reinforce slab flexural strength provides an effective solution to improve seismic resilience and ensure the building's safety and usability as a disaster management facility.

Keywords: Structural Assessment, Retrofitting, Shear Wall, Earthquake, RC structure

INTRODUCTION

The structural durability of buildings is a crucial factor in ensuring the safety of occupants and the sustainability of building functions [1,2], especially in areas with high seismic rates such as West Sumatra. The building, which is located behind the West Sumatra Gurbenur Office, is one of the strategic infrastructures located in Padang City, and it is planned to function as an office of the Regional Disaster Management Agency (BPBD).

The results of the visual review show that the existing condition of the building has experienced various damages, including cracks in the floor plates, damage to the beams, and indications of concrete segregation that have the potential to reduce the overall performance of the structure. This confirms that even though it is classified as a new building, its structural performance requires a thorough technical evaluation.

On the other hand, changes in earthquake design standards in Indonesia, especially the implementation of SNI 1726:2019 on earthquake resistance, SNI 2847:2019 on reinforced concrete structures, and SNI 1727:2020 on minimum load of buildings, require a re-evaluation of buildings designed using the old standards. This condition is a serious challenge considering that a number of public buildings, including the BPBD Back Building, have the potential to not meet the latest requirements.

Previous studies have shown that global reinforcement methods such as shear wall installation are an effective solution in increasing the capacity of structures against lateral forces, reducing inter-story drift, and increasing the rigidity of structural systems [3-5]. The application of shear walls is also able to transform the structural system into a double system, making it more reliable in withstanding earthquake loads [6-7].

RESEARCH SIGNIFICANCE

This study highlights the importance of retrofitting critical public buildings in seismic-prone regions. By assessing the BPBD office's structural deficiencies and implementing a combined retrofitting strategy with reinforced concrete shear walls and FRP sheets, the research demonstrates effective methods to enhance seismic resilience. The findings provide practical insights into improving global stiffness, reducing inter-story drift, and increasing slab flexural capacity, ensuring both safety and functionality. Beyond technical analysis, the study also emphasizes the need to address implementation challenges, including construction phasing and occupancy management, making it relevant for disaster management facilities in Indonesia and similar contexts.

EVALUATION OF THE EXISTING BUILDING

Existing Building Data

The existing condition of the BPBD building can be seen in Fig. 1.

Fig. 1 Existing conditions of BPBD building

The technical specifications of the structure for the analysis of this building are as follows:

Building Location : Padang City, West Sumatra Province
Structural System : Reinforced Concrete Portal
Floor Plate Width : 12 cm
Concrete Grade : 260 kg/m^2
Reinforce Grade (Fy): 240 MPa
Soil Condition : Medium Soil (SD)

Details of the structure of columns, including reinforcement, can be seen in Tables 1 and 2.

Table 1 Column details

Modeling

The modeling of the BPBD Building structure was carried out using the ETABS V.22 software in 3-dimensional form, as shown in Fig. 2, where the beams and columns were modeled as element frames, and the floor was modeled as element slabs.

To analyze the building structure of the BPBD Office Rear Building, the standard regulation SNI 2847:2019 for Structural Concrete Requirements for Buildings, SNI 1726:2019 for Earthquake Resilience Planning Procedures for Buildings and Non-Buildings, and SNI 1727:2020 for Minimum Loads for the Design of Buildings and Other Structures.

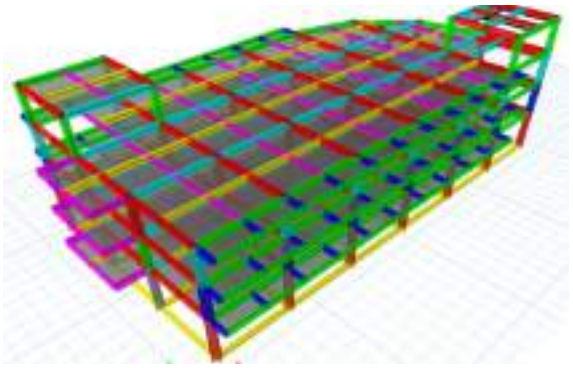

Fig.2 BPBD building modeling on ETABS V.22

Response Spectrum Design

The design response spectrum was developed according to SNI 1726:2019, using seismic hazard data from PUSGEN 2019–2020 for Padang (soil class SD). The short-period spectral acceleration (Ss) is approximately 1.54 g, and the one-second period spectral acceleration (S1) is 0.62 g. With site coefficients Fa = 0.80 and Fv = 2.0, the maximum considered earthquake parameters become SMS ≈ 1.23 g and SM1 ≈ 1.24 g, resulting in design values SDS ≈ 0.82 g and SD1 ≈ 0.83 g. These were adopted to generate the elastic design spectrum in ETABS for both principal directions. The primary hazard considered in this study is earthquake loading. Tsunami-induced hydrodynamic loads, while relevant for coastal facilities, were not included in this numerical study and are recommended for future multi-hazard evaluations.

Loading

The load cases defined in the ETABS model consisted of dead load (DL), live load (LL), and earthquake load (EQX, EQY) applied in both positive and negative directions. These were combined according to the load combinations prescribed in SNI 2847:2019 and SNI 1727:2020, such as 1.2DL + 1.6LL + 0.5EQ, and 1.2DL + 1.0EQ + 0.5LL, among others. This ensured that both gravitational and seismic actions were captured in accordance with code requirements.

Analysis of the Existing Building's Structure

Inter story-drift

Table 3 Results of inter-story drift in the building

Story	h (mm)	Inelastic Drift		Drift Limit (mm)	Cek
		Δ_X (mm)	Δ_Y (mm)		
4	3000	23,445	23,650	34,615	OK
3	3600	37,217	33,216	41,538	OK
2	3600	51,150	46,816	41,538	NOT OK
1	4600	51,671	47,542	53,077	OK

The determination of inter-story drift must be calculated as the difference in displacement at the center of mass above and below the level under review. Based on calculations of inter-story drift in SNI 1726: 2019, inelastic story drift Δ = δ * Cd / Ie and drift limit, Δa = 0.015 h = 41.54 mm in terms of X-direction and Y-directions. Based on the results of the analysis (Table 3), the value of inter-story drift on the 2nd floor exceeded the permit limit determined by SNI 1726:2019, namely ΔX = 51,150 mm and ΔY = 46,816 mm, greater than the drift limit of 41,538 mm. This shows that the existing structure has not met the requirements for the intersection between floors, so it needs to be retrofitted.

Load-bearing capacity of the column

From the results of the structure analysis, a diagram of column interaction was obtained, as seen in Figs. 3-7. From Figs. 3–7, it can be seen that the moment and axial values (in the form of points) do not pass through the P-M interaction diagram of the columns, so that the column structure is able to bear the working load.

	BK2	48,0	4,0	OK	100,0	2,4	OK
	BK3	109,9	55,9	OK	126,0	55,4	OK
	BT1	70,2	22,0	OK	100,0	21,4	OK
	BT2	70,2	57,3	OK	100,0	50,2	OK

The results of the beam capacity analysis (Table 4) indicate that, in terms of flexural strength, most elements are still able to withstand the design moment, so they can be considered relatively safe in bending. However, in the shear aspect, several critical beams particularly B3 and B2a on the second floor and B3b on the third floor exhibit shear demand (Vu) that exceeds their factored shear capacity (ϕVn). This

condition confirms that the main weakness of the existing beams lies not in flexural capacity but in shear resistance, meaning that these elements do not meet the minimum shear strength requirements stipulated in SNI 2847:2019 (Clause 22.5). Consequently, the insufficient shear resistance significantly increases the seismic vulnerability of the overall structure.

Floor plate bending capacity

The floor plate in the building behind the Governor's Office is a 2-way plate where the width of the direction x is 3 m, equal to the width of the direction of y, which is also 3 m, so that the ratio of the width of the direction x and the width of the direction y is less than 1.

Table 5. Floor plate bending capacity

Description	Reinforcement	
	X Dir.	Y Dir.
Load combination	EQX load	EQX load
Outside Moment (tm/m)	2.515	1.6157
Upper reinforcement	D10-250	D10-250
Bottom reinforcement	D10-250	D10-250
Momen Nominal (tm/m)	0.887	0.887
Check Nominal Moments > External Moments	Not Ok	Not OK

From Table 5 above, it can be seen that the flexural capacity of the floor plate is still smaller than the external moment due to the working load, or the condition of the plate is unsafe.

RETROFITTING OF THE BUILDING STRUCTURE WITH SHEAR WALLS

Based on the results of the evaluation of the existing structure, it is known that some key elements, such as columns and beams, are not fully able to withstand the workload, coupled with the deviation between floors that exceeds the permitted limit. This condition emphasizes the need for comprehensive strengthening efforts. The method chosen is the installation of a shear wall, as this technique has proven to be effective in increasing the global rigidity of the building, lowering the deviation between floors, and reducing the internal force on structural elements.

Shear Wall Location

The placement of shear walls in existing buildings is determined by considering the dominant direction of earthquake forces, spatial function, and the need to minimize eccentricity between floors. The selected location is focused on the weak axis of the building so that it can optimally increase lateral rigidity without disturbing the spatial layout. With this configuration, the torque moment on the structure can be suppressed, and the distribution of the earthquake force to the structural elements becomes more even. The shear wall used has a concrete quality of 30 MPa and is installed as high as the existing building, so that it can function as the main reinforcement element while transforming the structural system into a double system. The location of the shear wall placement can be seen in Fig. 8.

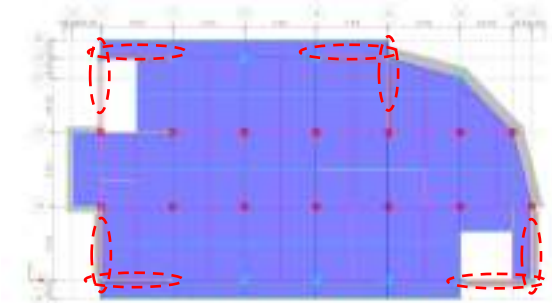

Fig.8 Location of shear wall placement

Through retrofitting of the structure with shear walls, a transformation occurs in the building's structural system, transitioning into a dual system. This alteration affects earthquake parameters, including the adjustment of the response modification coefficient (R) to 7, the over-strength factor system (Ω) to 2.5, the reinforcement parameter (Ct) to 0.0466, and the period parameter (x) to 0.9.

Structural Re-Analysis Results for the Retrofitted Building

The re-analysis of the building after being given a shear wall was carried out using the same procedure as in the existing structure, but earthquake parameters were used for the double system due to the addition of shear wall elements.

Inter-story drift of the retrofitted building

Table 6 Inter-story drift of the retrofitted building

Story	h (mm)	Inelastic Drift		Drift Limit	Cek
		$\Delta_{X\ (mm)}$	$\Delta_{Y\ (mm)}$		
4	3000	16,691	16,654	23,077	OK
3	3600	1,456	1,584	27,692	OK
2	3600	1,577	1,749	27,692	OK
1	4600	1,456	1,584	35,385	OK

After the installation of the shear wall, the value of inter-story drift on the entire floor has decreased significantly (Table 6) and is below the SNI 1726:2019 permit limit. This shows that reinforcement has succeeded in increasing the lateral rigidity of the building, so that the deviation between floors can be controlled well and the structure becomes more stable against earthquake loads.

Load-bearing capacity of columns on a retrofitted building

A re-analysis showed that the entire column after installing the shear wall had adequate capacity, as indicated by the axial load points and moments that were still within the P-M interaction curve (Figs. 9-13). The addition of a shear wall also lowers the force in the columns, with the reduction in moment and shear reaching more than 80% at some points (K1, K2, and K3). This condition confirms that reinforcement is able to increase the ability of the column to withstand earthquake loads and maintain structural stability.

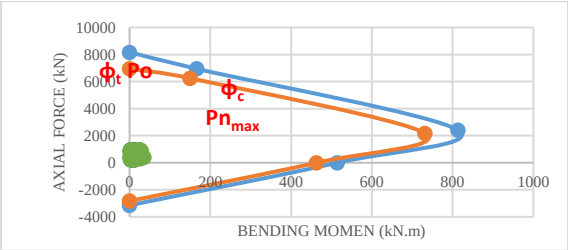

Fig. 9 K1 column interaction diagram after retrofitted

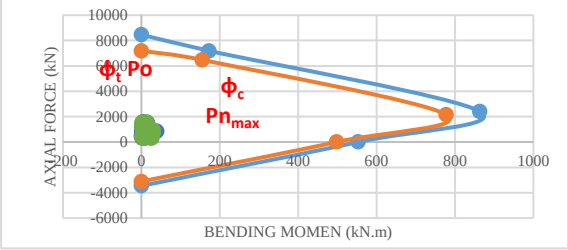

Fig. 10 K2 column interaction diagram after retrofitted

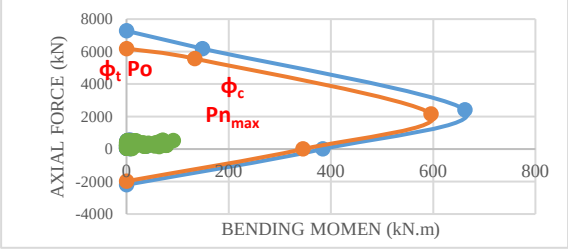

Fig. 11 K3 column interaction diagram after retrofitted

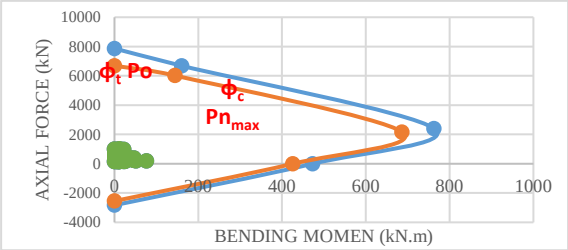

Fig. 12 K4 column interaction diagram after retrofitted

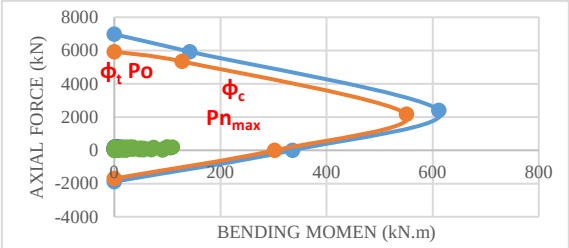

Fig. 13 K5 column interaction diagram after retrofitted

Load-bearing capacity of beams on the retrofitted building

After the installation of the shear wall, the beam capacity showed a significant increase. The results of the analysis showed that almost all blocks were able to withstand the moment and shear force according to the provisions. The decrease in inner force is also quite large, with a maximum moment reduction of about 81% and a shear force of up to 63%. This proves that shear wall reinforcement is effective in improving beam performance and reducing the potential for damage due to earthquake loads.

RETROFITTING OF SLAB

Slab Retrofitting with Fiber Reinforced Polymer (FRP)

The flexural reinforcement of the floor plate given with FRP is carried out by providing additional FRP to the bottom of the floor slab, and to the top of the floor plate (Fig. 14).

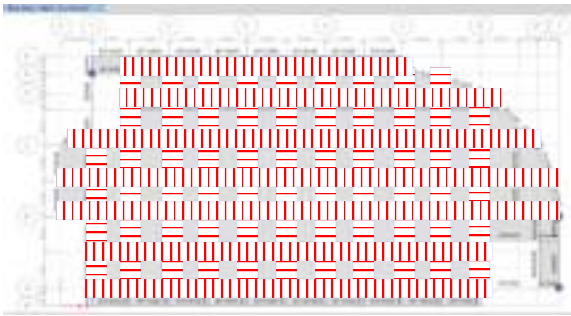

Fig.14 Installation of FRP retrofitting of the focus of the second floor plate

Analysis Result of Slab Capacity After Retrofitting

The analysis shows that after flexural strengthening with Fiber Reinforced Polymer (FRP) sheets, the slab's moment capacity increased from 0.89 t.m to 2.62 t.m. This value exceeds the external moment of 2.51 t.m, confirming that the retrofitted slab can safely resist bending loads. Thus, FRP

reinforcement effectively improves slab performance and reduces the risk of failure under seismic demands.

In addition to the structural capacity improvements demonstrated by the numerical analysis, the practical implementation of shear wall retrofitting in existing buildings also presents significant challenges. The installation of shear walls requires careful construction phasing to minimize disruption to building operations. For the BPBD office building, phasing strategies must be designed to allow temporary closure of certain areas without interrupting critical functions. Furthermore, building occupancy management during the retrofit is crucial to ensure user safety. This may include zoning of construction areas, temporary evacuation of floors under strengthening, and strict enforcement of safety procedures. These considerations highlight that the success of retrofitting is determined not only by compliance with analytical design requirements but also by effective management of on-site construction logistics.

CONCLUSION

Based on the results of the assessment and analysis of the reinforcement of the West Sumatra Province BPBD Office Building, it can be concluded that:

1. The existing structure does not meet the requirements of inter-story drift, and some of the beams show weakness in the shear capacity, so the building is not completely safe against earthquake loads.
2. The installation of shear walls was chosen as a reinforcement method because it was able to increase the global rigidity of the building, reduce the deviation between floors, and reduce the internal force on structural elements.
3. Re-analysis after reinforcement showed that all column and beam elements had met the strength requirements, with a significant reduction in force in the column, which was up to 95% at the moment and column shear, as well as about 81% at the moment and 63% at the beam shear. With the shear wall, the performance of the structure meets the provisions of SNI so that the building becomes more stable, safe, and suitable to function as a BPBD operational office in earthquake-prone areas.
4. After being strengthened with FRP, the flexural capacity of the floor plate increased from 0.89 t.m to about 2.62 t.m, so that it was able to surpass the external moment that occurred of 2.51 t.m. This shows that reinforcement with FRP effectively improves the performance of the slab in resisting bending loads.
5. Although the analytical results confirm that the combined retrofitting strategy using shear walls and FRP significantly enhances seismic performance, practical implementation challenges must also be addressed. Key issues include planning construction phasing to allow building operations to continue, managing occupancy during retrofit to ensure safety, and maintaining strict quality control in both shear wall casting and FRP installation. Therefore, the effectiveness of the proposed retrofitting solution can only be fully achieved when accompanied by well-prepared implementation planning in real conditions.

ABSTRACT

Padang City is highly vulnerable to earthquake and tsunami hazards due to its location along the subduction zone of the Indian and Eurasian plates. To address evacuation challenges, the government constructed the Ulak Karang Shelter as a vertical evacuation facility. However, this structure was not originally designed to withstand tsunami loads. This study evaluates the structural performance of the shelter and proposes retrofitting using the concrete jacketing method. The research involved field surveys, collection of technical data, and structural modeling using ETABS V.22. The analysis was based on Indonesian building codes (SNI 1726:2019, SNI 2847:2019, SNI 1727:2020) and FEMA P-646 tsunami guidelines. The results of the structural analysis revealed that some columns and beams lacked sufficient capacity to withstand the combined loads of earthquake and tsunami, indicating critical weaknesses. After retrofitting with concrete jacketing, column strength improved by 151% in moment, 106% in axial capacity, and 45% in shear capacity, while beam strength increased by 181% in flexure and 68% in shear. Structural displacement was also reduced by up to 36% in the X direction and 22% in the Y direction. These findings confirm that concrete jacketing is an effective retrofitting method, enabling the Ulak Karang Shelter to function safely as a vertical evacuation facility.

Keywords: Earthquake, Tsunami, Shelter, Retrofitting, Concrete Jacketing

INTRODUCTION

The location of Padang City on the West Coast of Sumatra, which is directly adjacent to the open sea (Indian Ocean) and the active collision zone of two plates, namely the Indian and Asian plates, makes Padang one of the most vulnerable cities to tsunami wave hazards [1]. Tectonic earthquakes along subduction areas and active seismic events can result in extraordinarily powerful waves. The tsunami disaster caused damage to facilities and infrastructure and caused many casualties.

At the time of the earthquake on September 30, 2009, the city of Padang had a problem with the horizontal evacuation route. This is due to the horizontal evacuation route located on the main road, which has a fairly high density of area. Coupled with very little road infrastructure that is perpendicular to the location of the highlands. In order for the evacuation process to continue to be carried out and minimize the risk of casualties during a tsunami, a rescue strategy is needed, one of which is vertical evacuation to avoid tsunami waves by climbing to a place or floor higher than the height of the tsunami wave. By using shelters, people in Padang City can reach a safe place from tsunami inundation in a shorter time [2]. Therefore, the Padang City government took action by building a temporary evacuation site (TES) named SHELTER located in Ulak Karang District, North Padang District.

Shelter buildings must be designed and built according to earthquake- and tsunami-resistant building standards because shelters must remain functional during natural disasters such as tsunamis [3,4]. However, the Ulak Karang shelter building was not designed for the tsunami load by the planning consultant because Indonesia has no standard regulations on tsunamis. In fact, if a tsunami occurs, it will definitely hit the shelter and adversely affect the strength and ability of the shelter building to bear the existing load, causing damage to the structure.

Researchers have previously analyzed the building using SNI Earthquake 2019 and FEMA P-646 [5]. The results showed that columns with cross sections of 60×40 cm and Ø60 cm could withstand gravity and earthquake loads, but did not have sufficient capacity to withstand tsunami loads. However, if given an additional tsunami load, the columns are not strong enough to withstand the structure". Therefore, it is necessary to carry out a method of improvement to the structure of the building by increasing the ability of the building or adding new structural elements that were not available or considered non-existent when the structure was built. Structural reinforcement is usually done as a preventive measure before the structure undergoes destruction due to the new load to be supported [6,7].

One solution to overcome this is the jacketing method, which is one of the many techniques used in the repair and reinforcement of reinforced concrete. Jacketing is carried out by enlarging the cross-section of the existing reinforced concrete columns, with a new layer of additional concrete that is also

reinforced with reinforcement that serves to increase the rigidity of the shelter structure.

RESEARCH SIGNIFICANCE

The significance of this research is its direct impact on public safety in Padang City, an area highly vulnerable to tsunamis. The study addresses a critical gap, as the existing Ulak Karang shelter was not designed for tsunami loads due to a lack of standard regulations in Indonesia. By designing a structural reinforcement plan using the jacketing method, the research ensures the shelter can withstand these loads, minimizing casualties, and providing a reliable vertical evacuation option when horizontal routes are congested or compromised.

RESEARCH METHOD

The structural performance evaluation in this study was based on explicit design criteria and acceptance benchmarks from both national and international standards. According to SNI 1726:2019 [8], the maximum inter-story drift was limited to 2% of the story height for buildings classified as Category IV (essential facilities for post-disaster functions), which includes tsunami vertical evacuation shelters. The strength of structural members was assessed by comparing the applied demands with the nominal capacities. For beams, flexural and shear capacities were calculated following SNI 2847:2019 [9], and adequacy was determined by checking whether the applied moment and shear forces (Mu, Vu) exceeded the nominal capacities (ØMn, ØVn). For columns, combined axial and flexural capacities were verified using P-M interaction diagrams, where demand points outside the interaction curve indicated insufficient capacity. Load considerations followed SNI 1727:2020 for dead loads, live loads, and special evacuation live loads [10], while tsunami loads were determined based on FEMA P-646, which include hydrostatic, hydrodynamic, impulsive, debris impact, and additional gravity effects [11]. In addition, an evacuation live load of 250 kg/m², as recommended in FEMA P-646, was applied to represent designated shelter occupancy.

EVALUATION OF EXISTING BUILDING

The evaluation of the existing Ulak Karang Shelter was conducted by comparing analytical results with the established acceptance benchmarks. Inter-story drift results were compared to the maximum allowable limit of 2% of the story height, as specified in SNI 1726:2019 for Category IV essential buildings. The performance of beams was assessed by comparing applied demands with nominal flexural and shear capacities; elements where Mu or Vu exceeded ØMn or ØVn were classified as inadequate. Columns were evaluated through P-M interaction diagrams, and demand points located outside the interaction curve indicated insufficient axial-flexural strength. Load effects were checked against SNI 1727:2020 to ensure proper consideration of dead loads, live loads, and evacuation live loads. Tsunami-induced forces, including hydrostatic, hydrodynamic, impulsive, debris impact, and additional gravity loads, were determined following FEMA P-646. Members that could not sustain these combined demands were identified as critical elements requiring retrofitting through the concrete jacketing method.

Location of Region and Topography

Fig. 1 Shelter location on Google Earth

The Ulak Karang shelter (Fig.1) is located near the coastline at a distance of 0.7 km from the Padang coastline. The pattern of land use around the location is a residential area. Based on the tsunami hazard map of Padang City issued by the Padang City Regional Development Planning Agency, the depth of the tsunami flood at the planned location is 4 - 5 m. The estimated depth of the tsunami flood is based on the contours of the Padang city area and the prediction of tsunami waves in the city of Padang.

Building Structure Data

To conduct structural analysis, the parameters used in the technical data of the building and the existing condition of the building are as follows:

- Building Name : Temporary Evacuation Places (TES) or SHELTER
- Structure Type : Reinforced Concrete Portal
- Concrete Grade : K-350 (f'c = 30 Mpa)
- Rebar Grade : 400 Mpa
- Number of Floors: 5
- Building Function: Evacuation
- Floor Plate Thickness : 12 cm
- Column Dimensions on Table 1 and Beam Dimensions on Table 2:

Table 1. Column dimensions

Code	Dimension (cm)	Main rebar	Shear rebar	concrete cover
K1	D 60	16D22	D10-100	25
K2	60 x 40	16D22	D10-100	25

Table 2. Beam dimensions

Code	Dim. (cm)	Support Area		Midspan Area	
		Tensile	Comp.	Tensile	Comp.
BA1	40 x 60	6D22	4D22	3D22	4D22
BA2	40 x 60	7D22	3D22	3D22	3D22
EB1	40 x 50	4D22	3D22	3D22	3D22
EB2	40 x 50	4D22	3D22	3D22	3D22
EB3	40 x 50	4D22	3D22	3D22	3D22
BA3	40 x 50	4D22	3D22	3D22	3D22
BC1	30 x 30	4D22	3D22	3D22	3D22

Structure Modeling

Structural modeling was made in 3 dimensions using ETABS V.22 software (Fig.2).

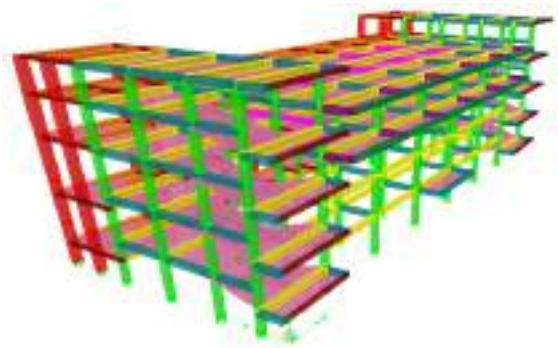

Fig. 2 Modeling of existing structures

Loading

The structural analysis considered dead loads, live loads, earthquake loads, and tsunami loads. Dead loads include the self-weight of structural elements and non-structural components such as walls, calculated according to SNI 1727:2020. Live loads were determined based on SNI 1727:2020, while the specific evacuation live load of 250 kg/m² was adopted from FEMA P-646 for designated shelter areas.

Earthquake loading followed SNI 1726:2019, with response spectrum values obtained from soft soil conditions (SD1 = 0.958g and SDS = 0.805g). Tsunami loads were calculated using FEMA P-646, which considers floating, hydrodynamic, impulsive, debris impact, and additional gravity effects. Load combinations were arranged according to both SNI 1726:2019 and FEMA P-646 to represent the most critical structural demands.

RESULTS AND DISCUSSION

Structure Analysis

Inter-story drift

The results of the calculation of the inter-story drift in the X direction and the Y direction can be seen in Tables 3 and 4. The inter-story drift analysis indicates that the shelter experiences displacement in both X and Y directions under earthquake and tsunami loads. Although the additional tsunami load only slightly increases the drift compared to the earthquake load alone, the cumulative effect shows that several upper stories approach critical limits. This finding highlights the structural vulnerability of the shelter, particularly at higher levels, and emphasizes the need for retrofitting measures to improve overall lateral stability.

Table 3. Comparison of the inter-story drift in the X direction with and without tsunami load

Floor	Without Tsunami Load (mm)	With Tsunami Load (mm)	Upgrade Ratio (%)
1	0.00	0.00	0.000%
2	4.65	4.65	0.000%
3	10.67	10.71	0.378%
4	15.54	15.65	0.708%
5	19.42	19.68	1338%
Rooftop	21.42	21.56	0.654%

Table 4. Comparison of the inter-story drift in the Y direction with and without tsunami load

Floor	Without Tsunami Load (mm)	With Tsunami Load (mm)	Upgrade Ratio (%)
1	0.00	0.00	0.000%
2	10.83	10.83	0.000%
3	20.33	20.34	0.049%
4	26.15	26.23	0.306%
5	29.85	30.04	0.637%
Rooftop	32.29	32.39	0.310%

Cross-sectional capacity of the structure

a. Column

The results of the analysis of the cross-sectional capacity of the columns can be seen in Figs. 3 and 4 below. The analysis shows that the K1 (Ø60 cm) and K2 (60×40 cm**)** columns are unable to resist combined earthquake and tsunami loads, as their demand points exceed the safe interaction curve. While sufficient for gravity and seismic forces, they remain vulnerable under tsunami pressure. Concrete jacketing is required to enhance flexural and shear strength.

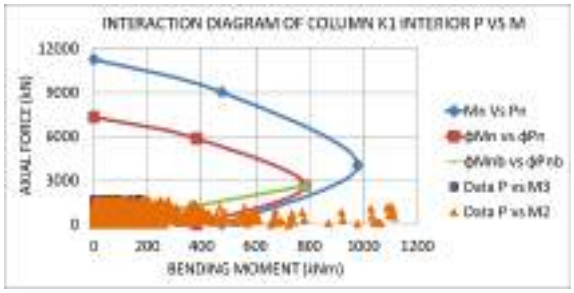

Fig. 3 Interaction diagram of column K1 1st floor

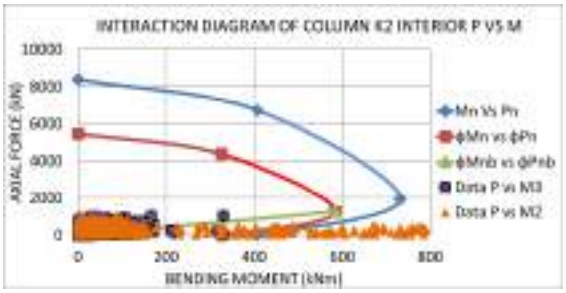

Fig. 4 Interaction diagram of column K2 1st floor

b. Beam

The results of the recap of the bending capacity of the beams of the shelter can be seen in Table 5. The beam capacity analysis indicates that several first-floor beams, particularly BA1 (40×60 cm) and BB1 (40×50 cm)**,** fail to meet flexural requirements under tsunami loads. Some midspan and support reinforcement sections show moment values exceeding the nominal moment capacity, proving their vulnerability. Strengthening with concrete jacketing is therefore necessary to significantly improve flexural and shear resistance.

Table 5. Recapitulation of the bending capacity of the beams of shelter structures with tsunami loads

Floor	Beam	Location	Dimension		Rebar		ØMn	Mu

					4D22	4D22	119,297	237,085	Field	NOT OK

Structure Retrofitting Analysis

Fig. 5 shows the location of the first-floor beam elements requiring strengthening, while Fig. 6 highlights the second-floor column elements that also require additional reinforcement.

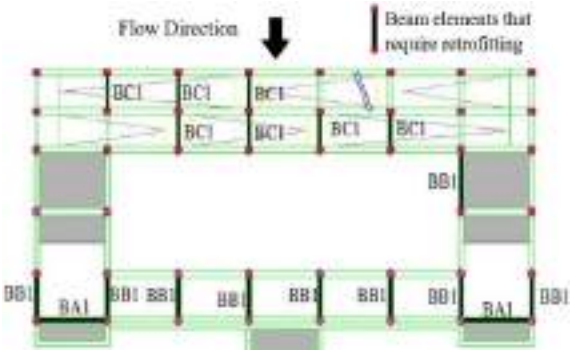

Fig. 5 Position of 1st floor beam elements that require retrofitting

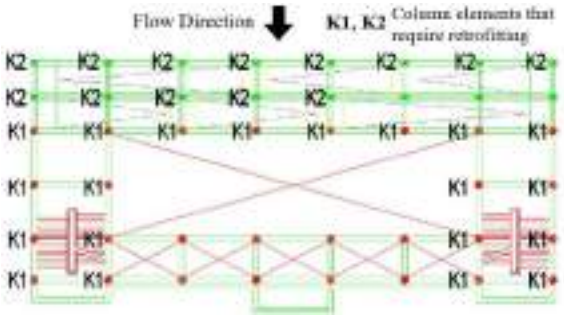

Fig. 6 Position column elements that require retrofitting

Modeling of structures with reinforcement jacketing

The location of the modeled column retrofitted with concrete jacketing can be seen in Fig. 7 below.

- K1 = 750 mm, main rebar: 32D22
- K2 = 750 x 550 mm, main rebar : 32D22
- BA1 = 600 x 800 mm, main rebar: 18D22
- BB1 = 600 x 700 mm, main rebar: 16D22

- BC1 = 500 x 500 mm, main rebar : 15D22

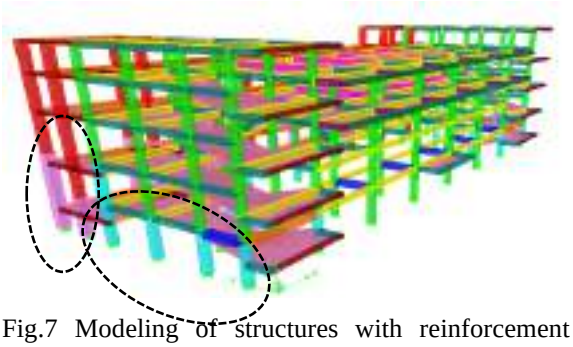

Fig.7 Modeling of structures with reinforcement jacketing

Cross-sectional capacity of the structure

a. Column

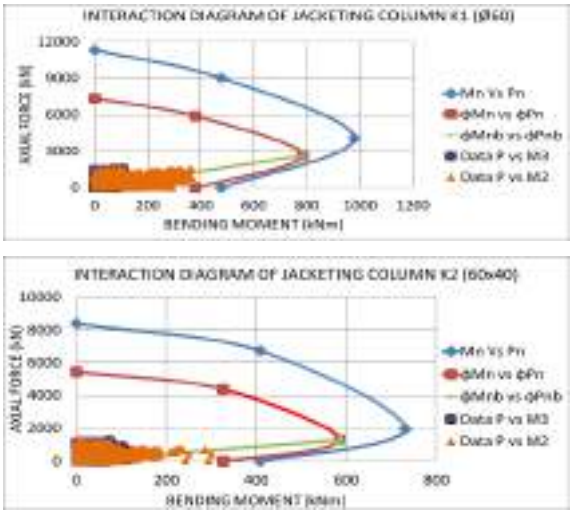

Fig. 8 Interaction diagram of the 1st floor retrofitted structure columns

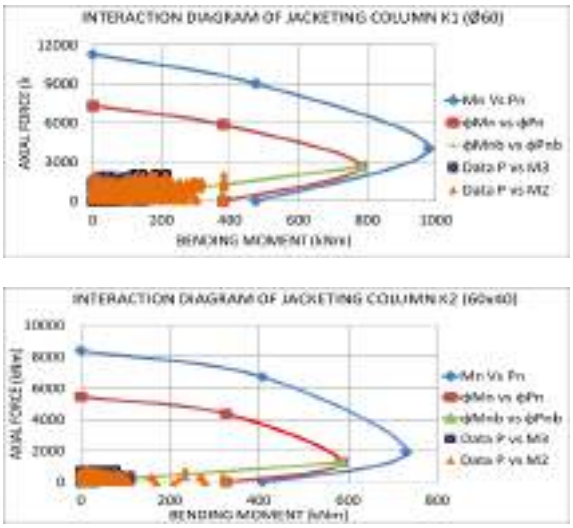

Fig. 9 Interaction diagram of the 2nd floor retrofitted structure columns

In the cross-sectional capacity analysis after retrofitting with the concrete jacketing method, a significant improvement was observed in both columns and beams. Fig. 8 presents the interaction diagram of the first-floor columns, while Fig. 9 shows the interaction diagram of the second-floor columns after strengthening.

b. Beam

The beam results are summarized in Tables 6 and 7, which compare the flexural and shear capacities between the existing and retrofitted conditions. Overall, the jacketing method effectively enhanced the structural performance, with column flexural capacity increasing by more than 150%, and beam capacity improving up to over 180% for flexure and more than 60% for shear.

Table 6 Comparison of the bending capacity of existing and retrofitted structure beams

Beam	Location	Moment Nominal		Increased (%)
		Existing	Retrofitted	
BA 1	Support	395.439	782.679	98%
BA 1	Field	265.829	706.645	166%
BB 1	Support	322.453	577.980	79%
BB 1	Field	217.172	505.904	133%
BC	Support	119.297	335.383	181%
BC	Field	119.297	335.383	181%

Table 7 Comparison of existing and retrofitted structure beams shear capacity

Beam	Location	Shear plan		Increased (%)
		Existing	Retrofitted	
BA1	Support	514,242	723,512	40,695%
	Field	335,172	497,317	48,377%
BB1	Support	424,025	623,024	46,931%
	Field	276,370	428,245	54,954%
BC	Support	315,665	531,493	68,372%
	Field	315,665	531,493	68,372%

Beyond analytical improvements, several practical considerations must also be addressed in implementing the jacketing retrofit method. Quality control during construction is critical, particularly in ensuring adequate bonding between the existing concrete and the new jacketing layer, proper placement of additional reinforcement, and sufficient compaction of the new concrete. Without strict quality control, the effectiveness of the retrofit may be compromised. Potential cracking at the interface between old and new concrete should also be anticipated, requiring the use of bonding agents, roughening of the existing surface, and adequate curing practices. From a construction logistics perspective, jacketing requires careful planning in terms of access to structural elements, installation of

formwork, and work scheduling, especially since the shelter is located in a densely populated area. These practical issues must be taken into account to ensure that the retrofitting design can be effectively implemented in the field.

CONCLUSION

From the research that has been carried out, it can be concluded that several things are as follows:

1. The existing Ulak Karang shelter cannot fully withstand the burden of earthquakes and tsunamis, as some columns and beams do not have sufficient capacity. This condition highlights the urgent need for structural reinforcement before the shelter can safely carry out its evacuation function.
2. Retrofitting with concrete jacketing proves effective, increasing column strength significantly. The moment capacity rises by 151%, axial capacity by 106%, and shear by 45%, ensuring that the columns can better sustain combined loads.
3. Beam elements also benefit from the strengthening, with flexural capacity improving by 181% and shear by 68%. These gains make the beams much more reliable in resisting tsunami-induced forces that previously caused overstress.
4. Structural displacement is reduced by 36% in the X direction and 22% in the Y direction, showing that the building becomes stiffer and more stable against lateral movement during seismic and tsunami events.
5. The building is suitable for use as a shelter for evacuation in the event of a disaster after reinforcement
6. In addition to the numerical improvements demonstrated through structural analysis, the success of the concrete jacketing method also depends on proper field implementation. Quality control, prevention of interface cracking, and construction logistics are essential aspects that determine whether the retrofit will perform as intended. Therefore, the findings of this study not only highlight the technical effectiveness of jacketing but also emphasize the importance of addressing practical challenges to ensure reliable and durable retrofitting of evacuation shelters.

NUMERICAL ANALYSIS OF SMALL-SCALE EARTH RETAINING STRUCTURES DURING LIQUEFACTION

Kakuta Fujiwara[1], Yan Boyu[1]

[1]Graduate School of Engineering, Tokai University, Japan

ABSTRACT

In repair work for underground pipelines, small-scale excavations of approximately 1 to 2 meters in depth are often carried out. In narrow or confined areas, lightweight sheet piles are frequently used for earth retaining purposes. Due to the small scale of the construction, earth retaining walls (lightweight sheet piles) and other materials are sometimes used based on conventional practices rather than detailed calculation procedures. Furthermore, since these are temporary structures, seismic considerations are typically not conducted. However, given the large number of such construction activities at the same time, it is likely that some will incur damage during an earthquake. Therefore, this study conducts numerical analysis of small-scale earth retaining works under seismic conditions. The target site is assumed to be a sandy and saturated ground near the coast, and the numerical analysis takes liquefaction into account. The results confirmed that liquefaction leads to the uplift of the entire structure and an increase in stresses acting on structural components such as short struts and walers. Based on this analysis model, additional simulations were conducted to compare three scenarios: without considering liquefaction, with varying spacing of struts, and with the application of surcharge loads. This paper also shows these analytical results in different three scenarios.

Keywords: Small-scale excavation, Retaining wall, Numerical analysis

INTRODUCTION

In repair work for underground pipelines, small-scale excavations approximately 1 to 2 meters deep are often carried out. In narrow or confined areas, lightweight sheet piles are frequently used for earth-retaining purposes.

The retaining wall is often constructed using lightweight and durable aluminum sheet piles. These sheet piles are aligned and supported by walers, and the opposing aluminum sheet piles are further braced at the top by horizontal struts, called “Double sheet pile cut-off structures”. While increasing the number of struts and walers helps to distribute the stresses generated during excavation and enhances structural stability, an excessive number of these structural members can reduce the working space and lower constructability.

Double sheet pile cut-off structures have been widely applied in various fields and are often effective in mitigating liquefaction associated with seismic events [e.g. 1, 2]. Although design guidelines [e.g. 3] are available as references for earth-retaining walls in small-scale excavation work, the extent to which they are applied in design calculations varies depending on the site. Due to the limited scale and low risk associated with potential collapse, construction is sometimes carried out using a simplified structure rather than one derived through detailed design calculations.

Based on these circumstances, the authors have conducted model experiments and numerical analyses on earth-retaining walls for small-scale excavations to verify the safety of structural member stresses and related factors under static conditions [4]. As these structures are temporary, seismic considerations are typically not included in the design. However, given the large number of such construction activities occurring simultaneously, it is likely that some may be damaged during an earthquake. Therefore, this study performs numerical analyses of small-scale earth-retaining works under seismic conditions. The target site is assumed to be a sandy, saturated ground near the coast, and the numerical analysis incorporates the effects of liquefaction. Additional simulations were also conducted to compare three scenarios: without considering liquefaction, with varying spacing of struts, and with the application of surcharge loads.

RESEARCH SIGNIFICANCE

While numerous studies have been conducted on excavation work of standard scale, research on small-scale excavation projects remains limited. This is likely because smaller structures are considered to pose less risk. However, the number of small-scale excavations is extremely high, and some form of research-based validation is necessary. Therefore, this study investigates the deformations that occur in small-scale earth-retaining walls and their associated structural members during liquefaction, using numerical analysis.

NUMERICAL CONDITION

The numerical analyses were conducted using LIQCA3D20. The target embankment was constructed on two layers of sandy ground shown as Fig. 1. Aluminum sheet piles were installed facing each other to construct an earth-retaining system, followed by excavation to form a space measuring 2 m in depth and 2 m in width. The ground was discretized into 5400 cuboid elements. To perform numerical analysis, parameters such as dimensions, soil parameters, and countermeasures needed to be specified. The following sub-sections describe the ground condition, these parameters and their corresponding values.

Soil

The ground condition was a representative loose sandy soil with a relative density (Dr) of 40 %. The soil parameters used in the numerical model were shown in Table 1. Sand above the groundwater was modeled as dry, while that below was modeled as saturated. The soil parameter values were inferred and determined from the academic paper by Fujiwara et al [5]. The sand layers were modeled as elasto-plastic models created [6, 7], which is often used to model a loose sand layer. This model represents sand behavior resulting from an increase in excess pore water pressure which causes motion, making the sand soft, and finally causing liquefaction.

Countermeasure

The sheet piles are installed facing each other and are supported near their top ends by struts. The sheet piles are also connected in the longitudinal direction by walers. Table 2 shows the actual cross-sectional properties, and the corresponding values adopted in the numerical model for the sheet piles, struts and walers.

The sheet piles were 2.5 m long, with an embedment depth of 0.5 m. The sheet-piles were modeled by cuboid meshes with linear elastic material having no yield. The mesh thickness was set to 20 mm, and the Young's modulus was set to 1.22 x 10^9 kN/m^2 so that the flexural rigidity would be equivalent to that of the sheet pile. The density was set to 0.75 g/cm³ to match the mass of the sheet pile, thereby ensuring that the inertial force during seismic loading would also be equivalent.

The strut and waler were modeled using beam elements. The strut was connected at both ends to the sheet piles at positions 0.5 m below their tops (x = 0 m). The walers were connected to the sheet piles in the longitudinal direction at positions 0.5 m below their tops. The strut and waler were assigned properties that were sufficiently lightweight and had high rigidity, so that their own deformation and the effect of self-weight were negligible. Only the actual second moment of area property was assigned to the waler to accurately reproduce its bending deformation.

Dilentancy parameter	D_0		3
	n		3
Reference strain parameter	γ^{P*}		0.01
	γ^{E*}		0.02

Boundary condition

The coordinate system was set up with the y-axis extending along construction longitudinal direction, the x-axis perpendicular to the y-axis in the horizontal plane, and the z-axis pointing vertically upward. The z-x dimensions of the model were as follows: 22 m in the x-direction and 6.5 m in the z-direction.

Taking symmetry considerations into account, fixed boundary conditions were assigned at the locations of the side nodes in the x-direction, at x = 0 m and x = 22 m. In the y-direction, fixed boundary conditions were assigned at the locations of the side nodes at y = 0 m and 1 m. In the z-direction, the bottom nodes were fixed at z = 0 m in all cases.

Numerical case

Numerical cases are listed in Table 3. For Case 1, the groundwater table is at a depth of 1 m, and the spacing of the struts is 2 m; this is taken as the basic structure. For Case 2, there is no groundwater, and the entire ground is assumed to be dry sand. Liquefaction is not considered. For Cases 3-1 and 3-2, the spacing of the struts is 1 and 4 m, respectively. For Case 4-1, a vertical load is applied to both sides of the ground surface. For Case 4-2, the vertical load is applied to the right side of the ground surface. The vertical load is set to 10 kN/m^2, which is the design load specified in [3], taking into account the weight of construction equipment and materials.

Input motion

The dynamic analyses were carried out from the results of the initial analyses, using the input motion, which was the Level 1 earthquake motion publicly released for a coastal area was employed, as represented by the plot (Fig. 2). National Institute for Land and Infrastructure Management (NILIM) provided the data [8]. This wave had a maximum acceleration of 1.49 m/s^2, and a duration of 163 s.

The Newmark method was used to solve the responses of the soil and the structure. An incremental time interval of 0.005 s was used, while a value of 0.3025 was used for the coefficient β in the Newmark method and the value of γ was set at 0.6. We used a stiffness-proportional coefficient of 0.003 for Rayleigh damping.

NUMERICAL RESULT

In this chapter, the results of the numerical analysis are explained with a focus on the presence or absence of liquefaction (Case 2), the spacing of struts (Cases 3-1 and 3-2), and the presence or absence of surcharge loading (Case 4-1 and 4-2), compared to the basic structure (Case 1).

Table 2 Parameters for structural components

Sheet-pile		Unit	Value
Density	ρ	t/m^3	0.75

4-1	✓	2 m	Both sides
4-2	✓	2 m	One side

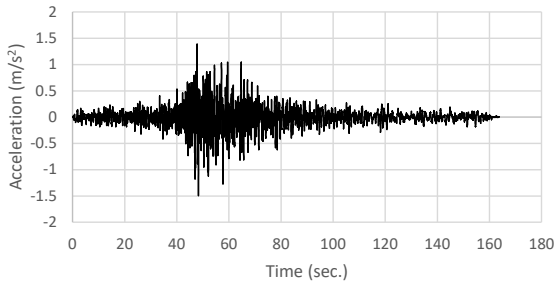

Fig. 2 Input motion

The presence or absence of liquefaction

For Cases 1 and 2, the deformations with excess pore water pressure ratio, corresponding to the end of shaking (t = 163 s), are represented by the heat maps shown in Fig. 3. The excess pore water pressure ratio is obtained by dividing the excess pore water pressure by the initial effective stress. In Case 1, the entire ground underwent significant deformation due to liquefaction. In contrast, in Case 2, no liquefaction was observed, and large deformation occurred only in the vicinity of the sheet pile. In both cases, due to the restraint provided by the struts near the top, the sheet

pile exhibited bulging deformation around their mid-height. Regarding the behavior in the vertical direction, in Case 1, the liquefied ground flowed beneath the sheet pile, resulting in an upward thrust that lifted the entire sheet pile; however, such behavior was not observed in Case 2.

The time histories of the axial force in the strut and the maximum bending moment in the waler are presented in Fig. 4, respectively. Compressive axial force was generated in the strut to resist the deformation of the sheet piles. The waler exhibited bending deformation as a beam supported at two points, with the supports located at the intersections with the strut. The maximum bending moment developed at the midpoint between the supports (y = 1 m). In Case 1, the strut experienced a maximum axial compression force of 35 kN and a maximum bending moment of 2.3 kNm, both of which occurred around 50 seconds, coinciding with the peak of the input acceleration. In Case 2 as well, the axial force and bending moment in the strut reached their maximum value around 50 seconds; however, these were significantly smaller than those in Case 1, at 16 kN and 1.3 kNm, respectively. Notably, little significant vibrational components were observed.

Fig. 5 shows the depth-wise distribution of horizontal and vertical displacements of both sheet pile walls at y =1 m. The horizontal displacement was generally similar between Case 1 and Case 2. However, in Case 1, an upward vertical displacement (uplift) was observed, whereas no such uplift was seen in Case 2.

The spacing of struts

For Cases 3-1 and 3-2, the deformations with excess pore water pressure ratio (t = 163 s) are represented in Fig. 6. In comparison with Case 1, little difference was observed in the occurrence of liquefaction and the deformation of the ground.

The time histories of the axial force in the strut and the maximum bending moment in the waler are presented in Fig. 7. In Cases 3-1 and 3-2, the strut experienced a maximum axial force of 20 kN and 47 kN, and a maximum bending moment of 0.8 kNm and 6.0 kNm, respectively. The axial force generated in the strut was approximately proportional to the spacing between them, while the bending moment in the waler was approximately proportional to the square of the spacing between the struts, that is, the distance between the supports of the waler.

Fig. 8 shows the depth-wise distribution of horizontal and vertical displacements of both sheet pile walls at the plane in the middle of the waler. In Case 3-2, where the spacing between struts is large, slightly larger horizontal displacements were observed at the top of the sheet pile. No significant differences were observed in other displacements.

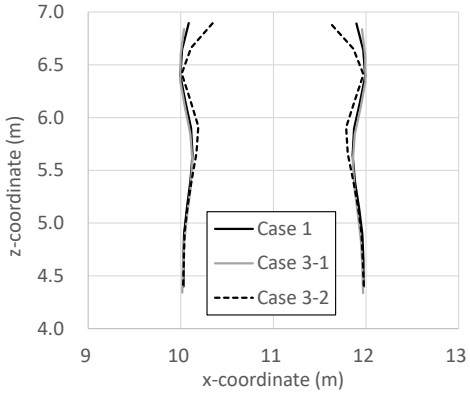

Fig. 8 Horizontal and vertical displacement in both sheet piles (Cases 1, 3-1 and 3-2)

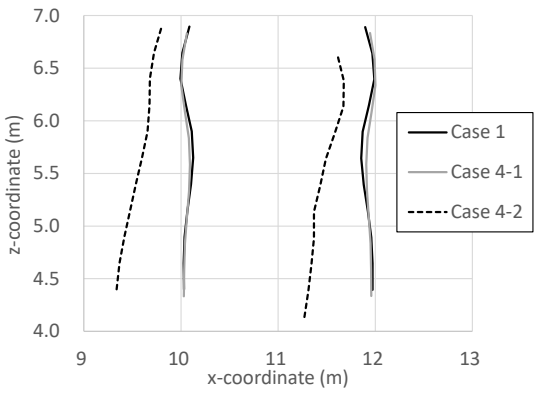

Fig. 11 Horizontal and vertical displacement in both sheet piles (Cases 1, 4-1 and 4-2)

The surcharge loading

For Cases 4-1 ~ 4-2, the deformations with excess pore water pressure ratio (t = 163 s) are represented in Fig. 9. Due to the application of a surface surcharge, the ground deformation in these cases was larger than that in Case 1. In particular, in Case 4-2, the eccentric load caused the ground to deform predominantly in the leftward direction.

The time histories of the axial force in the strut and the bending moment in the waler at y=1 m are presented in Fig. 10. The strut experienced a maximum axial force of 41 kN and 47 kN and a maximum bending moment of 2.7 kNm and 3.1 kNm. Compared to Case 1 without loading, the axial forces in the struts and the bending moments in the waler increased in Cases 4-1 and 4-2, where loading was applied.

Fig. 11 shows the depth-wise distribution of horizontal and vertical displacements of both sheet pile walls at y =1 m. Little significant differences were observed between Cases 1 and 4-1. In Case 4-2, the two sheet piles moved while undergoing rotation. The soil on the loading side pushed against the sheet piles, causing both rows of sheet piles to shift toward the non-loading side. As a result, the working space required for pipe installation and other construction activities was reduced, indicating a potentially hazardous situation.

CONCLUSION

This study conducted numerical analysis of small-scale earth retaining works under seismic conditions. The target site is assumed to be a sandy and saturated ground near the coast, and the numerical analysis takes liquefaction into account. The following results could be gained:

1) In the analysis results for the basic structure, liquefaction of the ground due to the earthquake caused horizontal loads from the soil to act on the two sheet piles and resulted in the compression of the underground space. To resist this, compressive axial force was generated in the strut, and bending moment was induced in the waler.

2) When liquefaction was not considered, the axial force in the struts and the bending moment in the waler were reduced to approximately half. In particular, the dynamic components of these forces were almost eliminated.

3) The axial force generated in the strut was approximately proportional to the spacing between them, while the bending moment in the waler was approximately proportional to the square of the spacing between the struts, that is, the distance between the supports of the waler.

4) Application of the surcharge load to only one side of the ground poses a greater risk of underground space deformation compared to loading on both sides during liquefaction.

5) In the future, the validity of the present analytical results will be examined by the authors through model experiments and full-scale construction tests.

DEVELOPMENT AND PERFORMANCE EVALUATION OF A UPV-BASED MODEL FOR EARLY FROST DAMAGE

ABSTRACT

This study evaluates the applicability of high-frequency ultrasonic testing and machine learning-based regression models for diagnosing early frost damage in mortar. Ultrasonic pulse velocity (UPV) and compressive strength were measured under varying curing ages and frost exposure depths. Based on these data, a multi-stage prediction model was developed. In the first stage, compressive strength was predicted using UPV and curing age as input variables. In the second stage, the predicted compressive strength was used to estimate the depth of early frost damage. Four regression algorithms were applied, and the combination of the 250 kHz frequency with the Gradient Boosting model demonstrated the highest prediction accuracy. In contrast, the 54 kHz-based linear regression model showed low explanatory power and high error. Taylor diagram analysis further confirmed that high-frequency models were more closely distributed around the reference line, indicating higher predictive reliability. These findings suggest that the combination of high-frequency ultrasonic testing and nonlinear regression algorithms is effective for quantifying early microstructural damage in cementitious materials. Furthermore, the proposed model provides a foundation for the future application of ultrasonic-based, machine learning-enhanced diagnostic techniques in real-world concrete structures and field evaluations.

Keywords: Early frost damage, Ultrasonic pulse velocity, Non-destructive testing, Machine learning

INTRODUCTION

Early frost damage (EFD), which can occur during the early stages of construction in winter, is one of the major deterioration factors that can critically impair the strength development and durability of concrete structures. In particular, when concrete is exposed to subfreezing temperatures before sufficient strength has developed the internal free water freezes and expands in volume. This volumetric expansion induces local stress concentrations, primarily leading to microcracks between the cement paste and aggregates. Such damage hinders the progress of the hydration reaction, ultimately resulting in a reduction of compressive strength. Since these microstructural damages are often not visible externally, early diagnosis through appropriate non-destructive testing (NDT) methods is essential [1–3].

Among various NDT techniques, the ultrasonic pulse velocity (UPV) test is one of the most widely used methods for assessing internal defects and degradation in concrete. It is particularly advantageous due to its relatively easy application in construction sites. The primary factors affecting the propagation velocity of ultrasonic waves through a material include density, elastic modulus, and porosity—all of which are sensitive to changes induced by early frost damage. Therefore, UPV can serve as an indirect indicator of internal structural conditions [4,5].

However, most existing studies have employed ultrasonic waves with a center frequency of 54 kHz. Due to the relatively long wavelength at this frequency, its sensitivity to microstructural damage is limited [6–8]. In contrast, high-frequency ultrasonic waves (above 250 kHz), characterized by shorter wavelengths, have the potential to more precisely detect fine cracks and localized damage within structures [9]. In particular, for detecting early-stage microcracks and localized deterioration caused by EFD, the use of high-frequency ultrasonics is considered more appropriate.

Meanwhile, traditional UPV-based degradation assessments have primarily relied on linear regression models or empirical correlation formulas, which have limitations in capturing the complex and nonlinear interactions among variables such as curing age, damage depth, and exposure conditions [10]. To address these limitations, recent studies have actively explored the use of artificial intelligence techniques, such as machine learning (ML) and deep learning (DL), to predict structural damage based on ultrasonic data [11,12]. Machine learning models are capable of effectively learning nonlinear relationships among multiple input variables. In particular, ensemble-based nonlinear regression models, such as Random Forest and Gradient Boosting, offer high predictive accuracy and the advantage of enabling influence analysis among variables [13].

Table 1 Experimental plan

Specimen	Conditions of experiments				W/C	C:S	Measurement items
	Freezing depth (mm)	Curing before freezing (h)	Freezing temperature (°C)	Freezing time (h)			
Plain	Non-frozen	-	-	-	0.5	1:3	· Ultrasonic pulse velocity · Compressive strength
FD-00	0	6	-10	24			
FD-03	30						
FD-06	60						
FD-10	100						

Table 2 Physicochemical properties of the fine aggregate constituents

Type	Fineness modulus	Density (g/cm^3)	Water absorption (%)	Stability (%)
Natural river sand	2.46	2.57	1.16	3.2

Therefore, this study aims to develop a machine learning-based multi-stage prediction model using ultrasonic pulse velocity and curing age as input variables, and compressive strength and early frost damage depth as output variables. Specifically, in the first stage, compressive strength is predicted based on ultrasonic velocity and curing age, and in the second stage, the predicted compressive strength is further used to estimate the depth of early frost damage. In addition, by comparing the predictive performance of models based on 54 kHz and 250 kHz ultrasonic data, this study experimentally evaluates the applicability and effectiveness of high-frequency ultrasonic techniques.

MODEL DEVELOPMENT PLAN AND METHODOLOGY

Specimen Preparation

The experimental plan of this study is presented in Table 1. The primary objective is to develop a machine learning-based model to predict the compressive strength and early frost damage depth of mortar using UPV, and to evaluate the predictive performance across two frequencies (54 kHz and 250 kHz). In particular, the applicability of high-frequency ultrasonic waves (250 kHz) is investigated to identify an optimal diagnostic frequency for early frost damage assessment. As a preliminary step toward practical application to concrete structures, this study focused on precisely analyzing the sensitivity of ultrasonic signals to microstructural damage at different frequencies by using mortar specimens, which provide relatively homogeneous material properties and minimize signal scattering caused by aggregates.

The specimens were fabricated as cylindrical molds with dimensions of Ø 50 mm × 100 mm and classified into five levels based on the depth of low-temperature exposure: Plain, FD-00, 03, 06, and 10. The FD series specimens were exposed to freezing at −10 °C for 24 hours at target depths of 0, 30, 60, and 100 mm, following an initial curing period of 6 hours. The mix proportion was fixed at a water-to-cement ratio (W/C) of 0.5 and a cement-to-sand ratio (C:S) of 1:3, using ordinary Portland cement. The properties of the fine aggregate are summarized in Table 2.

Implementation of Early Frost Damage Conditions and Data Acquisition Procedure

To simulate early frost damage at specific depths, an insulation device was designed to expose only the designated section of each specimen, minimizing external air intrusion with an additional 5 mm insulation sheet to enhance experimental precision. Plain specimens were demolded after 24 hours and cured underwater at 20 ± 1 °C, while FD series specimens underwent initial curing for 6 hours at 20 ± 1 °C and 60 ± 5% relative humidity, followed by 24 hours of freezing exposure at −10 °C before subsequent water curing.

UPV measurements were conducted using a Pundit Lab(+) device at two frequencies, 54 kHz and 250 kHz, employing the direct transmission method. A constant load of 2 kg was applied during measurements to minimize errors caused by variations in contact pressure. The ultrasonic pulse velocity tests were performed in accordance with ASTM C597. Compressive strength tests were conducted after ultrasonic testing in accordance with KS L ISO 679 and KS F 2405. The overall procedure for implementing early frost damage conditions and acquiring data is illustrated in Figure 1.

Development of the Predictive Model Regression Algorithm Configuration

For model development, UPV and curing age were set as input variables, while compressive strength and early frost damage depth were defined as output variables. A total of 90 data points were collected for each frequency, and the dataset was randomly divided into training (80%) and validation (20%) subsets to objectively evaluate model generalization. A multi-stage prediction model was applied to reflect strength development and

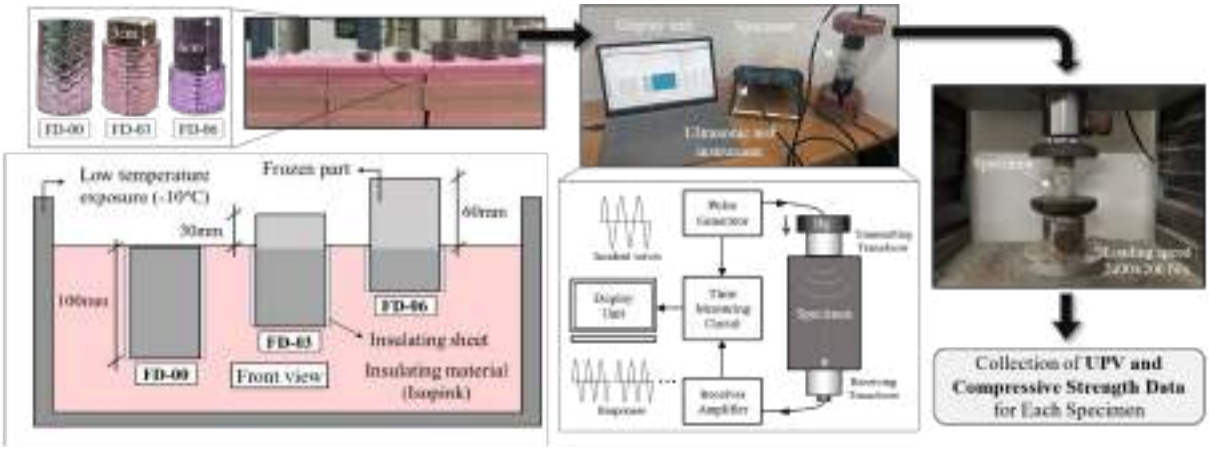

Fig.1 Schematic of the experimental procedure for early frost damage simulation and data acquisition

and degradation characteristics over curing time and to improve prediction accuracy. In the first stage, compressive strength was predicted using UPV and curing age, and in the second stage, the predicted compressive strength was used to estimate early frost damage depth. This structure was designed to incorporate causal relationships between stages, thereby enhancing both prediction precision and model interpretability.

For the model implementation, four regression algorithms were employed: Linear Regression (LR), Decision Tree (DT), Random Forest (RF), and Gradient Boosting (GB). LR assumes a simple linear relationship, while DT captures nonlinear interactions through a tree structure. RF and GB are ensemble learning methods, with GB particularly excelling in prediction accuracy and generalization performance through iterative learning. Since these algorithms differ in their structural characteristics and learning mechanisms, all four models were applied in this study to compare predictive performances under both linear and nonlinear assumptions. This approach enabled a visual and quantitative understanding of the structural differences between the algorithms and ensured a rational model selection process.

Hyperparameter Settings

The performance of machine learning-based predictive models is not solely determined by the choice of algorithm but is also highly influenced by the setting of hyperparameters. Hyperparameters are values manually set prior to model training, and they critically impact various aspects such as model complexity, learning speed, predictive accuracy, and prevention of overfitting. Therefore, in this study, the range of hyperparameters for each regression algorithm was preliminarily reviewed, and through multiple iterative trainings and experimental comparisons, the optimal combination was determined. The key hyperparameters set for each model are summarized in Table 3. All models were optimized by considering data characteristics, overfitting prevention, and predictive accuracy, ensuring a fair comparison of model performance.

Table 3 Hyperparameter settings for machine learning regression algorithms

Model	Hyperparameter	Value
Linear Regression (LR)	-	-
Decision Tree (DT)	Max depth	4
	Min samples splits	5
	Min samples leaf	2
	Random state	42
Random Forest (RF)	N estimators	100
	Max depth	6
	Min samples split	2
	Min samples leaf	2
	Random state	42
Gradient Boosting (GB)	N estimators	150
	Learning rate	0.1
	Mad depth	3
	Random state	42

Evaluation of Predictive Model Performance

One of the primary metrics used to evaluate the performance of regression models is the coefficient of determination (R^2), which indicates how well the model explains the variability of the data. An R^2 value closer to 1 signifies that the regression model has a stronger explanatory power. In this study, R^2 was used to assess how accurately the UPV reflects changes in compressive strength. A higher R^2 value implies a stronger relationship between UPV and compressive strength, thereby suggesting that the corresponding frequency provides a more suitable Table 3 Hyperparameter settings for machine learning regression algorithms basis for UPV-based compressive strength evaluation.

In addition, the root mean square error (RMSE) was employed to measure the average magnitude of the errors between the predicted and actual values. A lower RMSE indicates higher predictive accuracy.

Table 4 Prediction performance of compressive strength according to frequency and regression algorithm

Frequency	Model	R^2		RMSE (MPa)		MAE (MPa)	
		Training	Testing	Training	Testing	Training	Testing
250 kHz	Linear Regression (LR)	0.929	0.979	1.673	1.673	1.316	0.650
	Decision Tree (DT)	0.995	0.983	0.427	0.427	0.277	0.521
	Random Forest (RF)	0.998	0.987	0.253	0.253	0.173	0.460
	Gradient Boosting (GB)	0.999	0.990	0.093	0.093	0.053	0.262
54 kHz	Linear Regression (LR)	0.759	0.863	3.092	3.092	2.193	1.589
	Decision Tree (DT)	0.924	0.916	1.741	1.741	1.052	1.190
	Random Forest (RF)	0.983	0.951	0.813	0.813	0.612	0.979
	Gradient Boosting (GB)	0.991	0.971	0.592	0.592	0.632	0.611

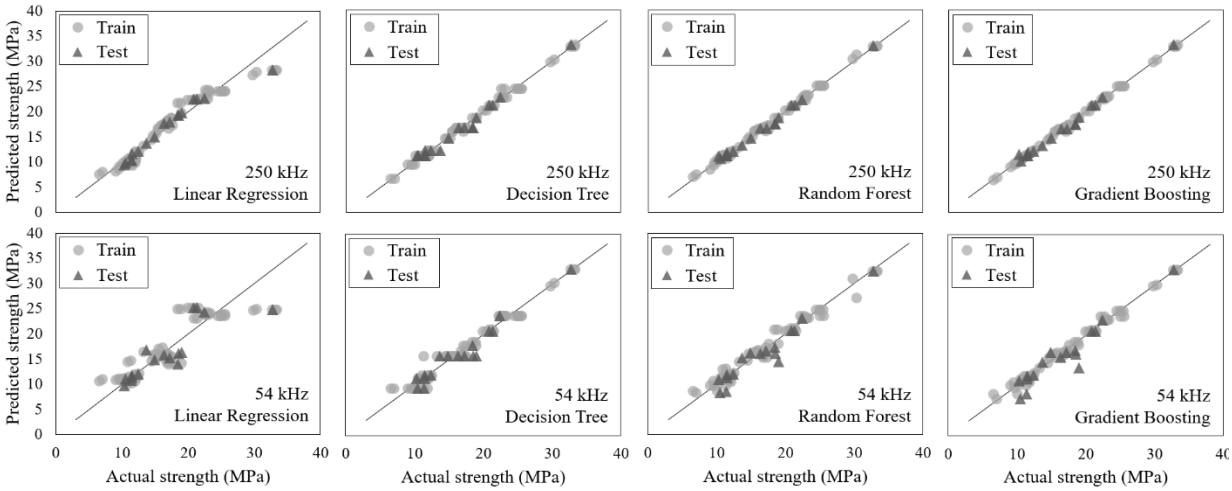

Fig. 2 Scatter plot of compressive strength prediction

The mean absolute error (MAE) was also used, which calculates the average absolute difference between the predicted and actual values. Unlike RMSE, MAE is less sensitive to outliers. Therefore, both RMSE and MAE were utilized to quantitatively compare the prediction errors of compressive strength models based on different ultrasonic frequencies.

These evaluation metrics were applied to both the compressive strength prediction model (Stage 1) and the early frost damage depth prediction model (Stage 2) to compare and analyze which algorithm exhibited the highest predictive accuracy and which frequency more sensitively reflected the extent of damage.

EVALUATION AND ANALYSIS OF MODEL PERFORMANCE

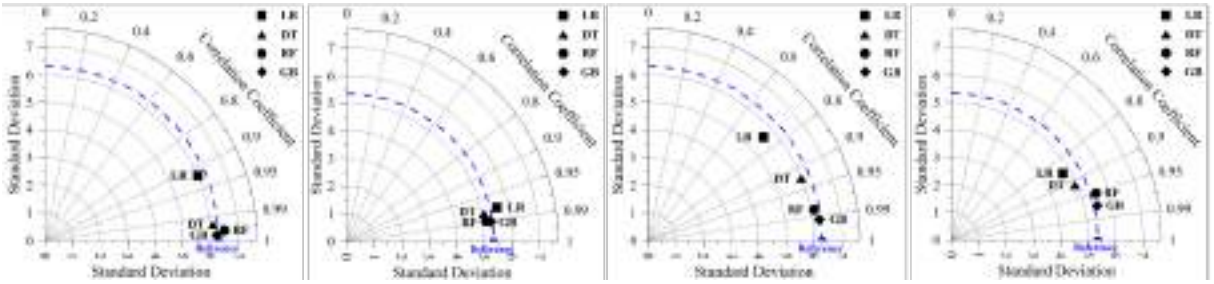
Compressive Strength Prediction Model

Performance evaluation using quantitative metrics

Table 4 presents the quantitative evaluation results (R^2, RMSE, and MAE) for the compressive strength prediction models using UPV and curing age as input variables. The analysis showed that models based on 250 kHz exhibited higher predictive accuracy and generalization performance compared to those based on 54 kHz. In particular, the 250 kHz GB model achieved the best performance, recording an R^2 value of 0.989, RMSE of 0.093, and MAE of 0.262 on the test dataset. In contrast, models using 54 kHz data, especially the LR model, demonstrated relatively lower predictive performance. Furthermore, nonlinear regression models (GB and RF) consistently outperformed the linear regression model (LR), experimentally confirming the nonlinear relationship between UPV and compressive strength.

Prediction results and error analysis based on scatter plots

The compressive strength prediction results for different frequencies (54 kHz and 250 kHz) and regression algorithms were analyzed using scatter plots, with the training and test results separately presented in Figure 3. Models based on 250 kHz generally showed distributions closely aligned with the reference line (1:1 line), indicating high predictive accuracy, and the GB and RF models demonstrated strong generalization performance even on the test data. In particular, the GB model achieved the highest performance with an R^2 value of 0.990 on the test



(a) Training (250kHz) (b) Testing (250kHz) (c) Training (54kHz) (d) Testing (54kHz)

Fig.3 Taylor diagram of compressive strength prediction performance

Table 5 Prediction performance of early frost damage depth according to frequency and regression algorithm

Frequency	Model	R^2		RMSE (mm)		MAE (mm)	
		Training	Testing	Training	Testing	Training	Testing
250 kHz	GB-LR	0.248	0.821	33.185	13.298	27.238	10.338
	GB-DT	0.600	0.501	24.195	22.215	16.944	14.444
	GB-RF	0.842	0.410	15.035	25.362	9.742	19.775
	GB-GB	0.899	0.634	12.148	19.029	5.978	11.945
54 kHz	GB-LR	0.316	-0.226	31.319	36.546	26.323	32.102
	GB-DT	0.647	0.275	22.491	28.108	15.683	21.698
	GB-RF	0.803	0.259	16.820	28.408	12.025	21.895
	GB-GB	0.835	0.246	15.400	28.665	9.085	18.578

dataset. In contrast, the 54 kHz models exhibited greater deviations from the reference line, with the LR model showing particularly low predictive accuracy. Additionally, the RF and GB models produced more concentrated distributions near the reference line compared to the LR model, visually confirming the nonlinear relationship between ultrasonic pulse velocity and compressive strength

Comprehensive performance comparison using taylor diagram

The predictive performance of the models across different frequencies and regression algorithms was analyzed using a Taylor diagram, as shown in Figure 4. Overall, models based on 250 kHz demonstrated higher predictive accuracy than those using 54 kHz, with the Gradient Boosting (GB) model achieving the best performance under all conditions. The GB model maintained distributions very close to the reference point for both the training and test datasets, indicating excellent generalization capability. These results suggest that combining high-frequency ultrasonic data with nonlinear regression algorithms can maximize predictive performance. Based on these findings, the next stage of this study will involve developing an early frost damage depth prediction model using the GB model's predicted compressive strength values as input.

Early Frost Damage Depth Prediction Model

Based on the Stage 1 compressive strength prediction results, a machine learning regression model was developed to predict early frost damage depth using the predicted compressive strength values from the GB model. The predictive performance for each frequency condition is summarized in Table 5.

Overall, models using 250 kHz data demonstrated higher accuracy than those using 54 kHz, with the GB-GB model showing the best performance (R^2 = 0.634, RMSE = 19.029, MAE = 11.945) on the test dataset. In contrast, the 54 kHz LR model exhibited very poor predictive accuracy. Nonlinear regression algorithms generally outperformed linear regression, and the GB-GB model achieved the highest accuracy in both the compressive strength and early frost damage depth prediction stages. These results validate the effectiveness of the multi-stage prediction approach and highlight that high-quality predicted compressive strength values can serve as meaningful inputs for subsequent early frost damage depth prediction.

In conclusion, this study confirmed that an early frost damage depth prediction model can be effectively established using predicted compressive strength values. In particular, the combination of high-frequency ultrasonic data and nonlinear regression algorithms contributed significantly to maximizing prediction accuracy, suggesting that a multi-stage prediction strategy based on high-frequency ultrasonic pulse velocity data is a viable approach for developing practical early frost damage diagnostic models in field

applications.

Although previous studies have widely utilized ultrasonic pulse velocity and similar input variables to estimate compressive strength, relatively few have attempted to predict early frost damage severity or depth based on such data. The present study confirmed the potential of a multi-stage machine learning framework to extend beyond strength prediction and evaluate internal damage conditions caused by early-age freezing. This represents a meaningful contribution to the field by expanding the applicability of ultrasonic-based diagnostics.

CONCLUSIONS

This study proposed a machine learning-based multi-stage model using UPV and curing age to predict both compressive strength and early frost damage depth in mortar. The 250 kHz–Gradient Boosting model achieved the best performance (R^2 = 0.990), confirming the advantages of high-frequency ultrasonics and nonlinear learning. Unlike previous studies focused solely on strength prediction, this research demonstrated the potential to quantify frost damage severity. The findings support the practical applicability of this approach for early-age diagnostics in cementitious materials, with further validation suggested for future work.

ABSTRACT

The effects of high-temperature damage on Recycled Aggregate Concrete (RAC) remain insufficiently studied. In RAC, the presence of residual mortar attached to the aggregates increases the heterogeneity of the material, potentially causing it to respond differently to high temperatures compared to conventional concrete. The decline in strength when exposed to elevated temperatures is largely attributed to the mismatch in thermal expansion between the aggregates and the cement paste. This mismatch generates thermal stresses in the Interfacial Transition Zone (ITZ), which significantly affects RAC's performance, especially during the re-curing phase after heat exposure. This research investigates the effectiveness of re-curing as a method to restore the compressive strength of RAC that has been exposed to high temperatures. Recycled Concrete Aggregate (RCA) was sourced from parent concrete with compressive strengths of 25 MPa and 40 MPa and incorporated at replacement levels of 50% and 100%. Mixes with water-to-cement ratios of 0.3 and 0.45 were prepared and cured for 28 days before being subjected to 550°C and 800°C. Compressive strength tests indicated a maximum strength loss of 62% at 550°C and 87% at 800°C in RAC containing 50% RCA with a w/c ratio of 0.45. After re-curing, the highest strength recovery was observed in RAC with 100% RCA and a w/c ratio of 0.45, achieving recovery levels of 53–74% at 550°C and 32–40% at 800°C. This recovery is believed to result from the regeneration of hydration products due to the rehydration of previously unhydrated mineral oxides.

Keywords: RCA, RAC, High Temperature Exposure, Concrete Compressive Strength, Re-Curing

INTRODUCTION

Previous research [1] has indicated that concrete incorporating Recycled Concrete Aggregate (RCA) can exhibit comparable properties to conventional concrete and meet structural performance requirements, even at high replacement levels. Despite the substantial progress made in recent years, several challenges still hinder the widespread adoption of RCA. One such challenge is the limited understanding of how recycled aggregate concrete responds to high-temperature exposure. This is particularly important because the presence of residual mortar on recycled aggregates introduces additional phases in the concrete, potentially resulting in behavior under high temperatures that differs significantly from that of normal concrete [2].

Aggregates make up about 60–75% of the total volume of concrete, making the thermal behavior of concrete largely dependent on the type of aggregate used, as different aggregates react differently to high-temperature exposure [3]. The reduction in concrete strength at elevated temperatures is primarily due to the incompatibility between the thermal expansion of the aggregate and the cement paste. This mismatch induces thermal stress in the Interfacial Transition Zone (ITZ). When the stress surpasses the tensile strength of the cement paste, it can lead to radial cracking in the paste originating from the ITZ, which may link up with cracks from nearby ITZ regions [4]

Consequently, the choice of aggregate plays a critical role in maintaining concrete stability under thermal stress. In the case of Recycled Aggregate Concrete (RAC), this is especially important, as recycled aggregates may exhibit varied responses to high-temperature exposure [5].

Furthermore, understanding how concrete behaves under high-temperature conditions is essential, as fire safety plays a crucial role in the structural design of concrete buildings [4]. While the general behavior of concrete at elevated temperatures is relatively well understood, exposure to heat triggers a series of physicochemical transformations that affect its thermo-mechanical characteristics. These changes can significantly reduce the material's mechanical performance, particularly as the temperature increases.

RESEARCH SIGNIFICANCE

Recycled Aggregate Concrete (RAC) is recognized as an environmentally friendly material in civil engineering due to its sustainability advantages [6,7]. However, its compressive strength tends to

decline markedly when subjected to elevated temperatures, such as those experienced during fire events. This study examines the performance of RAC after exposure to high temperatures and explores the effectiveness of re-curing as a method for strength recovery. Concrete samples were heated to 550°C and 800°C, then underwent a controlled re-curing process for a defined period. This study provides insights for structural rehabilitation using recycled materials under thermal stress conditions.

LITERATURE REVIEW

The results of research in several literatures [2,8–12], obtained contradictory results. Gales, [13] reported that concrete containing recycled aggregates exhibited a lower relative compressive strength compared to that made with natural aggregates, with strength decreasing as the proportion of recycled aggregates increased. This decline is attributed to the lower strength and larger Interfacial Transition Zone (ITZ) associated with recycled aggregates. In contrast, Zhao [14] found that concrete with recycled aggregates performed similarly to that with natural aggregates. Additionally, Sarhat [15], observed a gain in the mechanical behavior of concrete incorporating recycled aggregates [16]. This enhancement likely arises from the closer alignment of thermal expansion between recycled aggregates and the cement paste, which serves to suppress crack propagation within the paste and on the surface.

METHODS

This study investigates the presence of Unhydrated Cement Granules (UCG) in Recycled Concrete Aggregate (RCA) using SEM and XRD analysis. SEM was conducted at 15 kV, 10 mm working distance, 2000x magnification, and 10 μm layer thickness. XRD was performed using Rigaku SmartLab (θ–2θ mode, Cu $K\alpha_1$, 40 kV, 30 mA, 10°–70° range). Recycled concrete aggregates (RCA) obtained from original concrete with compressive strengths of 25 MPa and 40 MPa were incorporated into new concrete mixtures at replacement levels of 50% and 100%, using water-to-cement ratios of 0.30 and 0.45. After a 28-day curing period, the RAC specimens were subjected to temperatures of 550°C and 800°C to assess the decomposition of the C-S-H phase. The impact of this thermal exposure was analyzed by measuring the compressive strength of the concrete both immediately after heating and following a re-curing treatment

RESULTS AND DISCUSSION

RCA morphology testing using SEM to identify the possible presence of UCG minerals in RCA, which affect the mechanical behavior of RAC before and after exposure to high temperatures. This test was carried out at a magnification level of 2000x. The results of the RCA morphology test can be seen in Fig.1, while the identification of mineral chemical compounds can be seen in Fig. 2.

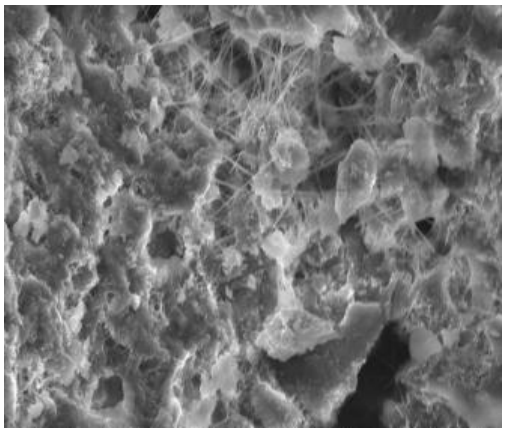

Fig.1 2000x magnification level

Fig.1 shows the presence of C3S, C2S, CSH, CH, ettringite and pores in RCA which affect the mechanical behavior of RAC.

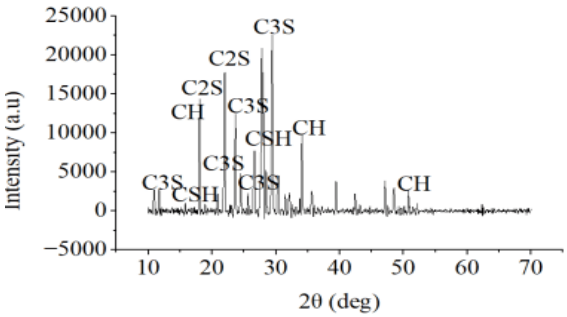

Fig.2 Mineral chemical compounds in RCA

Concrete Compressive Strength

The test results indicated a noticeable decline in compressive strength when concrete was exposed to high temperatures. This reduction is primarily due to dehydration caused by moisture loss, which leads to the breakdown of calcium silicate hydrate (C-S-H)—a key contributor to concrete strength—into its original compounds, C2S and C3S. Additionally, elevated temperatures create thermal incompatibility between the cement paste and aggregates, as the paste tends to contract while the aggregates expand. This mismatch in thermal strain generates internal stresses that can lead to microcracking within the cement paste and the Interfacial Transition Zone (ITZ), ultimately diminishing the concrete's mechanical performance.

Concrete exposed to 550°C exhibits behavior that contrasts with that at normal room temperature (20°C). At 550°C, the highest compressive strength is observed in concrete made entirely with natural aggregate (100% NA) (can be seen in Fig. 3). Concrete with 100% natural aggregate shows better performance against exposure to a temperature of 550°C compared to concrete with recycled aggregate.

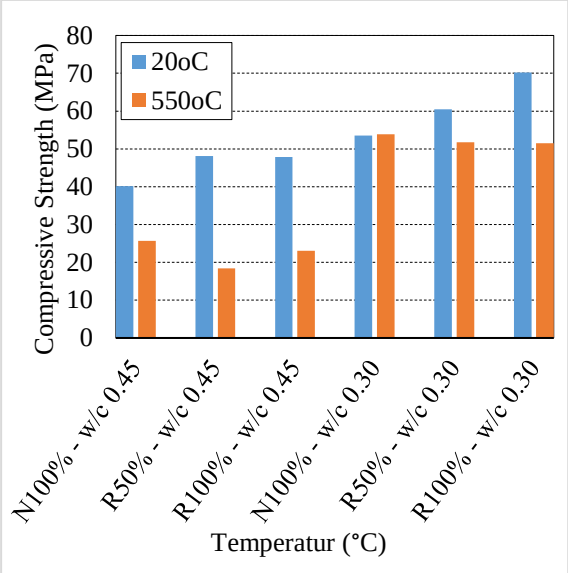

Fig.3 Concrete Compressive Strength After Exposure to Temperature 550°C

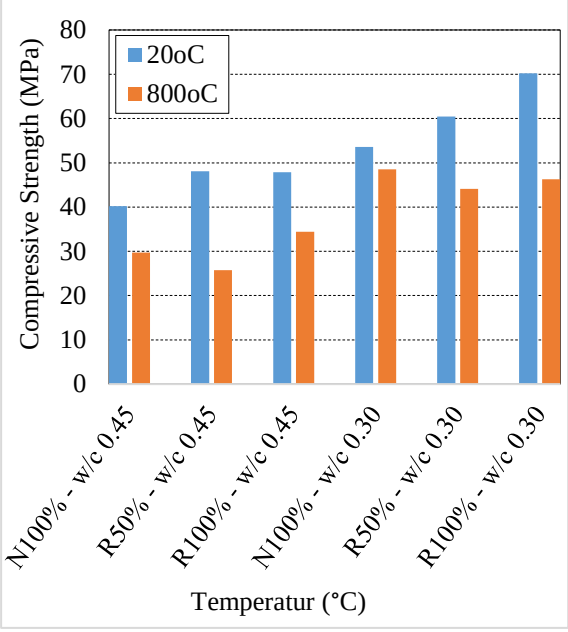

Fig.4 Concrete Compressive Strength After Exposure to 800°C

Similar to when exposed to 550°C, the highest compressive strength of concrete exposed to 800°C is in concrete with 100% natural aggregate (can be seen in Fig.4). Concrete with 100% natural aggregate shows better performance against exposure to 800°C compared to concrete with recycled aggregate.

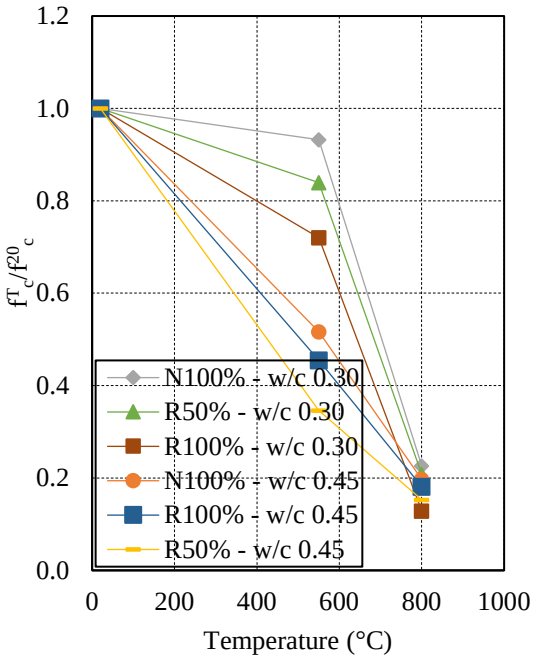

Fig.5 Concrete Compressive Strength Reduction Coefficient Due to High Temperature

Residual compressive strength tests (as shown in Fig. 5) revealed that the largest strength reduction at 550°C occurred in concrete with a water-cement ratio of 0.45 and 50% recycled aggregate content. In contrast, at 800°C, the most substantial decrease in strength was found in concrete with a water-cement ratio of 0.30 containing 100% recycled aggregate. Across all concrete mix variations, exposure to 800°C consistently resulted in compressive strength reductions ranging from 77% to 85%. This aligns with the findings in [17], which state that at 800°C, a significant reduction in strength results from the breakdown of the secondary phase of calcium silicate hydrate (C-S-H). The more pronounced strength loss in recycled aggregate concrete, compared to concrete made with natural aggregates, is mainly due to the inferior thermal resistance of the recycled aggregates. This is primarily due to their heterogeneous composition, which may include a mix of natural aggregate and old mortar, solely natural aggregate, or only mortar. When recycled aggregates contain more mortar and are exposed to high temperatures, the mortar tends to weaken and disintegrate so that the strength of the concrete aggregate decreases followed by a drop in the strength of the concrete itself.

Water cement ratio variation

For concrete mixes with a water-cement ratio of 0.30 containing 50% and 100% recycled aggregate, exposure to 550°C resulted in compressive strength reductions of approximately 14% and 23%, respectively. In contrast, concrete with a water-cement ratio of 0.45 experienced significantly greater losses, with strength reductions of 62% and 52% for the 50% and 100% recycled aggregate mixes, respectively. These findings suggest that a water-cement ratio of 0.30 offers better resistance to high temperatures up to 550°C. However, beyond this temperature, its performance tends to decline sharply. At temperatures of 550°C - 800°C, concrete with a water cement ratio of 0.45 is superior. When concrete is exposed to a temperature of 800°C, it is found that the water-cement ratio does not provide a significant difference in behavior to the compressive strength of concrete. This phenomenon also occurs in research conducted by Zega [18], where a gradual reduction in compressive strength occurred due to improved interaction between the old and new mortar in concrete with a lower water-cement ratio. This leads to more uniform thermal expansion between the aggregate and the mortar, minimizing thermal stress differences and, consequently, reducing crack formation in the interfacial transition zone (ITZ) and mortar. On the other hand, concrete with a water-cement ratio of 0.45 exhibits a relatively steady decline in strength. This is attributed to its higher water content, which absorbs and dissipates heat energy, thereby moderating the internal temperature rise. In contrast, concrete with a water-cement ratio of 0.30 contains less water, making it more vulnerable to thermal cracking under high temperatures. As a result, exposure to elevated temperatures leads to a sharp drop in compressive strength for concrete with a low water-cement ratio.

Compressive strength comparison of concrete with recycled, silica, and calcareous aggregates.

The settlement coefficient When subjected to elevated temperatures, recycled aggregate concrete shows determined from the test results, is compared to those of silica aggregate and calcareous aggregate concretes. The settlement coefficients for silica and calcareous aggregate concretes are established in Design Guidelines for Concrete Structures under Fire Conditions – Eurocode 2 [19]. In this study, the natural aggregate used is lime aggregate, as illustrated in Fig. 7. The settlement coefficient for the compressive capacity of concrete made with recycled aggregates falls between the values for silica and calcareous aggregate concretes. However, its behavior is more similar to silica aggregate concrete. This similarity can be influenced by the remaining mortar consisting of cementitious materials which usually contain significant amounts of silica. This makes the chemical composition of recycled aggregate similar to silica aggregate.

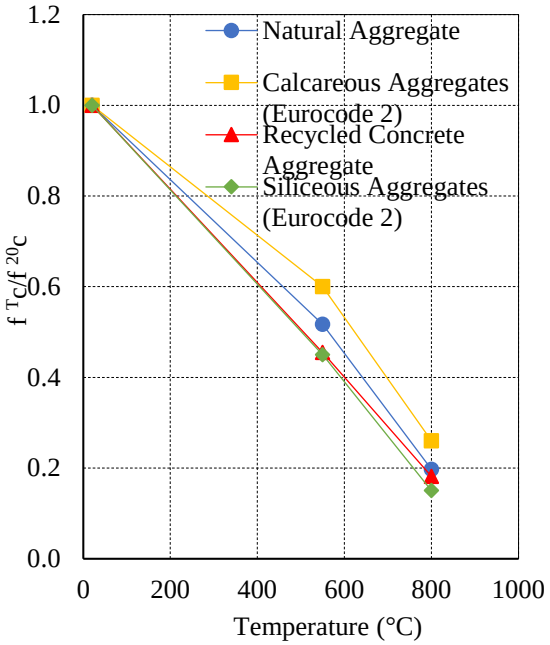

Fig.7 Comparative Analysis of Compressive Strength Reduction Coefficients in Recycled, Silica, and Calcareous Aggregate Concrete

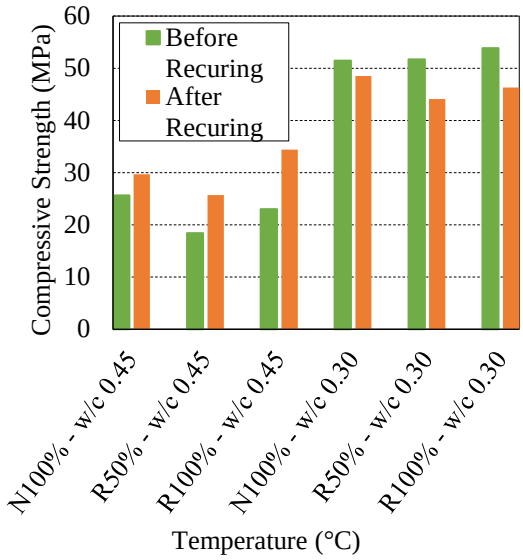

Fig.8 Residual Compressive Strength at 550ºC After Recurring

Evaluation of Re-curing Effects on Concrete Affected by High Temperature Conditions

According to prior research [20], water recuring can restore the strength and Post-fire durability of concrete by regenerating hydration products through the rehydration of CaO and hydration of unreacted cement. In this study, samples were soaked in water for 7 days. As shown in Figures 8 and 9, recuring improved the Strength characteristics of concrete using a 0.45 w/c ratio but reduced it in concrete with a 0.30 ratio. This decline is likely due to Delayed Ettringite Formation (DEF), which occurs in high-quality concrete when ettringite forms later during the recuring process after heat exposure. This is due to the lack of water availability during the recuring process. This DEF phenomenon can cause internal expansion and cracking which causes a decrease in strength. This DEF phenomenon occurs in concrete with recycled aggregates considering Excessive water uptake by recycled aggregates results in insufficient water that can be sufficient for the rehydration and hydration processes. A longer recuring duration in high-quality concrete may increase its strength.

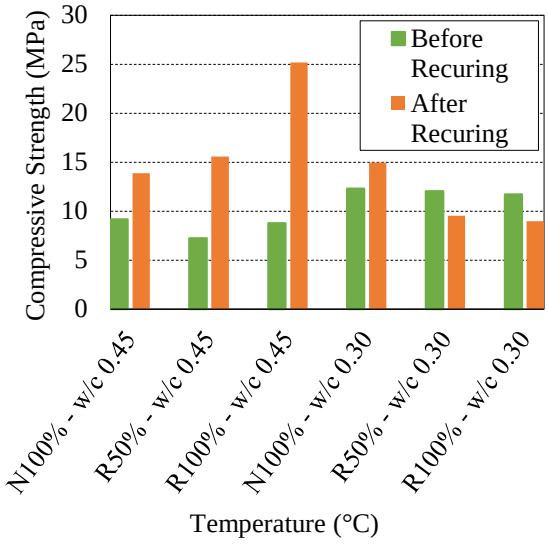

Fig.9 Residual Compressive Strength at 800ºC Temperature After Recurring

CONCLUSIONS

1. RAC exhibits a compressive strength reduction of 4%–62% at 550°C and 76%–87% at 800°C, significantly greater than NAC due to its lower thermal resistance, higher porosity, weaker ITZ, and pre-existing microcracks. Concrete with a 0.30 water-cement ratio shows a gradual strength loss up to 550°C, then a sharp decline at 800°C, while mixes with a 0.45 ratio display a more uniform strength reduction due to better heat absorption and dissipation
2. NAC performs better at a water-cement ratio of 0.45, while RAC performs slightly better at 0.30, although the difference is small. This is likely Because RAC has lower heat transfer properties made with normal-quality recycled aggregates. The strength reduction coefficient of RAC is between that of silica and lime aggregates, but its

behavior is more similar to silica aggregate concrete because the leftover mortar in recycled aggregates usually contains high silica content.

3. Recovery of compressive strength after 7-day water recuring: Concrete with a 0.45 water-cement ratio regains 53%–74% strength after 550°C exposure and 32%–40% after 800°C. In contrast, 0.30 w/c ratio concrete shows a further strength decline of 6%–15% (550°C) and 13%–16% (800°C) due to Delayed Ettringite Formation (DEF)

ABSTRACT

This study introduces a newly developed high-strength nut featuring a tension-control (TC) mechanism designed to deliver uniform pretension in structural steel connections. Drawing inspiration from the pin-tail fracture approach used in conventional TC bolts, the proposed nut integrates a shear-off tail that detaches at a predefined torque threshold. This innovation eliminates the dependence on torque-calibrated tools or custom bolt assemblies, enabling straightforward and consistent preload application. To evaluate its mechanical behavior, finite element analysis (FEA) was employed to simulate the stress distribution and torsional fracture process of the nut. Complementary experimental tests were conducted using high-strength steel bolt-nut assemblies compliant with ASTM A490M standards and categorized as Group 150 in AISC 360-22. Key performance metrics such as preload capacity, torque coefficient, and fracture behavior were assessed and compared with conventional high-strength bolts. The experimental results indicate that the TC-type nut delivers a pretension level comparable to or greater than the AISC-prescribed values. Moreover, the simplified installation process enhances usability and quality control. These findings confirm the feasibility of the proposed fastening solution as a practical alternative for achieving reliable pretension in steel structures governed by AISC design requirements.

Keywords: Tension-Control nut; Shear-off tail; Pretension; High-strength bolts; Steel structural connections; Finite element analysis

INTRODUCTION

Reliable bolted connections play a critical role in ensuring the structural integrity of steel frameworks. Among the various fastening systems available, tension-control (TC) bolts are widely adopted due to their ability to apply uniform pretension via a fracture-based mechanism. This mechanism typically involves a pin-tail designed to shear off when a specific torque is reached, thereby achieving a standardized preload without requiring direct tension measurement. The effectiveness of this method has led to its widespread application in structural steel construction.

However, conventional TC bolts still present notable limitations in practical use. The requirement for specialized shear wrenches increases tool dependency and complexity during installation. In addition, the length of the pin-tail must be tailored to the thickness of the connection components, which complicates inventory management and often necessitates multiple bolt lengths on-site. These constraints hinder operational efficiency and flexibility in field conditions.

To address these challenges, this study introduces a novel TC-type high-strength nut designed to replicate the fracture-based preload mechanism commonly found in TC bolts. By integrating a shear-off tail into the nut itself, the proposed system eliminates the need for custom bolt designs and torque-calibrated tools. This design innovation simplifies the assembly process and allows compatibility with standard high-strength bolts of various lengths.

The objective of this study is to develop and evaluate the structural performance of the proposed nut through a combined approach of finite element analysis (FEA) and experimental validation. The analysis focuses on the torsional fracture behavior, preload consistency, and comparative performance against conventional bolt systems defined by the AISC 360-22 standard.

DESIGN CONCEPT AND FEA

The proposed TC-type nut is engineered to provide consistent pretension by integrating a shear-off tail directly into the nut body. This tail is connected via a precision-machined shear groove, which serves as a predefined fracture point under torsional loading. When torque is applied during assembly, shear stress concentrates at the groove, resulting in a clean separation once the critical torque threshold is reached. This mechanism enables visual confirmation of proper pretensioning without the need for torque-calibrated tools.

In contrast to conventional TC bolts, where the fracture mechanism is built into the bolt itself, the

new design transfers this function to the nut. This modification allows compatibility with standard high-strength bolts of varying lengths, regardless of joint thickness. Consequently, the proposed nut enhances installation flexibility, simplifies inventory management, and reduces dependence on bolt length variations.

To assess the structural behavior of the proposed design, finite element analysis (FEA) was performed using Abaqus/Explicit. The 3D models were created in Autodesk Inventor and included the nut body, shear tail, and loading plates. C3D10 tetrahedral elements with a 0.5 mm mesh size were used to capture localized stress accurately. Boundary conditions fixed the bolt and plate, while a torsional moment was applied to the shear-off tail.

The simulation results confirmed that shear stress was concentrated along the groove, and the nut consistently fractured at the intended location. For both M16 and M20 configurations, the resulting axial forces exceeded the design pretension values of 114 kN and 179 kN as specified in AISC 360-22. These results validate that the proposed TC-type nut can achieve structural performance equivalent to, or better than, conventional TC bolts.

Fig. 1 illustrates the conceptual tightening sequence of the proposed TC-type nut, from hand insertion to the fracture of the pin-tail under applied torque.

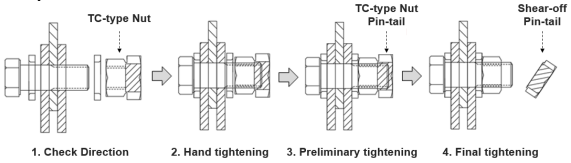

Fig.1 Structural concept of the TC-type nut

Fig. 2 presents the von Mises stress distribution obtained from the FEA simulation, highlighting the stress concentration at the shear groove that leads to controlled fracture.

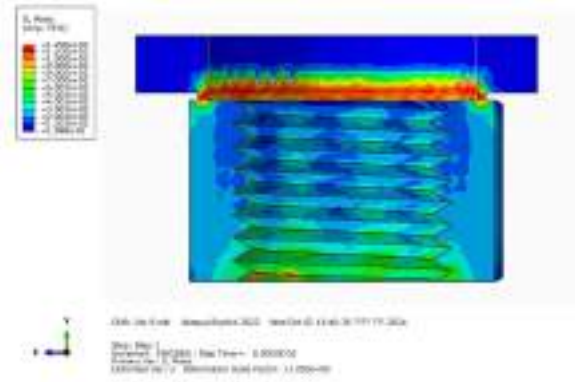

Fig.2 Stress distribution simulated by FEA

EXPERIMENTAL METHOD

To evaluate the preload behavior and loosening resistance of the proposed TC-type nut, a series of experimental tests were conducted. The experiments were designed to simulate actual steel connection conditions and compare the proposed nut with conventional high-strength bolts and TC bolts under repeated lateral displacement.

Test Specimens

Bolt-nut assemblies were fabricated using high-strength steel bolts conforming to ASTM A490M specifications, classified as Group 150 under AISC 360-22. Two bolt sizes, M16 and M20, were used in combination with the developed TC-type nuts. The nuts were manufactured from medium-carbon steel and included an integrally machined pin-tail with shear groove thicknesses ranging from 0.60 mm to 0.80 mm for M16, and 1.00 mm to 1.20 mm for M20. The naming convention for each specimen follows the format. "TC" denotes the tension-control type nut, "M16" represents the nominal bolt diameter, "A" indicates the lubrication condition (A: with lubrication, B: without lubrication, AI: with lubrication and impact wrench), and "60" refers to the shear groove thickness in hundredths of a millimeter (i.e., 0.60 mm).

Test Procedure

Each specimen was preloaded by installing the nut and tightening it until the pin-tail fractured, indicating completion of the preload. After pretensioning, cyclic lateral displacement was applied under constant frequency. The test was continued until the axial force dropped below 120 kN for M16 bolts and 185 kN for M20 bolts. The retained axial force was recorded at regular intervals to evaluate the loosening behavior.

RESULTS AND DISCUSSION

This section presents the results from both finite element analysis and experimental testing, with a focus on validating the fracture mechanism and evaluating preload performance of the proposed TC-type nut.

Fracture Behavior Validation

The fracture behavior of the TC-type nut was confirmed through both finite element analysis (FEA) and physical testing. As shown in Fig. 2, the torsional stress concentrated at the shear groove resulted in a controlled fracture, which was consistently reproduced in all specimens.

The fractured specimens shown in Fig. 3

demonstrate clean and reproducible breakage at the designed shear groove, validating the reliability of the fracture-based tightening mechanism.

Fig. 3 Fractured shapes of TC-type nuts after final tightening

Preload Capacity of M16 Series

Fig. 4 illustrates the average axial forces measured from the M16 series with five different shear groove thicknesses (0.60 to 0.80 mm) and three tightening conditions (Type A: with lubrication, Type B: without lubrication, Type AI: with lubrication and impact wrench).

The results show that as the groove thickness increased, the axial force generally improved. The AI-type consistently showed the highest performance. While several specimens with thinner grooves (e.g., 60 mm, 65 mm) failed to reach the AISC 360-22 minimum pretension (114 kN), specimens with 75 mm and 80 mm grooves all exceeded this threshold under all tightening types.

These results suggest that an SGT of 0.75 mm or more is optimal for M16 bolts.

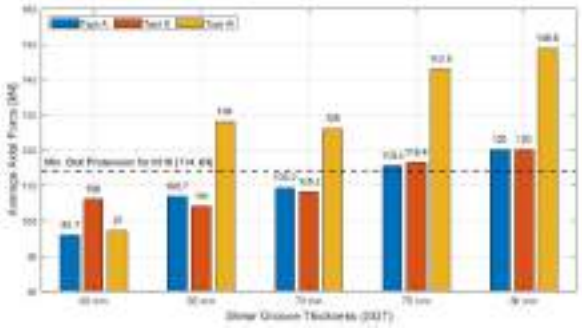

Fig. 4 Average axial force of M16 series by shear groove thickness and tightening condition

Preload Capacity of M20 Series

Similarly, the M20 series results are shown in Fig. 5, covering groove thicknesses from 1.00 mm to 1.20 mm. Type AI achieved the highest axial forces in all cases, with values ranging from 200 kN to 216 kN. For Type A and B, the optimal groove thickness was found to be 1.10 mm, where both types exceeded the minimum required pretension of 179 kN. This confirms that a groove thickness of 1.10 mm is suitable for M20 configurations, achieving both structural reliability and efficient fracture under torque.

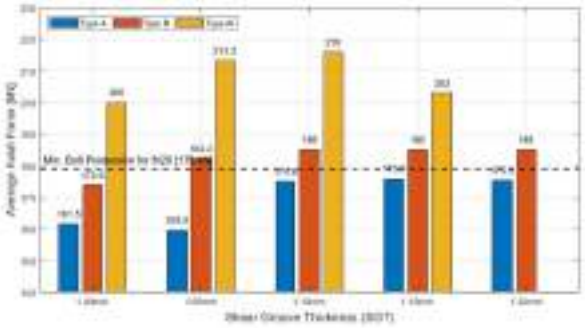

Fig. 5 Average axial force of M20 series by shear groove thickness and tightening condition

CONCLUSIONS

This study developed and evaluated a novel TC-type high-strength nut that applies a fracture-based pretension mechanism by integrating a shear-off tail into the nut body. Finite element analysis and experimental testing were conducted to verify its structural performance.

The results confirmed that the proposed nut successfully replicates the fracture mechanism of conventional TC bolts, providing consistent pretension without requiring torque-controlled tools. All test specimens exhibited reliable fracture behavior at the machined groove, and the resulting axial forces exceeded the minimum values specified by AISC 360-22 for both M16 and M20 bolts.

Parametric testing of the shear groove thickness identified the optimal configurations to be 0.75 mm for M16 and 1.10 mm for M20. These values balance fracture reliability and pretension capacity, while also ensuring compatibility with standard bolt assemblies.

The proposed TC-type nut demonstrates equivalent or improved structural performance compared to conventional systems, while simplifying installation and enhancing field applicability. These findings suggest that the new fastening solution offers a practical and efficient alternative for structural steel connections requiring consistent preload.

ABSTRACT

In concrete mixtures, Portland cement is a common building material. By replacing some of the cement with supplemental cementitious materials (SCM), concrete mixtures can be made more environmentally friendly, their qualities improved, and their cost decreased. This study investigates the mechanical performance of self-compacting concrete (SCC) incorporating two SCMs, zinc ash (ZA) and blasting grit (BG), industrial waste by-products, as partial cement replacements. The average particle size for BG and ZA are 300 nm and 60 nm, respectively, with high specific gravity, and spherical shaped powder. The tests were created using response RSM, and the mix proportions were tuned to get the best results. Using a Box-Behnken design under Response Surface Methodology (RSM), experiments were conducted to model and optimize the compressive (CS) and flexural strength (FS) of SCC to develop mathematical models. The independent variables were mass percentages of ZA (0–0.75%), BG (0–1.5%), and curing time (7, 14, 21 or 28 days). Analysis of variance (ANOVA) confirmed the statistical significance of the models, with R^2 values exceeding 95% for both strength properties. The optimal mix was found to be 0.5% ZA and 1% BG, which resulted in a 21.2% increase in 28-day CS and a 17.8% improvement in FS compared to control mixes. The combined use of ZA and BG not only enhances mechanical properties but also promotes waste valorization in concrete production. The RSM provided a reliable predictive model for identifying strength-efficient mix proportions, offering a practical tool for sustainable SCC mix design.

INTRODUCTION

Self-compacting concrete (SCC) is considered as a new construction material with the adaptability to pass through small areas, around rebar, and under formwork, is the key development in structural concrete in the last few years. It coagulates due to gravity alone; no further vibration, separation, or aeration are needed. To make the paste more viscous, a viscosity modifier can be added [1]. These frequently contain polymers consisting of long-chain molecules that may absorb and immobilize free water molecules. It is crucial to verify all the fundamental hypotheses and test findings of the design model of the SCC structure [2] since this mixed design modification might alter the material's mechanical characteristics. Concrete was initially employed in building construction perhaps less than a century later. With the increased usage of concrete, however, substantial research has recently been effective in enhancing its qualities by adding different extra cementitious ingredients, such as pozzolans and nanoparticles [3].

Recent advances in nanotechnology have drawn significant scientific interest to new uses of particles with a size of 10–9 nanometers or less. This could be because materials with the same chemical make-up lack the qualities that nanoscale particles do [4], which are significantly superior in terms of particle size. Six different iterations of the ideal SCC were created, using different design methodologies like statistics, factorial design, etc. Particle packing and mixed design, often known as Eco-SCC, were used to build high-performance SCCs and their SCC-Design [5].

Investigated the likelihood of mistakes and uncertainties. To considerably replace up to 63% of the cement in fly ash slag, research is being done to create SCC [6]. Lightweight SCCs (LWSCCs) that are simple to deploy and made of lightweight concrete (LWC) have been investigated for mixed ratios, densities, and mechanical qualities [7-8]. In the coarse aggregate and mortar stages of the SCC, five suggested design approaches—statistical factor models, compressive strength (CS) techniques, dense filling methods, paste model rheology, and empirical design methods were investigated [9]. The design of SCC compounds and the link between their properties and fresh and tempered attributes were studied empirically [10]. The compressive

strength, split tensile strength, and durability of SCC with silica, metakaolin, rice husk incineration residue, and fly slag (10% and 20% of cement load) samples after 7 and 28 days revealed better attributes of freshly installed and cured concrete [11].

The mechanical characteristics of palm oil fuel powder (POFA), an agricultural waste that is risky to dispose of unless it is recycled, were originally deteriorated with the goal of forming a sturdy SCC as a partial cement substitute [12]. In addition to SCC with SiO_2, TiO_2, and Al_2O_3 nanoparticles, fresh concrete's rheological qualities as well as the physical and mechanical characteristics of hardened concrete were improved, demonstrating the effectiveness of this technique [13]. When tested under standard corrosion and sulphate attack circumstances, SCC combined with POFA at varied concentrations (10%, 15%, and 20%) demonstrated good mechanical and durability qualities of SCC with corrosion and sulphate destruction. Additionally, drying shrinkage and surface moisture absorption are decreased without negatively compromising compressive strength [14]. By mixing red mud with nanoparticles of SiO_2, Al_2O_3, and CaO, fresh concrete and hardened SCC were produced, both of which had increased compressive strength as determined by XRF and XRD [15].

Additionally, incorporating red mud into SCC increased its shear strength and modulus, which decreased drying shrinkage. In SCC, fly ash (FA) and ground blast furnace slag (GGBFS) were combined in varied ratios (20, 30, and 40%). Mechanical qualities are negatively impacted by decreased wet density, increased cement setting time, and early water porosity [16]. Effect of waste volume on the final mortar's rheological and strength properties Sandblasting chemicals have substituted natural sand partially or entirely, which has decreased the expense of disposal and storage [17]. This experimental work using cement mortar revealed that compressive strength reduces with increasing nano concentration, particularly with nano SiO_2 and 0.5% ZnO_2 [18]. The effects of solid waste-derived zinc on the delay of hydration and loss of mechanical characteristics of zinc-containing Portland cement diminish both the maximum temperature and heat flux [19]. When ZnO_2 powder and water were mixed at a certain constant (W/Z), phase composition, crystal structure, and microstructure of cement composites were examined. It was discovered that the zinc hydroxide ($Zn(OH)_2$) phase had an impact on hydration delay (>48 h) [20].

Concrete's ability to hydrate is slowed down by the usage of electric arc furnace dust (EAFD), which emphasizes the necessity for alternate recycling. Cement pastes were studied using a ZnO_2 cement hydration model. By lowering cement mortar shrinkage and interacting favorably with calcium hydroxide, Zinc oxide nanoparticles have been discovered to significantly affect the microstructure and mechanical characteristics of cementitious materials [21]. By boosting their mechanical strength and longevity, Zinc oxide nanoparticles enable concrete's compressive strength, strength, and the hydration of cement particles.

Rich in zinc oxide, zinc ash, a by-product of the galvanizing industry, can improve cementitious systems' pozzolanic activity and filler effect. Because of its angular shape and mineral content, blasting grit—an abrasive leftover from surface treatment processes—helps to promote particle packing and mechanical interlocking. When used together, they encourage recycling of garbage and may improve SCC's strength performance.

There hasn't been much investigation into the use of nanoparticles to SCC to enhance its mechanical and physical qualities [5]. The nanoparticles' strong reactivity makes them operate as a heterogeneous core for the cement paste, which further encourages cement hydration [22-23]. They also serve as nano-fillers and nano-reinforcers, increasing the microstructure's density and lowering porosity [24]. For all nanoparticles, effective dispersion is a significant issue [5-7]. The "smart" (temperature and strain measurement) and hyper mechanical potential of cement mortar combined with nanoparticles.

RESEARCH SIGNIFICANCE

To date, research has, however, mostly concentrated on employing microscale cement replacement materials to attain superior strength performance without applying Response Surface Methodology (RSM) for multi response optimization. How ultra-fine and nanoscale particles impact the properties of concrete in optimum way is still a mystery with various mix proportions and curing period [25]. While silica fume, fly ash, and metakaolin nanoparticles have been studied in SCC, comprehensive study on the combined usage of ZA and BG nanoparticles is lacking, especially when it comes to mechanical performance modeling utilizing statistical techniques like RSM.The current work employed ZA and BG nanoparticles to find impact of them on compressive, flexural, and pore structure measurements on the concrete including obtaining mathematical models, optimum input values using RSM, while encouraging the utilization of environmentally friendly industrial waste.

MATERIALS AND TEST METHODS

Raw Materials

Ordinary Pozzolana Portland Cement (PPC) that complies with ASTM C150 standard was utilized in this study. Table 1 provides information on the cement's chemical and physical characteristics.

When producing self-compacting concrete or regular concrete, aggregates with a 60mm average size are employed. Molten zinc metal produces zinc oxide (ZnO), commonly referred to as zinc ash (ZA), which is oxidized zinc. Hot dip galvanizing and other zinc coating procedures are the typical sources of zinc ash (Figure 1 a). To create zinc oxide suitable for agricultural use, another person combines the zinc ash. Various procedures, like galvanizing, make use of the metallics once again. Other people recovered the zinc in metallic form by smelting both treated and raw ashes. The formation of SCC, high-performance concrete, depends heavily on chemical additives like water reducers, retarders, viscosity modifiers, flow agents, and superplasticizers. Without impacting the strength of the concrete, an effective superplasticizer may minimize slump and water by 20–30%. Depending on the kind of concrete that is needed, the dose ranges from 0.5 to 2% by weight of cement. The mixed water came from the tap. Since steel grit/steel shot is softer than aluminum oxide and doesn't shatter as easily, it is frequently used in airless applications. Additionally, it is used in direct weight applications where a large profile is necessary. When shot peening ferrous materials, steel shot is used. Metallic abrasives are ideal for shot peening and airless impacting because of their extended lives. Table 2 shows the compositions of ZA and BG.

Table 1 Portland cement's characteristics (chemical and physical)

Mix Proportion Design of SCC

Using the absolute mass method, the SCC mixture fraction was constructed in this study. The SCC required a compressive strength of 69 MPa. This is standard for concrete of strength class C60 with a guaranteed rate of 95%. The objective workability characteristics of fresh SCC are slump greater than 260 mm, slump greater than 700 mm, flow time T500 less than 5 seconds, and a density of at least 2450 kg/m3 is preferred for fresh SCC. A total of four sets of mixtures were prepared for SCC using the relevant factors shown in Table 3.

Table 3. Self-Compacting Concrete mix proportions

Materials	C	ZA	FA	BG	AC	CA	W	W/C	SP
SCC1	466	0	1016	0	0.02	747	186	0.4	6
SCC2		1.165		2.4	0.015				
SCC3		2.33		4.8	0.01				
SCC4		3.495		7.3	0.005				

Preparation for Test Specimens

Cement, ZA and BG nanoparticles of average 200 nm, coarse aggregate, and fine aggregate were mixed in a laboratory concrete drum mixer to create the SCC. Cement, various mass percentages of ZA (0,0.25, 0.5, and 0.75), and BG were all included in the powder (0, 0.5, 1, 1.5). Water was then added, and the mixture was dry combined for 2 minutes before being mixed again for 3 minutes. Following mixing, samples of ready-mixed concrete were tested for flexural strength (FS). The supplied concrete CS is assessed in terms of the specific 150 mm cubes evaluated after 28 days. The stated code of practice determines the strength of these specimens, which are cured for 28 days, guaranteeing that 95% of tested cubes fulfil this criterion [14]. The ASTM C293 Standard. Like the tensile tests, flexural tests were carried out on three specimens and average flexural strength values were obtained. After being saturated for 24 hours, the molds were wrapped with polyethylene sheets. Prior

to the experiment, the specimens were demolded and given a water cure at 20 °C. The concrete specimens underwent FS testing on 7 and 14 days. The averaging of three replicates produced the results that were presented.

Compressive Strength Test

The strength of the cement that not more than 5% of test results are anticipated to fall below is known as the typical strength. The concrete cube test's compressive strength gives information about all of concrete's properties. One may determine whether concrete work has been done properly by using this test. Concrete's compressive strength is calculated using a typical 150 mm cube whose compressive strength was tested after 28 days. Concrete specimens that have been cast, tested, and cured for 28 days are considered to have characteristic strength; 95% of the tested cubes should not have that is less than this value [24]. Figure 2 shows the Compressive Strength Test kit.

Fig. 2 Compression test set up

Flexural Strength Test

The load at which the material fails under bending is referred to as this bending strength. Analyze the non-reinforced concrete beams' or slabs' resistance to lateral failure. An unreinforced concrete slab, beam, or other structure's flexural strength is the amount of force and pressure it can bear before ceasing to bend. Flexural strength is sometimes referred to as breaking strength, rupture modulus, or flexural strength. For bend testing, beam specimens in the sizes 150mm length, 150mm width, and 700mm height and 100mm length, 100mm width, 500mm height were tested. These samples are put through bending tests in accordance with ASTM C-293 and the Structural Design Qualification Standard as a universal guide of concrete strength. The average flexural strength of SCC samples was assessed utilizing three samples and a simple central loaded beam. Figure 3 shows the Flexural Test Set up

Fig. 3 Flexuraltest set up

RSM for Mathematical Modeling

Statistical analysis provides meaning, breathing life into the data and useful statistical tests can produce precise conclusions from the results. It provides a brief definition of the variables, an understanding of quantitative yet distinguishing variables, and measures of central tendency. To ascertain the link between a collection of independently quantifiable parameters and one or more answers, the Response Surface Methodology (RSM) combines mathematical and analytical methodologies [26, 27]. Finding functional parameters that may or may not have a major impact on the underlying reaction is possible using RSM [28]. RSM may also be thought of as a collection of analytical and mathematical problem-solving methods. The outcomes are influenced by several elements (input variables) [26]. RSM is especially beneficial for multidimensional models because it sets desirable objectives in terms of responses or variables [29]. There are several design models accessible, including Central Composites (CCD), Box-Behnken, and historical data. Both independent variables and correlated arithmetic results can be produced with them.The arithmetical correlation response and independent variables may be produced using these. The number of variables and each variable's variance are important factors in determining the sort of design model [26]. Equation (1) illustrates the use of a second-order function with a higher degree polynomial model [11].

$$y=\beta_0+\sum_{i=1}^{k}\beta_i X_i+\sum_{i=1}^{k}\beta_{ii}X_{2i}+\sum_{i<1}\sum_{j}\beta_{ij}X_iX_j+\xi \quad (1)$$

The CCD contains a factor planning component of 2k, where k is the quantity of connected variables or factors that are handled at two levels of a low and high value [24] using positive and negative values are used to code where the average of these limits serves as the focal point of it. The Zero-Point region that satisfies ideal requirements is called focal point. RSM from Minitab version 23 software was employed in this work to design the experiment and conduct a statistical analysis in constructing the mathematical relationships between the variables and the responses. To model a variable using RSM, a series of procedures must be followed to realize the research goal, which necessitates identifying the research problem based on the established objectives for research optimization. The four levels of nanoparticle (ZA and BG) substitution for fine aggregate and curing period were the independent factors considered. The type of experimental design—CCD under RSM using total of 20 mix combinations were tested, each with triplicate specimens for compressive and flexural strength tests to ensure data reliability.

RESULTS AND DISCUSSION

The experimental strategy comprises examining the effects of six factors on the establishment of strengths under various degrees of control. From the experimental designs, 20 trial runs were chosen to determine the best conditions. The technical information sheet and some preliminary tests were used to determine the lowest and highest levels for variables. Table 4 displays the design matrix for the 20 trial runs. The results of investigations on solid states (different weight percentages of nanoparticles, such as ZA and BG, and curing times between 7, 14, 21, 28 and 56 days compressive and flexural strengths) were statistically assessed using design of experiments. The effort aimed to enhance compressive and flexural strengths depending on selected factor values with the least 20 number of tests possible.

Flexural Strength

Nano composite particles are used to test the flexural strength of SCC. Out of SCC1, the reference mix, 4 other types of mixes were created, with 0% fine aggregate and ZnO and BG additions to the cement. Mass percentages of ZnO (0 to 0.75% @ 0.25%) and of BG (0 to 1.5%@ 0.5%) in the remaining types of combinations. Figure 4 shows the curing period over a 28-day, mix SCC3's flexural strength is 10% higher than mix SCC1's. The quick consumption of Ca $(OH)_2$ framed by Portland Pozzolana during cement hydration at young ages, along with the strong reactivity of nano-sized zinc oxide in cement particles, is what causes the significant increase of flexural quality in nano composites concrete. As a result, cement hydration is accelerated, and more response elements are framed. Additionally, nanocomposite particles restore the concrete's molecular density, which reduces the amount of large holes in the material. The best results were obtained at 0.5% ZA and 1% BG addition, although later addition of the nano composites to self-compacting concrete causes a decrease in the concrete's flexural strength while bringing the test results for SCC_4 closer to the control mix. It might be because there are more BG and nano-zinc oxide particles in the blends than is necessary for them to consolidate with the unmanaged lime throughout the hydration process, which causes excess silica to drain out and lowers quality because it takes the place of some of the cementitious material without improving performance. Furthermore, powerless zones may be caused by the deformities that result from the dispersion of nanoparticles. As can be observed, the insertion of nanoparticles reduces the pore area of self-compacting concrete while simultaneously increasing its density using nanocomposites. So, the self-compacting concrete's pore structure is enhanced.

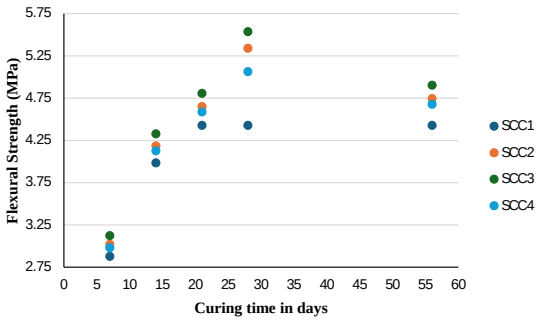

Fig.4 Flexural Strength vs curing time

Table 4 displays the effects of all parameters, including those of type A_1 to A_4, on the flexural strength of SCC. Table 5 provides a summary of the ANOVA findings holding p-values for each flexural strength parameter. The major implications (A_1, A_2, A_3, and A_4), the quadratic impact of A_4*A_4, and the interactions (A_1*A_4, A_2*A_4, and A_3*A_4) were all statistically meaningful at the 95% level of confidence (p 0.05), according to the p-values.

Only the Curing period A4 was noteworthy as the primary influence for the flexural strength. The quadratic relationships of the A_4*A_4 and the interactions of A_3*A_4 were also statistically significant ($p<0.05$), suggesting that the impact on the flexural strength was not straight or that the response surface had curvature. The regression coefficients for the models are displayed in the coefficient columns (Table 5), which represent the average changes in solution when one factor's

level is changed while keeping the levels of the other components of the model remain the same. For illustration, it is clear from ANOVA that when ZA is 0.5% and BG is 1%, the flexural strength will improve significantly when the level of the curing period is increased by one.

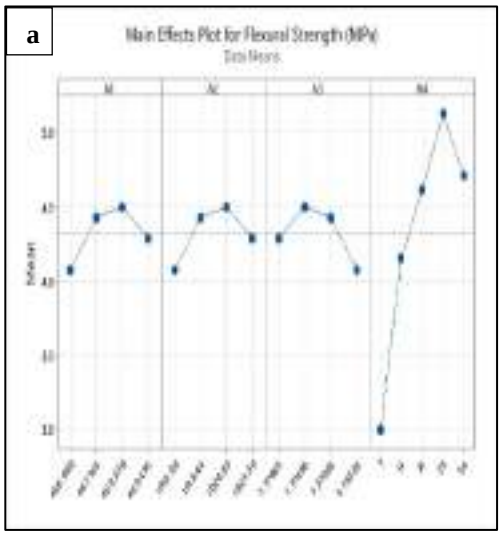
	0.189241	96.55%	94.04%	73.67%	

Equation (2) shows the polynomial functions that match the data and explains the bulk of the deviations in the flexure strength. These polynomial functions contain linear terms and 2nd order terms, which include both nonlinear and two-variable interaction terms.

Flexural Strength (MPa)= 58100 - 87.5 *A1 + 23.2* A2 – 10829* A3 + 700* A4 - 0.002336 *A4*A4 - 0.90 A1*A4 + 0.207* A2*A4 – 130*A3*A4 (2)

Figure 5a and 5b, which depict the main effect plots and Pareto diagrams of the standardized impacts for flexural strength, show that factor A4 (curing period), which had the most positive or biggest influence, was followed by factors A2 and A1 (BG% and ZA%). Another noteworthy element was the quadratic component A4* A4, which affects the response in conformity with a second order polynomial. The entire collection of standardized residuals in Figure 5c also illustrates the statistical relevance of the data distribution being close to the baseline line graph. The equivalent models of flexural strength are found to account for 96.4% and 83.2% of the total variation by the adjusted coefficients of regression (R^2(adj)) in Table 4. The predicted coefficients of results (R^2(pred)), which were predicted to be 94.04% and 73.67%, respectively, demonstrated how well the models predicted the data.



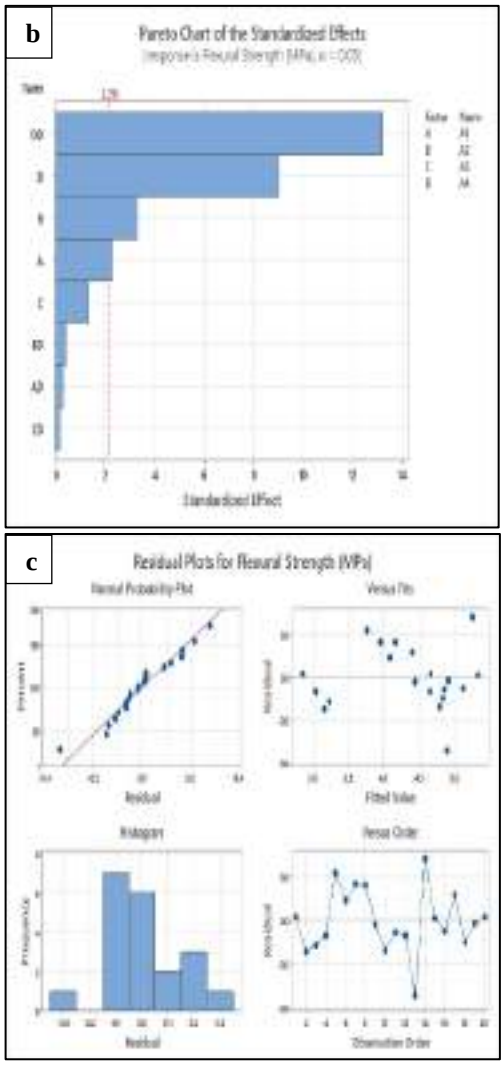


Fig. 5 (a) main effect plots and (b) Pareto diagram of the standardized effects for flexure strength

The surface plot of flexure strength (Figure 6a to 6e) on the 3D contour plot shows that it may reach a maximum of 4.9 MPa when varying two distinct factors while holding the other two constant. Similar values for other factors for the percentage of nanoparticles were also observed to have an impact on the FS. To verify the statistical models' estimated values for the FS of the SCC, they were tested experimentally in a lab under identical circumstances.

Compressive Strength

Table 4 displays the results of the four factors' effects on CS, including the curing times of 7, 14, 21, 28- and 56-days. An ANOVA's findings for CS are shown in Table 6, where the p-values reveal that the four main effects (A1 to A4), the quadratic components of A4, and the interactions A1*A2, A2*A4, and A3*A4 were statistically meaningful at the 95% confidence level for the examined levels. According to the P-values, only the curing duration has a significant positive impact on individual and quadratic terms, and the ratio of nanoparticles (ZA+BG) was significant when there was interaction ($p<0.005$). Introduction of nanoparticles and a 28-day curing period resulted in an increase in compressive strength.

Equations depict the polynomial functions used to describe the connection in both the observed strengths and the variable levels (3).

Compressive Strength (MPa) = -136030 - 287*A1 + 178*A2 + 23494*A3 + 19015*A4 -0.02266*A4*A4 - 6.7*A1*A4 - 2.76*A2*A4 – 3457*A3*A4 (3)

According to the high R^2(adj) values for the CS, the model explains 95.69% of the total variance. As shown by the anticipated coefficient of determination value of 85.46%, the model is reasonably predictable. Figure 7b displays the Pareto

diagrams of the standardized effects for CS, and all terms that cross the reference line are marked as statistically significant at the 5% level. These plots demonstrate that the curing length (A4), with Figure 6a displaying the sole level 4 (28-day) curing period rise in strength, is the factor at both the single and nonlinear terms having the biggest influence on the CS. Every increase or decrease over this threshold of the component denotes a reduction in the strength results. The distribution of the data matched with the trend line in Figure 7c's residual plots, which displays the normal distribution, indicates that the data are statistically meaningful. The biggest negative coefficient in the equation, A1, causes the compressive strength to decline. However, even though it is a quadratic term with curved lines, A1 was statistically significant.

A1's varying effects on compressive and flexural strength are probably caused by ZA's microfiller behavior, which densifies the matrix to increase compressive strength but might not have as much of an impact on tensile stress distribution, which controls flexural performance. Imperfect dispersion or interfacial gaps between the grit and cement paste may provide uneven results in A3, where a larger percentage of BG is present. This locally reduces flexural performance while still enhancing compressive strength through particle packing.Uneven, angular particles in BG are seen in the SEM images (Fig. 1); these particles enhance interlock but might create micro-voids if overused. The tiny, porous shape of ZA aids in matrix densification and the filler effect.

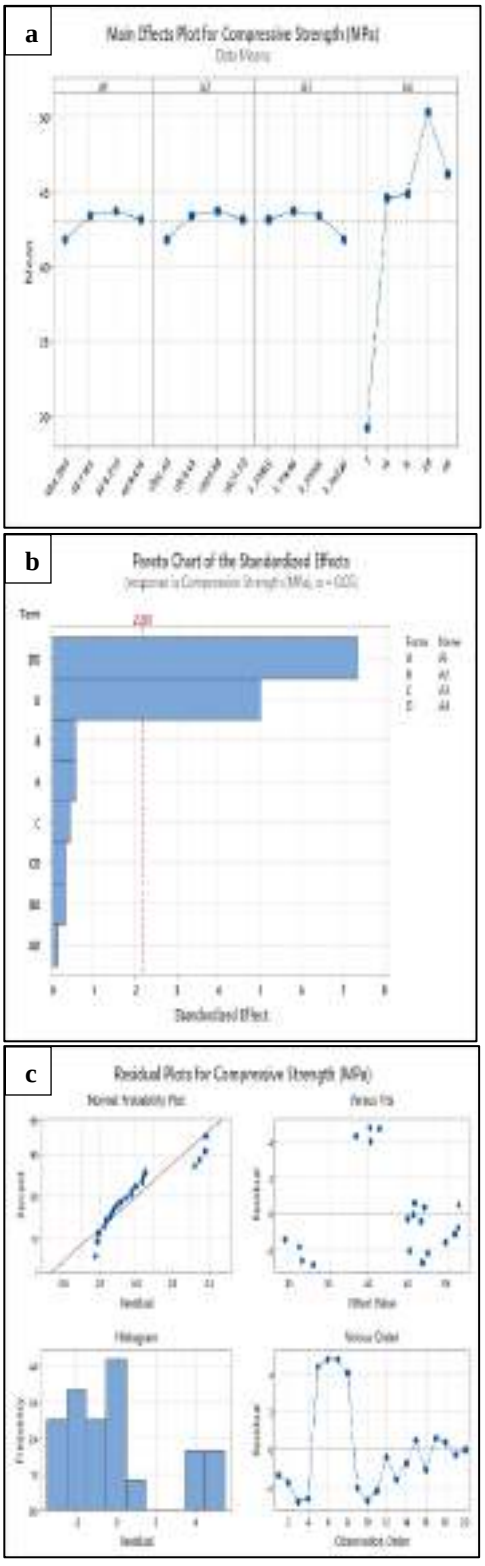

Fig. 7 (a) Main effect plots, (b) Pareto chart of the standardized effects for compressive strength, and (c) residual plots

The addition of nanoparticles shows the enhancement in the results of the strength of concrete with nanoparticles as compared to concrete

without nanoparticles. It is obtained in normal concrete about compressive strength that is same as the compressive strength results of SCC shown in Figure 8. SCC3 shows a 10% increase in compressive strength of SCC than SCC1. There is continuous improvement in compressive quality in the nano composites SCC are because of the drastic consumption of Ca (OH)2 framed by Portland Pozzolana during hydration cement at early stages identified with the increased reactivity of nanosized zinc oxide in cement elements. Therefore, cement hydration is quickened, and greater quantities of response items are framed. In addition, nanocomposite particles regain the concrete's molecular density, leading to fewer big pores in the concrete. The optimum results were obtained at 0.5% addition but later further addition of the nano composites in SCC gives the decreasing results of the CS but results of test of SCC4 observed nearer to the control mix. The similar effect of incremental CS of SCC with different types of nano particles in concrete [6]. It was experienced such an increase in CS of SCC in occurrence of Jarosite [25]. It may be due to the rise in nano-zinc oxide particles present in the blends greater than the amount necessary during the hydration process to consolidate with the uncontrolled lime, causing excess silica to drain out and causing lack of quality as it substitutes some portion of the cementitious substance, and it doesn’t add to the performance. Additionally, it might be because of the deformities created in scattering nanoparticles that cause powerless zones. It is evident that with the addition of nanoparticles, gives decrease in the pore area of SCC and at the same time nanocomposites increases the density of the SCC. As a result, the SCC's porous structure has been enhanced.

Uneven, angular particles in BG are seen in the SEM images (Fig. 1); these particles enhance interlock but might create micro-voids if overused. The tiny, porous shape of ZA aids in matrix densification and the filler effect. The observed patterns in strength responses can be explained by the considerable effects of dose and dispersion on the efficiency of these particles.

Multi-Objective Optimization Response Analysis

To maximize the specimen's strength performance using nanoparticles, ratio of nanoparticles to cement and fine aggregates, and curing time, multi-objective optimization has been done using RSM. The process of finding the ideal combinations of the factors that may be employed to generate the best SCC performance outcomes. In the specified water/cement, coarse aggregate into SCC mix, the nano particles (ZA+BG) were used as a partial replacement to cement and sand aggregates. The maximal compressive strength and flexure strength were both attained throughout the curing phase. In Table 7, the multi-objective optimization outcomes derived from the RSM using Minitab software are shown along with a summary of the optimization criteria. The SCC mixes performed best when 0.5% ZA and 1% BG, at a given fine aggregate, were substituted with water/cement of 0.4 for 28 days per mix. The ideal mix percentage achieved has a high attractiveness of 100%.

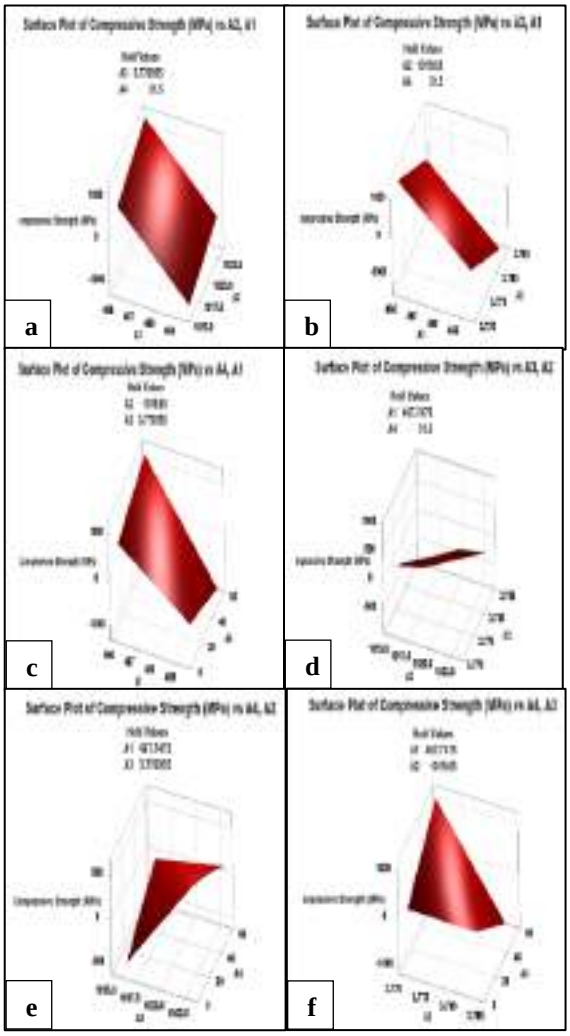

Fig. 8 3D Response surface plot for CS with (a) A_1xA_2 (b)A_1xA_3 (c)A_1xA_4 (d)A_2xA_4 (e)A_2xA_4 and (f)A_3xA_4. Wide prediction intervals and the existence of negative values, especially in forecasts for flexural strength, indicate model uncertainty and potential extrapolation outside of the range of valid data. Increasing the number of experimental runs, particularly at critical ZA and BG concentrations, may assist narrow confidence limits and increase model resilience,

Confirmation Experiments

If the deviation is within the limits imposed by the statistical models of RSM are confirmed using trial results utilizing combinations of attributes for CS and FS. When the expected trial outcomes are compared, the percentage deviation is calculated and reported in Table 8 by calculating the ratio of trial and predicted to trial value. Deviation demonstrates that the selected approach has a strong acceptance limit.

Table 8. Validation of results for CS and TR

Table 8 that shows strong consistency and model dependability, with an average forecast error of 5.4% for CS and 6.1% for FS throughout all curing times. Notwithstanding considerable variation in the forecasts, this overview serves to support the model's utility. The possibility that batch-to-batch variations in the ZA and BG, inconsistent hand mixing, or localized nanoparticle agglomeration may be the cause of certain discrepancies above 10%. These elements may introduce outliers that the model is unable to detect and affect the mechanical response**.**

CONCLUSIONS

The greater flexural strengths of the concrete containing ZA and BG nanoparticle blends demonstrated that cement may be successfully substituted with these at the optimal levels of ZA (0.5%) and BG (1%). The strength and pore structure of concrete are both enhanced by the inclusion of nanoparticles overall. One way that nanoparticles can improve concrete is by acting as a filler to increase its density, which greatly reduces

the porosity of the concrete. Nanoparticles, on the other hand, can also serve as a matrix in cement paste because of their enhanced activity, which limits the dimensions of the Ca (OH)2 particle and increases the possibility of tropism. They can also function as an activator to quicken the hydration of cement.

Additionally, the experiment was planned to use RSM, and models were created to estimate the strength performance of SCC mixes in terms of nanoparticles (ZA and BG) with curing time and weight percentage of the SCC mixes. The factors considered were ZA, BG, FA, and the amount of time needed to cure additional cementitious material. The investigation's findings and interpretation led to the following conclusions. The replacement of up to 0.5% ZA and 1% BG with fixed fine aggregate, water, CR improved the flexure and compressive strengths of SCC. On the contrary, higher curing period and nano particles content decreased strengthsof the SCC. Similarly, curing period below and above 28-days with nano particles strength of SCC mixes are slightly improved.

1. The flexure and compressive strengths of SCC were increased by substituting fixed fine aggregate, water, and CR with up to 0.5% ZA and 1% BG. On the other hand, a longer curing time and the presence of nanoparticles reduced the SCC's strengths. Likethis, SCC mixtures' curing times below and above 28 days with nano particles are somewhat enhanced.

2. With the addition of nanoparticles and their replacement of fine aggregate, SCC’s strengths improved. Strengths dropped as the amount of nanoparticles in SCC increased.

3. The models created using RSM to forecast the SCC's strong performance were very significant, correlated, and predictable.

4. The results of the multi-objective optimization revealed that the ideal mix combination based on maximal strength was reached by maintaining a 28-day curing time; otherwise, there were minor alterations, such as substituting ZA% with cement and BG% with fine aggregate.

SCC mix strengths were the only ones covered in this investigation. Only specific percentages of nanoparticles were allowed. The maximum replacement by weight of cement for nano ZA was capped at 0.75%, while the maximum replacement by volume of cement for BG was 1.5%. In terms of curing time, inclusion of nanoparticles, and their impacts as factors, the established models can forecast the strength performance of SCC mixes. This will lessen the necessity for doing experiments, which will save money and time.

Future studies should examine the impact of acid and salt solutions at higher concentrations and over longer periods of time on SCC mixtures. According to statistical analysis of both strengths of different types of SCC using various methods, there is a good correlation between the dependent and independent variables. The model's prediction of the strength qualities for the parameters is great since the residuals are low. As per the statistical analysis of the strength of both concrete by different methods shows there is a strong relation between dependent and independent variables.

FOAM CONCRETE WITH UNIFORMLY GRADED AGGREGATES AND TAILINGS: STRENGTH AND MICROSTRUCTURE

Kevin Chandra Nurwadji[1], Herlien Dwiarti Soemari[1], and Ivan Sandi Darma[1]

[1]Faculty of Civil and Environmental Engineering, Bandung Institute of Technology, Indonesia.

ABSTRACT

This study investigates the effect of uniformly graded quartz sand and varying proportions of mining tailings on the mechanical and microstructural properties of foam concrete. Two water-to-cement (W/C) ratios, 0.3 and 0.5, were used to evaluate their influence on compressive strength, workability, and internal structure. Tailings were incorporated as partial replacements for sand at 0%, 5%, 10%, and 20% by mass. Mechanical testing included compressive strength and slump flow tests, while microstructural analysis employed Scanning Electron Microscopy (SEM) and X-ray Computed Tomography (CT). Results showed that the W/C ratio of 0.5 produced significantly higher compressive strength and better slump flow, attributed to improved mix consistency. At W/C 0.3, the optimum tailings content was 10%, beyond which strength and workability declined. SEM and CT imaging revealed that the W/C 0.5 samples had a denser matrix, more uniform pore distribution, and no surface flaking, while the W/C 0.3 samples exhibited microstructural flaws and lower surface integrity. These findings highlight the importance of optimizing both water content and aggregate gradation to enhance the performance and durability of lightweight foam concrete.

Keywords: Foam Concrete, Cellular Lightweight Concrete, Mechanical Properties, Microstructure Analysis

INTRODUCTION

Foam concrete, also known as cellular lightweight concrete (CLC), has emerged as a promising material in modern construction due to its low density, thermal insulation properties, cost-effectiveness, and ease of placement [5-6]. It consists primarily of cement, water, fine aggregates, and a foaming agent that introduces a high volume of air voids into the mix. These voids significantly reduce the concrete's self-weight while imparting sufficient strength for various applications, including non-structural walls, thermal insulation layers, and even semi-structural components in low-rise buildings. As the demand for sustainable and energy-efficient construction materials grows, foam concrete has gained renewed interest among researchers and practitioners [5-6].

One of the critical factors that govern the performance of foam concrete is the nature and grading of the aggregates used. While much attention has been given to the binder system and foaming methods, the role of aggregate gradation, particularly uniformly graded aggregates remain relatively underexplored. Traditional studies have often emphasized well-graded or gap-graded aggregates for improving packing density and reducing voids in normal-weight concrete [4]. However, foam concrete behaves differently from conventional concrete due to its aerated matrix and unique pore structure.

Several studies have attempted to investigate the impact of aggregate types and gradations on foam concrete. Jones and McCarthy [1] reported that the particle size distribution of fine aggregates significantly affects the workability, strength, and stability of foam concrete mixes. Similarly, Kearsley and Wainwright [2] found that finer sand gradations can enhance compressive strength by reducing pore connectivity and improving the uniformity of the air void distribution. However, these studies mainly focused on broadly graded or fine aggregate systems, without isolating the effect of a uniformly graded aggregate system.

Uniformly graded aggregates consist of particles that are nearly the same size, resulting in lower packing efficiency and higher inter-particle voids. In conventional concrete, this typically leads to weaker mechanical performance due to the lack of smaller particles to fill the gaps between larger ones. Nonetheless, in foam concrete, where air voids dominate the matrix, the interaction between aggregate packing and air bubble distribution may yield different outcomes. Uniformly graded systems may influence the bubble stability, matrix cohesion, and ultimately, the mechanical strength and microstructural integrity of the composite.

The microstructure of foam concrete, especially the distribution and connectivity of pores, plays a crucial role in determining its strength and durability. According to Ramamurthy et al. [4], factors such as pore shape, size, and distribution are affected by the mix design and the physical characteristics of aggregates. Understanding how a uniform aggregate gradation interacts with the foam matrix can thus offer new insights into the optimization of lightweight concrete mixtures.

Despite these considerations, limited research has been conducted on the direct comparison of foam concrete with uniformly graded aggregates versus

other gradation profiles in terms of both compressive strength and microstructure. This knowledge gap forms the core motivation of the present study.

This research aims to investigate the influence of uniformly graded aggregates on the strength and microstructural properties of foam concrete. The study involves experimental testing of compressive strength and detailed microscopic analysis to characterize the internal structure. By evaluating how uniform gradation affects void distribution, matrix-aggregate bonding, and overall performance, this study seeks to provide a deeper understanding that can contribute to the development of high-performance, lightweight, and sustainable construction materials.

RESEARCH SIGNIFICANCE

This study contributes to the limited body of knowledge on the role of aggregate gradation in foam concrete, specifically focusing on uniformly graded aggregates. By examining the effects on both compressive strength and microstructure, the findings offer valuable insights for optimizing lightweight concrete mix designs. The research supports the development of more reliable and structurally sound foam concrete, promoting its use in sustainable and cost-effective construction. It also lays the groundwork for further exploration into aggregate behavior in aerated cementitious systems.

TESTING PROCEDURE

This research investigates the mechanical and microstructural properties of foam concrete incorporating uniformly graded quartz sand and varying proportions of mining tailings. Two water-to-cement (W/C) ratios (0.5 and 0.3) and four levels of tailings replacement (0%, 5%, 10%, and 20% by mass of sand) are used as shown in Table 2. Portland Composite Cement (PCC) serves as the primary binder. The procedure includes mechanical tests and microstructural evaluations to understand the effect of these variations on the performance of foam concrete.

Materials and Sample Preparation

- Cement: Portland Composite Cement (PCC), conforming to SNI standards.
- Fine Aggregate: Uniformly graded quartz sand with a grain size range between mesh No. 20 and 30 (approximately 600–850 μm).
- Tailings: Processed, oven-dried tailings used to replace quartz sand by mass. Chemical composition is detailed in Table 1.
- Water-to-Cement Ratios: 0.5 and 0.3.
- Foaming Agent: A protein-based/synthetic agent to ensure uniform air distribution.

Materials are batched by weight. The foam concrete mix is prepared in a laboratory mixer, ensuring uniform dispersion of foam. The fresh mix is cast into standard molds—100 mm cubes for strength tests and cones for slump measurements. All specimens are demolded after 24 hours and cured in water at 25 ± 2°C for 28 days.

Fig.1 Compression test of foam concrete cylinder

Fig.2 Sand, tailings, and PCC materials

Mechanical Properties Testing

Compressive Strength Test

- Specimen Size: Cylinder 100 mm Diameter & 200 mm Height.
- Age at Testing: 28 days.
- Equipment: Universal compression testing machine (capacity ≥ 2000 kN).
- Procedure: Load applied at 0.5 MPa/s until failure. Strength is calculated by dividing the peak load by the cross-sectional area.

Slump Flow Test

- Standard: Modified ASTM C1611 (suitable

for low-consistency materials).

- Apparatus: Slump cone (100 mm top dia., 200 mm bottom dia., 300 mm height).
- Procedure: Fresh foam concrete is poured into the cone, which is lifted vertically. The average spread diameter is recorded from two perpendicular directions.

Table 1 Chemical composition of Tailing

No.	Component	Result % mass
1	SiO2	47.7
2	CaO	12.1
3	SO3	10.2
4	Fe2O3	10.1
5	Al2O3	9.8
6	K2O	4.74
7	MgO	3.73
8	Na2O	0.518
9	P2O5	0.329
10	TiO2	0.315
11	CuO	0.114
12	MnO	0.105
13	Cl	0.0596
14	SrO	0.0506
15	Rb2O	0.016
16	MoO3	0.0131
17	ZnO	0.0126

Microstructural Analysis

A. Scanning Electron Microscopy (SEM)

- Objective: To observe the morphology of hydration products, especially Calcium Hydroxide (CH) and Calcium Silicate Hydrate (C-S-H)—with focus on regions adjacent to pores.
- Sample Preparation:
  - 28-day cured samples are cut and oven-dried at 50°C.
  - Fractured surfaces are gold and carbon coated for conductivity.
- Equipment: High-resolution SEM (resolution <5 nm).
- Focus Areas: Interfacial transition zones (ITZ), pore boundaries, and internal matrix.

B. X-Ray Computed Tomography (X-Ray CT)

- Objective: To evaluate 3D pore structure, total porosity, and void distribution.
- Sample Size: Cylindrical cores, 50 mm diameter × 100 mm height.
- Procedure:
  - Scanning performed at high resolution (voxel size <50µm).
  - Data analyzed using software (ImageJ) to segment pores, quantify:
    - Porosity volume (%)
    - Pore size and distribution
    - Connectivity maps
- Outcome: 3D visualization and quantitative mapping of internal pore networks.

Table 2 Experimental matrix

W/C Ratio	Tailings Content (%)	Test Conducted
0.5	0, 5, 10, 20	Slum, Compressive Strength, SEM, CT
0.3	0, 5, 10, 20	Slum, Compressive Strength, SEM, CT

TEST RESULT AND ANALYSIS

Strength Properties

Table 3 28th day compressive strength result

fc'	w/c ratio	
Tailing Content	0.5	0.3
0	4.58	0.48
5	1.98	0.26
10	2.81	0.16
20	2.49	0.26

Based on the compressive strength test results on Table 3, foam concrete samples with a water-to-cement (W/C) ratio of 0.5 achieved significantly higher strength compared to those with a W/C ratio of 0.3. This performance can be attributed to better mix consistency and workability at the higher W/C ratio, which allowed for more uniform distribution of the foam and aggregates within the matrix. In contrast, the 0.3 mix was prone to inconsistency during mixing and casting, leading to poor compaction, uneven air voids, and weak bonding. These factors likely contributed to the lower and more variable compressive strength observed in the lower W/C ratio samples.

Interestingly, differences in surface quality were also observed between the two mixes. The W/C 0.5 samples showed no visible signs of flaking off or surface degradation after curing, indicating good surface cohesion and uniformity. However, the W/C 0.3 samples exhibited signs of “flaking off,” particularly on the edges and corners, where surface material appeared to detach or crumble slightly. This surface imperfection may be due to poor compaction and low water content, which limited the development of a dense and cohesive outer layer.

These observations suggest that W/C ratio not only affects internal strength but also plays a key role in the surface durability of foam concrete.

Slump

Table 4 Slump test results in cm

w/c \ Tailings	0%	5%	10%	20%
0.3	41.5	42	51.25	45
0.5	59.25			57.5

The slump flow test on Table 4, conducted according to ASTM C1611, demonstrates the influence of water-to-cement (W/C) ratio and tailings content on the workability of foam concrete. As expected, the foam concrete with a W/C ratio of 0.5 exhibited greater slump flow than the corresponding mixes with a W/C ratio of 0.3. This is attributed to the higher water content, which improves the mobility of particles and allows for better dispersion of the foam within the matrix. The increased fluidity in the 0.5 mix makes it easier to handle, place, and consolidate—an important consideration in practical construction scenarios, especially when dealing with lightweight aerated materials.

For the W/C 0.3 samples, the slump flow remained relatively low and showed limited variation with increasing tailings content. The slightly higher flow observed at 10% tailings substitution may indicate a temporary improvement in particle packing or lubrication, possibly due to the finer particle distribution from the tailings. However, beyond 10%, the benefit seems to be reduced, potentially because excessive replacement introduces angular particles or inconsistent surface textures that reduce flow. This trend aligns with the compressive strength data, where 10% tailings also showed peak performance, suggesting a balance point between workability and particle interaction.

Fig.1 SEM result of Foam Concrete

In contrast, the W/C 0.5 samples maintained high workability across both measured points (0% and 20% tailings), with only a slight reduction in slump in the higher tailings content. This minor decrease could be due to the presence of coarser or less-reactive mineral particles in the tailings, which might absorb part of the mix water or disrupt paste cohesion. Nevertheless, the difference is not significant, implying that the 0.5 W/C mix is more tolerant to tailings addition in terms of flow characteristics. Overall, these results suggest that W/C ratio is the dominant factor influencing slump flow, with tailings content having a secondary, nonlinear effect depending on the mix proportion.

MICROSTRUCTURE PROPERTIES

The SEM image from Fig.1 of the foam concrete sample with a water-to-cement (W/C) ratio of 0.5 (coded WC05T00), taken at 33× magnification, shows a well-developed porous microstructure with a relatively uniform distribution of air voids. The pores appear mostly spherical or rounded, indicating effective stabilization of the foam during mixing and curing. The pore sizes vary, but the spacing and shape consistency suggests that the foaming agent was well-dispersed within the mix. Such a stable pore structure is essential in foam concrete, as it contributes to reduced density while maintaining internal cohesion. The visible pore walls also appear continuous and thick enough to suggest sufficient matrix development between voids.

Surrounding the air voids, the cementitious matrix appears dense and well-bonded, with no obvious signs of internal segregation or major microcracks. The texture of the matrix suggests a high degree of hydration, though the presence of some angular, bright particles may indicate anhydrate cement grains or residual mineral content from the quartz sand or tailings. While specific hydration products such as Calcium Silicate Hydrate (C-S-H) or Calcium Hydroxide (CH) cannot be definitively identified at this magnification, the absence of weak zones or disconnected regions between particles implies that the hydration process developed well. The lack of visible microcracking or interface separation near the pores also supports the notion that the interfacial transition zones (ITZ) are relatively strong in this mix.

Importantly, the surface of the sample shows no visible signs of flaking or deterioration, which supports the earlier mechanical findings that samples with a W/C ratio of 0.5 had higher compressive strength and better visual integrity. The dense matrix and stable pore structure both contribute to this observation. Compared to mixes with a lower W/C ratio, which were reported to show signs of “flaking off” or poor surface quality, the WC05T00 sample demonstrates a more cohesive and durable microstructure. These findings reinforce the importance of adequate workability in foam concrete mixes, particularly for ensuring uniform distribution

of air voids and hydration throughout the matrix.

CONCLUSIONS

The results confirmed that W/C ratio plays a dominant role in both compressive strength and workability. Foam concrete with a W/C ratio of 0.5 (e.g., fc' = 2.2 MPa at 0% tailing content) exhibited significantly higher compressive strength and superior workability compared to the 0.3 mix (fc' = 0.39 MPa at 0% tailing content). The better consistency of the 0.5 mix allowed for improved distribution of foam and aggregates, leading to a denser and more cohesive matrix.

Tailing replacement also influenced performance, particularly at the lower W/C ratio. A 10% tailings substitution provided optimal compressive strength in the W/C 0.5 mix, likely due to enhanced particle packing and interaction. However, further increase to 20% led to a reduction in strength and workability, possibly from poor compaction or reduced bonding. The slump test results reinforced these findings, showing limited flow in low W/C mixes and stable, high workability in W/C 0.5 mixes, even with tailings addition.

Microstructural analysis using SEM and X-ray CT further validated the mechanical observations. The W/C 0.5 samples exhibited a uniform pore distribution, dense matrix, and no visible flaking, while W/C 0.3 samples showed signs of surface deterioration and inconsistency. These findings underline the importance of balancing water content and tailings substitution to maintain structural integrity and workability. Overall, the study provides valuable insights into mix design strategies for developing strong, workable, and sustainable foam concrete using uniformly graded aggregates and industrial waste materials.

ACKNOWLEDGMENTS

I would like to express my deepest gratitude to P2MI (Program Penelitian Mahasiswa Indonesia) for their generous financial support, which has been invaluable in the completion of this research. I would also like to extend my sincere appreciation to the Structural Laboratory Program at Institut Teknologi Bandung (ITB) for providing the necessary facilities, resources, and technical assistance throughout the experimental and analytical phases of this study. Their support has greatly contributed to the successful execution of this research project.

THE BEHAVIOR OF AN EXPERIMENTAL HOUSE IN RESPONSE TO SHRINKAGE

Lamis Makki[1], Fabien Szymkiewicz[1], Céline Chesnais[1] and Ning Sun[1]

[1]University Gustave Eiffel, 14-20 Boulevard Newton, F-77447 Marne la Vallée cedex 2, Paris, France

ABSTRACT

The damage caused by the effects of drought is especially common in the houses built on shallow foundations. These damages result from the combination of the shrinkage of clayey soil, and the vulnerability of the construction. This paper presents the results of tests carried out on a full-scale model house built on jacks to simulate the different settlement distribution of its foundations during a period of drought. Results of observations made during several tests are presented. A numerical analysis of the behavior of the experimental house was realized. The three-dimensional finite element analysis using the FEM code CESAR-LCPC uses volumetric elements for the concrete blocks, the mortar joints and the concrete of the footing and of the wall ties, whereas the reinforcing bars are modelled using one-dimensional elements, superimposed to the volumetric mesh. Three analyses were performed, in order to match the conditions of the experiments: the supports were suppressed under one fourth, then the half, then another fourth of the house. The calculations gave results close to the measurements.

Keywords: Experimental House, Shrinkage, Finite Element, Settlement

INTRODUCTION

The construction of an experimental house was carried out to subject it to mechanical loads similar to those resulting from the cycles of shrinkage and swelling of the underlying ground. This work was performed within the framework of the ARGIC research program, funded by the French National Research Agency (ANR) and dedicated to the effects of shrinkage and swelling on buildings. To meet the project's timeline, the study was focused on the house itself, without a precise description of the behavior of clayey soils under these cycles. The house was built in a test hall and named MISS (Maison Individuelle Soumise au Sécheresse or "Single house subjected to drought"). The house was built to standard dimensions, in accordance with French construction regulations. Its only particularity is that its foundations were built on metal supports that can be replaced by jacks in various sectors, allowing the modification of the foundation support conditions. An experimental setup was designed to measure vertical displacements of the foundations, deformations of chaining elements, and forces in the jacks. A visual monitoring system was also implemented to track the formation of cracks in the walls and foundations.

RESEARCH SIGNIFICANCE

This paper aims to enhance the understanding of structural damage caused by the effects of drought on clayey soils and differential settlements. A full-scale masonry house was built on hydraulic jacks to modify the foundation support conditions. The structure's configuration was chosen to be similar to those affected by drought. This paper presents the construction of the experimental station and the results of the initial tests. It also details the finite element analysis performed using the CESAR-LCPC software. The results of these numerical simulations are then compared with observations from the experimental station. An important practical conclusion can be drawn from this study: the construction of houses in accordance with current regulations appears sufficient to provide good resistance to soil movements caused by drought.

To our knowledge, this test station is unique. It provides essential data for modeling, making it possible to validate full-scale calculations.

BIBLIOGRAPHIC ELEMENTS

The shrinkage-swelling phenomenon causes volume variations in clayey soils and, consequently, differential settlements that can damage houses. The mechanical response of masonry buildings under various loads—such as uniaxial compression, uniaxial tension, biaxial loading, and shear—has been extensively studied by [1]. These elementary load cases combine to form the overall mechanical response of the masonry structure, contributing to what is known as its "strength." In modern masonry, the differences in stiffness between bricks and joints are much smaller.

It is widely accepted that masonry compressive failure is primarily governed by the interaction between bricks/blocks and mortar. Estimating the performance of structural elements requires assessing their response values (strengths, stresses, drifts,

cracks, etc.) against various types of loads and external forces [2]. The fracture behavior of masonry structures is influenced by several factors: the material properties of the brick and mortar, the geometry of the bricks, joint thickness, and the properties of the brick-mortar bond. Zucchini et al. (2006) [3] conducted tests on solid soft-mud bricks measuring 250×120×55 mm with a mortar joint thickness of 10 mm. The non-linear behavior of the components was simulated using Drucker–Prager plasticity in compression and a Rankine model in tension. Their work aimed to identify the most significant parameters affecting masonry behavior under compression. The study showed that mortar strength has a limited influence on the masonry composite's response, while the results are more sensitive to the brick's compressive and tensile strength. Finite element simulations were performed to analyze the behavior of the MISS Station and to precisely identify the location of stress concentrations within the three-dimensional structure of the house. This required several preliminary choices. Chaimoon and Attard (2009) [4] explained that for numerical purposes, two main approaches are adopted for masonry modeling: macro-modeling and micro-modeling. In the macro-modeling approach, homogenization techniques and continuum-based theories are typically used for large, practical analyses. The global structural behavior is described by a relationship between average strains and average stresses. The material parameters for this approach must be obtained from masonry tests of a sufficiently large size under homogeneous stress states. Macro-modeling approaches have been adopted, for instance, by Grande et al. (2008) [5]. In the micro-modeling approach, a representation of the brick, mortar, and the unit/mortar interface must be included. Cohesive crack models are commonly adopted in the micro-modeling formulation through the use of interface elements. This approach is suitable for small structural elements where there is a particular interest in highly heterogeneous stress and strain states. Lourenco et al. (2006) [6] studied the ability of continuum models based on plasticity and cracking to reproduce the experimental compressive behavior of masonry. It was chosen chose to use a micro-modeling approach to reproduce the actual geometry of the bricks in the house and to employ an appropriate modeling technique for the mortar joints. This choice provides more detailed information on the stress distribution in the masonry but requires a large number of elements. We adopted a linear elastic-perfectly plastic behavior, characterized by only four parameters: Young's modulus, Poisson's ratio, and tensile and compressive strength. For this model, we considered the same geometry, boundary conditions, and loads as the real tests performed on the test house. Regarding the mechanical properties of the materials, due to a lack of specific measurements on the house's materials, we used typical values found in the literature [7].

DESIGN OF THE EXPERIMENTAL STATION AND CONSTRUCTION DETAILS

The experimental house was designed to allow the repetition of tests and to compare the behavior of a structure with or without slab. The configuration of the structure to be tested was chosen to be similar to actual structures affected by drought. A rectangular plan of 10.65 m x 8.65 m external dimensions, divided into four sectors, was adopted (Fig.1).

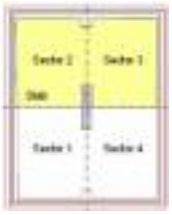

Fig. 1 Structure of the house and testing sectors.

The structure, from bottom to top, consists of foundations, basement walls, a lower concrete-slab floor, the walls, and an upper wooden floor. While the exterior walls have openings for doors and windows, only the main structure of the house has been built. Consequently, the MISS station currently has no roof or windows. The weight of the roof has been simulated by placing concrete blocks on the gable walls and façades. A view of the completed construction is shown in Figure 2.

Fig. 2 Overview of the house.

This section details the structure of the ceiling and the metal supports beneath the foundations. The foundations are strip footings measuring 45 cm x 20 cm, reinforced with three HA8 steel bars. The concrete for the foundations is a 350 kg/m³ mix of

CPJ 32.5 cement with a 4 cm coating. An additional, 3-meter-long isolated footing has been placed under the center of the experimental house to support the partition wall. The foundations were cast in place on mechanical supports using wooden formwork. The basement walls are constructed from three rows of hollow concrete blocks. They are positioned directly under the perimeter walls and the internal partition wall. The blocks used for the basement walls have a higher compressive strength than those used for the upper walls. Vertical reinforcing chains were installed at the corners of the house and in the middle of each façade. This reinforcement consists of two HA10 bars, with a mass of 2.78 kg/m. The 20 cm x 20 cm x 50 cm blocks used for the walls have a 15 cm diameter cavity to accommodate the steel reinforcing bars and the sealing concrete (a 350 kg/m³ cement mix). Horizontal reinforcing chains were added at each floor level. Lintels were also sealed in place at the top of every window and door. The reinforcement for these chains consists of two HA10 bars, with a mass of 1.4 kg/m. The chains were sealed between two rows of specially designed 5 cm thick (5 cm x 20 cm x 50 cm) hollow blocks for horizontal reinforcement, as shown in Figure 3.

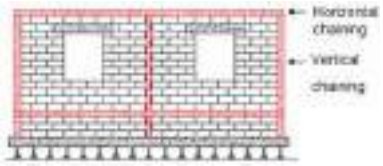

Fig. 3 Schematic of walls and chaining

The horizontal reinforcing chain has an overall cross-section of 10 cm x 20 cm. Only half of the lower floor was constructed. This floor consists of a composite slab made of concrete beams and blocks, reinforced for compression. The beams are 13 cm high and are topped with a 4 cm thick compression slab. This slab is reinforced with a wire mesh measuring 200 mm x 300 mm with a wire diameter of 3.5 mm x 3.5 mm, which is equivalent to 0.63 kg/m². There are 18 beams in total (9 in Sector 2 and 9 in Sector 3). The concrete blocks measure 12 cm x 53 cm x 20 cm and weigh 15.3 kg each. The other half of the house was left without a slab to facilitate a discussion on the role of the floor in the building's behavior. The walls are made of hollow concrete blocks. The building's roof height is approximately 2.60 m. An internal partition wall provides both support for the floor above and structural bracing. The thickness of the outer walls is 20 cm, while the internal wall is 15 cm thick. The walls are not coated, and the concrete blocks were joined with mortar. Openings for doors (2 m x 2.15 m) and windows (1.2 m x 1.35 m) were created and are arranged identically across all four construction sectors. The ties placed above the wall openings were sealed in place, with the reinforcement consisting of four HA10 bars. The top floor is designed to support an overload that simulates the presence of an additional floor and a roof. It is composed of wooden beams and slabs. This structure weighs 7.5 tons on the façade walls and 2.85 tons on the gable walls.

EXPERIMENTAL SETUP

The house's foundations rest on a series of removable mechanical supports, which are themselves placed on a rigid, cast-in-place concrete footing (Fig. 4).

Fig. 4 Foundations of the house

To perform tests on a single sector of the house, we simply replace the mechanical supports under that sector with hydraulic jacks. These jacks are then used to induce controlled settlements or heave in the house's foundation. The experimental setup therefore consists of a rigid reinforced concrete foundation, a set of mechanical supports, and a set of hydraulic jacks. The experimental house was built inside a covered hall. The overall construction includes a ground-level support structure, with metal supports holding the house's foundations and the house itself. A rigid, reinforced concrete footing was cast in place on a platform. This platform is composed of a 1-meter-thick layer of gravel (category B4, 0/40 mm) topped with a 20 cm layer of well-graded untreated gravel (D2, 0/31.5 mm). The footing has a 65 cm x 35 cm cross-section and is reinforced with 8 steel bars (10 mm diameter). The concrete mix was prepared with 350 kg/m³ of CPJ 32.5 cement, with a 4 cm coating. The house's mechanical supports were specifically designed and manufactured for this project. A total of 85 mechanical supports are required, with two supports per meter. Each support has a nominal capacity of 80 kN. The hydraulic jacks

are installed in place of the mechanical supports. These jacks have a capacity of 500 kN and a travel of 150 mm.

NUMERICAL MODEL

A three-dimensional model of the house structure was chosen. In this model, the concrete blocks and joints are represented by eight-node volume elements, while the horizontal and vertical reinforcing chains are represented by bar elements superimposed on the three-dimensional mesh. The total mesh consists of 111,644 elements. Each volume element is defined by five key parameters: density, Young's modulus, Poisson's ratio, and compressive and tensile strength. Figure 5 shows the house's mesh, which is composed of eight-node volume elements representing the concrete in the foundations, the concrete blocks, and the joints. The mesh was constructed by assembling elementary meshes, each including a single block and a layer of mortar, to first create wall portions and then complete walls.

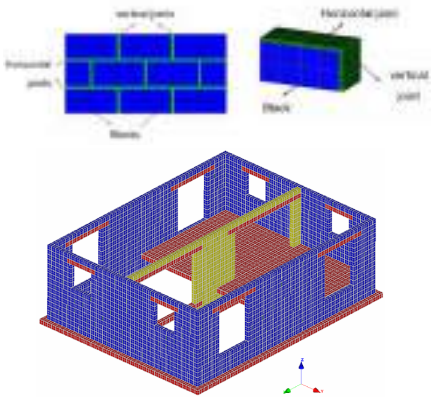

Fig. 5 Mesh of experimental house (joints end bricks)

Chaining was represented by means of a set of bar elements. The properties of the three types of material of volume elements are given in Table 1.

Table 1 Mechanical properties of materials

	Density (kg/m^3)	Young's modulus (MPa)	Poisson's ratio (-)	Compressive strength (MPa)	Tensile strength (MPa)
Concrete	2500	40000	0.2	20	2
Joints	1500	6000	0.2	6	1
Blocks	1000	400	0.1	4	0.5

To reproduce three tests conducted on the actual MISS station, three corresponding calculations were performed: (i) Removal of supports under Sector 1, (ii) Removal of supports under Sectors 1 and 4, (iii) Removal of supports under Sector 2. The experimental house is divided into four sectors. The test procedure involves gradually lowering the stems of hydraulic jacks placed under a part of the foundation and observing the house's resulting behavior. For a selected test sector, the experimental procedure begins by replacing the house's mechanical supports with jacks. The imposed displacement follows a parabolic curve, with the maximum settlement occurring at the house corner. The process starts with the first two jacks from the corner and continues by progressively imposing a parabolic differential settlement along the entire length of the foundations. The characteristic settlement values used are 1/1000, 1/500, and 1/250. These settlements are applied at every meter, which corresponds to the distance between two jacks. The observation and monitoring period between two phases is typically 24 hours. The test is stopped when a crack at least 2 mm wide appears in the walls. The measurements collected during the tests were: Foundation settlement, forces at the hydraulic jack heads, deformations in the foundations and horizontal reinforcement chains and cracks development.

Test On Sector 1

The test on Sector 1 involved applying a displacement to the hydraulic jacks that support the foundations at the corner of the house. This particular sector was chosen because it was constructed without a concrete-slab floor (Fig. 6)

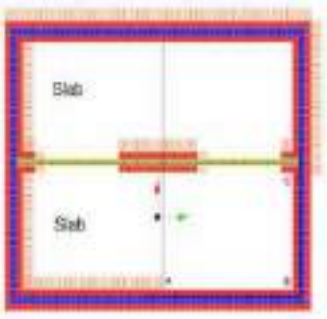

Fig. 6 Modelling of the test on sector 1- boundary conditions

This condition is equivalent to the absence of supports under this part of the foundation. In the experimental study, this condition was imposed incrementally to avoid causing any structural damage to the house. In the numerical calculation, however, it was imposed directly. The calculated maximum vertical displacement (at the house corner) was 3.4 mm, which is very close to the experimental value of 3.35 mm. Figure 7 compares the calculated and observed settlements under the foundations between points A, B, and C, as defined in Figure 6.

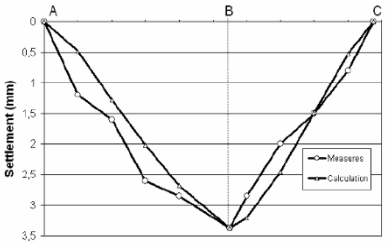

Fig. 7 Comparison of measured and calculated settlements (Foundation AB and BC)

Test On Sectors 1 And 4

The test on Sectors 1 and 4 involved imposing a displacement on the hydraulic jacks located under one half of the house (the side without a floor). For the numerical calculation, this condition is equivalent to simulating the absence of supports under that entire section of the foundation (Figure 8, line ABCD).

Fig. 8 Modelling of the test on sector 1 and 4-boundary conditions

This configuration was applied directly in the numerical calculation, whereas the actual test involved several phases. Figure 9 compares the measured and calculated foundation settlements along the line ABCD. The calculated and observed settlement values were very close. The calculation was performed in a phased manner to match the experimental procedure. In the first phase, Sector 1 was unloaded. The supports were then repositioned under its foundations, but they were not returned to their initial starting position. A settlement of a few millimeters was thus maintained. For the calculation involving Sectors 1 and 4, the final state of deformation and stress from the previous calculation (Sector 1) was used as the initial state. This explains why the calculated settlements for Sectors 1 and 4 are not symmetrical, even though the mesh and materials are.

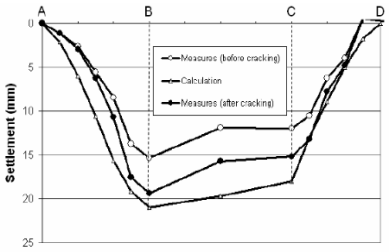

Fig. 9 Comparison of measured and calculated settlements (Foundation AB, BC and CD)

During the test on Sectors 1 and 4, the structure progressively deformed without any visible cracking. However, cracks appeared 14 days after the jacks were lowered. These cracks had an unexpected geometry: they originated from the foundation and ran along the central vertical reinforcement chain on the internal wall. The cracking in the foundation can be attributed to the way this section was reinforced. The steel bars were placed at the bottom of the beam, as it typically experiences tension in its lower part. However, the effect of soil shrinkage under the house's corner induces tensile stresses in the upper face of the beam, where there is no reinforcement. While the appearance of cracks in the wall blocks near the openings is logical, the horizontal cracking cannot be explained solely by a localized weakness in the vertical reinforcement chain at the house's corner. This specific weakness was not accounted for in the calculation presented here.

Test On Sector 2

The test on Sector 2 involved applying a displacement to the supports under a quarter of the house, on the side equipped with the lower floor. During this test, displacements of the mesh nodes for the previously tested half of the house (Sectors 1 and 4) were constrained in the x, y, and z directions. The house was not returned to its original state before the test on Sector 2 was performed. Instead, the simulation took into account the stresses, plastic strains, and displacements produced in the structure after the test on Sectors 1 and 4. Figure 10 compares the calculated and measured settlements. The maximum calculated settlement was 4.7 mm, which is close to the measured value of 5.6 mm. To identify its effect, a defect in the vertical reinforcement chain at the corner of the structure was introduced during the experiment.

This defect, however, was not included in the calculation. This discrepancy explains why the settlement observed during the experiment was higher than that of the model.

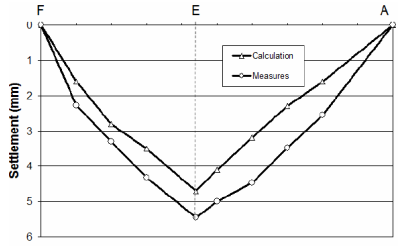

Fig. 10 Comparison of measured and calculated settlements (Foundation AE and EF)

CONCLUSIONS

A full-scale house was constructed to simulate the effects of soil shrinkage and to observe and measure the response of a typical individual masonry house subjected to various stresses. The objective of this work was to better understand the deformation mechanisms of masonry structures under imposed loading and to determine the maximum acceptable loads for this structure. The tests showed that, under the conditions of a new structure, a simple building constructed according to Eurocode 6 (EC6) regulations does not experience structural damage when maximum stresses are applied to a quarter of the structure, regardless of whether it is on its more rigid side (with a slab) or its less rigid side (without a slab). However, when half of the house (without a slab) was subjected to a differential settlement of 1/300, cracks appeared in the walls on both sides of a corner after a few days. A three-dimensional finite element model of the experimental house was developed. The model, which simulated foundation displacements in one or two sectors of the house, produced encouraging results regarding the settlements and deformations of the masonry structure. The deformation amplitudes were highly dependent on the material properties, particularly those of the concrete block, with values taken from a literature review. The choice of mesh was constrained by the capabilities of the finite element software and the computers used for this study, as the simulations involved approximately 450,000 degrees of freedom. For this specific problem, which concerns a particular mode of building deformation, the adopted approach appears to be reasonably sound and suitable for further studies on masonry buildings. An important operational conclusion can be drawn from this study: the construction of houses in accordance with current French regulations (EC6) seems sufficient to provide good resistance to soil shrinkage caused by drought. The calculation confirms the good performance of a masonry structure with concrete foundations and regularly spaced vertical and horizontal reinforcement chains. We plan to model the results of new experiments on the house, which will be carried out after reinforcing the areas where cracking occurred. To our knowledge, this test station is unique. It provides essential data for modeling by allowing for the validation of full-scale calculations. This study represents a first step toward modeling the behavior of a masonry structure subject to drought. A key limitation of the study is that only one house configuration was tested, which means the results cannot be generalized to all types of masonry construction and soil conditions.

IMPROVING RUTTING RESISTANCE IN STONE MASTIC ASPHALT PAVEMENT USING FINE SEIZED WASTE TIRE RUBBER

*****Enohmbey Chubisong Moses[1], and Yoshitaka Kajita[1]

[1]Department of Architecture and Civil Engineering, Tokai University, Japan

ABSTRACT

Rutting is one of the most common forms of pavement distress that leads to long-term damage and degradation of road surfaces, particularly under heavy traffic loads and high temperatures. The incorporation of waste tire rubber (WTR) into Stone Mastic Asphalt (SMA) has emerged as a promising solution to enhance rutting resistance and improve overall pavement durability. This study investigates the effect of different proportions of waste tire rubber on the rutting resistance of SMA. A series of Marshall Stability tests were conducted to assess the performance of rubber-modified asphalt compared to traditional SMA. The results suggest that the inclusion of waste tire rubber significantly enhances rutting resistance, offering a sustainable and effective approach to improving asphalt mixtures. The findings contribute to the development of more resilient, eco-friendly pavements by reducing waste tire disposal and improving the performance of asphalt under extreme conditions.

Keywords: Stone Mastic Asphalt, Rutting Resistance, Waste Tire Rubber, Marshall Stability Test, Sustainable, Asphalt Modification

INTRODUCTION

The increase in urbanization and rising vehicle traffic over the past few decades have placed a significant strain on the infrastructure of transportation networks, especially roadways. Since traffic loads continue to increase, we need to achieve high-performance pavements which can resist these conditions. Among the various forms of pavement distress, rutting defined as the permanent deformation of the pavement surface has emerged as a critical issue in maintaining road durability and safety. This is particularly significant in regions subjected to high temperatures and heavy traffic volumes. Rutting predominantly occurs due to the synergistic effects of repeated traffic loading, temperature fluctuations, and the intrinsic properties of the asphalt binder. The binder tends to soften under elevated temperatures, which consequently leads to the permanent deformation of the pavement surface. [1].

Stone Mastic Asphalt (SMA) is a specialized asphalt mixture widely used in road construction due to its high durability and superior resistance to deformation and wear. It is characterized by a high binder content and a coarse aggregate structure that creates a gap-graded mixture, enhancing its ability to resist traffic-induced deformations. However, despite these advantages, Stone Mastic Asphalt is not immune to rutting, especially when subjected to heavy traffic loads and high-temperature conditions [2]. To address these challenges, researchers and engineers have been exploring innovative ways to modify the properties of Stone Mastic Asphalt, with one promising approach being the incorporation of waste materials, such as waste tire rubber (WTR), to enhance its performance.

Waste Tire Rubber (WTR) has become a significant environmental concern due to the growing number of used tires that are discarded each year. In 2018 alone, over 1 billion tires were discarded globally, with many of them ending up in landfills or being incinerated, both of which contribute to environmental pollution. In response to this, various recycling methods have been proposed to repurpose waste tire rubber, particularly in asphalt mixtures. The use of WTR as an additive in asphalt has been studied for several decades, with early research focusing on the modification of bitumen to improve its properties, such as viscosity, elasticity, and resistance to rutting. However, it is the more recent research on its application in Stone Mastic Asphalt that has shown considerable promise in addressing rutting problems [3-4].

The concept of using waste tire rubber in asphalt was first proposed by Sullivan and Lytton in 1975, they explored the potential benefits of incorporating ground tire rubber into asphalt mixtures to enhance the binder's performance. Since then, a growing body of literature has emerged, indicating that rubber-modified asphalt mixtures exhibit improved performance characteristics, particularly in terms of rutting

resistance, flexibility, and cracking resistance [5]. The addition of rubber particles modifies the viscoelastic properties of the asphalt binder, which improves the ability of the mixture to withstand high temperatures and resist the permanent deformation caused by repeated traffic loads [6]. The incorporation of rubber also improves the adhesive properties between the binder and aggregates, leading to better cohesion and a more durable pavement structure [7].

The use of waste tire rubber improves low-temperature cracking resistance, as rubber-modified asphalt is less susceptible to brittleness at lower temperatures. Moreso, waste tire rubber -modified asphalt exhibits better moisture resistance, reducing the impact of water damage and stripping, which is a common issue in traditional asphalt mixes. These advantages are particularly important in regions with hot climates and high traffic volumes, where rutting can cause significant damage to roads and lead to costly repairs and maintenance. [8].

Despite the promising results from previous studies, the practical implementation of waste tire rubber -modified Stone Mastic Asphalt has been hindered by several challenges, including concerns regarding the optimal rubber content, compatibility with conventional asphalt binders, and the long-term performance of the modified mixes. Several studies have sought to determine the ideal proportion of waste tire rubber that maximizes rutting resistance without compromising the workability or durability of the mixture. For example, in 2029, Wang et al. found that adding 15-20% of waste tire rubber by weight of the binder resulted in significant improvements in rutting resistance, while higher concentrations of rubber led to reduced flow values, indicating potential issues with compaction and mix workability. These findings suggest that while WTR can effectively enhance the rutting resistance of SMA, the optimal rubber content must be carefully balanced to achieve the desired performance without introducing adverse effects [9].

Moreover, the compatibility of waste tire rubber with different asphalt binders remains an area of ongoing research. Most studies have focused on modifying standard asphalt binders, but recent work has also explored the use of polymer-modified asphalts in combination with waste tire rubber to further enhance the performance of the resulting mixtures. The use of polymer-modified asphalts has been shown to improve the binder's ability to accommodate higher rubber contents without sacrificing the mixture’s rheological properties [10]. However, the cost implications and the availability of suitable polymer-modified binders remain significant factors to consider when scaling up the use of waste tire rubber in real-world applications.

Despite these challenges, the incorporation of waste tire rubber into stone mastic asphalt is increasingly being seen as a sustainable solution to both environmental and infrastructure challenges. By recycling waste tires, which would otherwise contribute to landfill accumulation, waste tire rubber-modified Stone Mastic Asphalt offers a promising route for producing environmentally friendly, high-performance pavements. The use of waste tire rubber not only contributes to reducing the environmental impact of tire disposal but also helps improve the sustainability of road construction by enhancing the longevity and performance of pavements [11].

In summary, while previous studies have highlighted the potential of waste tire rubber to enhance rutting resistance in asphalt mixtures, further research is necessary to optimize the mixed design and performance characteristics of waste tire rubber-modified Stone Mastic Asphalt. This research aims to explore the effects of varying rubber seizes and contents to evaluate which seize works best resisting rutting and evaluate other performance aspects of Stone Mastic Asphalt, providing valuable insights into the development of more durable, sustainable pavements for the future.

RESEARCH SIGNIFICANCE

The disposal of waste tires has become a growing environmental concern due to their accumulation and the challenges associated with their recycling. Traditional disposal methods, such as landfilling and incineration, pose significant environmental and health risks, prompting the exploration of alternative uses for waste tires. One such solution is the incorporation of waste tire rubber (WTR) into asphalt mixtures, particularly in Stone Mastic Asphalt (SMA), which is known for its high durability and resistance to surface wear.Rutting is a major pavement distress that occurs when the asphalt binder softens under the influence of traffic load and high temperatures, leading to permanent deformations on the pavement surface. The inclusion of WTR in Stone Mastic Asphalt can potentially improve the resistance to rutting by enhancing the viscosity and elasticity of the asphalt binder. This research aims to evaluate the effects of different concentrations of waste tire rubber on the rutting resistance of SMA and explore its potential as a sustainable solution for road construction, reducing both environmental impact and maintenance costs.

METHODS

The aim of this experiment is to study the importance of Waste Tire Rubber (WTR) as an additive to Stone Mastic Asphalt (SMA) to improve its rutting resistance. Waste tires faces a major environmental challenge and recycling them into valuable materials for pavement construction gives birth to a sustainable solution. The incorporation of fine rubber into asphalt mixtures has been shown to improve the material's ability which can withstand deformation under traffic-induced stresses, which enhances the overall durability of road surfaces.

To achieve this, waste tire rubber was processed into fine and coarse particles and incorporated into the Stone Mastic Asphalt mix at varying concentrations. Stone Mastic Asphalt is a dense, highly stable asphalt mixture commonly used for high-traffic roadways. The mixture is known for its high stability and rutting resistance, but the addition of rubber may further enhance its performance under extreme conditions. This section outlines the preparation of the materials, sample mixes, testing procedures, and data analysis methods used to assess the rutting resistance of Stone Mastic Asphalt modified with waste tire rubber.

Fig. 1 Preparing mixture with straight asphalt without additive.

Fig. 2 Mixing the sample for 2.5 mins without additives.

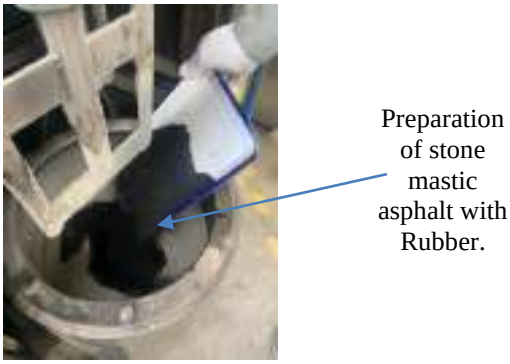

Fig. 3 Adding fine rubber to the mixture.

Figure 1 to 5 is a picture representation of our test preparation.

Materials and Mix Design

The Stone Mastic Asphalt (SMA) mix was prepared using standard aggregates with specific gradations to ensure high stability and durability under traffic loading. Aggregates were selected to meet the gradation specifications required for SMA, ensuring the creation of a dense and stable structure that can resist deformation. The bitumen used in this study was a 40/50 penetration grade, which is well-suited for road applications requiring durability and high-temperature performance.

Waste Tire Rubber (WTR) was obtained from discarded tires and processed into fine and coarse rubber particles using a bench grinder. The rubber was separated into two particle sizes, with fine particles used for one set of mixes and coarse particles for another. The rubber was incorporated into the asphalt binder at different weight percentages of bitumen: 0% (control), 10%, 20%, and 30%. This variation was intended to explore the impact of increasing rubber content on the rutting resistance and overall performance of the Stone Mastic Asphalt mixture.

Sample Preparation

The preparation of Stone Mastic Asphalt (SMA) mixtures was performed with varying amounts of Waste Tire Rubber (WTR) to evaluate its effects on rutting resistance. The SMA samples were categorized into four groups based on the rubber content, as follows: Group 1 (control mix with 0% WTR), Group 2 (SMA with 10% WTR by weight of bitumen), Group 3 (SMA with 20% Waste Tire Rubber by weight of bitumen), and Group 4 (Stone Mastic Asphalt with 30% Waste Tire Rubber by weight of bitumen). For each group, three replicate samples were prepared, totaling nine samples to ensure consistency and reliability.

The preparation process consisted of several

steps to achieve the desired mixed properties. First, the aggregates and bitumen were heated to their optimal temperatures to ensure proper mixing. The bitumen was heated to approximately 160°C, while the aggregates were heated to 170°C. This ensured that both components were fluid enough to allow for proper bonding.

Next, the rubber particles (either fine or coarse) were added to the heated bitumen and thoroughly mixed to ensure a uniform dispersion of the rubber within the binder. This step is crucial for achieving consistent performance characteristics across all samples, ensuring that the rubber is evenly distributed throughout the bitumen.

Once the rubber was fully incorporated into the bitumen, the rubber-bitumen mixture was combined with heated aggregates. The mixture was stirred until the aggregates were evenly coated with the modified bitumen, ensuring optimal material distribution for enhanced performance.

Finally, the mixture was placed into Marshall molds and compacted using the Marshall compaction method. Each sample was subjected to 75 blows from the Marshall compart; 50 blows applied around the circumference of the mold and 25 blows to the center. This compaction process ensured that each sample achieved the required density for testing, facilitating accurate performance evaluation of the rutting resistance of the WTR-modified Stone Mastic Asphalt mixtures.

The collected tires were cut using a pair of seizors to obtain coarse seized and grinded with a bench grinder to obtain the fine seized rubber.

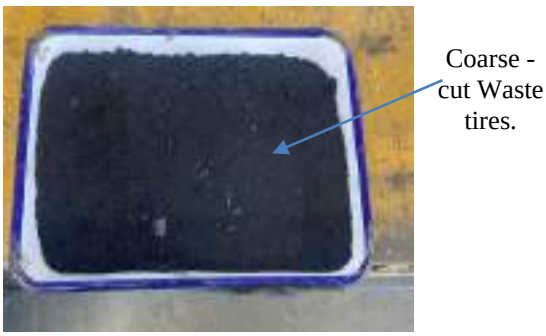

Fig. 6 Grinding of waste tire into fine seize.

Marshall Stability Testing and Observation

The Marshall Stability test was the primary method used to evaluate the rutting resistance of the WTR-modified Stone Mastic Asphalt mixtures. This test measures the maximum load that an asphalt sample can withstand before failure, which serves as an indicator of the material's stability under the stresses imposed by traffic. Additionally, the flow values were recorded to assess the workability and deformability of the mixtures. The stability and flow values were determined for all nine samples across the four groups (control and WTR-modified). The test involved applying a vertical load to the compacted samples until failure occurred, and the corresponding flow values were measured during this process. This test is critical in understanding how the incorporation of rubber affects the rutting resistance of the SMA mixture, which is directly related to the performance of road surfaces under traffic conditions [12-13].

The incorporation of Waste Tire Rubber (WTR) into Stone Mastic Asphalt (SMA) mixtures has been shown to significantly enhance rutting resistance, as evidenced by increased Marshall Stability values. This improvement indicates a stronger and more durable pavement mix capable of withstanding higher traffic loads without deformation. In contrast, the control mix which contained no waste tire rubber exhibited the lowest stability value, implying a greater susceptibility to rutting under traffic stress.

In this study, we used 0% of waste tire rubber recorded at 8.2 KN, reflecting relatively poor resistance to deformation. When 10% waste tire rubber was added to the mix, the stability increased to 9.6 kN, demonstrating an improvement in rutting resistance with even a modest addition of rubber. This trend continued with higher waste tire rubber content: at 20%, the stability value rose to 11.5 kN, and at 30%, the mix achieved its highest stability value of 12.3 KN. These results clearly indicate that the addition

of waste tire rubber enhances the mixture's resistance to rutting, with the most significant improvement observed at the 30% waste tire rubber level.

In terms of flow values ire the workability and ease of comp asphalt mix there was a slight increa ith the addition of waste tire rubber.

All prepared test samples for the experiment

Fig. 7 Marshal Stability testing.

Fig. 8 Samples without rubber and with fine Rubber and coarse rubber.

RESULTS AND DISCUSSION

The optimum bitumen content of 7.8% for the Stone Mastic Asphalt (SMA) was well-supported by the increased Marshall Stability observed with the incorporation of coarse seized waste tire rubber (WTR). In this study, both coarse-sized and fine-sized ground tire rubber were used as modifiers. The results showed that mixtures modified with fine waste tire rubber exhibited superior stability compared to those with coarse waste tire rubber, 30% content of course waste tire rubber - modified mix reached a peak stability value of 12.3 kN**,** indicating an important improvement in rutting resistance. The improved performance of fine rubber that was obtained using a bench grinder, can be attributed to its better mechanical interlocking within the asphalt matrix and its ability to absorb in powder form and dissipate traffic-induced stresses. Although 7.8% was identified as the optimum asphalt content, further evaluation at 8.2% asphalt content through air void analysis is recommended to explore whether better compact ability and durability can be achieved. Overall, the incorporation of coarse waste tire rubber at appropriate content levels significantly reduces rutting and enhances structural integrity, offering a sustainable solution for high-performance asphalt pavement.

Penetration test results done by adding coarse rubber into straight asphalt and fine rubber into straight asphalt revealed that, the properties of coarse tire rubber are significant in preventing rutting in asphalt pavement. To prevent rutting, we must grind the tire rubber into fine powder rubber so that its properties can easily blend with asphalt mixture as seen in this experiment.

This ratio provided the best strength and performance qualities and turned out to be quite accurate for the objectives of our study. The air void analysis at 7.8% further validated its suitability, showing excellent compaction and durability results. The results showed that 7.8% was still the most effective binder content under our testing conditions, even if 8.2% was assessed. The technical soundness of choosing 7.8% as the ideal asphalt content is demonstrated by these results.

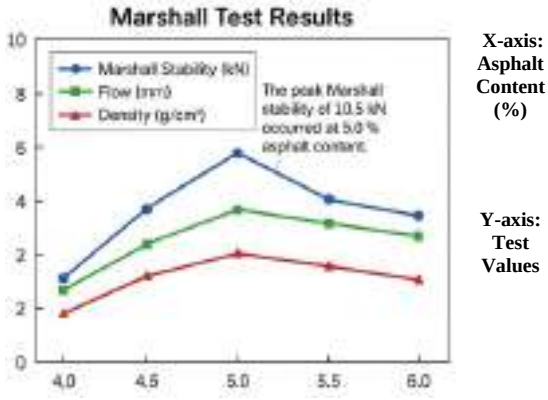

Fig. 9 graph of Marshal test results.

CONCLUSION

This study demonstrates that the inclusion of waste tire rubber in Stone Mastic Asphalt significantly improves rutting resistance. The Marshall Stability test results indicate that increasing the waste tire rubber content enhances the stability of the asphalt mixture, reducing the potential for rutting and improving the overall durability of the pavement. The findings support the use of WTR as a sustainable modifier for Stone Mastic Asphalt, offering an effective solution for improving pavement performance while addressing the growing environmental concerns associated with tire waste disposal.

Based on the Marshall Stability results of this

experiment, the selected optimum asphalt content was 7.8% because it provided a strong balance of strength and workability, particularly when enhanced with fine seized waste tire rubber. However, the final validation through air void analysis was 8.2% and it provided a more accurate, most efficient, and durable design mixture.

ACKNOWLEDGMENTS

The authors would like to express their sincere gratitude to the laboratory staff for their invaluable assistance in preparing the samples and conducting the necessary tests. We also extend our heartfelt appreciation to the funding agency for their generous support of this research project. Special thanks are given to Professor Yoshitaka Kajita of Tokai University for his outstanding supervision and guidance throughout the study. Additionally, we are grateful for the support provided by the Japan International Cooperation Agency (JICA). Finally, we would like to acknowledge Mr. Akira Nomoto of Gaeart Laboratory, Japan, for his technical assistance and expertise during the experimental phase of this research.

PHYSICAL AND MECHANICAL PROPERTIES OF FLY ASH-BASED CELLULAR LIGHTWEIGHT CONCRETE

Reni Suryanita[1], Yohannes Firzal[1], Harnedi Maizir[2] and Raihan Arditama[3]

[1]Faculty of Engineering, Universitas Riau, Indonesia; [2]Department of Civil Engineering, Sekolah Tinggi Teknologi Pekanbaru, Indonesia; [3]PT. Harista Karsa Mandiri, Indonesia

ABSTRACT

Cellular lightweight concrete (CLC) offers weight reduction and thermal insulation, but its relatively low compressive strength limits broader use. This study evaluated the influence of fly-ash replacement on the density and compressive strength of CLC. Mortar cubes with 0%, 10%, and 15% fly-ash by mass of cement were produced using a protein-based foaming agent and tested at 7, 14, 28, and 56 days. The 10% mix achieved the highest 56-day strength (0.960 MPa), exceeding the control (0.852 MPa) and the 15% mix (0.720 MPa), while maintaining lightweight densities (~998–1062 kg/m³). The improvement is attributed to pozzolanic densification and a more uniform pore structure; at higher replacement (15%), dilution of cementitious content likely delayed strength development. Within the ranges tested, a 10% fly-ash replacement provided the best balance between strength and density, indicating suitability for non-structural to semi-structural lightweight applications and supporting more sustainable cementitious materials use.

Keywords: Cellular lightweight concrete (CLC), Fly ash, Compressive strength, Physical properties, Sustainable construction materials

INTRODUCTION

In recent years, the demand for lightweight, efficient, and environmentally friendly building materials has continued to increase, particularly with the growing emphasis on sustainable construction. One promising material that has gained attention is Cellular Lightweight Concrete (CLC), a type of concrete produced without coarse aggregates and incorporating foam to create a porous structure. CLC offers several advantages, such as reduced weight [1], good thermal insulation [2], and ease of handling on construction sites [3]. However, one of its significant limitations is its relatively low compressive strength compared to conventional concrete, which restricts its use primarily to non-structural applications, such as partition walls and lightweight blocks [4].

At the same time, fly ash—an industrial by-product from coal combustion in thermal power plants—continues to accumulate and pose environmental challenges when not adequately managed [5] Interestingly, fly ash contains significant amounts of silica and alumina, which exhibit pozzolanic properties [6]. Concrete's strength and durability can be increased by adding more binding chemicals through a chemical reaction between fly ash and the calcium hydroxide generated during cement hydration [7]. In addition to lowering dependency on Portland cement, whose manufacture significantly increases CO2 emissions, using fly ash in concrete provides a practical way to recycle industrial waste [8].

Recent studies have demonstrated that partially replacing cement with fly ash in CLC mixtures can result in improvements in microstructural density [6], resistance to aggressive environments, and long-term compressive strength. However, there is still a lack of specific research focusing on how fly ash affects the physical and mechanical properties of lightweight CLC blocks, particularly in terms of optimal mix proportions, dry density, water absorption, and compressive strength [4]. On the other hand, the use of high-volume fly ash must also be evaluated for its practicality and consistency in delivering quality results.

This study aims to address two critical issues: improving the technical performance of CLC blocks and reducing the environmental impact of fly ash disposal. By evaluating the effect of fly ash as a partial cement replacement in CLC mixtures, this research aims to identify an optimal formulation that offers a balance of strength, durability, and material efficiency. The findings are expected to support the development of greener, more sustainable, and resource-efficient construction practices.

RESEARCH SIGNIFICANCE

This research is significant as it addresses both environmental and engineering challenges by utilising fly ash, a major industrial byproduct, to enhance the performance of lightweight concrete. By optimizing the composition of Cellular Lightweight Concrete (CLC) with fly ash, the study contributes to advancing sustainable construction practices. The findings have the potential to reduce cement usage, lower carbon emissions, and provide a viable solution for managing fly ash waste, thus offering practical

value to the construction industry and supporting global efforts toward greener infrastructure development.

MATERIALS AND METHODS

Materials

The chemical composition of the Portland Composite Cement (PCC) and fly ash used in this study was determined using X-Ray Fluorescence (XRF) analysis. The chemical composition of the PCC used in this study is dominated by oxides, including CaO (62.3%), SiO_2 (min. 20%), and Al_2O_3 and Fe_2O_3 (max. 6%), as typically reported in technical data sheets of domestic cement manufacturers. This type of cement contains a blend of clinker, gypsum, and supplementary cementitious materials. Based on ASTM C 150-04 , the chemical composition of cement must have a minimum concentration of CaO, SiO_2, Al_2O_3, and Fe_2O_3 compounds. XRF testing of PCC cement showed that the CaO, SiO_2, Al_2O_3, and Fe_2O_3 content in the cement met the ASTM C 150-04 standard. The results of XRD testing on the PCC showed the diffraction pattern of the PCC, which identified that the dominant phase in the material was the calcite phase of calcium carbonate, $Ca(CO_3)$ and calcium silicate (Ca_3SiO_5) monoclinic crystals.

The major constituents of the fly ash (Fig.1) include silicon dioxide (SiO_2) at 53.74%, followed by aluminium oxide (Al_2O_3) at 22.568%, and iron oxide (Fe_2O_3) at 9.251%. Fly ash characteristics were tested using X-Ray Fluorescence (XRF) to determine chemical characteristics and X-Ray Diffraction (XRD) to identify atomic and oxide content in fly ash. XRF test results showed that fly ash contained 85.559% SiO2 + Al2O3 + Fe2O3 and met ASTM class C specifications.

Based on the XRD test results, fly ash material shows a diffraction pattern with the dominant phase identified as the quartz (Q) crystal phase at an angle between (20-30) for the silica (SiO_2) structure and the mullite crystal phase at angles between 30-40, 40-45 and 60-65 for the alumina (Al_2O_3) structure. The highest relative intensity peak for silica is at an angle of $2\theta \approx 26.62$ in the quartz crystalline phase. Furthermore, the alumina (Al_2O_3) structure with an orthorhombic crystal system at an angle of $2\theta \approx 26.27$ in the mullite crystal phase. The XRF testing results indicating that silica (SiO_2) has the highest composition, followed by alumina (Al_2O_3) as the second-largest component.

To create the cellular structure of the lightweight concrete, a protein-based foaming agent was used. The type of foaming agent was selected for its ability to produce stable and consistent bubbles, resulting in a uniform pore distribution and improved mechanical performance. The foaming agent was diluted with water and mechanically pre-foamed using a high-speed mixer before being incorporated into the concrete mix. Clean tap water was used in all mixes for hydration and foam preparation, ensuring no impurities that could interfere with the chemical reactions. Additionally, silica sand with a particle size passing 1.18 mm was included in selected mixtures to enhance packing density, reduce segregation, and improve the mechanical interlocking of particles in the matrix. All materials were stored in dry conditions and brought to room temperature before use. Their selection and proportions were based on preliminary trials and previous literature to ensure practical relevance and optimal performance of the CLC blocks.

Fig.1 Fly Ash

Methods

The experimental program evaluated three fly ash replacement levels—0%, 10%, and 15% by mass of cement. Prior to mix design, fine aggregate characterization included moisture content, bulk density, specific gravity, organic impurities, silt content, and particle size distribution, following relevant ASTM procedures. For each replacement level, five CLC mortar cubes (100 mm) were prepared and cured for 7, 14, 28, and 56 days prior to testing (Table 2).. All aggregate tests were conducted in accordance with standard ASTM procedures [9], [10].

Table 1. Composition of CLC mortar mixture

Variation of Fly ash (%)	Water (kg)	Sand (kg)	Foam (kg)	Cement (kg)	Fly Ash (kg)
0	1.01	3.45	0.29	2.03	0.00
10	1.01	3.45	0.29	1.82	0.10
15	1.01	3.45	0.29	1.72	0.20

Table 2. Total of CLC mortar specimen

Variation of Fly ash (%)	(Testing Day) 7	14	28	56	Total of each variation	Total of Specimen
0	5	5	5	5	20	
10	5	5	5	5	20	60
15	5	5	5	5	20	

The design strength of the CLC mortar mixture is 1 MPa with a wet density of 1.013 t/m³. The configuration of the CLC test specimens is presented in Fig.2**.**

Fig.2 Cellular Light Concrete

Compressive strength testing and surface settlement measurements of the test specimens were conducted after preparing a set of testing equipment, including a loading frame, according to the setup shown in Fig. 3.

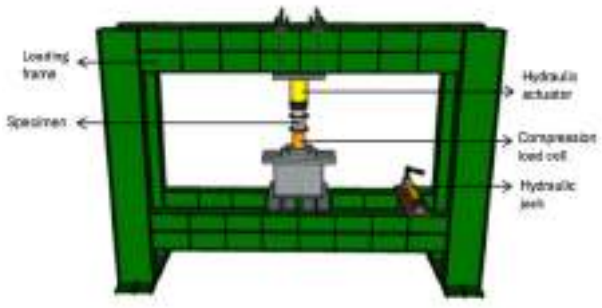

Fig. 3 Loading Frame

Compressive strength testing was conducted on steel plates at the centre of a flat loading frame, ensuring the load was distributed evenly. A load cell was used for compressive strength testing to apply vertical pressure to the specimen. Meanwhile, CLC surface deflection testing was measured using a linear variable displacement transducer (LVDT) installed vertically on the specimen.

The compressive strength test at 56 days was intended to observe the trend in the development of the specimen's compressive strength values. The compressive strength values were calculated based on Equation (1) as follows.

$$f'c = \frac{P}{A} \quad (1)$$

where:
f'c = Compressive Strength of CLC Mortar (MPa)
P = Axial Load (N)
A = Specimen Surface Area (mm^2)

RESULTS AND ANALYSIS

Material Characteristics

The results of fine aggregate material testing have met the ASTM C136 , ASTM C40 and ASTM C33 standards [11]. The results of fine aggregate properties testing are shown in Table 3. The fine aggregate utilized in this study was subjected to a series of standard laboratory tests to evaluate its suitability for use in construction materials. The results are summarized in Table 3. The water content of the aggregate was measured at 3.43%, which falls within the acceptable range of 3–5%. The mud content was recorded at 1.11%, which is well below the maximum allowable limit of 3%, indicating the material's good cleanliness. The organic impurities test yielded a value of 2, which complies with the maximum permissible limit of No. 3, ensuring minimal organic contamination. The bulk density was determined under two conditions: 1470.26 g/cm³ in a dry state and 1679.15 g/cm³ in a compacted state. These values are within the standard range of 1400–1900 g/cm³, confirming that the material has appropriate packing characteristics. Specific gravity tests revealed that the apparent specific gravity was 2.80, while the bulk specific gravity in dry and saturated surface dry (SSD) conditions were 2.65 and 2.71, respectively. These values comply with the typical specification range of 2.58–2.85. The

absorption capacity was found to be 2.01%, which lies within the standard 2–7% range, suggesting a moderate absorption potential suitable for concrete applications.

Additionally, the fineness modulus of the aggregate was determined to be 2.65, which lies within the standard range of 1.5–3.8. The aggregate has a moderate grain size distribution, which contributes to balanced workability and strength development in mortar or concrete mixes. These test results collectively indicate that the fine aggregate meets the required standards and is suitable for use in the production of lightweight or conventional concrete materials**.**

Table 3. The Results of Fine Aggregate Properties Test

No.	Testing	Specification Standard	Results
1	Water content (%)	3-5	3.43
2	Mud rate (%)	<3	1.11
3	Organic Impurities	Max No.3	2
4	Volume weight (g/cm^3)		
	a. Dry condition	1400-1900	1470.26
	b. Solid condition	1400-1900	1679.15
5	Specific Gravity		
	a. Apperent Specific Gravity	2.58-2.83	2.80
	b. Bulk Specific Gravity on Dry	2.58-2.84	2.65
	c. Bulk Specific Gravity on SSD	2.58-2.85	2.71
	d. Absorption	2-7	2.01
6	Finess Modulus	1.5-3.8	2.65

Mechanical Properties

Lightweight mortar bricks are manufactured using a job mix design that achieves the target quality, as specified by the density and compressive strength of the specimen. The wet density value of the mixture was determined before mixing and is by the standard requirements (SNI 8640:2018), which is 1.013 t/m³. Table 4 presents the average compressive strength and corresponding densities of CLC mortar specimens incorporating fly ash at substitution levels of 0%, 10%, and 15% by weight of cement. The performance was evaluated at curing ages of 7, 14, 28, and 56 days. At 7 days, the control mix (0% fly ash) exhibited a compressive strength of 0.660 MPa with a density of 1.062 kg/m³. The inclusion of 10% fly ash slightly improved early strength to 0.696 MPa, despite a reduced density of 1.019 kg/m³. However, a 15% substitution resulted in a notable reduction in strength to 0.510 MPa, indicating a slower early hydration process. On 14 days, the strength continued to improve for both the control and the 10% fly ash mixes, reaching 0.796 MPa and 0.808 MPa, respectively. The 15% fly ash mix achieved a lower strength of 0.602 MPa, suggesting that higher fly ash content may delay strength development due to its pozzolanic nature. By 28 days, the compressive strength of the 10% fly ash mix (0.850 MPa) had slightly surpassed that of the control (0.848 MPa), demonstrating the beneficial long-term pozzolanic reaction. In contrast, the 15% mix remained lower at 0.682 MPa.

After 56 days, the specimen with 10% fly ash achieved the highest strength of 0.960 MPa, followed by the control at 0.852 MPa, while the 15% fly ash specimen reached only 0.720 MPa. The trend indicates that a moderate fly ash content (10%) enhances the long-term strength performance of CLC mortar, whereas excessive replacement (15%) may hinder mechanical development. Overall, the results suggest that a 10% fly ash substitution offers an optimal balance between density reduction and compressive strength enhancement in CLC mortar formulations.

Physical Properties

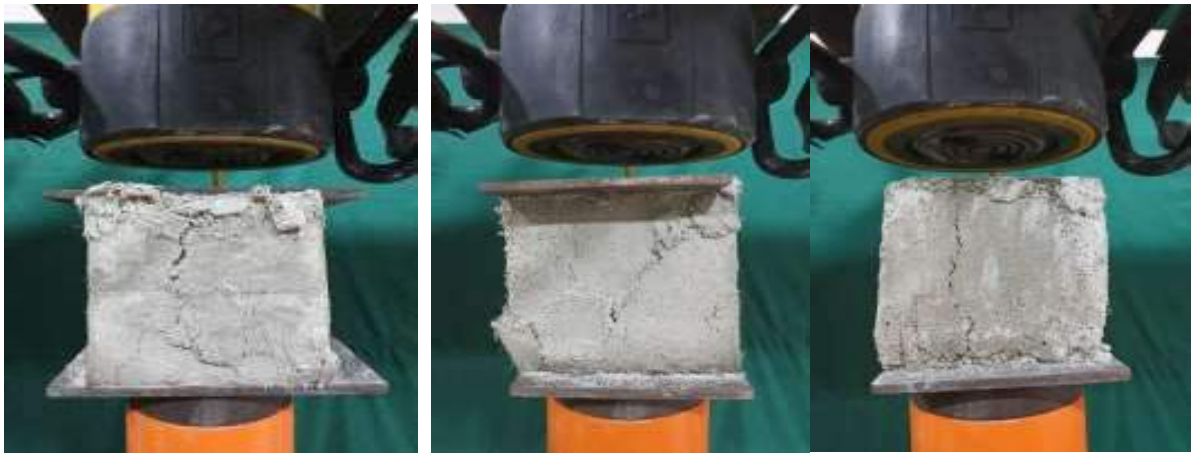
Fig.4 illustrates the failure modes of CLC mortar specimens incorporating 0%, 10%, and 15% fly ash after compressive strength testing at 28 days of curing. The visual evidence demonstrates distinct differences in crack propagation and structural integrity associated with each fly ash content. In Fig. 4(a), the specimen without fly ash (0%) exhibits brittle failure, characterised by multiple vertical cracks and partial collapse of the upper edge. A typical fracture pattern for lightweight cementitious materials with limited tensile strength and moderate cohesion. In Fig. 4(b), the specimen with 10% fly ash substitution exhibits a relatively cohesive failure surface, characterised by fewer visible cracks and a more intact shape post-failure. The specimen exhibits enhanced microstructural bonding and matrix densification, resulting from the pozzolanic reaction of fly ash, which improves the material's integrity under axial load. In contrast, Fig. 4(c) shows the

specimen with 15% fly ash, where more distributed but shallow cracks are visible, indicating a reduced load-bearing capacity. The surface remains largely intact, but the internal structure appears to have experienced microcracking, suggesting that excessive fly ash may hinder early strength development and compromise the internal matrix.

Overall, the images support the mechanical test results, highlighting that a 10% fly ash substitution provides the best balance between strength and ductility in the CLC mortar. At the same time, excessive replacement reduces structural stability under compressive stress.

Table 4. The average compressive strength test of CLC mortar specimens

Fly ash (%)	7 Days		14 Days		28 Days		56 Days	
	Avg. Density	Avg. fc'	Avg. Density	Avg. fc'	Avg. Density	Avg. fc'	Avg. Density	Avg. fc'
	kg/m^3	MPa	kg/m^3	MPa	kg/m^3	MPa	kg/m^3	MPa
0	1.061	0.660	1.027	0.796	1.004	0.848	0.998	0.852
10	1.018	0.696	1.003	0.808	0.997	0.850	0.997	0.960
15	1.070	0.510	1.003	0.602	0.999	0.682	0.998	0.720



(a) (b) (c)

Fig. 4 Collapse of Specimen with 0% (a), 10% (b) and 15% (c) Fly Ash on 28 days

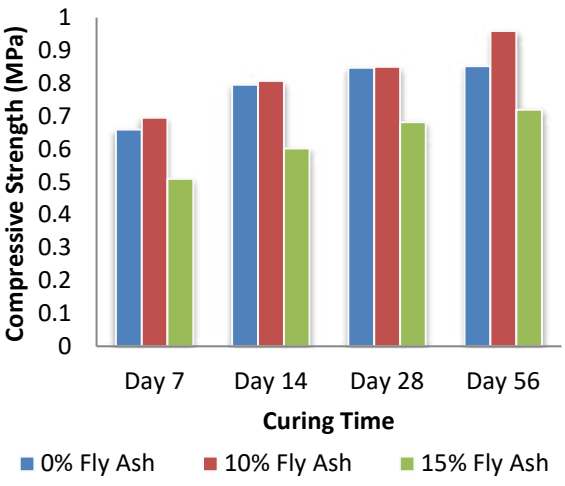


Fig. 5 Compressive Strength with Variation of Fly Ash

Fig. 5 illustrates the compressive strength development of CLC mortar at 7, 14, 28, and 56 days as a function of fly ash content (0%, 10%, and 15%). The bar chart shows a clear trend in strength performance influenced by the substitution level of fly ash over the curing period. At early age (7 days), the compressive strength was relatively low across all mixes, with the highest value observed for the 10% fly ash mix, followed by the control (0% fly ash), while the 15% mix showed the lowest strength (0.51 MPa). On 14 days, strength values increased for all specimens, with the 10% fly ash mix again exhibiting the highest strength. The condition exhibits an active pozzolanic contribution, which begins to manifest after one week of curing. By 28 days, both the control and the 10% fly ash mixes reached nearly equal compressive strengths (above 0.84 MPa), while the 15% mix continued to lag. At 56 days, the 10% fly ash mixture outperformed all others, reaching a maximum compressive strength of 0.96 MPa. The condition reflects the long-term pozzolanic reaction benefits, contributing to continued densification of

the matrix. In contrast, the 15% fly ash specimen exhibited delayed strength gain, ultimately resulting in a lower final strength than both the control and 10% mixtures.

CONCLUSIONS

This study investigated the physical and mechanical properties of Cellular Lightweight Concrete (CLC) mortar incorporating fly ash as a partial cement replacement at 0%, 10%, and 15% by weight. The fine aggregate used in the mixture met all standard specifications, including water content, mud content, specific gravity, and fineness modulus, indicating its suitability for lightweight concrete applications.

Compressive strength tests conducted at 7, 14, 28, and 56 days demonstrated that a 10% fly ash substitution consistently produced superior performance in both early and long-term strength development compared to the control mix and the 15% fly ash mixture. At 56 days, the 10% fly ash mix achieved the highest strength of 0.96 MPa, confirming the long-term pozzolanic benefit of fly ash.

Visual observations of the specimen failure modes under compressive load revealed that the 10% fly ash specimen exhibited the most cohesive and stable failure pattern. In comparison, the 0% and 15% mixes showed more brittle or inconsistent behavior. This suggests that 10% fly ash content not only enhances strength but also contributes to better integrity under mechanical stress. Overall, the results indicate that a 10% fly ash substitution provides an optimal balance between strength, durability, and material stability in CLC mortar, making it a promising alternative for sustainable construction materials.

ACKNOWLEDGMENTS

EXPERIMENTAL INVESTIGATIONS ON SUSTAINABLE GROUND IMPROVEMENT USING SEASHELL POWDER AND RICE HUSK ASH

Rufayda Jannat[1] and Zakaria Hossain[2]

[1,2]Department of Environmental Science and Technology, Mie University, Japan

ABSTRACT

In response to the global push for sustainable and environmentally responsible construction practices, this study investigates the use of seashell powder (SSP) and rice husk ash (RHA) as sustainable materials for ground improvement. Both SSP and RHA are abundantly available from agro-industrial wastes. SSP contains high amounts of calcium carbonate, while RHA is rich in silica. These properties make them cost-effective and eco-friendly alternatives to conventional soil stabilizers such as cement and lime. Soil samples were treated with varying proportions of SSP and RHA, both individually and in combination. The experimental program included weak soil samples mixed with SSP (5–20%) and RHA (5% and 10%). Standard geotechnical laboratory tests, including Proctor compaction and Unconfined Compressive Strength (UCS), were conducted to assess the effects of these additives on soil behavior. The results showed that adding SSP and RHA improved the strength and stiffness of the soil. The best performance was observed in samples containing 20% SSP and 5% RHA. This improvement was mainly due to the filler effect and the synergistic interaction between SSP and RHA, which promoted pozzolanic reactions and stronger particle bonding. These mixtures also demonstrated better workability and compaction characteristics. The findings highlight the potential of SSP and RHA for sustainable ground improvement, especially in regions where marine and agricultural waste materials are readily available. This research supports the reuse of waste products while promoting greener construction practices.

Keywords: Seashell powder (SSP), Rice husk ash (RHA), Compactability, Unconfined compressive strength (UCS), Sustainable ground improvement

INTRODUCTION

Effective ground modification procedures are becoming more and more necessary to improve the engineering qualities of poor soils due to the fast increase of infrastructure construction. Despite their effectiveness, conventional soil stabilizing techniques frequently include cement, lime, and chemical additives, which raise building costs and contribute considerably to CO_2 emissions [1]. In response to global sustainability challenges, researchers are exploring alternative eco-friendly materials derived from industrial and agricultural waste to reduce environmental impact while maintaining geotechnical performance.

Among these waste materials, seashell powder (SSP) and rice husk ash (RHA) have emerged as promising candidates for sustainable soil stabilization. Seashells, a by-product of the seafood industry, are composed primarily of calcium carbonate ($CaCO_3$), which can act as a filler and pozzolanic material when finely ground [2]. Approximately 8 million tons of seashell waste are generated annually worldwide, much of which ends up in landfills, causing disposal challenges [3]. Similarly, rice husk ash is an agricultural waste obtained from burning rice husks, containing high silica content (85-95% SiO_2) that exhibits pozzolanic reactivity when combined with soil [4]. Over 120 million tons of rice husk are produced globally each year, with improper disposal leading to environmental pollution [5].

Previous studies have demonstrated the potential of SSP and RHA in soil stabilization. For instance, [6] found that adding 10% seashell powder improved the unconfined compressive strength (UCS) of clayey soil by up to 30%. Similarly, RHA has been shown to enhance soil strength due to its pozzolanic reaction with calcium hydroxide, forming cementitious compounds (C-S-H gel) that bind soil particles [7]. However, most existing research has focused on individual applications of SSP or RHA, with limited studies on their combined effects on soil behavior.

Research Gap and Objectives

Despite the growing interest in sustainable soil stabilization, there remains a need for comprehensive experimental studies evaluating the synergistic effects of SSP and RHA blends on different soil types. Key questions include:

- What is the optimal mix ratio of SSP and RHA for maximum strength improvement?
- How do these additives influence compaction?

- Can combined SSP-RHA stabilization reduce reliance on traditional binders like cement?

This study investigates the geotechnical properties of soils treated with varying proportions of seashell powder (5%, 10%, 15%, 20%) and rice husk ash (5%, 10%) through a series of laboratory tests, including:

- Standard Proctor compaction to determine optimum moisture content and maximum dry density,
- Unconfined compressive strength (UCS) to evaluate strength gain,
- Scanning Electron Microscopy (SEM) to analyze microstructural modifications.

The findings aim to provide a sustainable, cost-effective solution for ground improvement while promoting waste recycling and reducing the carbon footprint of construction projects.

RESEARCH SIGNIFICANCE

This research contributes to the growing body of knowledge on green construction materials by:

- Reducing environmental waste through the utilization of SSP and RHA,
- Lowering construction costs by replacing conventional stabilizers with waste-derived alternatives,
- Enhancing soil engineering properties for applications in road subgrades, embankments, and foundation support.
- By validating the effectiveness of SSP-RHA blends in soil stabilization, this study supports the United Nations Sustainable Development Goals (SDGs), particularly SDG 9 (Industry, Innovation, and Infrastructure) and SDG 12 (Responsible Consumption and Production).

MATERIALS AND METHODS

Materials

Soil

Among the supplies utilized in this investigation were clay soil (S) from Japan's Mie Prefecture, specifically from the Handa region. Its designation as a region dealing with issues related to loose, expansive, and weak soils served as the impetus for choosing this site. Three weeks were spent allowing the soil utilized in this study to air dry [8]. To guarantee that the moisture level was constant across all tests, the soil was allowed to air dry for three weeks [9]. Nowadays, expansive soil subgrades and slopes are typically treated using techniques like the replacement technique, cushion method, and core spun method to stop expanding soil from swelling, contracting, and cracking [10].

Rice husk ash (RHA)

A renewable agricultural byproduct of rice, rice-husk ash (RHA) is a plentiful waste resource for Asian nations [11]. 85% to 95% of all agricultural wastes are composed of amorphous silica, which is the most significant percentage [12]. The amorphous silica content of the well-brunt RHA is over 90% [13], and the ash's maximum pozzolanic reactivity occurs at temperatures between 600°C and 700°C [14]. A high silica content of 91.10% and a controlled-burnt RHA at 650–700°C were supplied by Make Integrated Technologies Co., Ltd., Osaka, Japan, which is used in this investigation.

Sea Shell Powder (SSP)

Mollusks such as snails, shellfish, clams, and many others have exoskeletons called sea-shells. One of the biggest environmental problems in coastal areas is the dumping of seashells. Shellfish farming is an industry that is expanding quickly [15]. The calcium carbonate (CaCO3) that makes up the majority of these shells makes them an excellent source for soil amendment [16]. In this study, the seashells were finely grained and provided by Make Integrated Technologies Co., Ltd., Osaka, Japan.

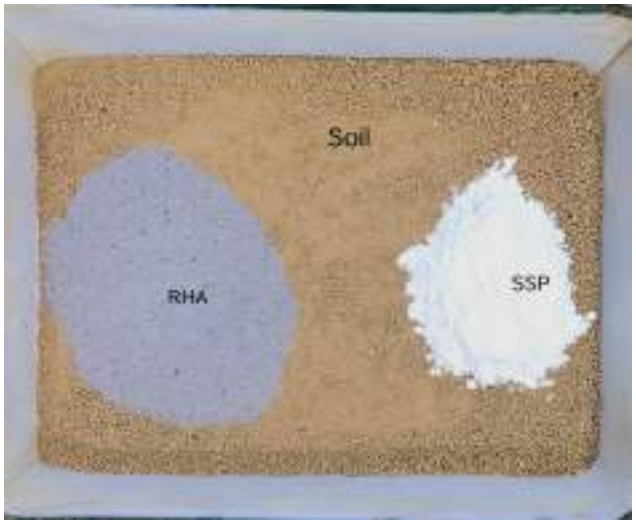

Fig.1 Experiment materials

Combine Specimen Designs

Fixing the appropriate mix design for specimens is crucial for the chemical stability of soil [17]. Several pertinent investigations have been carried out with varying proportions of RHA and cement or SSP

in the soil. Clayey soil stabilization was achieved using soil containing RHA at 5%, 10%, 15%, and 20% as well as 6%, 8%, and 10% cement [18]. Expansive soil was conducted by adding seashell powder with the variation of the ratio, which was 6%, 8%, 10%, 12%, and 14% [19]. In this study, 5% and 10% of RHA with the addition of 5%, 10%, 15% and 20% of SSP were used in the soil to understand the effect of RHA and SSP in expansive soil, as shown in Table 1.

Methodology

The expansive soil was admixed with Rice husk ash of varying 5% and 10% and Sea shell powder 5%, 10%, 15% and 20%. The Experimental Station on Engineering Materials, Faculty of Bioresources, Mie University, Japan, is where all of the present research experiments were conducted. The standard proctor compaction test and the unconfined compressive strength tests were performed according to Japanese Industrial Standards (JIS). Additionally, SEM examinations were conducted to detect any microstructural changes in the specimens.

Table 1 Details of specimen Combinations

Specimens Codes	Soil (S) (%)	Rice Husk Ash (RHA) (%)	Sea Shell Powder (SSP) (%)
S: (Control)	100	0	0
S:5SSP	95	0	5

Standard proctor Compaction test

A conventional proctor compaction test was performed for each material admixture listed in Table 1 to ascertain the ideal moisture content and the associated maximum dry density. A 1000 cm3 volume compaction mold with a collar and a base, and a 10 cm diameter cylinder were used to compress the soil-RHA-SSP admixture sample physically. Three layers of the admixtures were compacted, with a 2.5 kg rammer used to deliver 25 blows to each layer through a 30-cm drop [20]. Figure 2 displays the ideal dry density and moisture content for soil and soil mixtures.

Unconfined compressive strength test

On cylindrical specimens with a diameter of 5 cm and a height of 12.5 cm [21], the unconfined strength of soil in compression tests is determined. The stress-strain curve, which displayed the strain on the X-axis and the stress on the Y-axis, was used to calculate the stress-strain relationship, UCS values, and elasticity of the specimens.

Table 2 Relationship between OMC and MDD

Compaction test	Optimum Moisture Content (OMC) (%)	Maximum Dry Density (MDD)(g/cm^3)
S: (Control)	22	1.52
S:5SSP	26	1.45
S:10SSP	25	1.44
S:15SSP	25	1.45

Scanning electron microscopy test

The 500x magnification SEM photos of soil-RHA combinations were chosen to comprehend the microstructural alterations of the sample's particles. In this study, the SEM test samples were taken from UCS test specimens.

RESULTS AND DISCUSSIONS

Standard Proctor Compaction Test Results

The compaction curves in Fig.2 were used to determine the Optimum Moisture Content (OMC) and Maximum Dry Density (MDD) of soil with RHA and SSP combinations. As RHA-SSP was added to the soil mix, the OMC and MDD of the soil-RHA admixtures varied, with the OMC rising and the MDD falling, which is shown in Fig.2. Table 2 shows that the control soil's OMC is 22% and MDD is 1.52 g/cm3, and with the increase of the RHA-SSP ratio, the OMC has increased and the MDD has decreased.

Unconfined Compressive Strength Test Results

According to Fig.3, the average unconfined compressive strength of the soil, with various added materials, was tested after a curing period of 7 days. The control soil value was 211.33 kN/m^2 with the addition of 5% RHA-20% SSP, showing the highest value of 586.67kN/m^2. On the other hand, soil with 5%RHA-5%SSP, 5%RHA-10%SSP, and 5%RHA-15%SSP showed the value 385kN/m^2, 412.33kN/m^2,464.83kN/m^2 respectively where 10%RHA-5%SSP, 10%RHA-10%SSP, 10%RHA-15%SSP, and 10%RHA-20%SSP showed the results 314kN/m^2, 401.16kN/m^2, 411.67kN/m^2, and 431.16kN/m^2 respectively.

Fig.4 displays the soil's stress-strain relationship curves for the 0%, 5%, and 10% RHA and 0%, 5%,10%, 15%, and 20% SSP mix types. The compressive stress rose with displacement until it reached the highest value, at which point it began to soften, as seen by each curve in Fig.4, and it is noticed that this figure shows that, with the addition of 5% RHA and 20% SSP, the UCS values improved.

Scanning Electron Microscopy Test Results

The SEM test results of soil with 5%RHA and 20%SSP are shown in Fig.5. With pozzolanic reactions, soil containing 5% RHA-20%SSP showed the best mechanical coupling between soil particles and RHA-SSP, leading to the best development of microstructural and strength characteristics. It has shown no porosity with very highly compacted areas, which prevented the pozzolanic reaction and interlocking of soil-RHA-SSP particles.

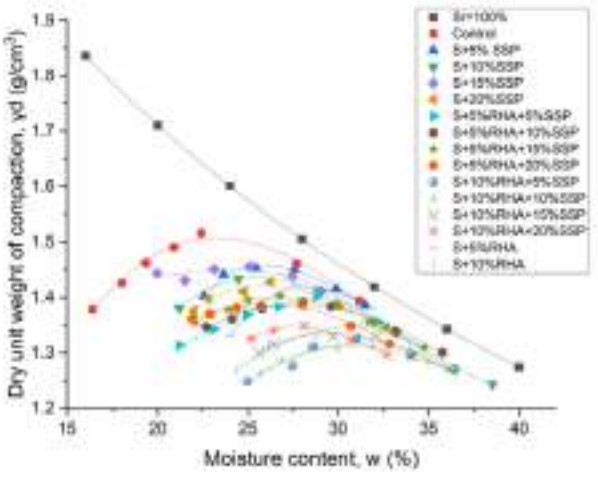

Fig.2 Effects of OSP and RHA on compaction characteristics

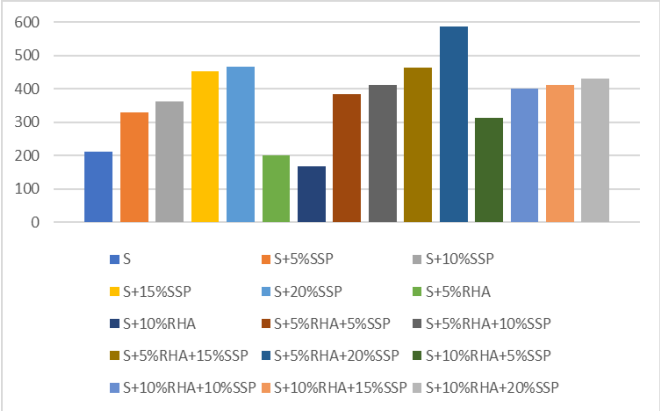

Fig.3 The average unconfined compressive strength of the soil with the variation of RHA-SSP

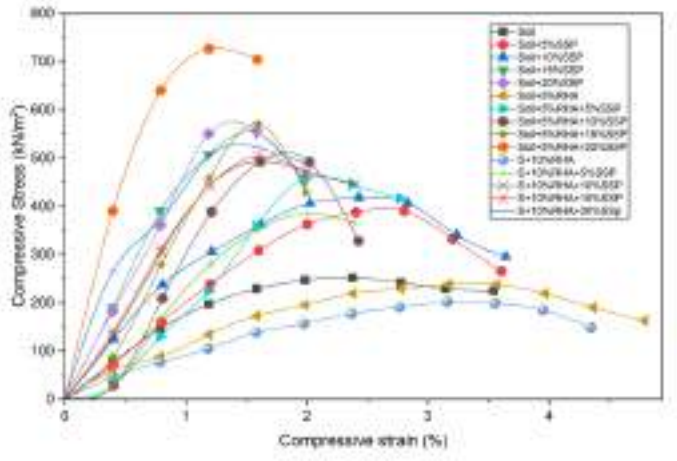

Fig.4 Relationship between compressive stress and strain

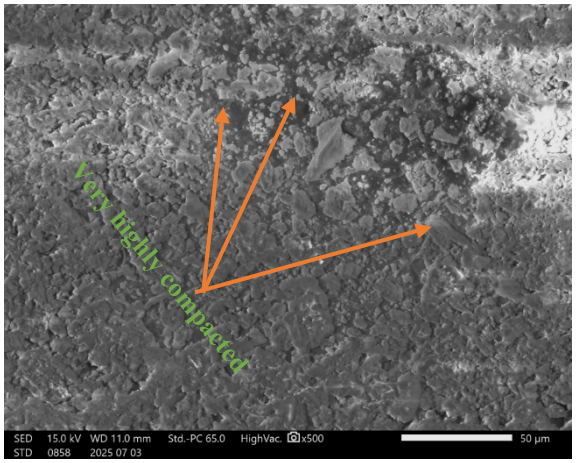

Fig.5 SEM image of S:5%RHA:20%SSP

CONCLUSIONS

The results of the experimental study on the addition of burned RHA and very fine-grained SSP to soil at regulated temperatures indicate that the compaction properties and UCS of soil were impacted by soil containing 0%, 5%, and 10% RHA and 0%,5%,10%,15%, and 20% SSP combinations. While the OMC increased, the MDD decreased as the amount of RHA-SSP increased. The test outcomes demonstrate that the unconfined compressive strength for seashell powder and Rice husk ash treated with Expansive soil expanded radically during the 7-day curing period. The highest compressive strength was estimated to be 5%RHA and 20%SSP (586.67kN/m^2).

This result implies that using this innovative building material for sustainable ground improvement projects has a bright future.

INFLUENCES OF BASALT GEOSYNTHETICS ON SOIL SHEAR STRENGTH

Mohamed Eltaher[1] and Zakaria Hossain[1]

[1]Graduate School of Bioresources, Mie University, Japan

ABSTRACT

Numerous variables affect the performance of reinforced soil structures, and the types of reinforcements used are the most crucial. Reinforcement evaluation, such as geosynthetics, is therefore an essential process in ensuring their successful application in a variety of fields. Thus, the triaxial compression test was utilized to measure the shear strength of a reinforced soil with two basalt geosynthetic types, one geotextile and another geogrid, in turn, in various layering patterns. Both types of basalt geosynthetics embedded in a single backfill sandy soil were tested under a variety of stress conditions. The stress and strain of the specimens were studied concerning the geosynthetic type used and the embedment position. The backfill soil reinforced with both types of geosynthetics showed significant improvement in shear strength as a result of this study's stress-strain behavior. The reinforcement type and embedding position were shown to have a substantial influence on the shear parameters. It has been found that each of these geosynthetics has an ideal embedment position for reaching maximum shear strength. In particular, when basalt geogrid was laid on the soil specimen's upper layer, shear strength peaked.

Keywords: Basalt geosynthetics, Triaxial compression test, Reinforced soil structures, Soil Shear strength.

INTRODUCTION

Because of their various advantages, earth structures can be used in a variety of infrastructure, depending on their intended use. Earth structures must be stable and safe under all kinds of expected stresses and loads [1, 2]. One fundamental feature of these structures is their resistance to deformation under various loads, and the cost of building a road, as an example, can be reduced by using strong subgrade soil [3, 4, 5]. Reinforcing the subgrade, which is a complicated process dependent on the type of reinforcement, might, for instance, reduce the necessary thickness of a flexible pavement for weaker subgrades [6, 7]. Thus, the reduction in expenses will be boosted by the reinforcement's resource-saving capabilities [8, 9]. Therefore, using geosynthetics to reinforce weak subgrade soils is an established way to enhance their shear strength [9, 10, 11].

The triaxial compression test is one of several tests used in laboratories to evaluate the shear strength of subgrade soils. Its benefits over other techniques and methods include its capacity to measure pore pressure and control specimen drainage. The triaxial compression testing method determines the angle of internal friction and cohesion of the soil structure, which are the key indicators of soil shear strength [2, 12, 13].

To examine and evaluate the shearing strength of soils reinforced with geosynthetics, many scholars used the triaxial compression test. They used a variety of geosynthetic materials, such as polypropylene, high-density polyethylene, and other materials [14, 15].

RESEARCH SIGNIFICANCE

The present study investigation concentrates on newly developed geosynthetic materials made from basalt fibers [16]. Under various layering patterns, a set of triaxial compression experiments was performed on a single type of backfill soil reinforced with these geosynthetics. The results of this investigation were used to analyze the reinforced soil's stress-strain relationships as well as its different mechanical properties. Assessing the influence on shear strength of the type of basalt geosynthetic and its embedding position as reinforcement for a single backfill soil is the main aim of this research. This will assist in minimizing the expenditures of building environmentally friendly soil structures in the future.

METHODOLOGY

Backfill Material

A single soil type was used as backfill material. This soil, collected from Mie Prefecture, Japan, was stabilized with two basalt geosynthetic products reciprocally, forming different reinforced soils for evaluating their shear strength.

According to the Japanese Geotechnical Society's geomaterials classification system, this soil is categorized as sandy soil (SF) [17, 18]. Additionally, Table 1 lists its main physical properties [18, 19, 20].

Table 1 Backfill soil physical properties

Soil properties	Measured value
Specific Gravity	2.779 g/cm^3
Gravel > 2 mm	2%
Sand (75 µm - 2 mm)	94%
Silt (5 µm - 75 µm)	2%
Clay < 5 µm	2%
Liquid Limit,	36.664%
Plastic Limit,	30.587%
Plasticity Index,	6.08%
Optimum Water Content	16.7%
Maximum Dry Density	1.713 g/cm^3

Geosynthetics

In this study, basalt geosynthetic products made by Tsuchiya TSCO Co., Ltd., Japan, were used. These geosynthetics exhibit high elasticity and stretch tension, along with good resistance to alkali, acid, vibration, and heat [16].

This research has employed two different basalt geosynthetic types: geogrid and geotextile. For explanatory purposes, the geogrid is referred to as GGR, and the geotextile is referred to as GTX, as shown in Fig. 1.

Fig. 1 Types of basalt geosynthetics utilized

Triaxial Compression Test

A triaxial compression mold (height 12.5 cm, inner diameter 5.0 cm), a compaction hammer (mass 1.0 kg, height 30 cm, diameter 4.9 cm), and a triaxial compression testing machine are among several tools used in this study [21, 22].

Preparation of Specimens

First, the triaxial control specimen, soil only, was formed in the triaxial mold, as shown in Fig. 2. Soil and water, 13% of the soil weight, were uniformly blended to form the control specimen [11]. After the mold was installed, the soil was placed into it in three successive layers, each of which had been uniformly tamped 25 times using a compaction hammer during the mold-filling process. Afterward, the specimen was removed from the mold [21].

Nine identical control specimens were prepared following the previously mentioned procedures to reduce the testing errors.

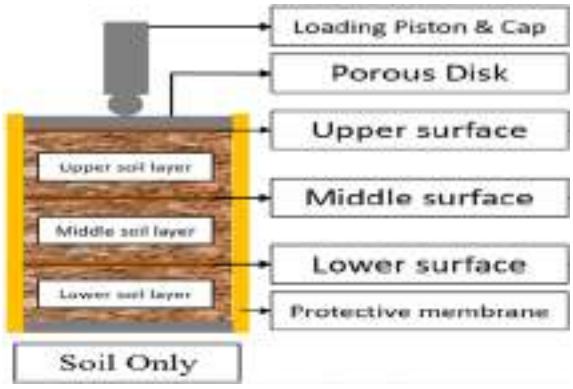

Fig. 2 Simplified representation of a control specimen made up of three separate soil layers only, each of which has a surface where geosynthetics can be placed.

In the same way, the test specimens containing GGR and GTX reciprocally were created by fitting the mold. Then three layers of the moist soil were filled into the mold; each was tamped with 25 blows. During this process, a geosynthetic layer was placed on the surface of the chosen soil layer to achieve reinforcement. This technique resulted in three patterns of test specimens, totaling six specimen types, illustrated in Figs. 3 and 4.

Based on the type of geosynthetic employed, these three patterns of test specimens were divided into two different sets. As shown in Fig. 3, the first set consists of three patterns of geogrid embedding: upper GGR (pattern I), middle GGR (pattern II), and lower GGR (pattern III).

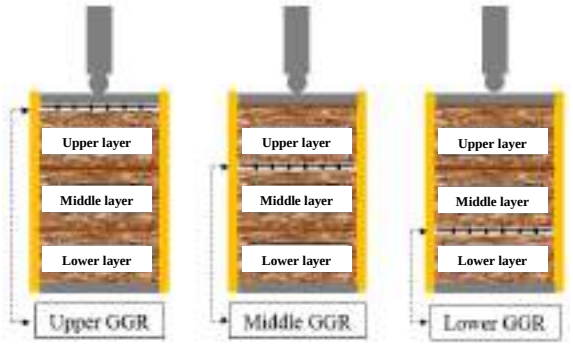

Fig. 3 Simplified representation of three specimen layering patterns of the GGR mesh placed between three layers of soil in three varying positions (I. upper, II. middle, and III. lower)

On the other hand, the second set of these layering patterns consists of three patterns of geotextile embedding: upper GTX (pattern I), middle

GTX (pattern II), and lower GTX (pattern III), illustrated in Fig. 4. For clarity, the test specimens were divided into two main groups: three types containing one GGR layer and three types containing one GTX layer. Nine identical specimens of each type have been prepared. It is worth noting that the specimens used in this study (5 cm diameter) represent a small-scale condition; potential scaling effects are recognized and are further discussed in the future work section.

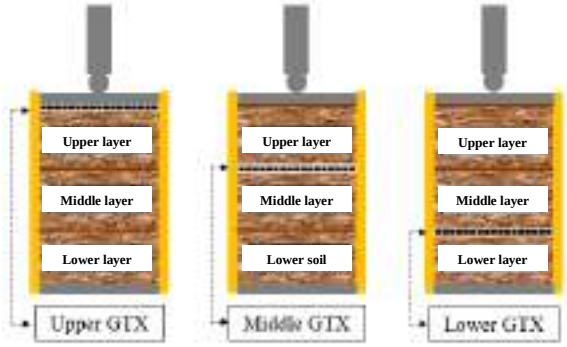

Fig. 4 Simplified representation of three specimen layering patterns of the GTX sheet placed between three layers of soil in three varying positions (I. upper, II. middle, and III. lower)

Testing Procedures

For assessing the shear strength of soil, the triaxial compression test is widely used in laboratory testing [12]. The testing machine's essential components are numbered and displayed in Fig. 5 to facilitate a clear understanding.

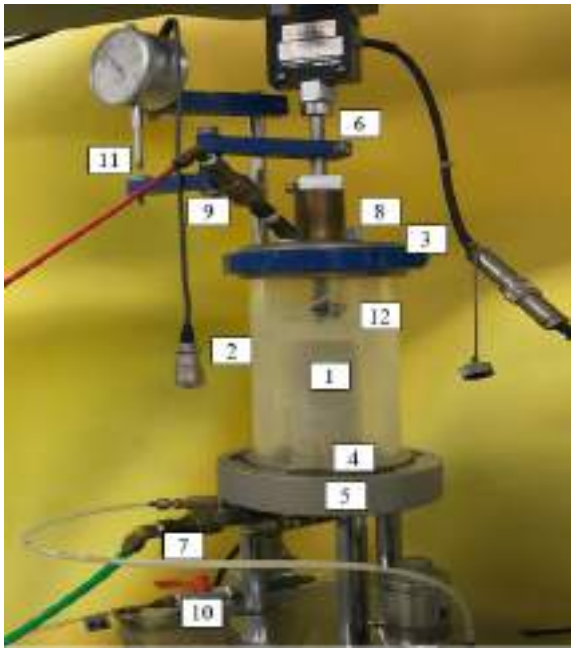

Fig. 5 Triaxial compression testing machine

The triaxial chamber was erected for the test by first placing the soil specimen, which was sealed with a membrane (No. 1, Fig. 5)**,** on the baseplate's pedestal (No. 4, Fig. 5). The chamber cylinder (No. 2, Fig. 5) and top plate (No. 3, Fig. 5) were then positioned on the baseplate groove. The tie ring (No. 5, Fig. 5) was tightened to lock the baseplate, cylinder, and top plate together. The loading piston (No. 6, Fig. 5) was then lowered until it made contact with the specimen cap.

Thereafter, the vent valve (No. 8, Fig. 5) on the top plate was left open, while the confining fluid valve and channel (No. 7, Fig. 5) were used to fill the chamber with water. The confining fluid channel was detached, and the vent valve was sealed after the chamber's water covered the sample and its cap.

The test's confining phase then began by using the pressured air valve and channel (No. 9, Fig. 5) to deliver a specific confining pressure [22]. Each specimen type was subjected to a sequence of confining pressures of 50, 100, and 150 kPa in this investigation.

Subsequently, the dial gauge (No. 11, Fig. 5) started to record the vertical deformation of the specimen as the shearing process began when the axial force was applied through the piston. Due to the drainage condition needed in the consolidated drained (CD) test because of the sandy soil specifications, the specimen drainage valve (No. 10, Fig. 5) was left open during the two phases of the test [12].

As the vertical load was incremented, the vertical deformation dial readings were measured. And according to Eq. (1), the axial strain (Ɛ) is therefore the height change (ΔH) divided by its initial height (H_0) [22].

$$\mathcal{E} = \Delta H / H_0 \quad (1)$$

On the other hand, the variables of applied stress could be distinguished as follows: (σ_1) the major principal total stress is equivalent to (σ_c) the pressure of the chamber in addition to (P) the piston's exerted vertical load divided by (A_c) the specimen's corrected cross-sectional area, as shown in Eq. (2).

$$\sigma_1 = \sigma_c + P/A_c \quad (2)$$

As a second stress variable, (σ_c), the confining pressure is equivalent to (σ_3), the minor primary total stress. For the third stress variable, the application of axial loading induces a deviatoric stress ($\Delta\sigma$) within the specimen. It is defined as the major principal total stress (σ_1) minus the minor principal total stress (σ_3), as expressed in Eq. (3) [2, 22].

$$\Delta\sigma = \sigma_1 - \sigma_3 \quad (3)$$

The internal friction angle (φ) and cohesion (*c*) were then calculated using the Mohr-Coulomb theory, as determined by Eq. (4), where (τ_f) and (σ_f) represent shear and normal stresses at failure, respectively [14].

$$\tau_f = c + \sigma_f \tan\varphi \quad (4)$$

The tests and calculations were performed in this research for one control specimen type and six test specimen types. Nine identical control specimens were examined so that three control specimens were tested under each confining pressure of (50, 100, and 150 kPa), for a total of nine tests for the control specimen type. Regarding test specimens, for each of the six types, nine identical specimens were examined so that three specimens were tested under each of the confining pressures of (50, 100, and 150 kPa). Thus, the total number of tests for each test specimen type was nine, as in the control specimens. These repetitions were designed to ensure the accuracy of the results and minimize the margin of error. The results presented below represent the mean of (σ_1 and $\Delta\sigma$ at peak) for each case, providing a reliable representation of the data.

RESULTS AND DISCUSSION

For investigating and achieving soil reinforcement, two different basalt geosynthetic types were placed inside the soil in turn in this study. Civil engineering projects that have high upfront costs and limited investment returns, such as roads, are subject to the use of soil reinforcement [2]. The triaxial compression test was used to evaluate the strength of both geosynthetic-reinforced and control soil. To gain a clearer understanding of how geosynthetic-reinforced soils behave in terms of shear strength, this study assessed three layering patterns that formed six distinct test specimen types. To determine how varying the basalt geosynthetics type and embedding position affected soil shear strength, a series of triaxial compression experiments was performed to determine the relationship between deviatoric stress and vertical strain.

Results of the Triaxial Compression Test for the Base Case

In order to assess the stress-strain response of the control specimens, three identical specimens of soil only (with their replicates) were subjected to three distinct confining stresses of 50, 100, and 150 kPa [12, 21, 22]. The relationship between the control specimens' axial strain and deviatoric stress is displayed in Fig. 6.

The results of the control specimens demonstrated that all specimens exhibited softening behavior after the ultimate deviatoric stress [2, 12].

According to the results, the mean values of major principal stresses and deviatoric stresses at failure were calculated, and then, with minor principal stresses, they were utilized to draw Mohr-Coulomb circles as shown in Fig. 7.

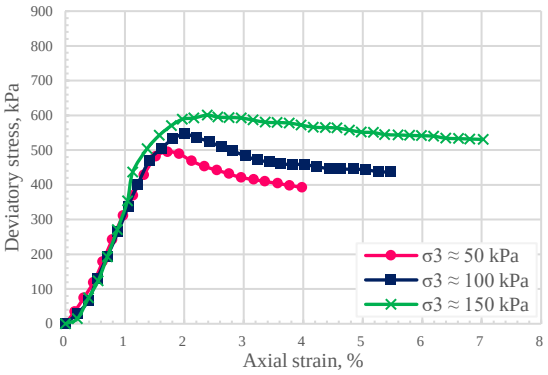

Fig. 6 Control specimens' stress-strain relationship at various confining stresses

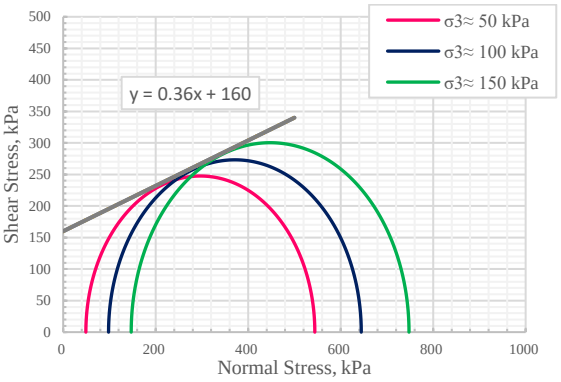

Fig. 7 Mohr-Coulomb stress circles of control specimens at different confining stresses

After that, the strength parameters were graphically determined. The mean angle of internal friction of the soil was determined to be 19.80˚, whereas the mean cohesion was 160 kPa. Although the internal friction angle seems to be very low and the cohesion value seems to be too high, the results of this test are representative of three independent experiments conducted in triplicate and are expressed as the mean.

Influences of Using Basalt Geogrid (GGR) to Reinforce the Soil

The test specimens that contain GGR in the upper, middle, and lower soil layers as three distinct inclusion places with their replicates were tested, and representative stress-strain relationships are displayed, respectively, in Figs. 8, 9, and 10.

The curves representing one GGR layer reinforced specimens in the three figures show a softening behavior toward the end of the stress-strain relationship.

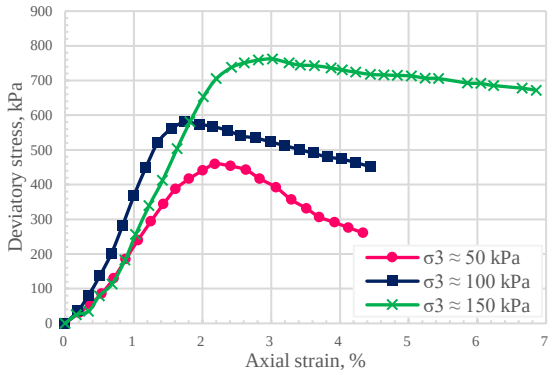

Fig. 8 Test specimens' stress-strain relationship for soil reinforced with GGR in the upper soil layer

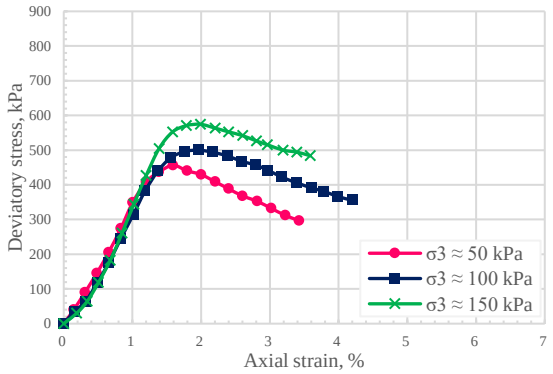

Fig. 9 Test specimens' stress-strain relationship for soil reinforced with GGR in the middle soil layer

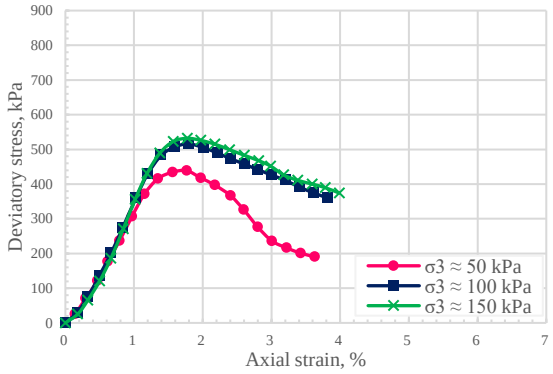

Fig. 10 Test specimens' stress-strain relationship for soil reinforced with GGR in the lower soil layer

As illustrated in Figs. 11, 12, and 13, respectively, shear strength parameters were obtained for soil reinforced with basalt geogrid on the upper, middle, and lower soil layers using the graphical Mohr-Coulomb circles representation. The mean cohesion values were 85, 130, and 140 kPa, respectively, and the mean angles of internal friction were 36.13˚, 22.78˚, and 19.37˚ [12]. As demonstrated by the upper layer scenario, where the internal friction angle was maximized, the results indicate that raising the inclusion position of the geogrid within the soil can enhance the angle of internal friction.

Influences of Using Basalt Geotextile (GTX) to Reinforce the Soil

Figs. 14, 15, and 16 display the results for the test

specimens, which had a geotextile on the upper, middle, and lower soil layers, respectively.

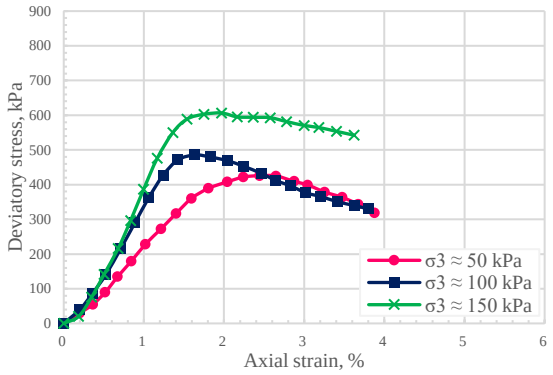

Fig. 14 Test specimens' stress-strain relationship for soil reinforced with GTX in the upper soil layer

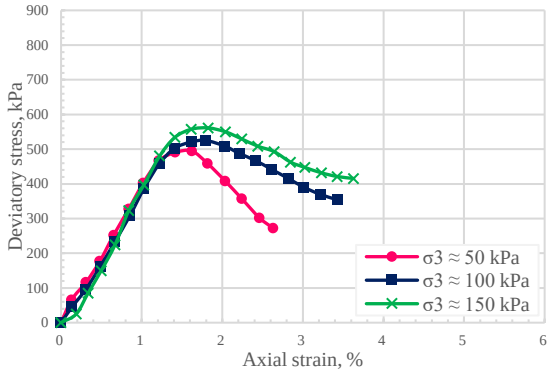

Fig. 15 Test specimens' stress-strain relationship for soil reinforced with GTX in the middle soil layer

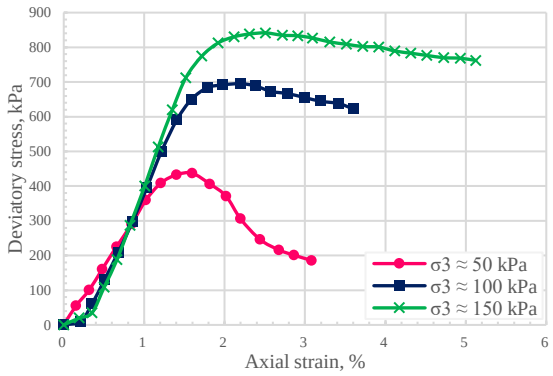

Fig. 16 Test specimens' stress-strain relationship for soil reinforced with GTX in the lower soil layer

As can be observed, the GTX-containing specimens in the middle or upper layer exhibit comparatively consistent trends, whereas the lower layer specimens revealed a distinct and higher growing tendency.

The parameters of shear strength for soil reinforced with geotextile on the upper, middle, and lower soil layers were then determined through the graphical method using the mean values of major principal stress and deviatoric stress at failure, as shown in Figs. 17, 18, and 19, respectively. [22]. The mean cohesion measurements were 100, 160, and 55 kPa, while the mean angles of internal friction were 27.71˚, 17.85˚, and 41.91˚, correspondingly.

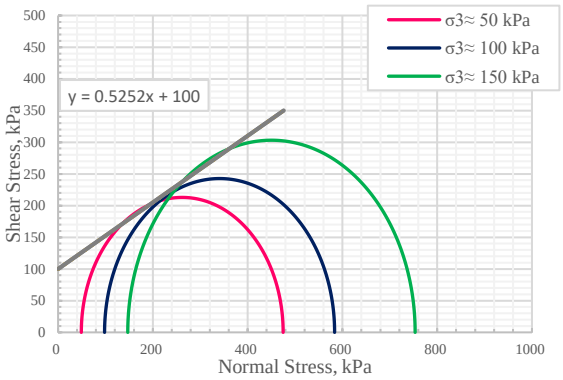

Fig. 17 Mohr-Coulomb stress circles of test specimens for soil containing one layer of GTX on the surface of the upper soil layer

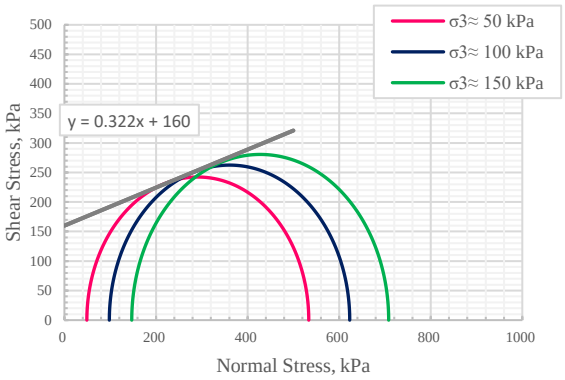

Fig. 18 Mohr-Coulomb stress circles of test specimens for soil containing one layer of GTX on the surface of the middle soil layer

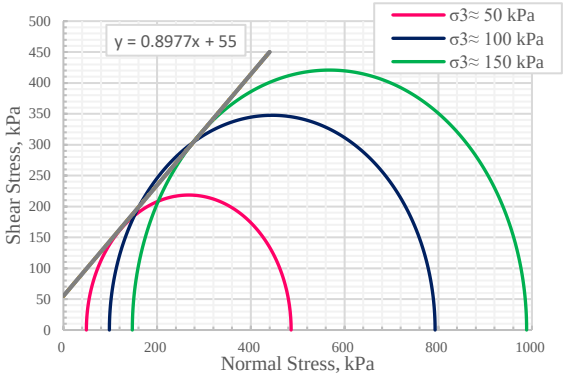

Fig. 19 Mohr-Coulomb stress circles of test specimens for soil containing one layer of GTX on the surface of the lower soil layer

Unlike the geogrid scenario, the angle of internal friction fluctuates but substantially improves when the GTX embedding position is in the lower soil layer.

The mean findings for every specimen type that was analyzed, as well as how the layering pattern and the type of geosynthetics affected the shear strength, were depicted in Table 2. Comparing the findings shows that adding basalt geogrid or geotextile increases the soil's shear strength in all patterns except for GGR on the surface of the lower soil layer and GTX on the surface of the middle soil layer. It is found that, out of all the GGR layering patterns, the soil reinforced with geogrid placed on the upper soil layer has the maximum angle of internal friction. Regarding geotextile, the greatest angle of internal friction was obtained when the GTX was positioned on the lower soil layer. It is essential to note that, for each specimen type, all the tests were repeated three times, and the results were very consistent. The calculated standard deviations were mostly less than 1, which indicates that the variations are negligible.

Table 2 Shear strength results comparison.

Layering pattern		Geogrid		Geotextile	
		Mean φ˚	*Mean c* (kPa)	Mean φ˚	*Mean c* (kPa)
Test Specimens	Upper	36.13˚	85	27.71˚	100
	Middle	22.78˚	130	17.85 ˚	160
	Lower	19.37˚	140	41.91 ˚	55
Control specimen	soil only	Mean φ˚ = 19.80˚		*Mean c* = 160 kPa	

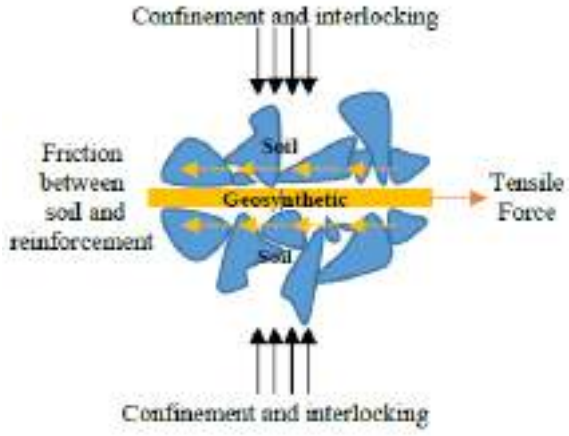

Fig. 20 Basic reinforcing mechanisms occurring in the basalt geosynthetic reinforced soil.

The confinement of the soil particles with the geosynthetic ribs, the interaction on the geosynthetic-soil irregular interface, which is dependent on the rolling and interlocking mechanism [1], and the developed tensile forces due to the load application—all of which depend on the embedding position and the type of geosynthetic [2, 10]—are the leading causes of the high internal friction angle values in nearly all test specimens when compared to the control specimens. These established effects aid the total reinforcing mechanism between soil and basalt geosynthetic. [5], as shown in Fig. 20.

A single GGR layer placed in the lower soil layer and a single GTX layer placed in the middle soil layer, however, did not increase shear strength as a result of these reinforcement mechanisms; rather, the internal friction angle values were lower than those seen in the control. This suggests that more complicated parameters may influence the shear responses in such embedding places for each type of basalt geosynthetic, necessitating ongoing research.

In contrast, cohesion values reveal expected declining trends due to the separation of soil layers and the anti-synergistic action between the angle of internal friction and cohesion [2]

These results are in line with earlier studies that determined CBR values using the same layering patterns and the same materials, showing that the GGR lower pattern and GTX middle pattern also have CBR values lower than the control [11]. Therefore, these findings offer significant insights for enhancing the strength of soil structures reinforced using geosynthetics. For field reinforcing applications, these newly innovated basalt geosynthetics are therefore advised.

FUTURE WORK

Future studies should consider using larger triaxial chambers and specimen sizes to better capture potential scaling effects. Such investigations would enhance the understanding of how specimen size affects shear strength parameters at different embedding positions for each type of basalt geosynthetic. Additionally, complementary direct shear tests using shear boxes of different sizes could provide further insights into scaling effects from another perspective.

CONCLUSIONS

Overall, it may be said that the inclusion of the newly innovated basalt geogrid or geotextile in the soil in any position significantly enhances its shear strength.

The type of geosynthetics and the layering pattern were discovered to affect the angle of internal friction, which can rise by as much as 111.7% when compared to a soil-only specimen. On the other hand, cohesion is inhibited by placing basalt geosynthetics in almost any position.

Moreover, it is feasible to determine that, for each type of basalt geosynthetic, there is an embedment position that optimizes the shear strength of the soil composite. The most effective position for the basalt geogrid type inclusion was on the upper soil layer,

which produced the highest angle of internal friction of 36.13˚, and the most effective position for the basalt geotextile type inclusion was on the lower soil layer, which produced the highest angle of internal friction of 41.91˚.

In light of these results, it is advised that the basalt GGR upper layer pattern and the basalt GTX lower layer pattern be applied in field settings, taking into consideration the additional purposes that the geosynthetics may serve beyond reinforcement, such as filtration and separation.

ACKNOWLEDGMENTS

I extend my gratitude to the Graduate School of Bioresources, Mie University, and Japan Science and Technology Agency (JST), Support for Pioneering Research Initiated by the Next Generation (SPRING), Japan, for providing the opportunity to pursue this research.

CHARACTERIZATION OF SOIL-RICE HUSK ASH-CEMENT MIXTURES FOR SUSTAINABLE GROUND IMPROVEMENT: MECHANICAL AND MICROSTRUCTURAL INSIGHTS

Abdelmageed Atef[1], and Zakaria Hossain[2]

[1]Graduate School of Bioresources, Mie University, Japan.

ABSTRACT

The growing global demand for ground improvement necessitates sustainable alternatives to conventional cement, given its significant environmental impact. This study investigates rice husk ash (RHA), an agricultural byproduct rich in amorphous silica, as a promising sustainable supplementary cementitious material for soil stabilization. While RHA reduces CO_2 emissions and costs, it's typically combined with cement for adequate strength. Previous research on soil-RHA-cement mixtures often lacked comprehensive mechanical property data beyond UCS and detailed microstructural analysis. This research addresses these gaps by evaluating the strength characteristics of soil stabilized with controlled-burn RHA and ordinary Portland cement. This approach is crucial for developing countries grappling with RHA disposal. We conducted standard Proctor compaction tests and unconfined compressive strength (UCS) tests on specimens with varying RHA (2-6%) and cement (2-6%) content across different subgrade layers. Scanning electron microscopy (SEM) and Energy-dispersive X-ray Spectroscopy (EDS) provided microstructural insights. The study details optimum moisture content (OMC), maximum dry density (MDD), stress-strain relationships, UCS values, modulus of deformation, strain at compressive strength, and failure modes, supported by SEM images and EDS graphs. Our findings aim to promote the optimal, sustainable use of RHA in ground improvement, fostering a greener construction industry.

Keywords: Rice husk ash, UCS test, Subgrade layer, Ground improvement

INTRODUCTION

The global demand for ground improvement in construction is escalating, with over 40,000 soil enhancement projects undertaken annually worldwide. This surge fuels rapid advancements in construction technologies, yet also introduces new challenges in their application. Traditional soil improvement often relies on external materials, such as cement, geosynthetics, chemical grouts, and strips. Among these, cement is the most prevalent due to its widespread availability and versatility. However, the extensive use of cement, with global production reaching 4.1 billion tons in 2019, poses significant sustainability threats. Cement production is a costly and energy-intensive process that depletes natural resources and contributes approximately 8% of global CO_2 emissions. To align with the Sustainable Development Strategy (SDS), the construction industry needs to reduce its CO_2 intensity by 0.8% annually through 2030, a stark contrast to the 0.5% yearly increase observed between 2014 and 2018. Consequently, environmental engineers are actively exploring sustainable and economical alternatives to traditional cementitious materials [1, 2].

Supplementary Cementitious Materials (SCMs) are emerging as a promising solution within the construction sector, offering both environmental advantages and enhanced material strength and stability. It's estimated that SCMs could replace 30% of global cement usage, substantially reducing CO_2 emissions from cement industries. Annually, the agricultural sector worldwide generates approximately 410 million tons of natural cementitious materials, such as rice husk ash (RHA), sugarcane bagasse ash, and palm oil fuel ash, with about 335 million tons remaining unutilized. The use of pozzolanic agricultural wastes in engineering projects has been gaining traction since the late 1960s. Rice husk ash (RHA) stands out as a readily available, carbon-based, renewable agricultural byproduct boasting the highest reactive amorphous silica content (85-95%) among agricultural wastes. This makes it a viable substitute for cement in soil stabilization. Incinerating rice husks, a byproduct of the rice milling process, produces RHA. [3, 4] With over 700 million tons of paddy rice produced globally each year, about 30-35 million tons of RHA could be generated if all rice husks were combusted. The disposal of RHA, being lightweight, poses environmental and health risks when it is dumped in open areas, riverbanks, and low-lying areas. Integrating RHA as a supplementary cementitious material in ground improvement offers numerous benefits: it reduces CO_2 emissions, lowers construction costs, mitigates environmental issues, and alleviates waste disposal challenges, all while significantly enhancing the strength and durability of stabilized soil and concrete. However, RHA is often used in conjunction with cement and lime in engineering projects because RHA alone typically doesn't provide sufficient strength due to its limited

cementitious properties. RHA improves stabilized soil through two mechanisms: chemically (pozzolanic effect), where its silica (SiO_2) reacts with calcium hydroxide ($Ca(OH)_2$ from cement hydration to form Calcium Silicate Hydrate (CSH) gel, which is crucial for strength gain, and physically (filler effect), where unreacted RHA particles, with their low specific gravity and highly microporous structure, act as a filler.

The strength and durability of stabilized soil are highly dependent on the soil type, the specific combination of additives, and the curing conditions. Crucially, the amount of amorphous silica in RHA, which directly influences the pozzolanic reactions and CSH gel formation, is determined by the incineration process (burning temperature, duration, and cooling). High-quality, chemically reactive silica-rich RHA is produced when rice husk is burned for over 12 hours at a controlled temperature of 500-700°C. Conversely, uncontrolled burning or open burning yields RHA with lower silica content. As-obtained RHA from improper burning often has coarser particles, lower bulk density, and reduced silica content compared to other pozzolans, which impacts the cement density and particle spacing in the mixture [5, 6]. While grinding RHA can produce finer particles, it may not always enhance pozzolanic reactivity and incur additional cost and time. Previous investigations into soil-RHA-cement combinations have explored their suitability for soil stabilization, RHA with various cement ratios for silty and clayey soils. However, these studies mainly reported unconfined compressive strength (UCS) values, often omitting critical data such as stress-strain relationships, modulus of deformation, strain at compressive strength, and failure modes of UCS specimens. Furthermore, detailed microstructural analyses, such as SEM images and EDS (Energy-dispersive X-ray Spectroscopy) data, which are vital for explaining the strength parameters of treated soil, were rarely presented. Given the variability in soil types, RHA processing (grinding and sieving), and silica content, existing research on soil-RHA-cement combinations remains insufficient for optimal utilization of RHA [7].

This study aims to address these gaps by investigating the strength characteristics of soil combined with controlled-burn, as-obtained RHA, and ordinary Portland cement, to achieve sustainable ground improvement. This research is particularly relevant for developing countries, which frequently face severe environmental pollution and RHA disposal challenges due to limited access to advanced waste management technologies. With increasing population demands in these regions, this study is crucial for promoting the extensive use of locally available RHA as a cement alternative in stabilization techniques for new housing, commercial buildings, roads, tunnels, and earth dams, thereby contributing to sustainable construction practices[8].

A comprehensive series of tests was conducted, including standard Proctor compaction tests and unconfined compressive strength (UCS) tests, complemented by scanning electron microscopy SEM and EDS analysis of UCS test specimens in three subgrade layers: upper, lower, and dual subgrade layers. The specimens comprised varying percentages of RHA (2%, 4%, 6%) and cement content (2%, 4%, 6%). This study will thoroughly discuss the optimum moisture content (OMC), maximum dry density (MDD), stress-strain relationships, UCS values, modulus of deformation, strain at compressive strength, failure modes of UCS specimens, and present detailed SEM images and EDS graphs of the soil-RHA-cement specimens.

RESEARCH SIGNIFICANCE

This study examines the feasibility of utilizing rice husk ash (RHA) to stabilize soil in subgrade layers. While conventional stabilizers, such as cement and lime, are effective, there's a growing need for materials that enhance soil strength while simultaneously reducing environmental impact. Our research focuses on improving soil durability and lowering carbon emissions by incorporating a minimal amount of cement alongside RHA in soil mixtures. Unlike traditional studies that primarily focus on concrete applications, this work emphasizes the critical role of soil reinforcement for infrastructure projects. This approach promotes a holistic, environmentally responsible method for ground improvement, addressing both ecological concerns and the need for resilient construction.

MATERIALS AND METHODS

Materials

Soil

The soil for this study was sourced from the Handa Area in Mie Prefecture, Japan, as depicted in Figure 1. It was air-dried for three weeks, then passed through a 200 mm sieve. We conducted sieve analysis, hydrometer analysis, and liquid and plastic limit tests to determine the classification. The measured plastic and liquid limits were 28.59% and 48.5%, respectively. The soil composition was 42.7% clay, 57.28% silt, and 0.02% sand. According to the American Association of State Highway and Transportation Officials (AASHTO) classification, it was categorized as A-7-6 clayey soil. Figure 1 also illustrates the grain size distribution for the soil, cement, and rice husk ash used. Testing procedures for sieve and hydrometer analyses followed Japan Industrial Standards (JIS) A 1204 [9], while liquid

and plastic limit tests adhered to JIS A 1205. Table 1 provides further geotechnical properties of the soil.

Rice husk ash

The rice husk ash (RHA) used in this investigation was acquired from Via Make Integrated Technology Co., Ltd. in Osaka, Japan. It was produced through a controlled combustion process at temperatures ranging from 650°C to 700°C. This meticulous 27-hour incineration process, conducted within an industrial incinerator under computer-controlled conditions, resulted in RHA with a high silica content of 91.10%. The particle sizes of the RHA ranged from 0.07 mm to 0.3 mm. Figure 2 presents a detailed particle size distribution for both the soil and RHA. Table 1 outlines the comprehensive chemical and physical characteristics of the rice husk ash.

Portland cement

Ordinary Portland Cement (OPC) was used as the other binding material in this study. Its physical and chemical properties are detailed in Table 2.

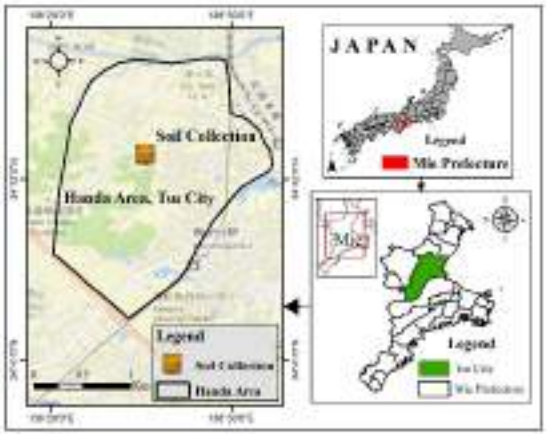

Fig.1 The exact location where soil samples were collected for this study.

Specimen Preparation

To investigate the effects of soil-RHA-cement mixtures on shear strength, a series of specimens for unconfined compressive strength (UCS) tests was meticulously prepared. Each cylindrical specimen had a total height of 12.5 cm and a diameter of 5.0 cm, with a total sample weight of 500 grams, equating to a weight ratio of 40 grams per 1 cm of height. For the experimental layers within the specimens, a specific mixture was formulated. Each such layer, intended to be 1 cm in height, consisted of 40 grams of a soil-RHA-cement mixture combined with 120 grams of plain soil, resulting in approximately 160 grams of total soil per layer [10]. The specimens were compacted manually in three layers within the mold. Compaction was achieved using a 4.9 cm diameter hand rammer weighing 1 kg, applying 20 blows per layer from a falling height of 30 cm. This standardized compaction protocol ensured uniform and consistent density throughout the soil-RHA-cement mixture within each specimen. Before compaction, the soil, RHA, and cement components were thoroughly dry-mixed in a large tray to achieve a homogeneous blend. Water was then gradually added to this dry mix, with the amount precisely determined based on the optimum moisture content (OMC) derived from compaction tests, ensuring proper hydration without over-saturation. This meticulous preparation and compaction methodology were crucial for guaranteeing the integrity and reliability of the subsequent shear strength testing.

In this study, the RHA dosage was selected at 2%, 4%, and 6% of the soil weight. This range was chosen to investigate the effects around the typically observed maximum utilization of amorphous silica at approximately 5%, as suggested by previous research [10]. This allowed for examining the impact of slightly lower, optimal, and slightly higher RHA percentages. Furthermore, the study intentionally incorporated a minimal dosage of cement. This inclusion complements the soil treatment by ensuring an optimal supply of Ca+ ions, which are essential for robust pozzolanic reactions with the RHA. This approach underscores the study's focus on enhancing soil properties sustainably, aligning with environmental conservation and carbon emission reduction objectives, rather than solely concentrating on concrete applications.

Testing Method

Compaction Tests

A Standard Proctor Compaction Test was performed to determine the key parameters for each material blend, as presented in Table 3. This test was crucial for identifying the maximum dry density (ρdmax) and the optimum moisture content (wopt) for each mixture. For each unique blend, compaction was carried out in a cylindrical mold measuring 10 cm in diameter and 12.73 cm in height. A 2.5 kg rammer, dropped from a height of 30 cm, was used to compact the material in three equal layers, ensuring consistent compaction throughout the specimen. This procedure was repeated for various carefully monitored moisture contents to establish a range of dry densities for each blend.

The results of the experiment were plotted as compaction curves, showing the relationship between dry density and moisture content. The peak point of each curve directly indicated the maximum dry density and the corresponding optimum moisture content. The entire compaction testing process strictly adhered to the requirements of Japan Industrial Standards (JIS) A 1210 (JIS, 2010) [9, 11], ensuring the precision and reliability of the experimental method. Figure 4 illustrates the obtained optimum moisture content and maximum dry density values for the natural soil and its various mixtures.

Unconfined Compressive Strength (UCS) Test

The Unconfined Compressive Strength (UCS) test stands as the most widely adopted and practical method globally for evaluating the strength of optimized stabilized soil mixtures [1-3]. Its versatility extends to numerous applications within the construction sector, offering insights into the bearing capacity of soil when combined with various additives [1, 2]. In this study, the UCS test was conducted meticulously in accordance with Japanese Industrial Standards [10].

To prepare the test specimens, soil-RHA-cement combinations were manually compacted within a mold measuring 12.5 cm in height and 5.0 cm in diameter. A 4.9 cm diameter hand-rammer, weighing 1.0 kg, with a consistent falling height of 30 cm, was used. Each specimen was compacted in three layers, with each layer receiving 20 blows to ensure uniform density. During the test, the UCS reading was

recorded precisely every 0.5 mm of displacement at a constant loading rate of 0.1 mm/min. To ensure statistical robustness, the average strength value was calculated from the results of three identical specimens tested for each mix type, providing a reliable measure of the stabilized soil's strength. This rigorous methodology ensures that the results accurately reflect the mechanical performance of the treated soil.

RESULTS AND DISCUSSION

To evaluate the influence of soil-RHA-cement mixtures on shear strength, a series of Unconfined Compressive Strength (UCS) tests was conducted. These tests aimed to determine the strength development in specimens incorporating varying percentages of RHA (2%, 4%, 6%) and cement (2%, 4%, 6%), as well as the effects of their placement in top, bottom, and dual subgrade layers.

The UCS values for all examined soil-RHA-cement composite specimens demonstrated a noticeable increase when RHA was combined with cement. This significant positive transformation is primarily attributed to the pozzolanic reactions occurring between the amorphous silica in RHA and the calcium hydroxide (Ca(OH)2 released during cement hydration. These reactions lead to the formation of Calcium Silicate Hydrate (CSH) gel. This insoluble binder fills soil voids, bonds particles together, and densifies the soil matrix, thereby enhancing its overall strength and stiffness over time. The irregular forms and denser microstructure resulting from these interactions significantly contribute to the improved bearing capacity.

Generally, increasing the cement content from 2% to 6% consistently led to an increase in UCS values across both upper and lower layers. The most pronounced improvement in single-layer specimens was observed at 4% cement content, yielding a notable UCS value. For the dual-layer specimens,

UCS values typically ranged, indicating a more complex interaction of the layers. The addition of 2% RHA showed modest variations in UCS values. However, higher RHA percentages, specifically 4% and 6% RHA, resulted in more significant increases in UCS values, particularly evident in the dual-layer configurations.

Remarkably, a mix of 4% RHA + 6% cement consistently demonstrated the most substantial strength enhancement. This specific combination achieved the highest UCS values across all testing conditions, with a peak UCS of 211 MPa for the dual-layer configuration. This finding aligns well with comparable results documented in previous research on RHA and cement-stabilized soils, where synergistic effects between these two binders are frequently observed [10,14].

When compared to the control (untreated) Soil, see the failure pattern for soil only in Fig. 5, all tested soil-RHA-cement combinations exhibited significantly improved UCS values, confirming that the mixture substantially enhances the Soil's unconfined compressive strength and, consequently, its bearing capacity. The optimal mix design identified in this study is the Soil + 4% RHA + 6% Cement, which consistently produced the highest UCS values, making it the most effective choice for enhancing soil strength under these testing conditions. It was also observed that beyond approximately 4% to 6% cement content, the rate of increase in UCS values began to diminish, suggesting an optimal balance between economic and performance considerations within this range. While RHA alone has a moderate effect on UCS values, its synergistic action with cement, particularly at a 4% RHA inclusion, leads to a remarkable improvement in strength. Therefore, the combination of 4% RHA and 6% cement in soil mixtures is strongly recommended for applications requiring enhanced soil strength and load-bearing capacity. Future investigations could further optimize these exact proportions, assess long-term durability, and examine performance under various environmental conditions.

CONCLUSION

This study comprehensively investigated the potential of rice husk ash (RHA) as a sustainable supplementary cementitious material for soil stabilization, addressing the pressing environmental concerns associated with the use of conventional cement in ground improvement. Our research aimed to fill existing gaps by evaluating the mechanical and microstructural properties of soil stabilized with controlled-burn, as-obtained RHA in combination with ordinary Portland cement, particularly focusing on their application in subgrade layers.

The Unconfined Compressive Strength (UCS) tests unequivocally demonstrated that the incorporation of RHA and cement significantly enhances the strength of the treated soil. This substantial improvement is primarily attributed to the pozzolanic reactions between RHA's amorphous silica and cement's calcium hydroxide, leading to the formation of strength-contributing Calcium Silicate Hydrate (CSH) gel. We observed a consistent increase in UCS values with higher cement content, with the most effective performance achieved by the combination of 4% RHA and 6% cement. This optimal mix yielded the highest UCS values across all tested configurations, especially in dual-layer applications, highlighting a synergistic effect between the two binders. Microstructural analyses, including SEM and EDS, would further corroborate these findings by revealing the formation of dense CSH networks and improved particle bonding. This research holds significant practical implications, particularly for developing countries where RHA disposal is a challenge and sustainable construction practices are crucial. The findings provide a robust recommendation for utilizing a specific blend of RHA and cement to achieve enhanced soil strength and load-bearing capacity, offering an environmentally responsible alternative for infrastructure development. By promoting the use of this agricultural byproduct, the study contributes to reducing carbon emissions, lowering construction costs, and fostering a more sustainable future for the geotechnical and construction industries. Future research should focus on validating the long-term durability of these optimized mixes and their performance under diverse environmental conditions.

ABSTRACT

This research explores the potential of refuse-derived fuel fly ash (RDF FA), a byproduct of municipal solid waste incineration, as a sustainable material for enhancing concrete pavement performance. The study investigates RDF FA as both a partial cement replacement and an additive to evaluate its mechanical and environmental impacts. Experimental results demonstrate that cement replacement with RDF FA reduces early-age compressive and flexural strengths. In contrast, its addition significantly improves 28-day strengths, surpassing standard requirements for rigid pavement applications. Microstructural analyses re-veal that RDF FA enhances hydration and densifies the concrete matrix when used as an additive, while leachate testing confirms heavy metal concentrations within environmentally acceptable limits. By incorporating RDF FA in concrete pavements, this research contributes to sustainable construction practices, resource conservation, and global efforts to mitigate the environmental footprint of infrastructure development. The study aligns with the goals of promoting a circular economy and advancing innovative solutions for waste management and climate resilience in construction.

Keywords: Sustainable concrete pavement, Refuse-derived fuel fly ash, Supplementary cementitious materials, rigid pavement, Municipal waste.

INTRODUCTION

The growth of urbanization and industrial development has resulted in a rapid increase in municipal solid waste (MSW), creating critical challenges in disposal and environmental management. Incineration is widely adopted for MSW treatment due to its effectiveness in volume reduction and energy recovery [1](Cho et al., 2020). However, this process generates large amounts of bottom ash (BA) and fly ash (FA), which require careful management to mitigate environmental risks. In particular, refuse-derived fuel fly ash (RDF FA), produced from pre-sorted and pelletized MSW incineration, is of growing interest due to its relatively consistent composition and potential reusability [2, 3](Kikuchi, 2001; Saikia et al., 2007).

In the construction industry, supplementary cementitious materials (SCMs) have been widely employed to enhance concrete properties while reducing cement consumption and associated CO_2 emissions. Previous studies have demonstrated that municipal solid waste incineration (MSWI) ashes can partially substitute cement or aggregates, contributing to strength development and improved sustainability [4-6](Abbà et al., 2014; Jurič et al., 2006; Yang et al., 2018). While bottom ash has been commonly utilized as aggregate replacement, the application of MSWI fly ash, particularly RDF FA, in concrete pavements remains limited and requires further investigation.

Rigid concrete pavements demand adequate compressive and flexural strengths to withstand heavy traffic loading and environmental stresses. Early studies reported that the incorporation of FA could influence hydration and microstructure, affecting both strength and durability [7, 8](Shi et al., 2009; Tang et al., 2016). However, the effect of RDF FA in pavement-grade concrete under different incorporation methods—cement replacement versus cement addition—has not been systematically evaluated.

This study aims to investigate the mechanical performance and microstructural development of concrete incorporating RDF FA for rigid pavement applications. Mechanical properties were assessed through compressive and flexural strength tests, while scanning electron microscopy (SEM) was employed to examine hydration products and matrix densification. The findings provide new insights into the potential of RDF FA as a sustainable construction material, highlighting the distinction between cement replacement and additive use, and supporting circular economy practices in pavement engineering.

MATERIALS AND METHODS

Materials

Refuse-derived fuel fly ash (RDF FA) used in this study was collected from a municipal solid waste incineration (MSWI) facility in Saraburi, Thailand. Its chemical composition, determined by X-ray fluorescence (XRF), indicated a high CaO content and significant SiO_2 and Al_2O_3 levels, suggesting pozzolanic potential. Type I ordinary Portland cement (OPC) conforming to ASTM C150 was used as the primary binder. Natural sand and crushed limestone, complying with ASTM C33, were employed as fine and coarse aggregates, respectively (Fig. 1).

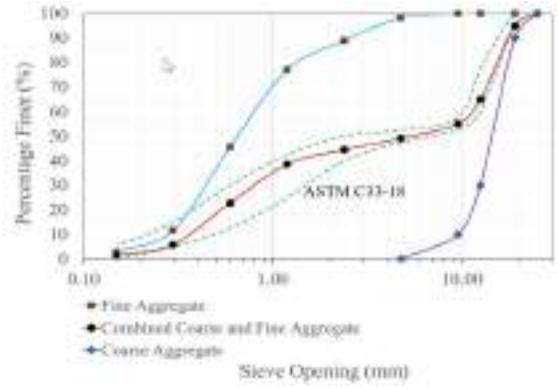

Fig.1. Particle size distribution of aggregates.

Mix Design and Specimen Preparation

Use at most three levels of headings that correspond to chapters, sections, and subsections. The first level headings for chapter titles should be in 10pt, bold, justified, and upper case font. Leave one blank line before and after the first level headings, respectively.

Two incorporation methods were adopted: (i) cement replacement by RDF FA at 5%, 10%, and 15% by weight of cement, and (ii) cement addition at the same percentages without reducing OPC content. A control mix (100% OPC) was prepared for comparison. All mixes were designed at a constant water-to-cement ratio of 0.5, with slump controlled at 75 ± 5 mm in accordance with the Department of Highways (DOH) of Thailand standards.

Concrete batches were mixed in a laboratory drum mixer following ASTM C192. Cube specimens (100 × 100 × 100 mm³) were prepared for compressive strength testing, while prism specimens (100 × 100 × 500 mm³) were cast for flexural testing. Specimens were demolded after 24 hours and cured in water at 23 ± 2 °C until testing ages of 7 and 28 days.

EXPERIMENTAL PROGRAMS

Mechanical Testing

Compressive strength was determined according to ASTM C39, and flexural strength was measured using the three-point bending test following ASTM C78. The flexural strength was calculated using:

$$f_r = \frac{bd^2}{PL} \quad (1)$$

where P = maximum load, L = span length, b = specimen width, and d = specimen depth.

Scanning Electron Microscopy (SEM) analysis

Microstructural observations were conducted using scanning electron microscopy (SEM) on fractured surfaces of 28-day cured specimens. Samples were oven-dried at 50 °C, gold-coated, and examined under 15 kV accelerating voltage. Morphological features such as calcium silicate hydrate (C-S-H), ettringite, and calcium hydroxide [$Ca(OH)_2$] were identified to assess the influence of RDF FA incorporation on hydration and matrix densification.

RESULTS AND DISCUSSION

Unconfined Compressive Strength Development

The compressive strength results of RDF FA-modified concretes at 7 and 28 days are presented in Fig.2. The control mix exhibited a 28-day strength of 34.1 MPa, satisfying the Department of Highways (DOH) minimum requirement of 32 MPa (DH-S 309/2544).

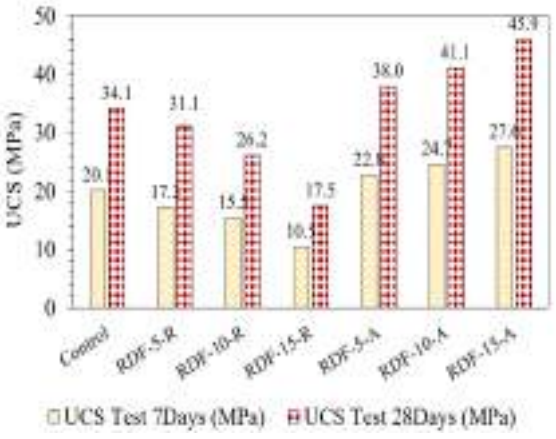

Fig.2 UCS results.

When RDF FA was used as a cement replacement, compressive strength decreased with increasing replacement levels. At 28 days, RDF-5-R, RDF-10-R, and RDF-15-R achieved 31.1, 26.2, and 17.5 MPa, respectively—all below the DOH standard. The reduction is attributed to the decreased cement content, which limits calcium silicate hydrate (C-S-H) formation, resulting in a weaker matrix.

In contrast, the cement addition method significantly improved strength. RDF-5-A, RDF-10-A, and RDF-15-A exhibited 28-day compressive strengths of 38.0, 41.1, and 45.9 MPa, respectively, surpassing both the control mix and DOH requirements. The improvement is due to enhanced hydration and pozzolanic reactions of RDF FA, which contributed to additional C-S-H formation and matrix densification.

Flexural Strength Development

The flexural strength results of RDF FA-modified concretes at 7 and 28 days are presented in Figure 2. The control mix achieved 4.2 MPa at 28 days, meeting the Department of Highways (DOH) requirement for rigid pavement concrete (Fig.3).

For the replacement method, flexural strength decreased with increasing RDF FA content. At 28 days, RDF-5-R, RDF-10-R, and RDF-15-R recorded 3.6, 2.7, and 2.0 MPa, respectively—below the DOH minimum requirement. The decline is attributed to reduced cement content, which limited C-S-H formation and weakened the bond between paste and aggregates, leading to early crack initiation under flexural loading.

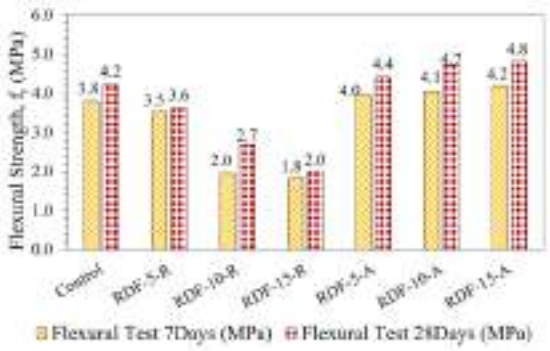

Fig.3 Flexural strength results.

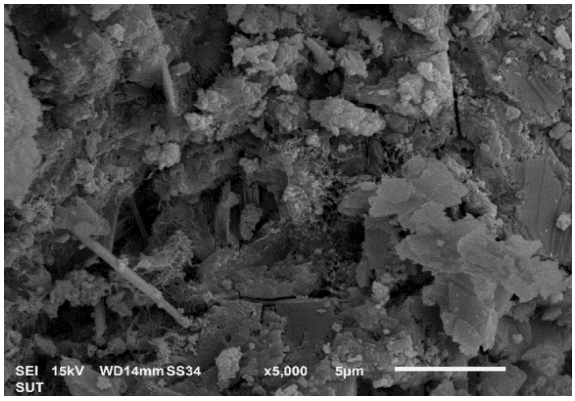
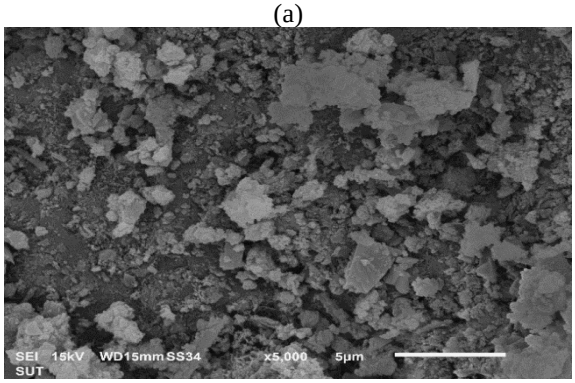
In contrast, the addition method showed a significant improvement. RDF-5-A, RDF-10-A, and RDF-15-A achieved 28-day strengths of 4.4, 4.7, and 4.8 MPa, respectively, surpassing both the control mix and the DOH standard. The enhanced performance is explained by improved hydration and pozzolanic reactions, which densified the matrix and increased resistance to tensile stresses.



(a)



(b)

Fig.5 SEM images: (a) RDF-5-A and (b) RDF-10-A.

Microstructural Analysis

The SEM micrographs of RDF FA-modified concretes at 28 days are presented in Fig. 4 and Fig. 5, comparing the replacement and addition methods. Clear distinctions in hydration products and matrix density were observed between the two approaches.

For the replacement specimens (Fig. 4a and 4b), the microstructure was relatively porous with less compact morphology. Calcium hydroxide [$Ca(OH)_2$] crystals and limited calcium silicate hydrate (C-S-H) gel were observed, indicating a weaker hydration process due to the reduced cement content. The lower availability of cementitious phases resulted in incomplete matrix development, which correlates with the decreased compressive and flexural strengths observed in RDF-5-R and RDF-10-R.

In contrast, the addition specimens (Figures 5a and 5b) exhibited a denser microstructure with abundant hydration products. Needle-like ettringite crystals and a well-distributed C-S-H gel were clearly visible, along with $Ca(OH)_2$ participating in secondary pozzolanic reactions. These features indicate improved hydration and matrix densification, which explain the higher strengths recorded in RDF-5-A and RDF-10-A. The presence of additional RDF FA particles provided reactive silica that enhanced pozzolanic activity, producing supplementary C-S-H and strengthening the concrete matrix.

Overall, SEM observations confirm that while cement replacement with RDF FA compromises matrix integrity, its addition promotes hydration, densifies the microstructure, and improves load transfer capacity. These microstructural findings are consistent with the mechanical test results, highlighting RDF FA addition as the more effective method for enhancing rigid pavement concrete.

CONCLUSIONS

This study demonstrated that the incorporation method strongly influences the performance of RDF FA in concrete pavements. When used as a cement replacement, RDF FA reduced compressive and flexural strengths below the DOH standard due to a porous microstructure. In contrast, RDF FA addition significantly improved strength development, surpassing DOH requirements, with SEM observations confirming denser C-S-H and ettringite formation. Therefore, RDF FA is more effective as an additive, offering both enhanced pavement performance and sustainable waste utilization.

EFFECT OF SUPERPLASTICIZER ON WORKABILITY OF RICE HUSK ASH AND SEASHELL POWDER BLENDED CONCRETE

Md Soybur Rahman[1], Zakaria Hossain[2]

[1,2]Graduate School of Bioresources, Mie University, Japan

ABSTRACT

The major challenge of incorporating supplementary cementitious materials (SCMs) in concrete is the reduction in workability, which often demands additional water. However, excess water negatively affects the mechanical performance of hardened concrete. The use of superplasticizer (SP) offers an effective solution to retain workability without compromising strength. This study investigated the optimum dosage of superplasticizer in concrete modified with rice husk ash (RHA) and seashell powder (SSP) as partial replacements for cement. Different dosages of superplasticizer were added at varying RHA–SSP levels and at the same RHA-SSP content. Workability was evaluated using the slump test. The results showed that the required superplasticizer dosage increased with higher RHA–SSP incorporation. At a given RHA–SSP level, slump values increased proportionally with the superplasticizer dosage. Finally, two predictive equations were developed to estimate the required SP dosage and the corresponding slump value for RHA–SSP modified concrete.

Keywords: Superplasticizer, Rice Husk Ash, Seashell powder, Workability

INTRODUCTION

The cement industry is a major contributor to global carbon emissions, with Portland cement production being the most energy-intensive process. Significant energy savings and emission reductions can be achieved by partially replacing cement with supplementary cementitious materials (SCMs), such as fly ash, rice husk ash (RHA), ground granulated blast-furnace slag (GGBS), silica fume, and calcined seashell powder. However, the angular and irregular shapes of SCMs increase particle friction, leading to reduced workability of fresh concrete.

In recent years, the use of superplasticizers (SPs) as chemical admixtures has gained considerable attention for addressing this challenge. It not only enhances the workability and mitigates slump loss but also often improves the compressive strength of concrete compared to ordinary mixes.

Superplasticizers are generally categorized into four types based on their chemical composition and method of production: polycarboxylic ether (PCE), lignosulphonates (LS), sulphonated melamine formaldehyde (SMF), and sulphonated naphthalene formaldehyde (SNF). PCE-based superplasticizers primarily act through steric hindrance, while LS, SMF, and SNF-based superplasticizers enhance workability mainly by electrostatic repulsion [1-2]. Despite differences in their mechanisms, all water-reducing agents operate on the same fundamental principle: inhibiting the flocculation of cement particles in concrete to improve its fresh-state characteristics. This flocculation, which entraps water between particles, is primarily propelled by Van der Waals forces, electrostatic interactions, and bridging effects among cement and water molecules [3]. The dispersion of cement in the water and concrete mixture design is the primary factor that controls the flow behavior of hardened cement paste and concrete, which in turn affects their properties. In practice, superplasticizers have been widely utilized to improve the workability of concrete and scatter the cement particles [4].

Previous studies have explored the use of superplasticizer dosages in concretes incorporating individual supplementary cementitious materials (SCMs) such as rice husk ash (RHA) and fly ash. However, the combined use of two SCMs presents new challenges. In particular, the optimal dosage of superplasticizer remains unclear when RHA and seashell powder (SSP) are applied synergistically as cement replacement materials: a novel strategy in sustainable concrete production. Therefore, the goal of this study is to determine the ideal superplasticizer dosage for RHA–SSP modified concrete to achieve the desired slump and ensure workable mixtures.

RESEARCH SIGNIFICANCE

Workability is an important parameter of fresh concrete for practical application. The physical characteristics of Supplementary cementitious material (SMCs) reduced the workability of concrete and created a demand for using superplasticizer to maintain proper workability without compromising concrete performance. As the synergistic application of RHA and SSP as cement replacement materials is a new approach, the dosage of superplasticizer for modified concrete is still unknown. The study aims to

determine the optimal dosage of superplasticizer for RHA and SSP-modified concrete to achieve a desirable slump.

MATERIALS AND METHODS

The materials used in this study included cement, fine aggregate, coarse aggregate, Rice Husk Ash (RHA), Seashell Powder (SSP), water, and locally available Ordinary Portland Cement (OPC). Natural river sand was employed as the fine aggregate, while gravel with a maximum size of 19 mm served as the coarse aggregate.

Superplasticizer

The FloricSV10 superplasticizer, supplied by Floric Co. Ltd., was employed in this study as shown in Fig.1. This admixture was specifically developed to provide high water-reducing efficiency while enhancing slump retention performance. It is classified as a JIS 6204 Type I (AE water-reducing agent) chemical admixture for concrete. Based on an advanced polycarboxylic acid technology combined with conventional AE water-reducing components, it offers excellent dispersion capability and prolonged slump retention. These characteristics improve the workability of fresh concrete and contribute to the long-term durability of hardened concrete structures. The admixture is liquid in form, with a density of 1.12 g/cm³, and its main constituents include lignosulfonates, oxycarboxylates, and polycarboxylate compounds.

Fig. 1: FloricSV10 superplasticizer

Rice Husk Ash and Seashell Powder

The rice husk ash production process was operated in a factory building using an industrial machine. Unlike traditional incinerators, this machine operates as a natural-type silica generator, eliminating the need for combustible materials such as gas, kerosene, or electricity. Instead, solid methanol fuel is used to ignite and burn the rice husks. This innovative process is environmentally friendly, as it does not produce dioxins, making it exempt from the Fire Services Act. The burning speed and temperature are meticulously controlled by a computer, reducing labor costs and minimizing personnel requirements. Additionally, the system can be remotely controlled, offering further convenience in managing the incineration process. The seashell powder production process involves collecting seashells, drying them, and then grinding them into a fine powder. Finally, the powder is subjected to a burning process at 900°C. Both materials were provided by Make Integrated Technology (M.I.T.) Company, Osaka, Japan. The RHA and SSP are shown in the Fig. 2.

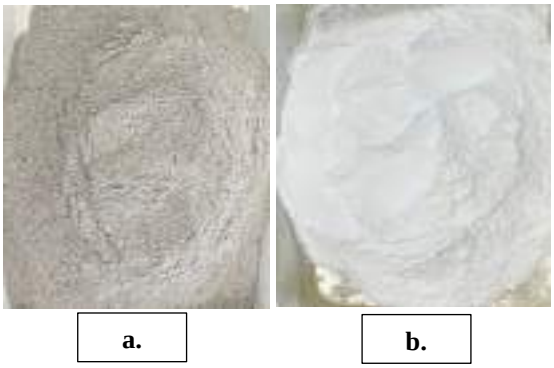

Fig. 2: Rice husk ash (a) and Seashell powder (b)

Preparation of Concrete Mixture

After accurately weighing the raw materials, the concrete mixture was prepared using a mix ratio of 1:1:3 by weight for cement, fine aggregate, and coarse aggregate. RHA and SSP were used as supplementary cementitious materials, replacing cement. The water-to-binder ratio was maintained at 0.50 throughout the all mixing process. The superplasticizer was used in proportion to the binder. The specific quantities of each material are provided in Table 1. The raw materials were mixed using a mixer machine as shown in Fig. 3.

Figure 3: Concrete mixer

Slump Test

Following proper mixing of raw materials, a slump test was conducted to evaluate the workability of the concrete. The slump cone used in the test has standard dimensions: 300 mm in height, a base diameter of 200 mm, and a top opening of 100 mm. The cone was placed on a smooth, level surface and filled with concrete in three equal layers. Each layer was compacted by rodding 25 times using a tamping rod with a diameter of 16 mm. After filling, the top surface was leveled, and the mold was lifted vertically. The slump testing and slump value measuring are shown in Fig. 4 and 5.

Fig. 4: Experimental equipment and slump testing at the laboratory

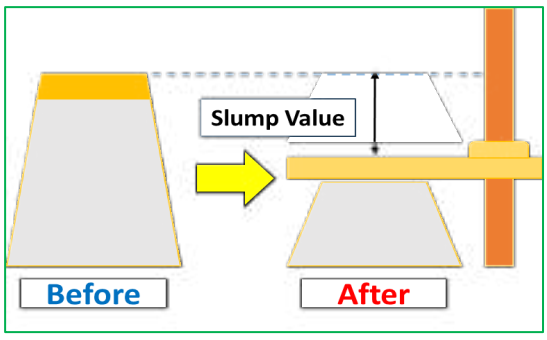

Fig. 5: Slump value measuring

RESULTS AND DISCUSSION

Effect of Superplasticizer on RHA-SSP-modified concrete

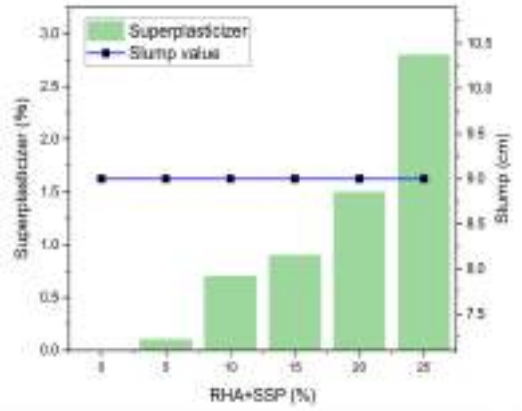

Fig. 6: Superplasticizer dosage at different percentages of RHA and SSP to maintain the same slump

Fig. 6 illustrates the effect of incorporating rice husk ash (RHA) and seashell powder (SSP) on the superplasticizer dosage required to achieve the target slump of 9 ± 1 cm. The control mix achieved the desired slump without the use of superplasticizer. However, the addition of RHA and SSP led to slump loss, thereby increasing water demand. Since excess water negatively affects strength, the superplasticizer was used to restore workability. As the RHA–SSP replacement level increased from 5% to 25%, the required superplasticizer dosage rose steadily from 0.1% to 3% in order to maintain the target slump. These results emphasize the crucial role of superplasticizer in counteracting the reduced fluidity induced by RHA and SSP, thereby ensuring consistent fresh properties in blended concrete.

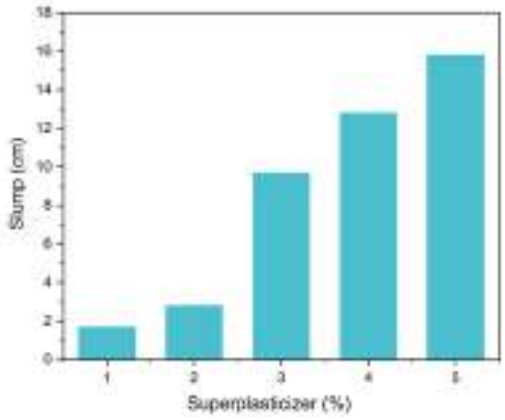

Fig. 7: Slump value with different dosages of Superplasticizer at RHA-SSP-modified concrete

Fig. 7 shows the variation in slump values with the increase in superplasticizer (SP) dosage for concrete mixtures containing 12.5% rice husk ash (RHA) and 12.5% seashell powder (SSP), replacing 25% of cement. The results indicate a steady rise in slump from 1.7 cm at 1% SP dosage to 15.8 cm at 5% dosage. This trend clearly demonstrates the positive influence of SP in improving the workability of RHA–SSP blended concrete. At lower dosages (1–2%), the mix remains relatively stiff, representing low workability. A moderate improvement in workability is achieved with a 3–4% dosage, while dosages above 5% produce a highly workable mix. These findings highlight the importance of optimizing SP dosage to achieve the desired workability to make RHA-SSP concrete.

Prediction of Superplasticizer dosage and Slump value

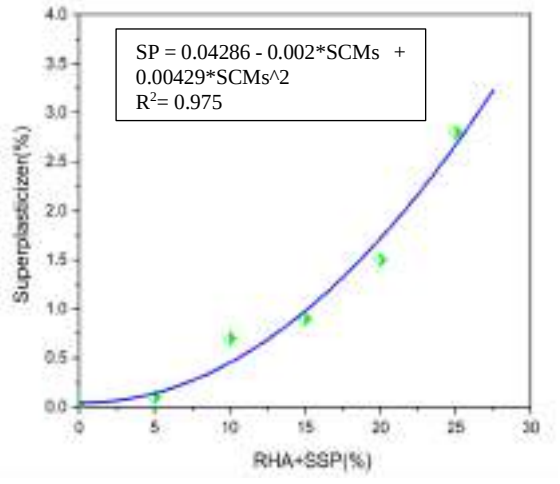

Fig. 8: Correlation of superplasticizer dosage and different percentages of RHA and SSP

Fig. 8 illustrates the relationship between RHA and SSP replacement levels and the corresponding dosage of superplasticizer required to maintain constant workability. As the combined percentage of RHA and SSP increased, the demand for superplasticizer rose in a nonlinear manner. At lower replacement levels (up to 10%), only a small amount of superplasticizer was necessary, while moderate replacement levels (15–20%) required a noticeable increment. Beyond 20% replacement, the demand of SP dosage rose steeply, exceeding 2.5% at 25% RHA-SSP. This trend indicates that higher levels of RHA and SSP significantly reduce the workability of concrete, thereby requiring greater amounts of superplasticizer to achieve the target slump. The following equation can be used to estimate SP dosage for RHA-SSP modified concrete.

SP = 0.04286 - 0.002*SCMs + 0.00429*SCMs^2

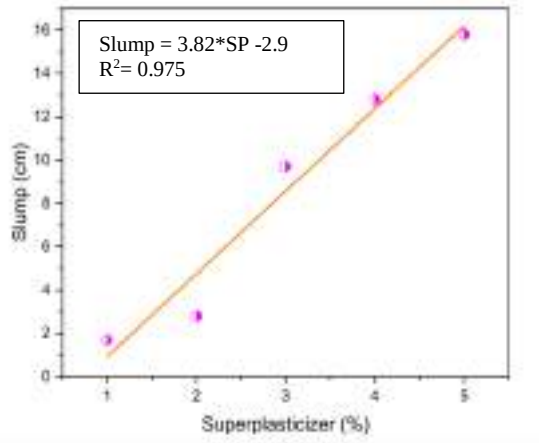

Fig. 9. Correlation of slump value with different superplasticizer dosage for RHA-SSP Modified concrete

Fig. 9 illustrates the linear relationship between superplasticizer (SP) dosage and the slump value of concrete mixtures containing 12.5% rice husk ash (RHA) and 12.5% seashell powder (SSP), replacing 25% of cement. The plotted trendline demonstrates a proportional increase in slump with increasing SP dosage, confirming the predictable effect of the water reducing admixture on the workability of fresh concrete. Accordingly, the equation as shown in below can serve as a practical tool for estimating the required SP dosage to achieve the desired workability in RHA–SSP modified concrete mixtures.

Slump = 3.82*SP -2.9

CONCLUSION

Based on experimental investigation, the following conclusion can be drawn-

- The dosage of SP was increased with an increment of RHA-SSP content in the concrete mixture.
- Low workability was observed at 1–2% dosage, moderate at 3–4%, and high above 5%.
- The developed equation provides a practical tool for estimating sp dosage in RHA–SSP concrete.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the Japan Ministry of Education, Culture, Sports, Science, and Technology (MEXT) for providing financial support through the MEXT scholarship at Mie University, where this study was conducted. The authors also wish to express their sincere gratitude to M.I.T. Company, Osaka, Japan, for supplying the RHA and SSP, and to Flowric Co. Ltd. for providing the superplasticizer used in this experiment.

EFFECT OF CEMENTITIOUS MORTAR FOR REPAIRING REINFORCED CONCRETE (RC) BEAMS

Leandro Madeira Branco[1] , Abel Fernandes[1], Isamu Yoshitake[1]

[1] Graduate School of Sciences and Technology for Innovation, Yamaguchi University, Yamaguchi, Japan

ABSTRACT

Defects in concrete structures can arise during and after construction due to inadequate materials, construction methods, and environmental conditions. In developing countries, the repair of reinforced concrete (RC) structures often faces constraints due to limited resources, making conventional cement-based materials necessary. A comparative analysis investigated three distinct repair materials: ordinary Portland cement mortar (OPCM) and a polymer-modified cement (PMC) mortar. Each repair material was prepared with and without epoxy resin (ER), and consistent surface treatment was applied to concrete and RC beam specimens before the repair materials were used. This study evaluated concrete specimens' slant shear and double shear and the flexural performance of repaired RC beams. The experimental study focused on the shear performance of cementitious materials and the load-bearing capacity of repaired RC beams, evaluating the deformation behavior, crack resistance, and failure modes of different repair cementitious material combinations. The proposed method successfully achieved the desired interfacial bond strength between the repair material and the substrate. In the case of RC beams, the results demonstrated the effectiveness of combining ER with OPCM in restoring and enhancing the load-bearing capacity of the repaired specimens. Furthermore, the findings underscore the critical role of material compatibility in achieving optimal bond conditions and the importance of mitigating crack progression for successful RC beam repair. This study offers guidance for implementing conventional cement in restoring damaged RC structures to their original condition.

Keywords: Ordinary Performance-cement mortar (OPCM), Polymer modified cement (PMC), Epoxy resin (ER), Shear performance, and Flexural performance.

INTRODUCTION

Concrete structures are inherently susceptible to defects arising during and after construction due to deficiencies in materials, poor workmanship, and environmental exposure [1,2]. In developing countries, these vulnerabilities are often exacerbated by systemic infrastructure challenges, including limited financial resources, weak institutional governance, inadequate technical expertise, deficient project planning, and broader environmental and social constraints [3,4]. Consequently, the development of effective repair strategies for deteriorating infrastructure, particularly RC structures, has become a critical area of research in such contexts [5]. Given frequent resource limitations, repair efforts typically rely on conventional cement-based solutions, emphasizing the need for cost-effective, durable, and locally sourced materials [6, 7].

The physical and mechanical properties of the repair material are central to the success of any intervention. Key performance criteria include workability, setting time, shrinkage characteristics, and long-term durability [8]. Research has shown that incorporating polymers into cementitious repair materials can enhance bond strength and reduce shrinkage [9]. Nonetheless, optimizing repair performance using conventional cement-based materials requires careful selection of application techniques and consideration of multiple influencing parameters [10].

The most significant factor affecting bond performance is the condition of the interface between the repair material and the existing concrete. Bond strength is influenced by surface preparation methods, material compatibility, curing regimes, and the age of the repair [11]. Surface preparation, in particular, plays a vital role in promoting adhesion. Techniques such as sandblasting, water jetting, and mechanical scarification are widely employed to remove contaminants and deteriorated layers, thereby exposing a clean and roughened surface that facilitates improved bonding [12,13].

Curing conditions are equally important, as improper curing can lead to premature cracking, reduced bond strength, and compromised durability [14]. Over time, factors such as environmental exposure, mechanical loading, and material degradation can weaken the bond between the repair material and the substrate [15]. Therefore, a comprehensive understanding of the long-term performance of repair systems is essential to ensure service life expectations are met [16].

Although the benefits of OPCM are well recognized [17], further investigation is required to

fully understand and optimize its long-term adhesion and durability in structural repair applications. This study presents an experimental evaluation of OPCM in comparison with alternative cement-based repair materials to identify effective, conventional options for improving bond strength and flexural behavior in RC elements. The research aims to demonstrate that OPCM, either used alone or in combination with supplemental materials, can serve as a viable repair solution due to its favorable strength characteristics, effective bonding performance, crack mitigation potential, and contribution to enhanced flexural capacity.

MATERIALS AND METHODS

An experimental study was conducted to evaluate the bond strength relevant to the structural analysis of flexural performance in damaged RC beams during the repair process and subsequent utilization. The bond strength between the repair mortar and the concrete substrate was identified as a critical parameter in the flexural test.

Materials of the experiment

For this experimental study, the materials utilized for production included concrete, OPCM, PMC, and ER as bonding materials, as shown in Table 1. These materials were combined and evaluated for their performance. OPCM was used as the binder, incorporating a water-reducing admixture to enhance workability and strength. It was mixed with fine aggregates following a proper mix design to produce both high-strength and PMC mortars. The standardized mixed procedures for concrete and repair mortars are detailed in Tables 2 and 3, respectively. ER bonding was applied as an interface layer between the repair materials and the substrate concrete (SC), facilitating adhesion between both the OPCM and SC, as well as the PMC mortar and SC, in the bond strength test specimens and RC beam repairing specimens.

Bond and Shear Strength Of Concrete

Two experimental methods for bond strength, the slant shear and double shear strength tests, were conducted in the study.

Slant shear

Following ASTM C882 and C1042, the slant shear test was originally proposed in 1976 as the Arizona Slant Shear Test, as illustrated in Fig. 1 [18]. In this method, an axial load is applied to the specimen at an interface angle, generating a combination of shear and tensile stresses. The resulting bond stresses are calculated as follows [19]:

$$\sigma_o = \frac{f}{A} \quad (1)$$

$$\tau_n = \frac{1}{2}\sigma_o \sin(2a) \quad (2)$$

$$\sigma_n = \sigma_o \sin^2 a \quad (3)$$

Here, f denotes the applied force (kN), A represents the cross-sectional area of the specimen (mm²), and σ_o is the applied stress. σ_n and τ_n represent the interfacial normal and shear stresses (bond stresses), respectively, acting on the bond plane as the result of σ_o. α denotes the slant shear angle. In this study, the specimens were prepared with an interface angle of ± 30° from the vertical axis, forming a composite cylinder with a total diameter of 100 mm and a height of 200 mm.

Table 5. Fresh concrete mix properties

No	Type of Mix	Slump (cm)	Air content (%)	Room temperature (C˚)	Concrete temperature (C˚)
1	RC-Control	14	5.5	25.2	26.4

Mix temp (°C)	21.5	21.5

Double shear

Double shear testing of concrete is a mechanical method to determine the shear strength of concrete

specimens. This experimental approach evaluates the capacity of a specimen to resist shearing forces applied simultaneously in two planes or along two parallel surfaces. A schematic of the double shear strength test (also referred to as the shear friction test) is presented in Fig. 2. As an alternative double-plane shear test design, a similar setup was proposed by the Japanese Society of Civil Engineering (JSCE, 1990) for uncracked fiber-reinforced concrete specimens [20]. The shear stresses were calculated as follows:

$$\tau = \frac{f}{2A} \quad (4)$$

where f denotes the applied force (kN), A represents the contact area of the specimen (mm²), and τ denotes the resulting shear stress applied to the specimen.

After preparing the substrate concrete for the slant shear and double shear tests, it was cured for 28 days and air-dried for 7 days. The concrete surface was then cleaned using a slightly coarse wire brush to remove any mortar or dust from the coarse aggregate. A paintbrush was subsequently used to thoroughly remove any remaining dust. Slant shear and double shear specimens were prepared by applying fresh OPCM and PMC, with and without ER. This procedure was followed to ensure the accuracy of measurements and test results. The specimens were cured for an additional 28 days before testing.

Flexural Loading Test

Five RC beams were made for this experiment. Each beam had a 160 mm × 250 mm cross-section and was 1200 mm long (900 mm for the four-point bending test). The concrete strength was around 30 MPa, with a 40 mm cover. Three 13 mm reinforcing bars were placed in the tensile and compressive zones. The properties of rebars are given in Table 6. Stirrups, made of 6 mm bars, were spaced at 200 mm intervals. The beams followed the ACI 318 standard

[21]. Fig. 3 shows the repaired areas and load positions.

The repaired beams were tested in a four-point bending test to check their strength. A control beam, fully cast and cured for 28 days, was also tested. Strain gauges on the concrete and bars measured strain. Before testing, the control beam was placed in a testing frame with displacement sensors in key spots. Fig. 4 shows the control beam preparation, curing, and test setup

RESULTS AND DISCUSSION

Concrete and Repair Mortar Properties

The ASTM C39 standard test method was used to determine the compressive strength of the cylindrical samples of substrate concrete [22], and the ASTM C109 standard test for compressive strength of the OPCM and PMC mortar samples [23]. Following a 28-day curing period, compressive strength tests were conducted on the samples of repair materials and concrete substrates in the laboratory.

The three different types of materials resulted in different strength outcomes that correlated with the designed w/c ratios. The graph in Fig. 5 displays the average compressive strength for OPCM and PMC mortar, as well as substrate concrete, with OPCM having the highest strength at 71.08 MPa, followed by PMC mortar at 44.8 MPa, and substrate concrete at 31.06 MPa.

Concrete and repair mortars were mixed at temperatures between 22 °C and 30 °C to evaluate workability, placement ease, repair suitability, and surface bonding. Table 4 outlines the mixing method for fresh concrete, applied consistently across all RC beam specimens, with comparable results. All samples were cured and tested after 28 days.

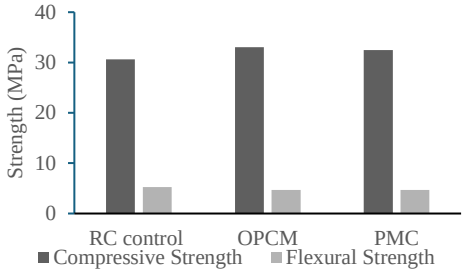

Fig. 6. Physical properties of concrete

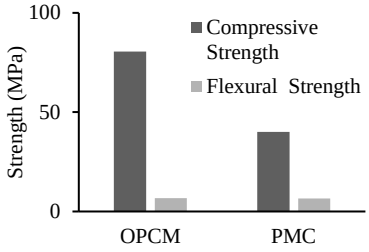

Fig. 7. Physical properties of repair mortar

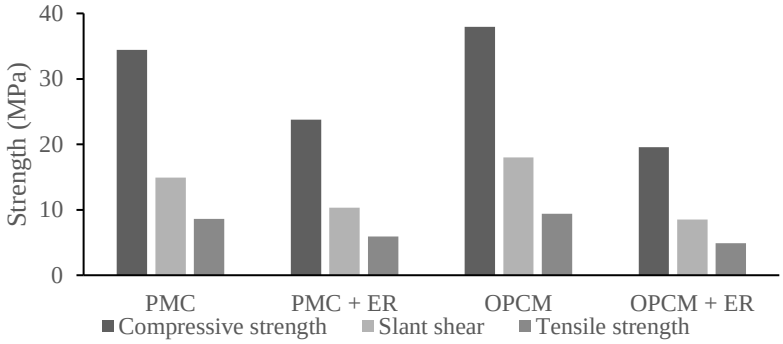

Fig. 8. Mechanical properties of slant shear

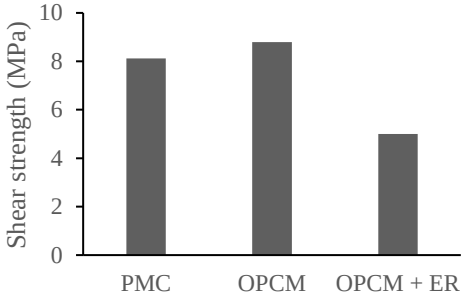

Fig. 9. Double shear results

To ensure consistency, repair mortar temperatures were carefully controlled, as shown in Table 5. Room temperature during casting varies with outdoor conditions, affecting mortar temperature based on the initial temperatures of aggregates and cement. This influenced casting and curing conditions. The flow rate [23] of fresh repair mortar, indicating workability, was highest for OPCM, showing excellent fluidity, while PMC achieved an acceptable 146 mm per the manufacturing guidelines. The flow rate results remained suitable for repair applications. Samples were prepared to test repair mortar properties, and compressive and flexural strength samples followed ASTM standards. All samples were cured and tested after 28 days.

Fig. 6 presents the average compressive and flexural strengths of concrete specimens at 28 days. The experimentally measured compressive strength closely aligned with the values predicted by the mix design for the RC beam concrete, indicating the accuracy of the mix design. Flexural strength [25] remained consistent among the specimens, with average values of approximately 30 MPa for compressive strength and 5 MPa for flexural strength. Fig. 7 compares the compressive strength of cylindrical specimens and the flexural strength of cubic specimens for repair mortars. OPC-based mortars demonstrated greater compressive strength than PMC mortars. However, in terms of flexural strength, both OPCM and PMC exhibited comparable performance.

Concrete Bond and Shear Strength

Slant shear strength

Fig. 8 shows the test results for compressive strength, slant shear strength, and tensile strength at the interface between the concrete substrate and repair materials.

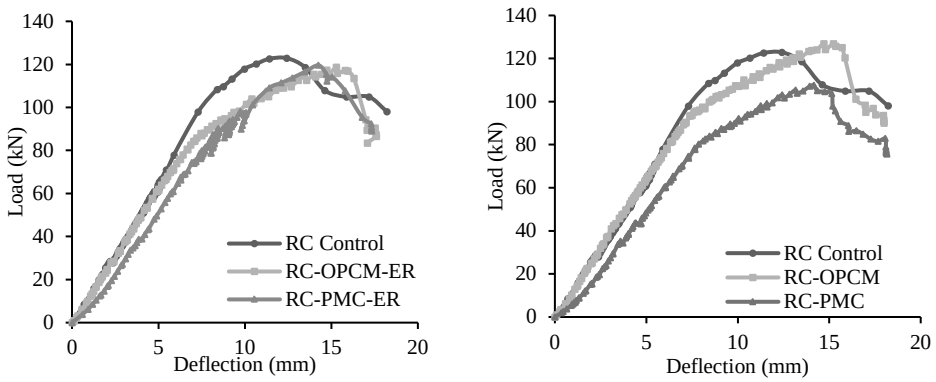
Compressive strength was calculated using Equation (1). For the joint between the concrete substrate and PMC mortar, the compressive strength was 34.4 MPa. However, when ER was used at the interface, the strength dropped by 35% to 23.8 MPa. Similarly, the concrete–OPCM joint had a compressive strength of 38.0 MPa, which decreased to 19.6 MPa with the use of ER.

When compressive load is applied to cylindrical specimens, it generates slant shear and tensile stresses at the rough interface. Bond strength, determined using Equation (2), was 14.9 MPa for PMC mortar, but decreased to 10.3 MPa with ER. OPCM showed the highest bond strength of 18.0 MPa, which dropped to 8.5 MPa when epoxy was used.

Tensile strength, calculated with Equation (3), was 8.6 MPa for PMC mortar and decreased to 5.9 MPa with epoxy. OPCM again had the highest

Table 7. The physical properties of RC beam specimens

Type of RC	Cracking load (kN)	Max. load (kN)	Deflection at max. load (mm)	Failure mode
RC-Control	25	122.9	12	Flexural
RC-OPCM	25	126.9	14.7	Flexural and shear
RC-OPCM-ER	26	118.7	15.3	Flexural and shear
RC-PMC	37	107.5	14.2	Flexural and shear
RC-PMC-ER	35	119.5	14.3	Flexural and shear



a). RC Specimens with ER b). RC Specimens without ER

Fig. 10. Load deflection relationship

tensile strength at 9.4 MPa, reducing to 4.9 MPa when ER was applied.

Double shear strength

Specimens with a vertical interface were tested under a single axial load to evaluate bonding between the concrete substrate and repair materials. Using Equation (4), the average bond strength for PMC mortar was 8.1 MPa, while OPCM achieved 8.8 MPa. In contrast, concrete substrates with ER and cement mortar had the lowest bond strength at 5 MPa. Fig. 9 shows that PMC mortar and OPCM outperformed ER-mixed repair mortar in bond strength.

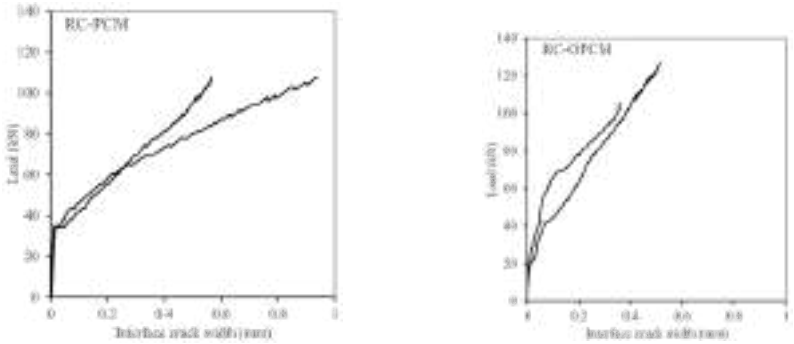
Flexural Loading Test

Load and deflection

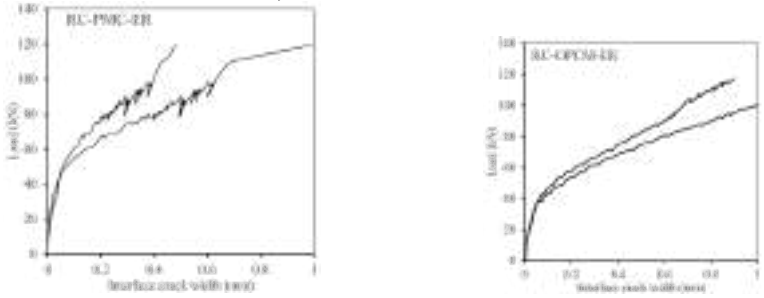
The load-deflection responses of the beam specimens, both with and without ER, are presented in Fig. 10. These responses are associated with the physical properties of the RC beam specimens listed in Table 7. The behavior of the beams was nearly linearly elastic up to the initial cracking load, which ranged from 24 to 28 kN for the RC OPCM specimens, including the RC control. The data indicate that the RC-PMC specimens exhibited a higher initial cracking load.

The RC-OPCM specimens demonstrated superior performance in terms of both deflection and maximum load. Regarding stiffness, the RC control and RC-OPCM specimens showed comparable behavior up to the yield load. Beyond this point, the RC control specimen exhibited higher stiffness, whereas the RC-OPCM specimen demonstrated

Fig. 11. Crack distribution of RC beam specimens



a) Without ER treatment



b) With ER treatment

Fig. 12. Interface crack width distribution of RC beam specimens at the bottom

improved ductility. All specimens with ER, including RC PMC, exhibited enhanced ductility.
In the RC control specimen, failure occurred in a flexural manner. However, in the repaired specimens, shear cracking was observed following the initiation of flexural cracks. This indicates a trade-off between stiffness and ductility. Such behavior is particularly beneficial for structures subjected to dynamic or seismic loading, where ductility and energy absorption are critical.

The results highlight the effectiveness of OPCM, especially when combined with ER applied to the bonding surface, in improving ductility while maintaining a load-carrying capacity comparable to that of the RC control. Additionally, the contribution of external reinforcement helps reduce stiffness degradation and enhances deformation capacity.

Crack opening

Fig. 11 shows crack propagation, spacing, and total crack count in RC control and repaired beam specimens. The RC control had many cracks with flexural failure and uneven distribution. Repaired beams were divided into two groups: one treated with ER and one without (RC-OPCM). The RC-OPCM group had more cracks than the PMC-treated group but fewer than the RC control, showing the treatments were effective. Additionally, following the initiation of flexural cracks, shear cracks were observed in all samples with and without ER treatment. The group treated with ER showed behavior similar to the RC beam specimens without ER. Although the use of ER reduced the number of cracks, the reduction was not statistically significant. While epoxy improved crack control, it did not eliminate crack formation.

The transducers were installed at three positions: the bottom, center, and either the left or right side. Each position was equipped with two transducers that were used to measure the opening of the joint between the repaired mortar and damaged concrete of the RC beam specimens. Data obtained from each transducer was used to determine the degree of bonding between the two materials. Fig. 12 illustrates the development of bond interface openings beneath the RC beam specimens in response to applied loading. The results indicate that RC-OPCM specimens, both with and without ER treatment, exhibited early crack initiation at an applied load of approximately 20 kN. In contrast, the RC-PMC specimens, regardless of ER application, demonstrated significantly higher resistance to cracking, with initial crack openings occurring only at loads exceeding 30 kN. Notably, across all repaired specimens, the crack widths remained limited to less than 1 mm, even as the applied load approached 100 kN.

An additional transducer recorded a similar response; however, a localized crack opening developed following the initiation of the first crack beneath the transducer. The crack location along the RC beam specimen influenced the extent of this opening
These findings highlight the significant influence of material composition and treatment on crack behavior. The application of ER effectively delayed crack initiation and limited the crack width, thereby enhancing the overall performance of the repaired RC beam specimens.

CONCLUSIONS

This study aimed to assess the bond strength and flexural performance of OPCM as a primary repair material, focusing on its effectiveness in restoring bond and flexural strength during the repair process. Two types of repair specimens were tested: those repaired without ER and those repaired with ER at their connection. Based on the results and discussion, the following conclusions were drawn:

- Bond strength experiments demonstrated that OPCM achieved significantly satisfactory performance for repair applications compared to PMC.
- RC beam specimens, encompassing control, ER-treated, and non-ER-treated types, exhibited peak load capacities ranging from 105 to 130 kN; notably, ER-treated beams demonstrated enhanced pre-failure behavior, particularly in terms of crack control and ductility.
- ER effectively mitigated crack severity and propagation, delaying crack growth and contributing to the structural integrity of the repaired specimens. However, the strength of the bond formed by ER with repair materials and concrete substrates was found to be variable and, in some cases, potentially lower than repairs undertaken without ER, depending on the degree and timing of the ER application.
- The midspan of the beams was observed to be the most prone to cracking, which is consistent with anticipated flexural behavior.
- The application of cemented repair material to a homogeneous concrete substrate in RC beam specimens was effective for the initial repair stage. Transducer measurements indicated that, before subsequent performance testing, crack openings in all repaired specimens were consistently addressed to approximately 1 mm

SUSTAINABLE SOIL IMPROVEMENT: THE SYNERGISTIC EFFECTS OF BASALT FIBER AND RICE HUSK ASH ON THE ONE-DIMENSIONAL CONSOLIDATION

Nguyen Thi Hong Nhung* and Zakaria Hossain

Department of Environmental Science and Technology, Mie University, Japan

ABSTRACT

This review examines the role of basalt fiber (BF) and rice-husk ash (RHA)–cement composites in enhancing the one-dimensional consolidation behavior of problematic soils. It focuses on three mechanisms: (1) the stress-redistribution through the three-dimensional network structure of basalt fiber; (2) the pore-filling and pozzolanic reaction effects of RHA–cement mixtures; and (3) the combined impact on the time-dependent compressibility, including changes in the volume-change coefficient (m_v) and coefficient of consolidation (c_v). These sustainable materials enhance consolidation performance while reducing environmental impact through the waste utilization and lower carbon emissions, offering both theoretical insight and practical guidance for geotechnical applications.

Keywords: Basalt fiber, Rice husk ash, Cement composites, One-dimensional consolidation, Sustainability

INTRODUCTION

The stabilization of weak soils, particularly soft and expansive clays remains a major challenge in geotechnical engineering due to their low-bearing capacity, high compressibility and long consolidation times, which often cause costly delays and structural problems [3]. Traditional stabilization using high doses of Ordinary Portland Cement (OPC) or lime effectively improves soil strength and reduces volume changes, but these methods contribute significantly to CO_2 emissions [28]. Moreover, these conventional approaches do little to valorize the vast quantities of agricultural and industrial byproducts that are otherwise destined for landfills or open burning [29].

A hybrid stabilization approach combining chopped basalt fibers, RHA, and reduced cement content offers an economically and environmentally sustainable alternative [30]. Basalt fibers improve tensile resistance and mitigate microcracking [3]. Concurrently, RHA's pozzolanic reaction with limited OPC produces calcium-silicate-hydrate (C-S-H) gels that enhance early strength and pore filling [13]. Laboratory studies have demonstrated that these composites achieved comparable consolidation characteristics to conventional high-cement mixes while reducing embodied carbon and cost.

This review paper synthesizes laboratory results focusing on one-dimensional consolidation, illustrating how basalt fibers and RHA-cement composites improve key parameters such as volume-change coefficient (m_v) and coefficient of consolidation (c_v), yield pressure, compression index and swelling index. Practical aspects including mix designs, environmental benefits and field implementation challenges are addressed.

This study investigates the consolidation behavior of reconstituted expansive clay reinforced with basalt fibers and RHA-cement mixtures. Oedometer tests were conducted to evaluate the influence of fiber length, RHA content and cement dosage on yield stress, compression and swelling characteristics, aiming to determine optimal mix designs for engineering applications.

MATERIALS AND METHODOLOGY

Materials

The materials utilized in this study comprised primarily clay soils as the base material, reinforced with supplementary materials including rice husk ash (RHA), basalt fibers (BF) and Ordinary Portland Cement (OPC).

Soil

The base expansive clay soil, sourced from Mie Prefecture, was air-dried, ground to pass a 2 mm sieve, and characterized by a liquid limit of approximately 60 % and a plasticity index near 32 %. Clay soil is a type of fine-grained soil composed primarily of hydrated silicate minerals. Due to its small particle size and high plasticity, clay often exhibits low shear strength, high compressibility, and significant volumetric changes under loading or moisture variation [1,2]. The index properties of the soil are shown in Table 1. These unfavorable geotechnical properties limit its direct use in construction without

proper improvement or stabilization.

Table 1 Properties of Soil [3]

Property	Value
Specific gravity	2.74
Sand (75 μm–2 mm) (%)	6.14
Silt (5 μm–75 μm) (%)	51.24
Clay (<5 μm) (%)	38.86
Liquid limit LL (%)	58.21
Plastic limit PL (%)	31.05
Plasticity index PI (%)	27.16
Optimum water content (%)	26.02
Maximum dry density (g/cm3)	1.65

Ordinary Portland cement (OPC)

The index properties of the OPC are shown in Table 2. OPC is a widely used hydraulic binder in soil stabilization and construction materials. It is produced through the calcination of limestone and clay [4,5]. When mixed with water, Portland cement undergoes hydration reactions that transform it from a dry powder into a hardened material with high compressive strength, making it essential for enhancing the mechanical behavior of weak soils. In this review paper, OPC was added at 3 % by dry weight to activate the pozzolanic reactions.

Rice Husk Ash

RHA was produced by the self-combustion of rice husks at 650 °C for 27 hours, yielding a finely divided ash with a highly reactive amorphous silica content ranging between 85% and 91%. Rice husk ash (RHA) is an agricultural byproduct obtained by controlled combustion of rice husk. It is rich in amorphous silica (SiO_2), which provides high pozzolanic reactivity when mixed with cementitious materials [7,8]. The incorporation of RHA into soil-cement mixtures improves strength, reduces permeability, and enhances durability by filling voids and refining the microstructure. Additionally, using RHA as a partial cement replacement promotes environmental sustainability by recycling agricultural waste and reducing CO_2 emissions associated with cement production base expansive clay soil, sourced from Mie Prefecture, was air-dried, ground to pass a 2 mm sieve, and characterized by a liquid limit of approximately 60 % and a plasticity index near 32 %. Clay soil is a type of fine-grained soil composed primarily of hydrated silicate minerals. Due to its small particle size and high plasticity, clay often exhibits low shear strength, high compressibility, and significant volumetric changes under loading or moisture variation [1,2]. These unfavorable geotechnical properties limit its direct use in construction without proper improvement or stabilization. The properties of the RHA and the particle size distribution are shown in Table 3.

Basalt Fiber

In this review paper, basalt fibers measuring between 6-30 μm in diameter, were chopped into lengths of 3, 6, or 12 mm and introduced at 1 % by the dry weight of the soil. Basalt fiber (BF) is an inorganic fiber produced by melting natural basalt rock at temperatures of approximately 1450–1500°C, followed by extrusion into continuous fibers without chemical additives.

Basalt fibers exhibit high tensile strength (2000–

4000 MPa), high modulus of elasticity (80–95 GPa), and excellent resistance to alkalis, acids, and elevated temperatures. When incorporated into soil or cementitious mixtures, basalt fibers act as reinforcement materials, increasing tensile resistance, controlling deformation, and limiting crack propagation. Due to its natural origin, non-toxic production process, and recyclability, basalt fiber is considered an environmentally friendly alternative to synthetic fibers [10]. The detail physical, thermal and chemical properties of BF are shown in Table 4.

Table 4 Properties of Basalt Fiber [11]

Property	Value
Breaking Strength (Mpa)	3000 - 4840
Modulus of Elasticity (Gpa)	79.3 - 93.1
Breaking Extension (%)	3.1
Fiber Diameter (μm)	6 - 21

Overall, the combination of clay, Portland cement, rice husk ash, and basalt fiber has the potential to create stabilized soil mixtures with enhanced engineering properties suitable for construction applications requiring improved strength, reduced compressibility, and greater durability.

Methodology

Standard proctor compaction test

The standard Proctor compaction test was carried out in accordance with JIS A 1210:2010 to determine the maximum dry density (MDD) and optimum moisture content (OMC) of the prepared mixtures. In this study, the term sample refers to the blended material comprising soil, RHA, cement, and basalt fiber at various mix ratios. Each mixture was compacted into a mold with a diameter of 10 cm and a height of 12.68 cm, in three layers. Compaction was achieved using a 2.5 kg rammer dropped from a height of 30 cm, applying 25 blows per layer to ensure uniform compaction. After compaction, a representative specimen was collected to measure the moisture content. This procedure was repeated for each increment of added water to obtain the compaction curves.

One-dimensional consolidation test

One-dimensional consolidation tests were carried out to evaluate the compressibility characteristics of the soil samples. Each specimen was placed in a rigid oedometer ring to prevent lateral deformation, ensuring vertical compression only. The samples were subjected to incremental loading, where the applied pressure was doubled at each stage (9.8, 19.6, 39.2, 78.5, 157, 314, 628 and 1256kPa). At each load increment, the settlement was recorded over time until the primary consolidation was considered complete, as indicated by minimal changes in deformation. After reaching the maximum load, the samples underwent unloading in reverse order to determine their swelling behavior and recompression characteristics. This loading and unloading procedure provided data to calculate coefficient of volume compressibility (m_v), and coefficient of consolidation (c_v), which are essential parameters for predicting settlement behavior under foundation loads [12].

The formulas for calculating the coefficient of consolidation (c_v) and the coefficient of volume change (m_v) are presented as follows:

Coefficient of consolidation (c_v):

$$c_v = 0.197\left(\frac{\bar{H}}{2}\right)^2\left(\frac{1440}{T50}\right)$$

Coefficient of volume change (m_v):

$$m_v = \frac{\Delta\varepsilon/100}{\Delta p}$$

RESULTS AND DISCUSSION

Literature review results

The comparison of results from previous studies considering different materials and soil type, is presented in Table 5.

Table 5 Literature review

Reference	Materials	Type of Soil	Results
[3]	S + RHA + Cement + BF	Clay Soil	Increasing basalt fiber length (3→12 mm) reduces consolidation coefficient cv, especially at 5-10% RHA, while slightly decreasing permeability k
[12]	S + RHA +Cement	River Sludge	The 10% RHA and 6% cement mixture enhances the yield pressure (σ' = 125 kN/m²), reduces the compression index (c_c) and swelling index (c_s) of river sludge by 70%
[13]	S + RHA + Cement + BF	Clay Soil	Adding basalt fibres to RHA-treated clay improved UCS and stiffness, with the best results from 5% RHA + 3% cement + 1% basalt fibre (12 mm) showing qu = 463 kN/m² and E50 = 29 MN/m² after 28 days
[15]	S + RHA	Clay Soil	At 9% RHA: significantly reduces soil plasticity (liquid limit by 11-18%, plasticity index by 32-80%) and maximum dry unit weight; optimally increases unconfined compressive strength (peaking at 6-8% RHA) and optimum moisture content
[16]	S + RHA	Lateritic soils	Adding RHA (up to 16%) reduces maximum dry density but significantly improves lateritic soil's physical properties and consolidation behavior (increased preconsolidation pressure, decreased C_c, C_s, m_v)
[17]	S + FA	Clay soil	Additives like fly ash (especially Type C), cement, and lime significantly optimize soil properties for construction: enhancing consolidation (reducing swell index by up to 50%), drastically increasing CBR (10x at 16% FA) and strength via pozzolanic reactions.
[18]	S + RHA	Black cotton soil	Treating black cotton soil with 8% rice husk ash (RHA) optimizes compressibility regardless of compaction moisture, while improving plasticity (liquid limit reduced 69.5% → 55%, plasticity index decreased 20%), swelling pressure (77% reduction at 16% RHA), and yielding stress (increased 182 → 261 kN/m²).
[19]	S + FA + Lime	Expansive Soil	30% FA + 4% lime eliminated swelling (100% FSI↓), raised OMC (52-37%↑), reduced density (10-7% MDD↓), boosted CBR, and achieved 286/192 kPa UCS
	S + Wool Waste + Lime		30% wool waste + lime also eliminated swelling but increased density (15-12% MDD↑) while lowering OMC (30-19%↓) yet improving CBR
[20]	S + RHA	Lateritic Soil	Adding 10% RHA to lateritic soil (SW) increases OMC, enhances volume stability and CBR, while decreasing MDD and plasticity index
[21]	S + Cement	Clay Soil	Cement at ~5% optimally enhances clay's dry density/UCS while reducing plasticity/permeability
[22]	S + RHA + PA + Cement	Clay Soil	RHA/PA reduce MDD and increase OMC while acting as pozzolanic cement substitutes. Optimal stabilization: 4% cement + 10% RHA + 40% PA yields peak CBR.

[23]	S + Polypropylene Fiber + Fly ash and Ground-Granulated Blast Furnace	Black cotton soil	the fibre content increased from 0% to 0.4%, the tensile strength and CBR of the AAB-treated soil increased by 63.1% and 52.6%, respectively, while the void ratio and swelling pressure decreased by 33% and 45%. Replacing 30% of fly ash with GGBS at a fibre content of 0.3% also significantly increased the CBR and UCS
[24]	S + PPF + NMK (Nano meta kaolin)	Expansive Soil	Replacing 20% NMK combined with 1% PPF fibers optimizes the strength of stabilized soil, reducing lime consumption by > 40% through effective cementitious gel formation and fiber tensile resistance
[25]	S	Clay slurries	The fine-grained clay slurry (w_L=180%, w_P=120%) its coefficient of consolidation (c_v) and coefficient of volume compressibility (m_v) decreased with increasing stress but increased with increasing void ratio and permeability
[26]	S + Cement	Soft clay	Excess pore pressure distributes uniformly between columns and clay. Settlement can be reliably predicted using the composite coefficient c_v via a simplified procedure suitable for geotechnical engineering

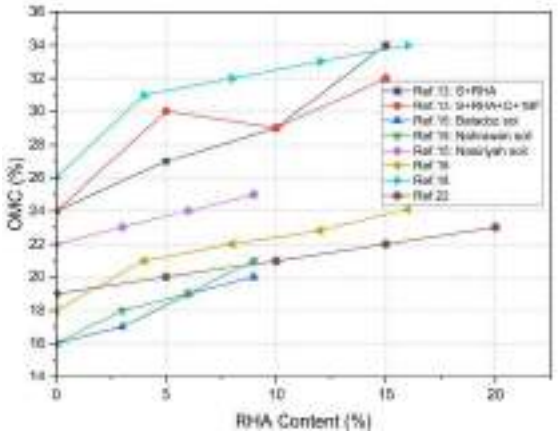

Fig.1 Optimum moisture content for soils mixed with different percentages of rice husk ash. [13, 15, 16, 18, 22]

The incorporation of RHA into soil mixtures consistently shifts the compaction curve toward higher optimum moisture contents (OMC), a behavior attributable to the highly porous nature and strong hygroscopicity of RHA particles (Fig.1). In soil + RHA systems studied by Owino et al. [13], OMC rose sharply from 24 % at low RHA contents to as much as 34 % at 16 % RHA, while a parallel investigation by Eberemu and Sada [18] reported an increase from 26 % up to 34 % over the same RHA range. This marked increase underscores RHA's capacity to absorb and retain moisture, necessitating additional water to achieve target compaction levels.

When RHA is combined with cement and BF, the moisture demand remains elevated but is notably tempered. In the soil + RHA + cement + BF mixtures of Owino et al. [13], the OMC plateaued between 30 % and 32 %, whereas Eberemu and Sada [18] observed a somewhat broader range of 26 % to 34 %. The presence of hydraulic binders appears to occupy some of RHA's pore volume and alter the fabric of the compacted matrix, thereby moderating but not eliminating the need for extra water.

Gupta and Kumar [22] documented an intermediate OMC response (19 %–23 %), suggesting their RHA source possessed a more balanced pore-size distribution or was partially stabilized prior to mixing. In contrast, natural soils without RHA incorporation exhibited stable OMC values (16 %–20 % and 22 %–25 % across two soil types in [15]), confirming that the moisture-demand shift is driven by RHA's intrinsic properties rather than test methodology.

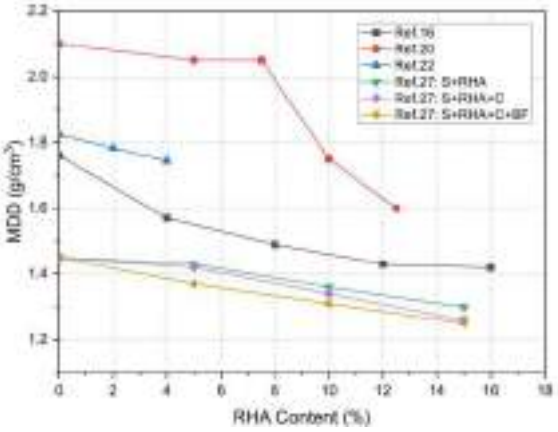

Fig.2 Variation of Maximum Dry Density with Rice Husk Ash content. [16, 20, 22, 27]

As shown in three independent investigations, the incorporation of RHA at contents up to 16% by weight leads to a systematic decline in maximum dry density (MDD), reflecting the lower specific gravity of RHA relative to conventional soils or binding agents (Fig.2). In the study by Eberemu [16], MDD decreased from approximately 1.76 g/cm³ (0 % RHA) to 1.42 g/cm³ (16 % RHA), indicating a loss of bulk mass as lightweight RHA displaced denser soil particles. Okafor and Okonkwo[20] observed an even more pronounced reduction, with MDD falling from about 2.10 g/cm³ to 1.60 g/cm³ over the same RHA range, suggesting that both the soil's mineralogy and the RHA's physical characteristics can amplify density loss. Gupta and Kumar [22] reported a subtler decrease, from 1.825 g/cm³ down to 1.744 g/cm³, which may be attributed to their lower initial soil density and possibly different compaction energy or moisture content. In the reported by Alex [27], the mixture of S+RHA+C and S+RHA+C+BF exhibits lower MDD compared to S+RHA, this suggests that the addition of additives may enhance the reduce in MDD.

These inter study variations highlight the sensitivity of compaction behavior to soil composition, compaction methodology (e.g., Proctor effort, moisture control), and RHA properties (particle size distribution, porosity). The consistently observed trend: that higher RHA dosages reduce MDD, underscores the need to adjust compaction parameters when designing RHA modified soil mixes to meet target density requirements. Further research into the interaction between RHA particle morphology and soil fabric could clarify the mechanisms governing these density reductions and optimize mix designs for geotechnical applications.

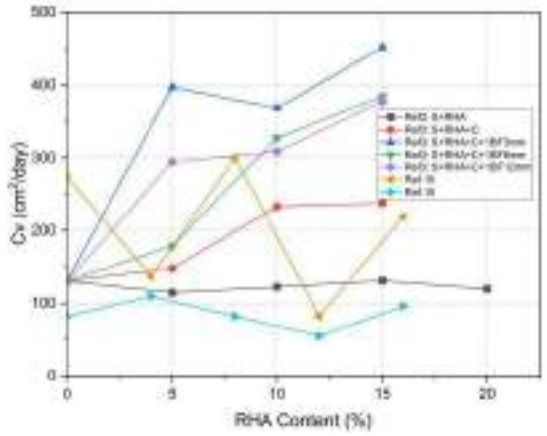

Fig.3 Variation of coefficient of consolidation with rice husk ash content for optimum moisture content. [3, 16, 18]

Across multiple investigations, increasing rice husk ash (RHA) content consistently accelerates soil consolidation (c_v) by enlarging the pore network with lightweight, porous ash (Fig.3). In unmodified soil–RHA blends [3], c_v climbs from ~120 cm²/day at 0 % RHA to ~400 cm²/day at 15 % RHA, then falls back at 20 % as excessive ash disrupts drainage continuity.

When cement is added [3], the rise in c_v is tempered, increasing from ~110 cm²/day to ~250 cm²/day at 15 % RHA because the binder fills some ash pores and stiffens the matrix. Introducing basalt fibers further alters drainage: all fiber reinforced mixes peak between 10–15 % RHA, with 3 mm fibers reaching ~450 cm²/day, as fine fibers most effectively sustain micro channels under load.

Distinct behaviors in other studies underscore RHA's sensitivity to testing conditions: [16] shows a transient spike to ~1,400 cm²/day at 7 % RHA (likely due to coarse ash or moisture variations), whereas [18] records a nearly constant c_v (~80–100 cm²/day) across all RHA contents. These outcomes highlight the need to optimize binder content, fiber reinforcement, and compaction parameters for balanced drainage and strength in RHA amended soils.

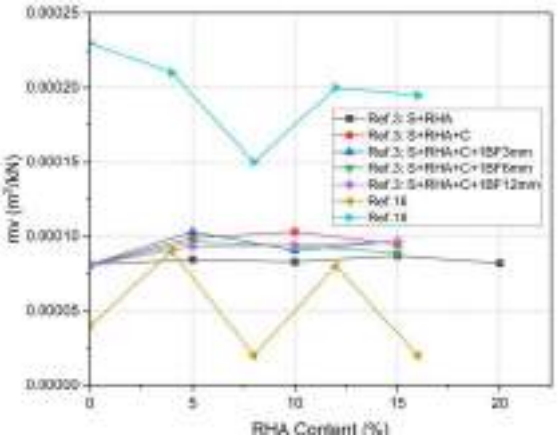

Fig.4 Variation of coefficient of volume compressibility with rice husk ash content for optimum moisture content. [3, 16, 18]

Across all investigations, the coefficient of volume compressibility (m_v) tends to rise as rice husk ash (RHA) content increases, reflecting the ash's intrinsic deformability and its effect on soil fabric (Fig.4). In the unmodified soil + RHA system of Eberemu [16], this increase is most dramatic: m_v grows from roughly 0.00002 m²/kN at 0 % RHA to about 0.00009 m²/kN at 15 % RHA. By contrast, the simple S + RHA mixtures in [3] exhibit a gentler climb, with m_v remaining below 0.00010 m²/kN across the entire RHA range.

When cement and basalt fibers are introduced ([3] with S + RHA + C + 1BF), compressibility is substantially curtailed. All three fiber-reinforced blends show m_v values between approximately 0.00007 and 0.00010 m²/kN, but the combination with 12 mm fibers (S + RHA + C + 1BF12 mm)

consistently records the lowest m_v, never exceeding 0.00008 m²/kN, demonstrating that longer fibers better reinforce the pore structure against volumetric collapse.

Eberemu and Sada findings [18] occupy an intermediate position: m_v values start near 0.00023 m²/kN at 0 % RHA, dip to 0.00015 m²/kN at 5 %, then rebound to about 0.00020 m²/kN by 15 %. This nonmonotonic trend suggests that their specific soil mineralogy or RHA processing technique modulates compressibility response.

Collectively, these data confirm that while RHA incorporation inherently increases soil compressibility, the judicious use of hydraulic binders and fiber reinforcement can effectively mitigate this disadvantage, an insight of practical importance when designing RHA-amended geomaterials for load-bearing applications

Discussion

The findings of this study underscore the considerable potential of basalt fiber and rice husk ash (RHA)-cement composites as a sustainable alternative for improving problematic soils, particularly soft clays and expansive soils, which are often prone to excessive settlement, low strength and long consolidation periods [31]. The synergistic effects of basalt fibers' stress-bridging capacity and RHA-cement's pore-filling and pozzolanic reactivity enable simultaneous enhancement of mechanical performance and reduction of environmental impact [27]. This dual benefit addresses both technical limitations and sustainability concerns inherent in conventional stabilization methods that rely heavily on Ordinary Portland Cement (OPC) or lime.

From a practical perspective, the integration of basalt fiber and RHA-cement composites can be implemented across a wide range of geotechnical projects. In embankment construction, the enhanced stress redistribution and lower compressibility can contribute to greater long-term stability, mitigating post-construction settlements that can compromise structural integrity [27]. For road foundations and weak subgrade treatment, the composite ability to limit differential settlement and cracking can significantly extend pavement service life and reduce maintenance requirements [32]. These improvements are particularly advantageous in regions where soft and expansive clays are prevalent and conventional high-binder treatments are economically or environmentally burdensome.

The environmental implications of this approach are equally significant. The utilization of RHA, an agricultural byproduct rich in reactive silica, not only valorizes waste but also reduces OPC demand, thereby lowering CO_2 emissions associated with cement manufacturing. Basalt fibers are derived from naturally occurring volcanic rock and fully recyclable, further enhancing the sustainability credentials of the method by providing durable reinforcement without introducing synthetic polymers or non-biodegradable additives [13]. These attributes align with global initiatives toward low-carbon construction, resource efficiency and circular economy principles [33].

CONCLUSIONS

This review demonstrates that basalt-fibers-RHA-cement composites present a promising, low-carbon alternative for stabilizing problematic soils, particularly soft clays and expansive soils. By leveraging the synergistic effects of basalt fibers for tensile reinforcement and RHA for pozzolanic activity, the approach effectively improves compressibility, swelling behavior and load-bearing capacity while significantly reducing OPC consumption.

From a sustainability perspective, incorporating agricultural byproducts such as RHA and recyclable natural materials like basalt fibers aligns with global initiatives toward greener construction and circular economy principles. The results from laboratory-scale studies suggest that comparable or superior soil performance can be achieved with up to 60% less OPC, lowering both embodied carbon and overall material costs.

FUTURE RESEARCH DIRECTIONS

Despite the clear benefits demonstrated in laboratory settings, the journey toward real-world implementation of basalt fiber–RHA–cement composites demands a deeper exploration of several key areas. First and foremost, long-term durability under environmental cycling must be rigorously assessed. In the field, stabilized soils face repeated wetting and drying, seasonal freeze–thaw cycles, and exposure to aggressive chemicals—such as sulfates in groundwater or chlorides from deicing salts—that can gradually weaken fiber–matrix bonds or alter the stability of pozzolanic C–S–H gel. Accelerated aging tests that simulate decades of environmental fluctuation will be essential to verify that the reinforcing network and cementitious binder maintain their integrity over the service life of an embankment or pavement.

Equally important is the systematic optimization of mix proportions. While a blend of 12 mm basalt fibers, 5 % RHA, and 3 % OPC has emerged as a promising baseline, soils vary widely in mineralogy, grain size distribution, and plasticity. By exploring a

matrix of fiber lengths, fiber dosages, ash contents, and cement percentages, researchers can identify cost-effective formulations tailored to specific site conditions—whether that means treating organic clay beneath a low-volume rural road or stabilizing silty loam for a highway embankment. Such parametric studies not only refine performance but also minimize waste and material expense.

Looking beyond rice-husk ash, the concept of circular-economy stabilization invites the incorporation of other agricultural or industrial byproducts. Fly ash, ground granulated blast-furnace slag, and even biochar offer unique chemical and physical properties that might complement basalt fiber reinforcement. Investigating how these materials interact—both with the soil matrix and with one another—could yield multifunctional composites that make fuller use of local waste streams, reduce reliance on virgin resources, and further lower the carbon footprint of geotechnical construction.

Finally, advanced modeling and simulation techniques stand to accelerate adoption by reducing dependence on extensive trial-and-error testing. Coupled hydro-mechanical finite-element models, informed by microstructural observations (SEM, XRD) and calibrated with consolidation parameters from laboratory oedometer tests, can predict how fiber–ash–cement composites will perform under complex loading patterns and boundary conditions. Discrete-element simulations, in turn, can elucidate the micromechanics of fiber pull-out, crack bridging, and particle rearrangement. Together, these tools will equip engineers with robust, predictive frameworks—enabling confident design of large-scale projects and ultimately paving the way for sustainable soil improvement technologies to become mainstream practice.

ABSTRACT

Climate change is a critical global issue, driven by carbon dioxide (CO_2) emissions from energy consumption, fossil fuels, waste mismanagement, deforestation, industrial production, and unsustainable agriculture. Addressing this crisis requires collaboration across all sectors and strong governance. As part of the global effort to combat climate change, local governments play a crucial role in implementing mitigation strategies. In Khon Kaen, Thailand, a dedicated task force has introduced 27 greenhouse gas (GHG) reduction measures across six sectors: energy efficiency, renewable energy, transportation, waste management, forestry, industrial production, and agriculture. The success of these initiatives depends on how effectively local administrative organizations (LAOs) plan strategies, allocate resources, and foster community engagement. This study systematically investigates key determinants that influence the success of GHG reduction initiatives at the local level. A structured survey of 246 participants from LAOs in Khon Kaen was conducted using a 75-item questionnaire. The data were analyzed using Structural Equation Modeling (SEM) to identify key success factors. The findings identify critical factors influencing the effectiveness of GHG reduction efforts, revealing both structural challenges and opportunities for improvement. These insights serve as a foundation for developing more targeted policies and scalable strategies to strengthen climate mitigation initiatives.

Keywords: Climate Change, Greenhouse Gas Reduction, Environmental Management, Policy Effectiveness, Local Administrative Organizations

INTRODUCTION

Climate change is one of the most serious global challenges today. It has wide-ranging impacts on economic, social, and environmental systems. The Intergovernmental Panel on Climate Change (IPCC) has warned that if greenhouse gas (GHG) emissions continue to rise, the consequences will become more severe. Immediate and joint action across all sectors is necessary [1].

Thailand has committed to reducing its GHG emissions by 40% by 2030 and achieving net-zero carbon emissions by 2065 [2]. Reaching these goals requires collaboration from all sectors, especially local governments. Local Administrative Organizations (LAOs) are closely connected to communities and can lead climate action from the ground up [3].

In recent years, LAOs have been recognized globally as important actors in turning national climate policies into real action at the local level. Their close relationship with communities and ability to adapt to local needs make them effective in responding to climate issues [4]. However, in Thailand, there is still a lack of research that explores the structural factors influencing the success of LAOs, especially studies that use Structural Equation Modeling (SEM) to examine causal relationships [5].

Khon Kaen Province is one of Thailand's leading areas for local climate action. A special task force was created to plan and implement 27 GHG reduction measures across five sectors energy, transport, waste management, forestry, and agriculture [6], [7]. The province aims to reduce GHG emissions by at least 30% by 2030 (Fig. 1).

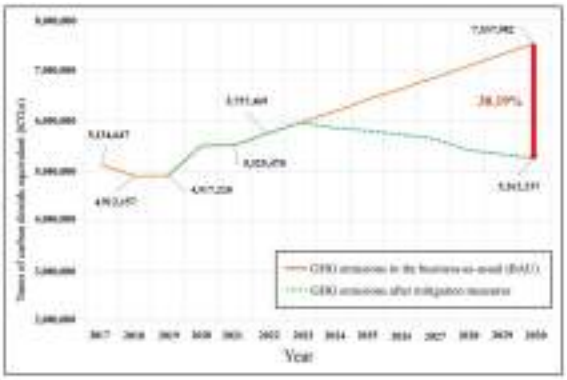

Fig. 1 Khon Kaen GHG emissions reduction by 2030

However, there are several structural challenges. These include centralized decision-making, limited financial capacity, and poor coordination between agencies [8], [9]. In addition, complex bureaucracy and low public participation remain barriers to effective local climate governance [10], [11].

Past studies have pointed out several success factors in local environmental governance. Byrne emphasized the role of social motivation in encouraging community participation [12]. Liu et al. found that creative leadership

and decentralization improve local government performance in developing countries [13]. Yuen et al. noted that centralized systems and the lack of local coordination are key barriers in the ASEAN region [14].

This study aims to identify key success factors in implementing local GHG mitigation actions using Structural Equation Modeling (SEM). Data were collected from 246 representatives of 225 LAOs in Khon Kaen Province. The findings will support policy recommendations that are practical, locally appropriate, and applicable to other areas.

LITERATURE REVIEW

Climate change has emerged as a defining global challenge, with significant emphasis placed on mitigation through policy mechanisms at both national and local levels. The Intergovernmental Panel on Climate Change (IPCC) [1] and the United Nations Framework Convention on Climate Change (UNFCCC) [2] emphasize that local implementation is vital for achieving nationally determined targets. In Thailand, the Department of Local Administration [3] and ICLEI [4] have highlighted the role of Local Administrative Organizations (LAOs) in contributing to climate mitigation through practical action at the subnational level.

Prior research has identified several enabling factors that contribute to effective local environmental governance, such as clarity of institutional mandates, participation from stakeholders, and adequate resource allocation [3], [4], [5]. In the Thai context, Limnirankul and Chompunth [5] point out that LAOs often encounter challenges related to capacity and legal authority yet can succeed when appropriate policy tools and technical support are provided.

From a theoretical perspective, Pressman and Wildavsky [8] emphasize the complexity of policy implementation, requiring alignment between central guidance and local operational capacity. Similarly, Edwards [9] and Sabatier [10] argue that successful execution involves not only organizational structure but also motivation, incentives, and contextual flexibility.

Recent national frameworks such as Thailand's Updated Nationally Determined Contributions (NDCs) [2] and provincial mitigation plans [6] underscore the need for coordination between national strategies and local institutions. Programs such as the Thailand Voluntary Emission Reduction Program (T-VER) and the Low Emission Support Scheme (LESS), led by the Thailand Greenhouse Gas Management Organization (TGO), represent mechanisms to incentivize measurable GHG reductions at the local level [10]. These frameworks and studies collectively highlight the importance of investigating the factors that influence LAO success in implementing climate mitigation policies forming the rationale for this research.

Research Hypothesis

Based on a synthesis of relevant literature and theoretical frameworks covering Management, Motivation, and Leadership combined with Policy Outcome analysis and the application of Structural Equation Modeling (SEM), the following research hypotheses were formulated **(**Fig. 2**)**

H_1: Management has a positive influence on the success of Policy Outcome.

H_2: Motivation has a positive influence on the success of Policy Outcome.

H_3: Leadership has a positive influence on the success of Policy Outcome.

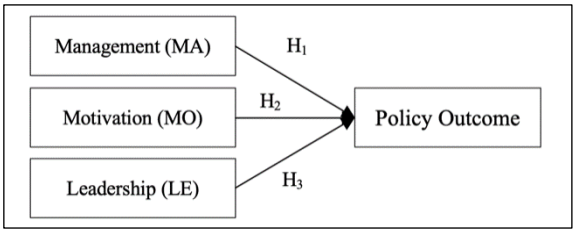

Fig. 2 Research Hypotheses

METHODOLOGY

Research Design

This study adopted a quantitative approach to examine the key factors that influence the success of LAOs in implementing GHG mitigation measures in Khon Kaen Province. The primary analytical tool used in this study is Structural Equation Modeling (SEM), which allows for the analysis of causal relationships between latent variables and observed variables within a single, unified model framework [31].

The use of SEM is appropriate for this study as it enables the simultaneous analysis of multi-dimensional relationships among variables. In addition, SEM provides key model fit indices and estimates both the direction and magnitude of causal effects, making it a systematic and rigorous method for analyzing structural relationships within complex policy environments [31].

Population and Sampling

The population of this study consisted of all LAOs in Khon Kaen Province, totaling 225 entities. These included city municipalities, town municipalities, subdistrict municipalities, and subdistrict administrative organizations.

The sample comprised representatives or executives from each organization who were directly involved in formulating policies or implementing environmental initiatives. A purposive sampling method was employed to ensure the selection of individuals with relevant knowledge and practical experience in GHG mitigation efforts.

A total of 246 respondents completed the questionnaire. This number exceeded the total number of LAOs because some organizations designated more than one representative. This approach was intended to gather more comprehensive and in-depth perspectives on local-level implementation processes and challenges.

The sample size of 246 is considered adequate for Structural Equation Modeling (SEM) analysis, following the guidance of Hair et al. (2022), who recommend a minimum of 200 cases or a ratio of 5 to 10 observations per estimated parameter [32].

Research Tools and Design

The questionnaire used in this study consisted of 75 items and was divided into two main sections. The first section included 66 items (SF1 - SF66) intended to assess key success factors in implementing GHG mitigation policies. These items were categorized into six thematic clusters to ensure comprehensive content coverage, as summarized in Table 1 below. The second section contained 9 items (EF1 - EF9) designed to evaluate policy outcomes such as effectiveness, sustainability, and integration into long-term development frameworks.

All items were rated on a five-point Likert scale ranging from 1 (Strongly Disagree) to 5 (Strongly Agree). Content validity was confirmed through expert review, and the instrument demonstrated high internal consistency (Cronbach's Alpha > 0.80).

Table 1 Questionnaire items

Code	Item
Success factors (Environmental Policy)	
SF1	Clear and easily policy
SF2	Policy supports from the government
SF3	Financial support from the government
SF4	Setting a clear and measurable time frame
SF5	Community and business sector participation
SF6	Effective promotion and supervision
SF7	Prioritize and allocate resources appropriately
SF8	Clear vision and encourage to cooperate.
SF9	Promoting education and training
SF10	Ability to motivate and engage
SF11	Supporting and promoting new innovations.
SF12	Supporting and developing infrastructure.
SF13	Enforcement laws increase incentives for action
SF14	Clear and time-bound rules and regulations
SF15	Inspection and enforcement of the law
SF16	Regulations or laws that clearly define standards
SF17	Providing tax incentives or benefits
SF18	Clear penalties and impacts.
SF19	Clear and systematic plan
SF20	Monitoring and evaluation
SF21	Appropriate resource allocation
SF22	Benefits for all parties in supporting
SF23	Clear goals management and performance monitoring
SF24	Transparent and accountable management
SF25	Public-private collaboration supports success
SF26	Community involvement in decision-making
SF27	Participation in innovation and technology development
SF28	Collaboration in policy and monitoring
SF29	Participation in policy formulation and evaluation
SF30	Multi-sectoral collaboration at local and national levels
SF31	Knowledge and education enhancement for stakeholders
SF32	Sufficient knowledge for practical implementation
SF33	Training and education
SF34	Involvement of academic and educational institutions
SF35	Promotion of local education
SF36	Understanding of climate change and related issues
SF37	Use of modern technology and innovations
SF38	Consistent use of technology in organizations
SF39	Enhanced production or energy efficiency
SF40	Use of carbon capture and storage (CCS) technology
SF41	Promotion of renewable energy innovations
Code	Item
SF42	Adoption of clean energy technologies in industry
SF43	Sufficient budget availability
SF44	Financial support from external funding sources
SF45	Properly allocated funding sources
SF46	Targeted budgets and suitable resource allocation
SF47	Financial support in the form of incentives or loans
SF48	Funding enhances investment in relevant technologies
SF49	Recognition and appreciation from leadership
SF50	Recognition from government or external agencies
SF51	Recognition from community and society
SF52	Public or external organization appreciation and honor
SF53	Recognition from authorities increases enthusiasm
SF54	Recognition encourages participation
SF55	Awareness of impacts strengthens commitment
SF56	Awareness motivates involved stakeholders
SF57	Community awareness of climate change impacts
SF58	Personal awareness
SF59	Awareness enhances support from various sectors
SF60	Fostering awareness among stakeholders
SF61	Promoting impact-conscious behavior
SF62	Habitual energy and resource conservation
SF63	Environmental conservation awareness from childhood
SF64	Habits of choosing eco-friendly products and services
SF65	Upbringing environmental awareness in families
SF66	Stakeholder behavior influences success
Results (Policy Outcome)	
EF1	Implementation yields tangible and sustainable results
EF2	Implementation is measurable
EF3	Society benefits from the implementation
EF4	Able to continue in the long term
EF5	Scalable in the future
EF6	Improves workflow and management
EF7	Enhances monitoring and evaluation
EF8	Integrated into long-term development plans
EF9	Sustained resource and budget allocation

Note: While the questionnaire was structured around six content clusters for design clarity, the SEM analysis was based on three latent constructs Management, Motivation, and Leadership as determined by exploratory factor analysis and theoretical alignment.

Respondents were instructed to reflect on their answers based on their organization's overall implementation experience with all 27 mitigation measures in Table 2, to ensure a structured and policy-level perspective in their responses.

Table 2 27 Greenhouse Gas Mitigation Measures

Sector	Measures	Details
Energy Efficiency (EE)	7	1. Replacement of Lighting with LED Bulbs. 2. Energy Consumption Reduction.

Alternative Energy (AE)	8	1. Installation of Rooftop Solar Panels. 2. Use of Biogas.
Transportation Management (TM)	4	1. Use of Electric Vehicles 2. Development of Public Transportation Systems.
Waste Management (WM)	3	1. Waste-to-Energy Conversion 2. Wastewater Treatment

Sector	Measures	Details
Forest (FOR)	2	1. Afforestation and Reforestation
Agriculture (AGR)	3	1. Promotion of Sustainable Farming 2. Reduction of Open Burning in Agricultural

Data Analysis

The analysis of questionnaire data was carried out using Structural Equation Modeling (SEM), a statistical technique that is particularly suitable for examining complex causal relationships between latent variables and observed indicators within a unified model framework [33]. This approach enabled the researcher to investigate multiple relationships simultaneously, while accounting for both measurement error and the multidimensional nature of the constructs.

To begin, Exploratory Factor Analysis (EFA) was conducted to explore the underlying structure of the latent variables based on the empirical data collected. This step was important because the questionnaire items had been adapted and synthesized from multiple theoretical and empirical sources. The EFA helped ensure that the factor structure was appropriate and contextually valid for the LAOs in Khon Kaen Province.

Following EFA, Confirmatory Factor Analysis (CFA) was employed to assess the fit between the observed data and the proposed theoretical constructs. This step provided evidence for the construct validity and internal consistency of the measurement model and confirmed that the indicators accurately represented the intended latent variables.

Finally, the full Structural Equation Model was estimated to examine the hypothesized causal relationships among the three main independent constructs Management, Motivation, and Leadership and the dependent variable, defined as the success of policy implementation. The analysis focused on identifying the direction and strength of these relationships to test the study's hypotheses.

All analyses were conducted using Jamovi, an open-source statistical software that offers robust support for SEM procedures and generates detailed model evaluation outputs. Model fit was assessed using several widely accepted indices, including the Comparative Fit Index (CFI) and Tucker–Lewis Index (TLI), for which values greater than 0.90 were considered acceptable. Additionally, the Root Mean Square Error of Approximation (RMSEA) and the Standardized Root Mean Square Residual (SRMR) were used, with values below 0.08 indicating a good model fit [33].

RESULTS

Analysis

Prior to conducting factor analysis using the Structural Equation Modeling (SEM) technique, the internal consistency of the research instrument was assessed using Cronbach's Alpha for the four main groups of latent variables. The results indicated that all constructs exceeded the minimum acceptable threshold of 0.80, in accordance with the criteria recommended by Hair et al. [34]. This finding confirms that the instrument demonstrated a high level of reliability. The reliability coefficients for each construct are presented in Table 3

Table 3 Reliability Analysis

Group of factors	Cronbach's Alpha Coefficient
Management (MA)	0.914
Motivation (MO)	0.898
Leaderships (LE)	0.932
Result (RE)	0.938

Exploratory Factor Analysis (EFA)

Exploratory Factor Analysis (EFA) was conducted using data from a sample of 246 respondents to identify the underlying structure of latent variables in the dataset. The analysis applied the Oblimin rotation method, which is appropriate when variables are assumed to be correlated [34].

The summary of the EFA results is presented in Table 4, which displays key statistical indices used to evaluate the suitability of the data for factor analysis.

Table 4 The summary of the EFA results

EFA Indicator	Value from Analysis	Interpretation	Reference
Kaiser-Meyer-Olkin (KMO)	0.95	Excellent sampling adequacy	Kaiser (1974)
Bartlett's Test of Sphericity	χ^2 = 15,413.07, df = 2775, p < .001	Significant correlation matrix: factor analysis is appropriate	Bartlett (1954)
Number of Factors	4	Four-factor solution is most appropriate	Hair et al. (2019)
Factor Loadings	0.68 - 0.92	Very strong item-factor correlations	Hair et al. (2019)
Cross-loading	No cross-loadings above threshold	No cross-loading issues observed	Hair et al. (2019)
Communality	All items ≥ 0.40	High shared variance across items	Hair et al. (2019)
Total Variance Explained	Over 70%	Acceptable level of explained variance	Hair et al. (2019)
Rotation Method	Oblimin	Appropriate for correlated factors	Fabrigar et al. (1999)
Cronbach's Alpha	All factors ≥ 0.79	High internal consistency	Hair et al. (2019)

The results of the exploratory factor analysis revealed that the data structure could be clearly grouped into four distinct factors, corresponding to the latent constructs used in the research model Management, Motivation, Leadership, and Policy Outcomes. Details of each factor are summarized in Table 5 Factor loadings which value greater than 0.70 are considered strong and indicate high structural alignment [34].

Table 5 Factor Structure Identified by EFA

Factor	Construct Name	Key Observed Variables	Factor Loading Range
F1	Management (MA)	SF24, SF26, SF31	0.79 - 0.83
F2	Motivation (MO)	SF59, SF60, SF61	0.78 - 0.81
F3	Leadership (LE)	SF7, SF9, SF10	0.82 - 0.84
F4	Result (RE)	EF1, EF2, EF3	0.82 - 0.92

Confirmatory Factor Analysis (CFA)

Confirmatory Factor Analysis (CFA) was conducted to evaluate the goodness-of-fit between the proposed measurement model and the empirical data, based on the factor structure identified in the Exploratory Factor Analysis (EFA). The model fit indices are summarized in Table 6, which demonstrates that the model achieves a statistically acceptable and satisfactory level of fit.

Table 6 Model Fit Indices for the Confirmatory Factor Analysis (CFA)

Fit Index	Value from Analysis	Acceptable Threshold	Reference
Chi-square/df	1.92	< 3.00	Hair et al., (2019)
CFI	0.961	≥ 0.95	Hu & Bentler, (1999)
TLI	0.949	≥ 0.95 (nearly acceptable)	Hu & Bentler, (1999)
RMSEA	0.045	≤ 0.06	Browne & Cudeck, (1993)
SRMR	0.038	≤ 0.08	Hair et al., (2019)

Although the Tucker-Lewis Index (TLI) value was slightly below the conventional threshold, it still falls within an acceptable range. When considered alongside the other fit indices, the results suggest that the CFA model exhibits a good overall fit with the empirical data [20]. The measurement model structure derived from the CFA is illustrated in Fig. 3.

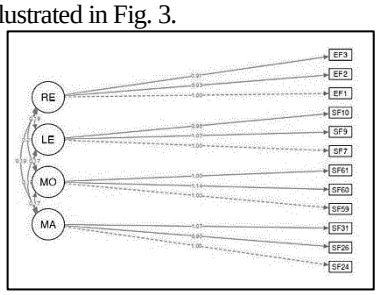

Fig. 3 Measurement Model (CFA) of the Four Latent Constructs

As shown in Fig. 3, the measurement model comprises four latent constructs Management (MA), Motivation (MO), Leadership (LE), and Result (RE). Each construct is measured by a set of observed variables that are conceptually aligned, with all factor loadings meeting the acceptable threshold of ≥ 0.70, indicating a strong level of structural alignment.

The analysis confirmed that the model demonstrates good measurement properties in terms of both loading values and statistical significance. Furthermore, all latent constructs were found to be positively correlated, which is consistent with the theoretical framework and research hypotheses particularly in evaluating policy implementation success at the local level [20], [21].

Structural Equation Modeling (SEM) Results

This study aimed to examine the causal relationships between three independent latent constructs Management (MA), Motivation (MO), and Leadership (LE) and the dependent construct, Results (RE), representing the success of GHG mitigation measures implemented by LAOs. (Figure 4)

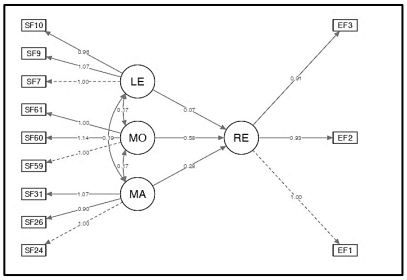

Fig. 4 SEM Diagram Showing the Influence of MA, MO, and LE on RE

The SEM results illustrated in Fig. 4 reveal the following

Motivation (MO) had the strongest positive influence on Result (RE) ($\beta = 0.58$, $p < .001$).

Management (MA) had a moderate positive influence ($\beta = 0.25$, $p = .002$).

Leadership (LE) did not exhibit a statistically significant influence ($\beta = 0.07$, $p = .251$).

These findings indicate that internal motivation among personnel plays the most critical role in driving the success of GHG mitigation measures at the local level, aligning with the theoretical perspectives of Hair et al. [20] and Byrne [10].

The fit indices of the SEM model are shown in Table 7, and the standardized path coefficients from hypothesis testing are presented in Table 8**.**

Table 7 Model Fit Indices for the SEM

Fit Index	Value	Threshold	Reference
Chi-square/df	2.05	< 3.00	Hair et al. (2019)
CFI	0.962	≥ 0.95	Hu & Bentler (1999)
TLI	0.95	≥ 0.95	Hu & Bentler (1999)
RMSEA	0.047	≤ 0.06	Browne & Cudeck (1993)
SRMR	0.04	≤ 0.08	Hair et al. (2019)

Table 8 Standardized Path Coefficients from SEM Analysis

Hypothesis	Path	β (Standardized)	p-value	Significance
H_1	MA → RE	0.25	0.002	Significant
H_2	MO → RE	0.58	< 0.001	Highly significant
H_3	LE → RE	0.07	0.251	Not significant

The results of the SEM analysis indicate that Motivation (MO) exerted the strongest positive influence on Policy Outcome (Result) ($\beta = 0.53$, $p < .001$). This finding aligns with Byrne [14] and Hair et al. [20], who argue that internal motivation within organizations plays a pivotal role in driving policy effectiveness particularly in environmental policies that require active engagement, shared commitment, and collective responsibility among front-line personnel.

Meanwhile, Management (MA) demonstrated a moderate positive effect on Result ($\beta = 0.27$, $p = 0.002$), highlighting the importance of clear administrative systems, cross-functional collaboration, and inter-agency coordination in achieving local policy success.

However, Leadership (LE) did not exhibit a statistically significant influence ($\beta = 0.08$, $p = 0.251$). This may reflect the constraints of centralized bureaucratic systems, which can limit the autonomy and policy-oriented leadership role of local government leaders in practical settings.

CONCLUSION

This study set out to explore the factors influencing the success of LAOs in implementing GHG mitigation measures in Khon Kaen Province. Using Structural Equation Modeling (SEM), the relationships between three key latent variables Management (MA), Motivation (MO), and Leadership (LE) and Result (RE) were tested.

The model showed a strong fit, with CFI = 0.99, TLI = 0.99, RMSEA = 0.03, and SRMR = 0.03, which are all within the recommended thresholds according to Hair et al. [20] and Hu & Bentler [21]. Based on responses from 246 individuals across 225 LAOs, the analysis demonstrates practical reliability.

The standardized path coefficients revealed that Motivation (MO) had the strongest positive influence on policy outcomes ($\beta = 0.53$, $p < 0.001$), reinforcing Byrne's [10] idea that social motivation plays a major role in driving environmental behavior, both among officials and within communities. Management (MA) showed a moderate influence ($\beta = 0.27$, $p = 0.002$), highlighting the importance of planning and inclusive decision-making, as suggested by ICLEI [3] and Setyowati et al. [13]. On the other hand, Leadership (LE) did not show a statistically significant effect ($\beta = 0.08$, $p = 0.251$), which may reflect the challenges of centralized governance and limited mechanisms for local leadership [7], [8].

While the results emphasize motivation and management, it's worth noting that many GHG mitigation efforts such as solar rooftop installations, biogas systems, or LED lighting ultimately rely on tangible infrastructure. This highlights the need to align administrative actions with practical engineering solutions to ensure that good plans lead to real outcomes.

Future research may look deeper into how administrative performance affects the actual use and performance of local mitigation technologies. For example, how well are solar panels functioning? Are biogas systems being maintained? These practical questions can help link governance and engineering in a way that supports truly sustainable outcomes.

DISCUSSION

This study demonstrates the key factors that contribute to the success of LAOs in Khon Kaen Province in implementing GHG mitigation measures. Through the application of Structural Equation Modeling (SEM), the analysis identifies three core dimensions consisting of Management, Motivation, and Leadership, as significant determinants, with Policy Outcome serving as the primary dependent construct.

Motivation

The results of the study found that motivation had the most significant influence on policy outcomes ($\beta = 0.58$, $p < 0.001$**)**, consistent with the views of Byrne [12] and Hair et al. [20], who argue that internal motivation within organizations is a critical force in driving policy objectives toward practical implementation. This is particularly relevant in the context of environmental management, where success often relies on active engagement and a shared sense of responsibility among those involved.

In Khon Kaen Province, the 27 mitigation measures across six sectors were designed to allow LAOs to select and apply them based on their specific local contexts. This approach has helped encourage meaningful participation from key sectors, including civil society, the private sector, and educational institutions. Moreover, national-level mechanisms such as the Thailand Voluntary Emission Reduction Program (T-VER) and the Low Emission Support Scheme (LESS) have further enhanced local motivation by providing both institutional support and recognition for local climate action efforts [40].

Management

Management was found to have a moderate positive influence on policy outcomes ($\beta = 0.25$, $p = 0.002$), underscoring the importance of effective internal organizational systems. This includes strategic planning, resource allocation, performance monitoring, and internal communication. These findings are consistent with the perspectives of ICLEI [4] and Setyowati et al. [25]**,** who emphasize the need for integrated management frameworks at the local level to support sustainable environmental governance.

In Khon Kaen Province, the performance of LAOs has been assessed using the LPA tool, developed under the framework of the Department of Local Administration, Ministry of Interior, as the lead agency, in collaboration with the Provincial Office of Natural Resources and Environment, which provides technical data and field-level support. This mechanism has played a key role in promoting ongoing improvements in local management systems. Additionally, the draft Climate Change Act, currently under development, is expected to further clarify and formalize the roles and responsibilities of LAOs in addressing climate-related risks in the future [29].

Leadership

Although leadership is widely recognized in theory as a key factor in driving environmental policy particularly in terms of establishing a clear vision and motivating stakeholders this study found that leadership had limited influence on policy outcomes. This may be due to structural constraints in Thailand's centralized administrative system, which often restricts the authority of local leaders to shape policy directions independently.

Despite these limitations, Khon Kaen Province has made efforts to foster collaborative forms of leadership by establishing a provincial-level task force that brings together representatives from government agencies, academia, the private sector, and civil society. This mechanism emphasizes integrated planning, cross-sectoral development, and structured stakeholder engagement to move GHG mitigation efforts forward across all sectors, [6], [7].

While such initiatives show promise and reflect a shift toward more inclusive local leadership, their impact may not yet be fully reflected in the perceptions of individual respondents captured in this study. Exploring this further through qualitative or comparative methods could help uncover how leadership manifests in decentralized settings and how it can be better supported [8].
across all sectors.

Policy Implications

The findings of this study clearly indicate that internal organizational motivation is the most critical factor influencing the success of local GHG mitigation efforts. This suggests that promoting participation, fostering a sense of institutional pride, and providing symbolic or public forms of recognition can effectively drive performance at the local level. At the same time, a strong internal management system plays a secondary but essential role in bridging national policy frameworks with on-the-ground implementation, particularly through strategic planning, resource allocation, and continuous performance monitoring. While leadership is often seen as a central component of policy advancement in theoretical frameworks, the highly centralized nature of Thailand's administrative system may constrain the capacity of local leaders to exercise meaningful influence. Therefore, efforts to cultivate authentic leadership at the local level should be accompanied by systemic reforms such as decentralization, targeted budget support, and enhanced policy capacity to empower local leaders to shape direction and effect change in a concrete and sustainable manner.

While motivation and management emerged as key drivers in this study, it is equally important to recognize that many GHG mitigation efforts such as solar installations, energy efficient lighting, and waste treatment systems are ultimately realized through physical infrastructure. This connection between local administrative action and environmental technology highlights an area where policy and engineering must go hand in hand.

RECOMMENDATION

The findings of this study indicate that motivation and management are critical determinants of the success of GHG mitigation efforts within Local Administrative Organizations (LAOs). Based on this, government agencies and related institutions should consider the following directions

1. Promote Positive Incentive Mechanisms, implement reward systems, recognition programs, or environmentally themed competitions to stimulate internal motivation and reinforce behavioral change among staff.
2. Design Open Governance Processes, encourage greater community involvement in co-designing policies and monitoring implementation to foster transparency, ownership, and accountability.
3. Strengthen Multi-Level Communication, enhance communication channels between LAOs and higher-level authorities (provincial or national) to ensure better alignment, resource support, and policy continuity.

While this study focused on all 225 LAOs in Khon Kaen Province, future research should explore the broader applicability of these findings. The following directions are recommended

1. Expand Comparative Studies, conduct cross-provincial or regional studies to validate the model in different administrative and socio-political contexts.
2. Incorporate Qualitative Methods, use in-depth interviews or case studies to capture behavioral nuances and leadership dynamics that quantitative measures may overlook.
3. Develop Extended Models, future models could integrate variables such as organizational culture, innovation capacity, or access to external resources to better understand LAO performance.

Lastly, local governments should be supported not only through institutional and policy incentives but also through technical assistance especially in planning, implementing, and maintaining green infrastructure. This includes renewable energy systems, sustainable waste management, and low-

emission construction. Such a dual-track approach can help ensure that policy ambitions lead to real, measurable environmental improvements.

A STUDY OF TEMPERATURE REDUCTION METHODOLOGY IN URBAN HEAT ISLAND USING MICROCLIMATE TECHNIQUE

Ekarin Sangthammarat.[1], Chokchai Chutakositkanon[1]

[1]Faculty Of Engineering, Mahidol University, Salaya, NakornPrathom, Thailand

ABSTRACT

To address the impact of global warming on localized temperature increases—commonly referred to as the Urban Heat Island (UHI) effect, this study focused on the application of microclimate modification techniques. The objective was to evaluate the potential for reducing ambient temperature and energy consumption by varying the shapes of trees and types of ground surfaces most suitable for enhancing the pavement areas along Ratchadamnoen Road, Bangkok. Five simulation scenarios were developed using ENVI-met V5.6.1, each incorporating equivalent amounts of vegetation and surface coverage, to identify the most effective configuration. The simulation results demonstrated a verification accuracy of 95%. The research results revealed that the optimal strategy for mitigating temperature and heat accumulation in UHI-affected areas involves increasing green space by planting round-shaped trees and utilizing ground cover materials for exposed floor surfaces. These interventions effectively absorb solar radiation, reduce ambient air temperature, and decrease energy consumption—resulting in potential monthly electricity savings of up to 24,225.44 baht.

Keywords: Microclimate, Thermal Comfort, Energy Saving, Landscape Adjustment, Urban Heat Island

INTRODUCTION

Rapid development of urbanization is suddenly in many major cities resulted in to population growing. Many major cities experience the impact of global warming for example flooding and drought as a consequence of climate change. The urban areas are now facing greater risks due to the development intensity as a solution for urban growth, lack of compatibility of these development typologies resulted in increased cooling load [1].

However, most of the urban and many cities are lack of appropriate energy consumption modelling and optimal climate analysis which is misleading to the energy analysis for space conditioning associated with rapid developments. This lack of understanding has major implications on energy budgeting and human health in tropics [2].

In order to model the energy consumption in the city due to climate change is complicated. On most occasions, these designers and planners tend to use subjective measures to evaluate their development proposals under complex climate premises [3] which leading to unforeseen risks.

Computer modelling is used as major tools in urban climate studies due to their capability to simulate complex fluid dynamic interactions. In the urban field, modelling approaches can be applied to different city condition, such as population distribution, mobility network as well as growth of population and climate change [4]. Modeling can be used as forecasting tools to investigate the certain actions effect on a selected domain [5]. Urban models enable making predictions on unbuilt conditions and testing hypotheses of future urban interventions (Batty 2009).

The in-depth analysis of a modelling case study, A conceptual model, including the climate phenomena to be represented the urban scene, is defined as starting point and associated to an urban domain. ENVI-met is applied with the goal of exploring microclimate effects of an urban area at the center of Bangkok, Thailand. To highlight the potential of usage of microclimate technique in order to modelling the possibility to reduce the energy consumption in the control area, several simulation models have been done to achieve the goals.

RESEARCH OBJECTIVE

The objective of the study is to determine the type and characteristic of tree and glass in order to reduce the Urban Heat Island (UHI) and to determine the possibility to reduce the temperature and heat gain in the city together with the possibility to reduce the energy consumption in the surrounding area.

RESEARCH SCOPE

Due to the numerous microclimate parameters that influence temperature and relative humidity, this research focused solely on the types of trees and mulch. The study was conducted during the summer season in Bangkok, Thailand. Climate data were obtained from the Visual Crossing Weather API.

RESEARCH METHODOLOGY

In order to reach research objective, there research

step had been classified into 5 steps as shown in Fig.1.

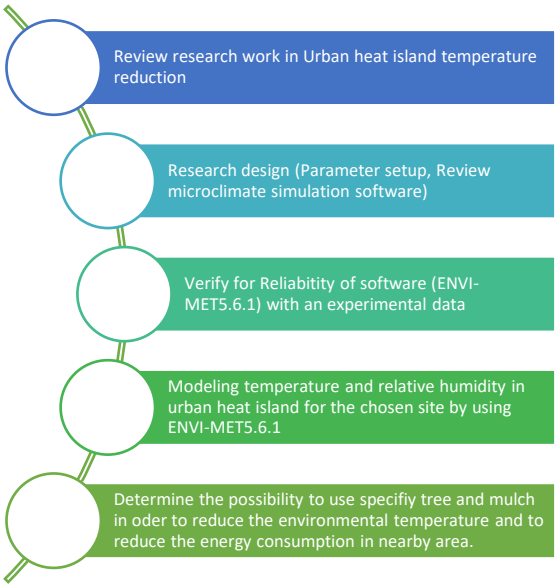

Fig.1 Research framework for urban heat island

Data Verification

In order to verify reliability of ENVI-MET 5.6.1 simulation software, researcher select the park area in Mahidol University, Salaya, Nakorn Prathom, Thailand which near to Bangkok to measure the actual temperature and relative humidity for 2 days as shown in Fig.2. And then verify the result with simulation software as shown in Fig.3.

Fig.2. The actual measurement area

Fig.3. Model from Envi-Met5.6.1

In figure 3 the model had been set up by using Envi-Met5.6.1 software in order to verify the simulation software reliability.

The result from measurement and simulation had been done to verify the reliability of software in terms of hourly temperature and relative humidity comparison in 4 positions. Found that the correlation coefficient of temperature is 96.39% and relative humidity is 95.74% consecutively. From the comparison result reveals that ENVI-Met5.6.1 have high accuracy for developing the simulation model.

Modeling Urban Heat Island Microclimate

The objective of this study is to determine the type of trees and cover crops that are optimized for temperature reduction in urban heat island by variate scenarios in the selected area in Ratchadamnoen Road Bangkok as shown in Fig.4.

Fig.4. Simulation area in Ratchadomnoen Road.

Ratchadamnoen Road was selected as the base case for this study due to its wide pedestrian walkways, which are well-suited for landscaping interventions. The study area measures 150 by 85 meters and consists of concrete pavement, buildings up to 21 meters in height, an asphalt road, and identical plant species on both sides of the sample area. The street median contains some concrete surfaces but is primarily covered with ground cover vegetation.

Simulation Model Setup

There are 6 scenario cases to be simulated by changing the ground surface and tree shapes as indicated in Table 1 and shown in fig.5.

Table 1 The scenarios for UHI Simulation model

Scenarios	Green Spaces				
	Perennials Trees		Cover crops		No tree & cover
	Layered shape	Round shape	Sandy loam	Ground cover	
Base	Actual environment				
1	-	-	-	-	√
2	√	-	√	-	-
3	√	-	-	√	-
4	-	√	√	-	-
5	-	√	-	√	-

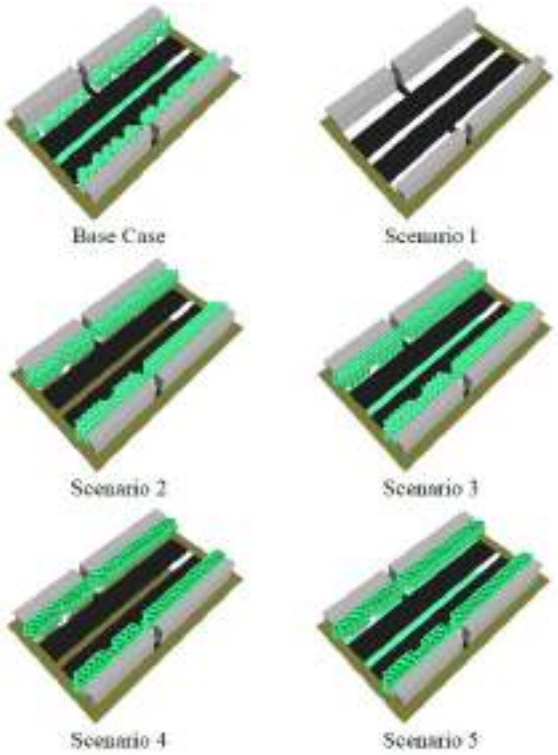

Fig. 5 Simulation case for each scenario

After simulation case had been designed for this study. The software configuration had been done in order to simulate the temperature and relative humidity in fig.6.

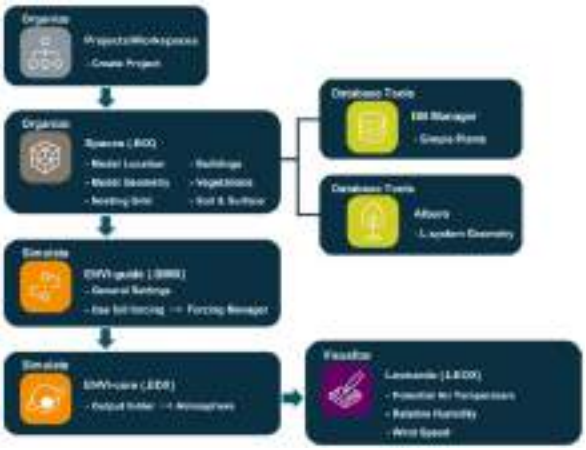

Fig.6. The setting up of ENVI-MET 5.6.1

Parameter configuration setup for simulation model consisted of workspace, geometry setup, plant setup, weather setup which separated to each software function. The example of data is shown in table 2

Table 2 Input data for simulation model

Parameter	Value
Model size	150x85x53
Grid Dimensions	170x105x18
Size of grid cell (m)	1x1x2

Parameter	Value
Geographic Location (Latitude, Longitude)	13.76°, 100.50°
Reference time zone	Indochina Time
Start & Duration of Simulation	06:00, 12 h
Wind speed (m/s)	1.59
Wind direction	45°
Min temperature	30.7 °C, 5:00 a.m.
Max temperature	39.4 °C, 1:00 p.m.
Min relative humidity	37.61%, 12:00 p.m.
Max relative humidity	79.68%, 4:00 a.m.

RESULTS

Zone Setup

In order to compare the result from simulation scenarios, the area has been separated into 5 zones as shown in fig.7. Each zone located 5 positions to simulate temperature and relative humidity.

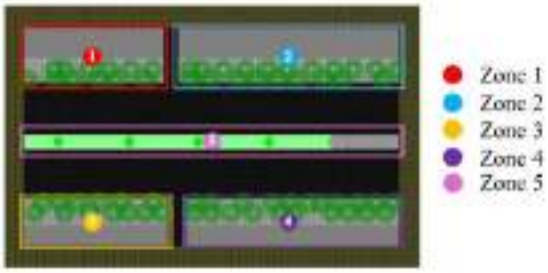

Fig.7 Zone setup for simulation scenarios comparisons.

The result from simulation has been done by using ENVI-MET5.6.1 in order to determine the temperature and relative humidity as shown in fig.8

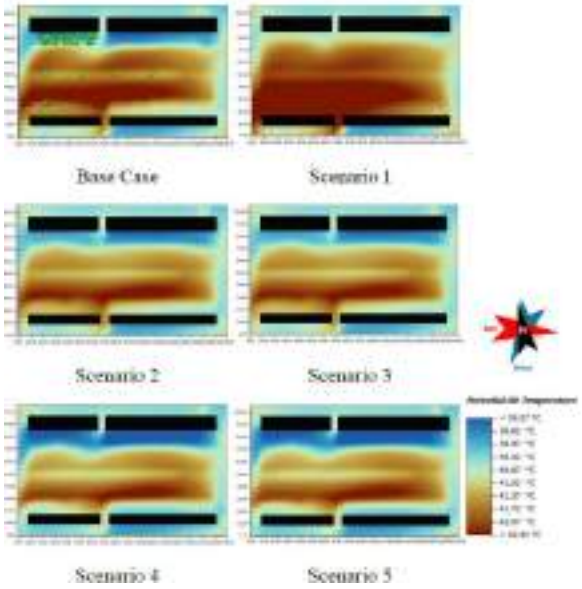

Fig.8 Simulation of Temperature at 1:00 pm.

The simulation results revealed that shaded areas whether by greenery or buildings significantly affect microclimatic conditions. In the morning, sunlight shines on Zone 2 more than on the other zones, resulting in a higher average air temperature and lower average relative humidity. Similarly, in the afternoon, Zone 3 receives the most sunlight, leading to increased air temperature and relative humidity compared to the other zones. In contrast, Zone 5, which is generally unshaded, consistently experiences the highest temperatures and lowest humidity levels among all zones. A comparison of the simulation results is illustrated in Fig. 9.

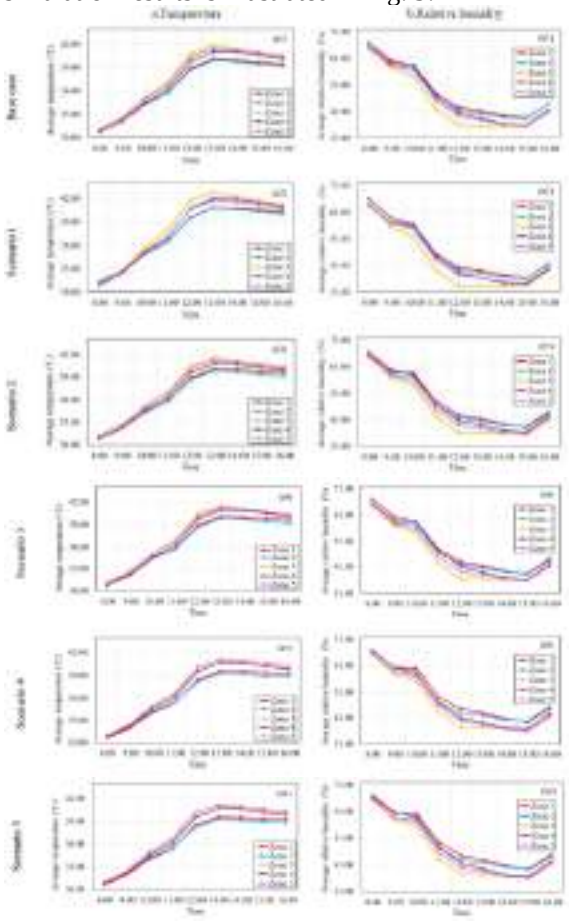

Fig.9 The temperature and relative humidity comparison between zone.

The comparison between each scenario has been separated by zone. Base Case is being used as a reference Scenario, in order to choose the best method to reduce air temperature in UHI. The comparison shows that green space has a lowering effect on urban heat islands, as areas without green space (Scenario 1) has the highest mean air temperature and the lowest mean relative humidity of all zones. In the scenario where different shape of trees planted, the areas planted with round shape trees will have lower average temperature and higher average relative humidity than the areas planted with layered shape trees. In the scenario where different ground cover are selected, the areas shaded by trees, in Zone 1-4, Scenario 3 will have a higher average temperature and lower average relative humidity than Scenario 2, just as Scenario 4 does to Scenario 5, which is very slight in comparison. But in scenario that areas exposed to sunshine, using ground cover (Scenario 3 and5) could assist in temperature reduction and increasing in relative humidity than using sandy loam

The comparison results of each scenario can be revealed separated by zone as shown in fig.10.

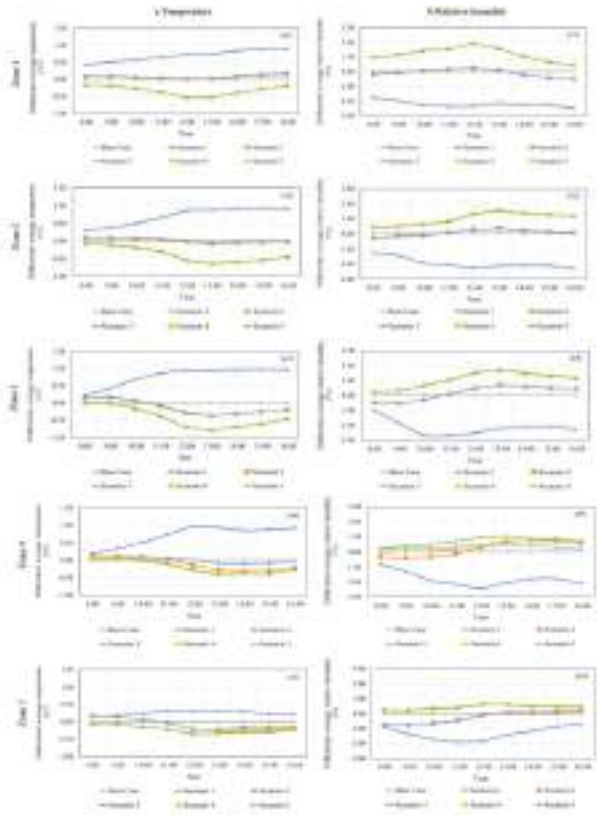

Fig.10 Differential temperature and relative humidity zone comparison

The temperature difference is applied in order to estimate the change in enthalpy change (as shown in fig.11) by using Eq. (1) and in order to calculate possible energy saving due to reduction of surrounding temperature near building, Eq. (2) has been applied. The comparison results shown that area without green space (Scenario 1) has the highest enthalpy change in positive value compared to base case. On the other hand, Scenario 5 has the highest enthalpy change in negative value compared to base case. Given an electricity cost is 4.18 Baht per unit, and coefficient of performance in air condition is 2.0 the results from changing in monthly electrical charge when compare with base case is shown in Fig. 12 represents.

$$\Delta Q' = m' \cdot (h_i - h_b) \quad (1)$$

$$E_{Saving} = \frac{\Delta Q'}{COP} \quad (2)$$

Where
$\Delta Q'$ = enthalpy change (kW/day)
m' = Air mass flow rate into building (kg/hour)
h_i = Enthalpy of scenarios (kj/kg)
h_b = Enthalpy of base case (kj/kg)

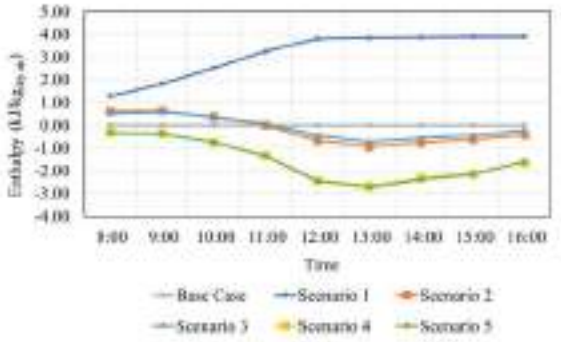

Fig.11 Enthalpy change comparing with Base Case

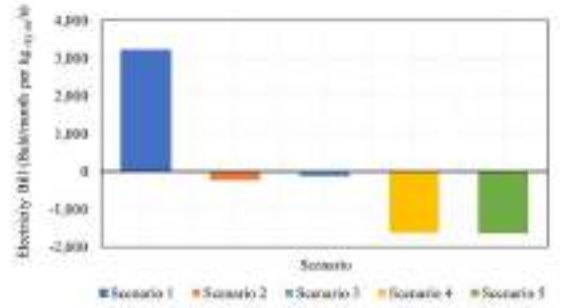

Fig.12 Change in Monthly electricity charge when comparing with Base Case

CONCLUSIONS

The objective of this research is to identify the most effective combinations of tree shapes and ground surface covers for landscape design in Urban Heat Island (UHI) areas to reduce air temperature and energy consumption. The results from simulated scenarios demonstrated that case studies incorporating green spaces exhibited significantly lower air temperatures and higher relative humidity compared to those without vegetation. Among the five scenarios, Scenario 5, featuring spherical-shaped perennial trees taller than the surrounding buildings and ground surfaces covered with vegetation—showed the greatest effectiveness in reducing air temperature and energy consumption. Conversely, Scenario 3 had the least impact on both temperature reduction and energy savings.

In Urban Heat Island (UHI) areas, one of the most effective strategies for reducing air temperature and energy consumption is to increase green space around buildings. Trees play a key role by absorbing solar radiation and providing shade to the surrounding environment. Among different tree forms, round-shaped trees are most effective due to their higher leaf density, which enhances their ability to block solar radiation compared to layered trees. To further improve effectiveness, concrete pavements should be replaced with sandy loam or ground cover. In sun-exposed areas, ground cover is more effective at lowering air temperature than sandy loam. However, in shaded areas beneath tree canopies, both ground cover and sandy loam perform similarly. This research indicates that energy savings from reduced air conditioning usage amount to approximately 1,650 Baht per month per unit of mass flow rate, total saving cost 24,225.44 Baht per month.

Future research should consider microclimate variables other than temperature and relative humidity variables, as well as other ways to reduce temperatures, such as increasing water sources, using a green roof and increasing soil moisture, including designing the position, direction and shape of the building to be consistent with the environment and suitability of that area to study other variables, factors, or methods that can be used to research ways to reduce temperatures and heat consumption around UHI. Furthermore, economic worth should be taken into consideration. To determine the break-even point before investing in landscaping, as well as the payback period for reduced electricity costs in surrounding buildings.

OPERATION PRINCIPLE OF ACTUATOR SYSTEM THAT COMBINES PHASE-CONTROLLED ACTUATOR WITH DIFFERENT DRIVE FREQUENCIES

Hiroyuki Yaguchi[1] and Sota Abe[1]

[1] Faculty of Engineering, Tohoku Gakuin University, Japan

ABSTRACT

In Japan, the shortage of construction workers and inspectors has become a social problem due to the declining birthrate and aging population. In addition, the slow progress of automation in challenging environments, such as construction sites and bridges, has been pointed out. Although various types of inspection robot have been developed, bridge inspection technology has not been fully established. In this study, the operation of a phase-controlled actuator equipped with vibration components with different drive frequencies is investigated. The phase-controlled actuator, in which a second-harmonic vibration component is coupled to a fundamental-wave vibration component to avoid vibration interference, exhibits excellent propulsive characteristics. To further improve the propulsion characteristics, a prototype actuator system, in which two phase-controlled actuators with different drive frequencies are coupled, is developed. Tests on prototypes show that this system can simultaneously achieve high-speed movement and good traction characteristics. Furthermore, the operation principle of this actuator system is established based on test results. The potential of an inspection device with the proposed actuator for the internal inspection of bridges with a small automatic tapping device is demonstrated.

Keywords: Actuator system, Operation principle, Second-harmonic vibration, Phase control, Inspection

INTRODUCTION

In Japan, the shortage of construction workers and inspectors has become a social problem due to the declining birthrate and aging population. The number of workers in the construction industry has decreased from 6.85 million in 1997 to 4.77 million in 2024. Furthermore, starting in 2025, the number of workers is expected to decrease by more than 100,000 per year. In the general manufacturing industry, task automation is relatively easy using industrial robots and artificial intelligence. However, automation in challenging environments, such as construction sites and bridges, is lagging behind. In particular, bridge inspection requires the operator to approach and touch the part to be inspected. Currently, inspection vehicles, aerial lifts, and boats are used to approach bridges, making bridge inspection dangerous and difficult. Since 2023, the 730,000 road bridges in Japan have to be inspected every 5 years. Various inspection robots have thus been developed to ensure worker safety and improve work efficiency.

Several inspection robots based on mechanisms that allow movement on walls, such as magnetic wheel systems [1], electromagnet systems [2], suction systems with negative pressure [3], crawler-type systems [4], and coupled vibration and suction systems [5], have been proposed. These inspection robots use a number of electromagnetic motors as the drive source, giving them good controllability. However, even robots equipped with large electromagnetic motors that have good torque characteristics exhibit significant degradation of movement characteristics when moving in a vertical plane. On the other hand, small electromagnetic motors lack torque, making it difficult to move on vertical surfaces. There is thus a limit to the improvement in robot movement characteristics that can be achieved by changing electromagnetic motors.

In recent years, drone-type flying robots have been developed [6, 7]. Although drones can perform inspection work in hazardous areas, they cannot perform inspections using automatic tapping devices**.** Furthermore, drone flights are affected by weather conditions and inspection technology for bridges using drones has not yet been established.

The present authors previously proposed an actuator for structural testing that consists of eight identical vibration components arranged in a square acrylic frame [8]. A prototype of this actuator was shown to be capable of rotational and translational reciprocating motion. However, vibration interference between the vibration components degraded the movement characteristics.

In this study, a phase-controlled actuator with vibration components with different drive frequencies is proposed. The phase-controlled actuator, in which a second-harmonic vibration component is coupled to a fundamental-wave vibration component to avoid vibration interference, exhibits excellent propulsive characteristics. To further improve the propulsive characteristics, an

actuator system in which two phase-controlled actuators with different drive frequencies are coupled is proposed. The operation principle of this actuator system is studied and its driving principle is established based on the results of tests on prototypes.

Measurements show that this actuator system can simultaneously achieve high-speed movement and good traction characteristics, which are usually in conflict with each other. This paper demonstrates the potential of an inspection device with the proposed actuator that can realize internal inspections of bridges with a compact automatic tapping device.

RESEARCH SIGNIFICANCE

The inspection of bridges and other structures has become an important issue in Japan due to the aging of infrastructure. However, the inspection of bridges over waterways (e.g., rivers, seas, and lakes) is extremely difficult. Although many inspection robots have been developed for visual or internal inspection, inspection techniques have not yet been established. The significance of this research is that it establishes an operation principle that significantly improves the propulsive characteristics of a vibration actuator previously proposed by the authors. The proposed actuator system enables the internal inspection of large iron structures.

PHASE-CONTROLLED ACTUATOR

Structure of Phase-controlled Actuator

Figs. 1(a) and 1(b) show the two types of phase-controlled actuator prototyped in this study, I and II, with multiple vibration components with the same specifications mounted in an acrylic frame (thickness: 5 mm, width: 15 mm, length 50 mm). Actuator I has vibration components A and B in an orthogonal arrangement. Actuator II has vibration components B and C coaxially arranged and vibration component A orthogonally aligned with components B and C. The stainless steel coil spring that constitutes a vibration component has an outer diameter of 12 mm, a free length of 32 mm, and a spring constant of 2,016 N/m. The NdFeB permanent magnet (diameter: 12 mm, height: 6 mm) at the top of each coil spring is magnetized in the height direction. The electromagnet consists of a 4.2-mm-diameter iron core with a 0.18-mm-diameter copper wire wound 1080 turns. The gap between the iron core and the permanent magnet in the static state is 5 mm. As shown in Fig. 1, height-magnetized NdFeB magnets (diameter: 10 mm, height: 2 mm) were mounted at the center of the acrylic frame and on each side 20 mm from the center. A 1-mm-thick rubber sheet was glued onto each of these magnets to increase the frictional force. The permanent magnets mounted on the sides of the center section stabilize the linear movement of the actuator. The positions of the permanent magnets were determined based on preliminary experiments. Actuator I is 53 mm high, 83 mm long, and 15 mm wide and has a total mass of 45.1 g. Actuator II is 53 mm high, 116 mm long, and 15 mm wide and has a total mass of 63.5 g.

Operation Principle of Phase-controlled Actuator

To illustrate the operation principle of the phase-controlled actuator, the displacement coordinates x and y are defined as shown in Fig. 1(b). The operation principle applies to both phase-controlled actuators I and II. The operation of actuator II is described here. Vibration components B and C are assumed to vibrate in phase in the x-direction. As shown in Fig. 2, when the actuator is set on a magnetic material, the attractive force of each of the three permanent magnets is P. The total attractive force $3P$ holds the actuator and allows the vibration components to vibrate.

As shown in Fig. 2(a), when vibration component A is displaced in the $+y$ direction, friction force F_f decreases due to the force generated by the permanent magnet. In this state, when components B and C are displaced in the $+x$ direction, the actuator moves in the $+x$ direction due to the force generated by the permanent magnets. On the other hand, as shown in Fig. 2(b), when the permanent magnet of vibration component A is displaced in the $-y$ direction, friction force F_f increases and the actuator

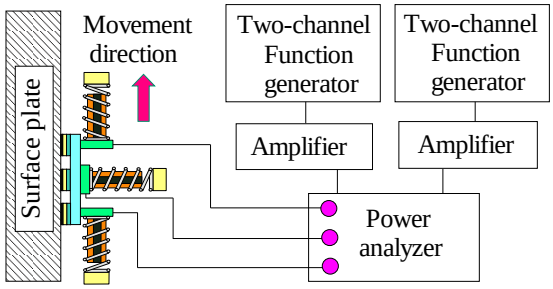

Fig. 3 Experimental apparatus

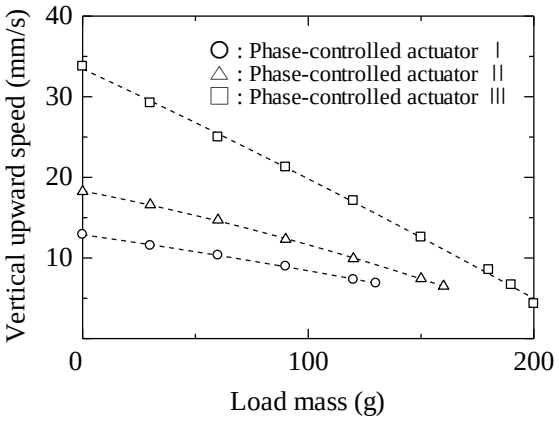

Fig. 4 Relationship between load mass and vertical upward speed

Movement Characteristics of Phase-controlled Actuator

does not move when components B and C are displaced in the -*x* direction. Therefore, the actuator can move only in the +*x* direction.

Fig. 3 shows a schematic diagram of the experimental setup. An iron surface plate (width: 300 mm, length: 300 mm, thickness: 60 mm) was used as the magnetic material. Two 2-channel signal generators with variable phase capability and two power amplifiers were used to resonantly drive the vibration components mounted on the phase-controlled actuator. The resonant frequency of each vibration component was 90.5 Hz. The AC current input to the electromagnets inserted in the vibration components was measured using a power analyzer.

Table 1 Vibration amplitude of each vibration component

Driving component (250 mA)	Amplitude of vibration component (mm)		
	A	B	C
A	3.90	0	0
B	0	3.26	2.36

Hereafter, the AC current input to the electromagnet is reported as an effective value. The attractive force on the permanent magnet to which the rubber sheet is attached is P = 2 N. Thus, the total pull force of the actuator is 6 N. The coefficient of friction between the rubber sheet and the surface plate is μ = 0.84.

Phase-controlled actuators I and II were set on a vertical plane. Fig. 4 shows the relationship between the load mass attached to the actuators and the vertical upward speed, with the input current to vibration component A set at 60 mA and that to vibration component B (= C) set at 250 mA. The load mass was attached to the acrylic frame of the actuator using string. From this figure, the propulsion characteristics of actuator II are only about 1.45 times, not twice, those of actuator I. The reason for this is likely vibration interference between the vibration components, which have the same dimensions.

Table 1 shows the vibration amplitudes of vibration components A, B, and C for phase-controlled actuator II when the electromagnet was driven resonantly with an input current of 250 mA. The vibration amplitudes were measured using a laser displacement meter and a digital oscilloscope. When vibration component A is driven, components B and C are orthogonally aligned, so there is no vibration interference between the vibration components.

On the other hand, when vibration component B is driven, the vibration wave propagates to component C. Since vibration components B and C vibrate symmetrically around the center of the frame, the interference between them is very large. Antisymmetric vibration of vibration components B and C is necessary for the actuator to move. This requires that a large input current be applied to vibration component C. The addition of a vibration component with the same characteristics is not a viable solution for improving the propulsive characteristics due to the vibration interference problem.

COUPLING OF VIBRATION COMPONENTS WITH DIFFERENT DRIVE FREQUENCIES

From the point of view of vibration, to completely prevent vibration interference between vibration components, the vibration frequency of one of the two components must be at least twice

that of the other component. To eliminate vibration interference, vibration components with different frequencies (denoted as actuator III) were installed and investigated.

Fig. 5 shows the displacements (x and y) of vibration components A, B, and C versus ωt, where ω is the angular frequency and t is time. In the figure, the second, third, and fourth harmonics are shown with respect to the fundamental wave ω, with the initial phase varying as in Eq. (1).

$$\left.\begin{aligned} y &= \sin \omega t \\ y &= \sin 2\omega t - \pi/2 \\ y &= \sin 3\omega t - \pi \\ y &= \sin 4\omega t + \pi \end{aligned}\right\} \quad (1)$$

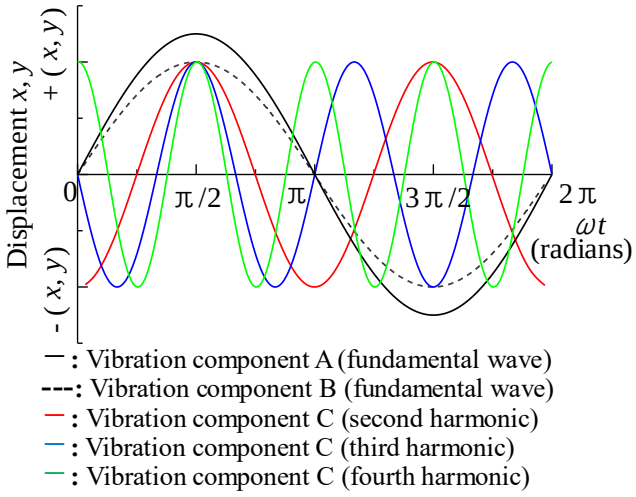

Fig. 5 Fundamental wave and second, third, and fourth harmonics

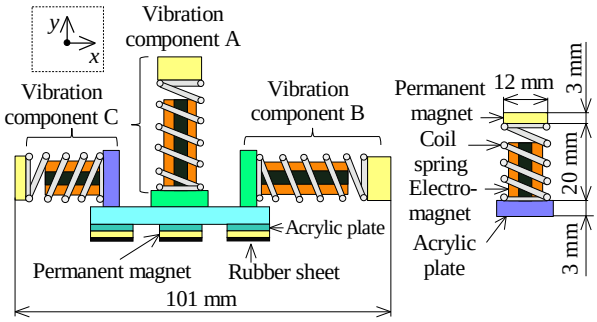

(a) Component C with different drive frequencies (b) Component with second harmonic

Fig. 6 Phase-controlled actuator III

The solid and dashed black lines in the figure show the vibration displacements of vibration components A and B, respectively, shown in Fig. 6(a) for the fundamental wave. The red, green, and blue lines show the vibration displacements of vibration component C shown in Fig. 6(a) for the second, third, and fourth harmonics, respectively, of vibration components A and B. As shown in Fig. 2, in the operation principle of the phase-controlled actuator, displacements x and y of fundamental-wave vibration components A and B are synchronized with a phase difference of 0 degrees.

The relationship between the second harmonic (red line) and fundamental-wave vibration component A (black line) is next discussed, including the displacement coordinates x and y in Fig. 6(a). As shown earlier, friction force F_f decreases (increases) when vibration component A is displaced in the $+x$ ($-x$) direction.

In Fig. 5, at ωt = 0 or π, the actuator does not move in the $-x$ direction when second-harmonic vibration component C is displaced in the $-x$ direction, because vibration component A is in a neutral state. On the other hand, at $\omega t = \pi/2$, friction force F_f decreases as vibration component A is displaced in the $+y$ direction. In this condition, when second-harmonic vibration component C is displaced in the $+x$ direction, the actuator tends to move in the $+x$ direction. In the range $\omega t > \pi$, friction force F_f increases as vibration component A is displaced in the $-y$ direction and the actuator does not move when vibration component C is displaced in the $+x$ direction. Therefore, the combination of the fundamental wave and the second harmonic allows the actuator to move in the intended direction (i.e., the $+x$ direction).

Consider the third harmonic (green line) and the fundamental wave (black line) in Fig. 5. For $0 < \omega t < \pi$, fundamental-wave vibration component A is displaced in the $+y$ direction and friction force F_f decreases. In this range, third-harmonic vibration component C makes one half-period motion in the $+x$ direction and two half-period motions in the $-x$ direction, so the actuator is expected to move less in the $+x$ direction. Furthermore, in the range $\omega t > \pi$, frictional force F_f increases due to the vibrational displacement of vibration component A. Thus, even if vibration component C is displaced in the $+x$ direction, the actuator cannot move in the intended direction (i.e., the $+x$ direction).

If the direction of movement of the actuator can be controlled by a combination of the fundamental wave and the second harmonic, the fourth harmonic, whose frequency is twice that of the second harmonic, can be considered an applicable frequency.

As shown in Fig. 6(a), a prototype of phase-controlled actuator III with vibration component C (see Fig. 6(a)), whose frequency is the second harmonic with respect to the fundamental wave, was developed. As shown in Fig. 6(b), the stainless steel coil spring that constitutes vibration component C has an outer diameter of 11 mm, a free length of 20 mm, and a spring constant of 3,926 N/m. The NdFeB permanent magnet (diameter: 12 mm, height: 3 mm) is magnetized in the height direction. The electromagnet consists of a 3.2-mm-diameter iron

core around which 0.18-mm-diameter copper wire was wound 880 turns. The gap between the iron core and the permanent magnet is 3 mm. The resonant frequency of second-harmonic vibration component C is 181 Hz. Except for vibration component C, the vibration components are identical to the actuator shown in Fig. 1(b). Preliminary experiments confirmed that no vibration interference occurs between the electromagnets of vibration components A, B, and C when they are each driven resonantly by applying a current of 250 mA. As shown in Fig. 5, the initial phases in the fundamental-wave and second-harmonic vibration components were adjusted using the 2-channel signal generator.

The movement speed of actuator III was measured when the same input current as that for the fundamental-wave vibration component was applied to second-harmonic vibration component C. The obtained results are shown in Fig. 4 (square symbols). The measurement results show that the movement characteristics of actuator III are more than twice those of actuator II. The combination of the fundamental wave and the second harmonic, which does not cause vibration interference between the vibration components, is a very effective method for improving the propulsive characteristics of the actuator.

ACTUATOR SYSTEM WITH TWO COUPLED PHASE-CONTROLLED ACTUATORS

Structure and Operation Principle

To further improve the propulsion characteristics, a prototype actuator system was developed in which phase-controlled actuators with fundamental-wave and second-harmonic vibration components are coupled, as shown in Fig. 7. The drive frequencies for the fundamental-wave and second-harmonic vibration components are 90.5 and 181 Hz, respectively.

Fig. 8 shows the prototype actuator system. In this actuator system, three fundamental-wave vibration components (A, B, and C) are mounted within an acrylic frame (thickness: 5 mm, length: 150 mm). The combination of these components is denoted as type I. In addition, four second-harmonic

--- : Vibration components E, F (second harmonic)

Fig. 9 Operation principle of actuator system (displacement and generated force of each vibration component)

vibration components (D_1, D_2, E, and F) are mounted. This combination is denoted as type II. This actuator system has second-harmonic vibration components E and F attached in parallel to enable rotational motion in addition to linear reciprocating motion. The fundamental-wave and second-harmonic vibration components were tuned to have the same vibration characteristics. For each vibration component, the displacement coordinates x_1, x_2 and y_1, y_2 were defined as shown in Fig. 8. When the actuator system moves, vibration components B and C vibrate anti-symmetrically with respect to displacement coordinate x_1. Vibration components E and F are displaced in the same direction with respect to displacement coordinate x_2.

The three permanent magnets and the rubber sheets attached to the bottom of the actuator system have the same dimensions as those for the actuators shown in Fig. 1. This actuator system is 53 mm high, components A and B (C is antisymmetric with B). 150 mm long, and 45 mm wide and has a total mass of 120 g.

Next, the operation principle of the combined type I and type II phase-controlled actuators is considered. Fig. 9 shows the displacements (x_1, x_2 and y_1, y_2) of the fundamental-wave and second harmonic vibration components with the initial phase adjusted versus ωt. The black solid and dashed lines show the vibration displacements of fundamental-wave. The red solid and dashed lines show the vibration displacements of second-harmonic vibration components D_1, D_2 and E, F, respectively.

In Fig. 9, at $\omega t = 0$ or π, fundamental-wave vibration components A and B (C vibrates anti-symmetrically with B) are neutral. On the other

hand, since second-harmonic vibration components D_1 and D_2 are displaced in the $-x_2$ direction, friction force F_f increases and the actuator does not move in the $-x_1$ direction even though vibration components E and F are displaced in the $-x_2$ direction.

At $\omega t = \pi/2$, when vibration components A and D_1, D_2 are displaced in the $+y_1$ and $+y_2$ directions, respectively, friction force F_f is minimal. Under these conditions, when vibration components B, C and E, F are displaced in the $+x_1$ and $+x_2$ directions, respectively, the actuator system tends to move in the $+x_1$ ($+x_2$) direction.

At $\omega t = 3\pi/2$, fundamental-wave vibration component A is displaced in the $-x_1$ direction and friction force F_f increases. On the other hand, friction force F_f decreases because second-harmonic vibration components D_1 and D_2 are displaced in the $+x_2$ direction. In addition, fundamental-wave vibration components B and C are displaced in the $-x_1$ direction and second-harmonic vibration components D_1 and D_2 are displaced in the $+x_2$ direction. The forces generated by these vibration components cancel each other and the actuator system is not expected to move. The above operation principle allows the actuator system to move in the intended direction (i.e., $+x_1$ ($+x_2$) direction) once every two cycles of the second harmonic.

The phase difference of the vibration in the state of displacement at each vibration component shown in Fig. 8 is defined as 0 degrees (in phase). Adjusting the phase difference of the vibration at vibration components A and D_1, D_2 to 180 degrees (out of phase) can reverse the direction of movement of the actuator system.

Movement Characteristics of Actuator System

The prototype actuator system was set on a surface plate and its movement characteristics were measured. Fig. 10 shows the movement speed of the actuator system in the horizontal plane when the input currents to vibration components A and D_1, D_2 were fixed at 60 and 100 mA, respectively, and the input currents to vibration components B, C, E, and F were varied. In the figure, open circles are the measurement results when the phase difference between vibration components is adjusted to be in phase (0 degrees), as shown in Fig. 8, and filled circles are the measurement results when the phase difference between vibration components is adjusted to be out of phase (180 degrees). The figure shows that the actuator system can move reciprocally at an almost constant speed.

Fig. 11 shows the movement speed of the actuators for the ceiling surface when the input currents to vibration components A and D_1, D_2 were fixed at 60 and 100 mA, respectively, and the input currents to vibration components B, C, E, and F were varied. The phase difference between vibration

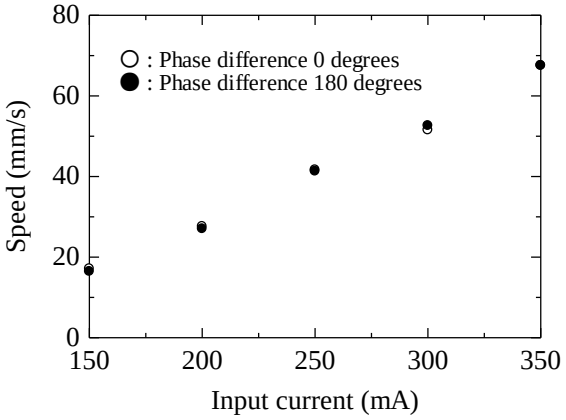

Fig. 10 Relationship between input current and speed (horizontal plane)

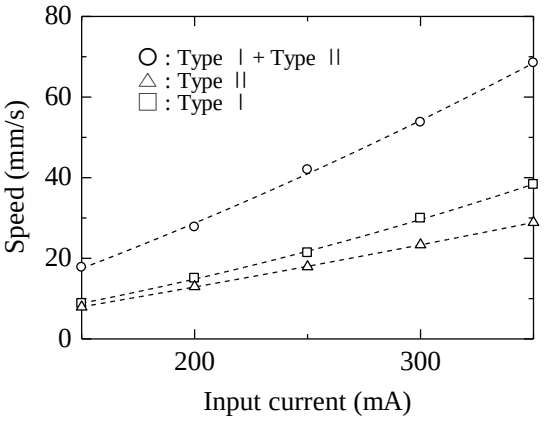

Fig. 11 Relationship between input current and speed (ceiling surface)

components was adjusted to be in phase for the measurements. The dashed lines are the results of a quadratic approximation of the measured values obtained using the least-squares method (in following figures, dashed lines are the results of a second-order approximation obtained using the least-squares method). The square, triangle, and circle symbols are the results for type I with fundamental-wave vibration components A, B, and C driven, type II with second-harmonic vibration components D_1, D_2, E, and F driven, and a combination of types I and II, respectively. Fig. 11 shows that the movement speed increases almost linearly with increasing input current. The movement characteristics for the combination of type I and II actuators driven are considerably better than those of actuators driven only with fundamental-wave or second-harmonic vibration components.

Figs. 12 and 13 show the relationship between the vertical upward speed of the actuator system and the load mass when the input currents to vibration component A and vibration components D_1, D_2 were fixed at 60 and 100 mA, respectively, and the input currents to vibration components B, C, E, and F

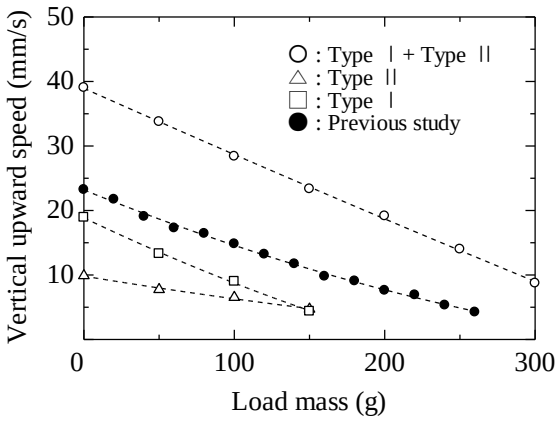

Fig. 12 Relationship between load mass and vertical upward linear speed (input current 250 mA)

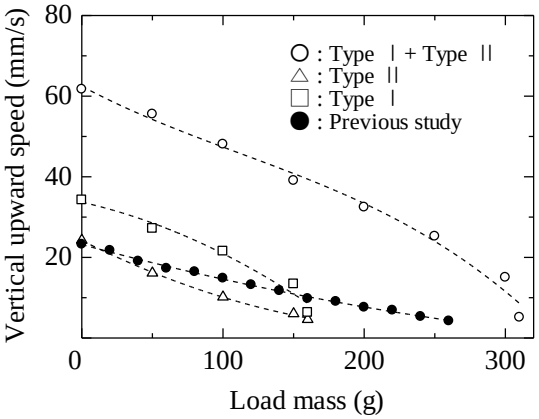

Fig. 13 Relationship between load mass and vertical upward linear speed (input current 350 mA)

were fixed at 250 or 350 mA. With both type I and II actuators driven and an input current of 350 mA, the actuator system is capable of vertical upward movement at the speed of 15.1 mm/s while pulling a 300-g load mass. The solid circles in both figures are the speed values for an actuator system [8] with the same total mass of 120 g and eight fundamental-wave vibration components when an input current of 250 mA is applied to each vibration component. Due to the reduced vibration interference, the movement characteristics of the proposed actuator system greatly exceed those of the actuator system in a previous study [8].

A fundamental-wave-type actuator has a low drive frequency, which allows a large vibration amplitude with a relatively small input current. This results in the generation of large elastic energy and high movement speed. In contrast, a second-harmonic-type actuator has a high drive frequency and cannot generate a large vibration amplitude. However, it can generate a large inertial force proportional to the square of the vibration frequency. The excellent performance of the proposed actuator system is due to the effective superposition of the conflicting movement characteristics of the two types of actuator.

Based on the above, the actuator system is considered to move based on the operation principle shown in Fig. 9. This paper thus establishes a new operation principle for a phase-controlled actuator system that has good movement characteristics and can instantly switch movement direction.

ACTUATOR SYSTEM OPERATION PRINCIPLE AND ROTATIONAL CHARACTERTICS

The above operation principle for linear motion can be extended to rotational motion. For rotational motion in the actuator system, only the type II phase-controlled actuator was driven. As shown in Figs. 8 and 14, when vibration components D_1 and D_2 are displaced in the $+y_2$ direction, friction force F_f decreases. In this state, when vibration components E and F are displaced in the $+x_2$ and $-x_2$ directions, a moment acts on the center of the actuator system. Therefore, the system rotates counterclockwise. On the other hand, if the vibration phases of vibration components D_1 and D_2 are set to be out of phase, the system rotates clockwise.

By controlling the phase difference of the vibrations in each vibration component, the actuator system can reciprocate in all directions (i.e., 360 degrees). The rotational characteristics of the actuator system were measured by fixing the input current to vibration components D_1 and D_2 at 100 mA and varying the input current to vibration components E and F.

Fig. 15 shows the rotational speed when the actuator system was set on horizontal and vertical planes and the phase difference of the vibration between vibration components D_1, D_2 and vibration components E, F was set to 0 degrees (in phase) or 180 degrees (out of phase). In the figure, square and plus symbols (triangle and diamond symbols) are the measurement results when the phase difference between the vibration components was in phase and

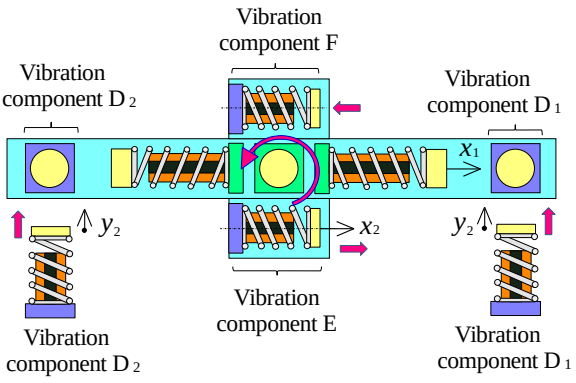

Fig. 14 Rotational principle of actuator system

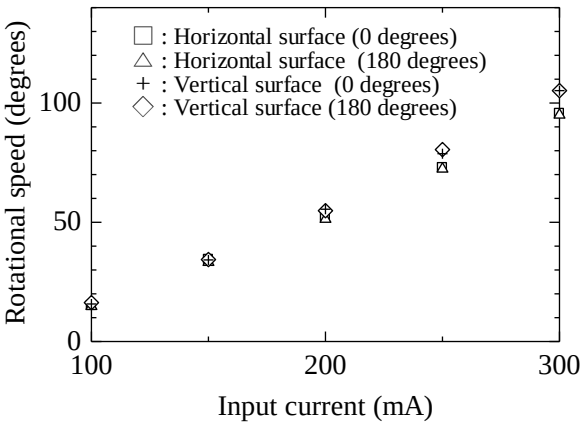

Fig. 15 Relationship between input current and rotational speed (rotational movement)

out of phase in the horizontal (vertical) plane, respectively. The rotational speeds of the actuator system are almost equal when the phase differences between the vibration components are in phase and out of phase. The rotational speed of the actuator system increases linearly as the input current to vibration components E and F is increased. In this actuator system, the mounting position of each vibration component is at the same distance to the center of the frame. When the actuator system is set in the vertical plane, the moments caused by gravity are canceled in each vibration component. Therefore, the rotational speeds of the actuator system in the horizontal and vertical planes are nearly equal.

CONCLUSIONS

In this study, an actuator system coupled with a phase-controlled actuator with fundamental-wave and second-harmonic vibration components was proposed to improve propulsion characteristics. The operation principle of the actuator system was discussed. Based on the results of tests on prototypes, the operation principle of the phase-controlled actuator system, which can instantly switch its direction of linear motion, was established. The movement and traction characteristics of the actuator system are excellent since the vibration interference between the mounted vibration components is considerably reduced and two actuators with different characteristics are coupled.

The proposed actuator system can move vertically at a speed of 15.1 mm/s even with a load mass of 300 g. A commercially available automatic tapping device with a mass of 260 g can thus be mounted. The possibility of the internal inspection of iron structures was demonstrated through tests on prototypes. Furthermore, this actuator system can move in any direction (i.e., 360 degrees) by combining rotational and translational reciprocating motions. Because the actuator system can move on ceilings and walls, it could be useful for inspection devices.

Future work will develop a prototype phase-controlled actuator with a power-of-two-type vibration component and conduct a theoretical motion analysis that takes into account the nonlinearity of the vibration component.

ABSTRACT

Driftwood disasters pose serious risks to river environments and infrastructure, making precise identification and quantification crucial for effective disaster assessment and mitigation. However, the complex nature of driftwood disaster scenarios presents challenges for existing automated recognition and quantification methods. To address these limitations, this study proposes a LiDAR-based deep learning approach for driftwood disaster investigation. A flume experiment was conducted to mimic a braided bar-channel pattern and subsequent driftwood transport-deposition in river channels, capturing high-resolution 3D point cloud data using a LiDAR scanner. To enhance model robustness and generalization, a dataset augmentation technique leveraging the geometric characteristics of driftwood was introduced. Three deep learning models—PointNet++, PointNet++ MSG, and GACNet—were applied for semantic segmentation of driftwood, integrating DBSCAN clustering and point cloud volume estimation to quantify driftwood volume. Experimental results demonstrate that the proposed segmentation method effectively adapts to driftwood disaster scenarios, with all deep learning models achieving an mIoU exceeding 80%. Notably, dataset augmentation significantly enhances segmentation accuracy compared to models without augmentation, confirming its effectiveness in optimizing deep learning models for driftwood recognition. Furthermore, comparative analysis reveals that GACNet outperforms other models in both segmentation accuracy and volume estimation, enabling more precise driftwood identification across various scenarios. Furthermore, the proposed method successfully clarified the relationship between the estimated driftwood accumulation and the riverbed morphology. This study validates the feasibility of integrating deep learning with LiDAR point cloud analysis for driftwood disaster assessment, offering a novel and effective approach for disaster investigation and mitigation.

Keywords: Driftwood; Point cloud; Semantic segmentation; Dataset augmentation; Flume experiment

INTRODUCTION

Driftwood disasters pose significant threats to river environments, infrastructure, and public safety worldwide. During flood events, large quantities of woody debris are mobilized and transported downstream, creating complex accumulations that can damage bridges, block channels, increase flood risks, and destabilize riverbanks [1]. In Japan, mountainous watersheds with dense forest cover are particularly susceptible to such disasters, with several catastrophic events recorded in recent decades causing substantial economic losses and environmental impacts. The effective management of driftwood disasters requires accurate and efficient methods for assessing accumulation patterns, quantifying volumes, and understanding the underlying transport mechanisms.

Traditional approaches to driftwood disaster investigation rely heavily on manual field surveys and visual estimation techniques [2]. These methods are often labor-intensive, subjective, and limited in their ability to capture the three-dimensional complexity of driftwood accumulations. More recently, remote sensing technologies have been employed to improve disaster assessment capabilities, with satellite imagery and aerial photogrammetry offering broader spatial coverage [3,4]. However, these methods still face significant challenges in accurately identifying and quantifying driftwood in complex riverine environments, particularly when dealing with densely packed accumulations.

Light Detection and Ranging (LiDAR) technology presents a promising solution for addressing these limitations. By providing high-resolution three-dimensional point cloud data, LiDAR scanners can capture the detailed geometric characteristics of driftwood pieces and their spatial arrangements [5].

The rapid advancement of deep learning techniques for point cloud analysis offers new opportunities for automating the identification and quantification of disasters in LiDAR data [6]. Unlike traditional machine learning methods that rely on hand-crafted features, deep learning models can automatically learn hierarchical representations directly from raw point cloud data. Recent developments in point-based neural networks, such as PointNet++ and Graph Attention Convolution Network (GACNet), have demonstrated remarkable performance in point cloud segmentation tasks across various domains [7,8]. However, the application of

these techniques to driftwood disaster scenarios remains largely unexplored, with unique challenges arising from the irregular distribution and complex arrangements of woody debris in river environments.

A significant obstacle to implementing deep learning approaches for driftwood disaster investigation is the limited availability of labeled training data. Unlike common objects in computer vision datasets, driftwood accumulations exhibit high variability in appearance and structure, making it difficult to create comprehensive training datasets that capture all possible scenarios.

To address these challenges, this study proposes an integrated approach combining LiDAR-based data acquisition with deep learning techniques for driftwood disaster investigation. Through controlled flume experiments simulating various driftwood transport and deposition scenarios, we create a dataset of high-resolution point clouds capturing the complex geometry of driftwood accumulations. We introduce a novel dataset augmentation technique specifically designed for point cloud data that leverages the geometric characteristics of driftwood to enhance model training. Three state-of-the-art deep learning models—PointNet++, PointNet++ MSG (Multi-Scale Grouping), and GACNet—are implemented and evaluated for semantic segmentation of driftwood in the point cloud data. Additionally, we develop a volumetric analysis procedure that integrates clustering algorithms with geometric reconstruction methods to quantify driftwood accumulation volumes. By investigating the relationship between riverbed morphology and driftwood distribution patterns, this study aims to provide insights into the underlying mechanisms of driftwood transport and deposition in river systems, contributing to improved disaster assessment and mitigation strategies.

RESEARCH SIGNIFICANCE

This study presents a novel integration of LiDAR-based point cloud acquisition and deep learning techniques for the automated investigation of driftwood disasters. By introducing a geometric-aware dataset augmentation method and evaluating segmentation models under controlled flume conditions, the research addresses key challenges such as class imbalance in driftwood environments. The findings advance the application of deep learning in geological hazard assessment and offer practical solutions for quantifying driftwood volume and understanding its interaction with riverbed morphology.

METHODOLOGY

Fig. 1 provides a schematic overview of the proposed methodological framework. Beginning with a controlled indoor flume experiment, the process proceeds through LiDAR-based point cloud acquisition. The raw point cloud data is enhanced using a multi-scale geometric feature augmentation strategy to mitigate the effects of class imbalance and improve model generalization. Semantic segmentation is performed using three state-of-the-art deep learning models, each trained with and without dataset augmentation. The segmented driftwood points are then clustered using DBSCAN, and their volumes are estimated using both convex hull analysis and voxelization with porosity correction. This integrated pipeline enables precise quantification of driftwood accumulation and analysis of waterway interaction.

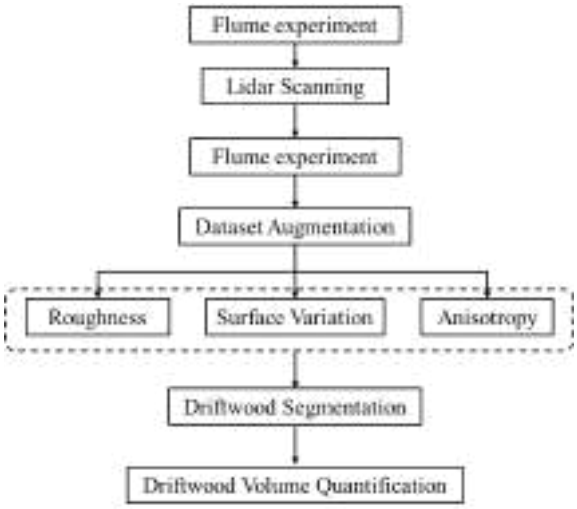

Fig. 1 Overall workflow

Experimental Design and Flume Setup

The experimental investigation was conducted in a hydraulic laboratory using a custom flume facility designed specifically to mimic a braided bar-channel pattern and subsequent driftwood transport-deposition in river environments, as shown in Fig. 2.

Uniform sand with a grain size of 0.765 mm (Northeast Silica Sand No. 4) was used for the movable bed. A straight channel with the channel width of 0.5 m was set for the initial channel, and we firstly imposed a constant, steady water discharge for 4 hours from the upstream end to generate the braided channel morphology as shown in Fig. 2.

After the initial phase, 10 pieces of driftwood with diameter of 1.8 mm and length of 100 mm were introduced every 5 minutes over a period of 4 hours. During this phase, riverbed changes and driftwood accumulation were continuously observed. Throughout the experiment, sediment was supplied from the upstream end to maintain sediment balance.

A critical aspect of the experimental design was the use of waterlogged wood instead of dry wood to

accurately simulate real driftwood buoyancy characteristics. Natural driftwood typically has a specific gravity ranging from 0.9 to 1.2. By using waterlogged specimens, the experiment more faithfully reproduced the transport and deposition behaviors observed in actual river systems during flood events.

The flume was configured with a longitudinal bed slope of 0.04, extending from the inlet to the outlet, to generate a unidirectional flow regime that effectively transported both sediment and driftwood through the channel. During the experiment, the discharge was maintained at 0.0005 m^3/s, corresponding to a dimensionless shear stress of 0.10, which ensured active sediment mobility and driftwood entrainment under controlled conditions. The channel width-to-depth ratio for the initial channel was set at 1151, reflecting a shallow, wide channel morphodynamic environment representative of braded bar-channel feature seen in natural rivers. This carefully controlled hydraulic setting, as shown in the schematic diagram in Fig. 2, enabled systematic observation of the complex interactions among water flow, sediment transport, and driftwood movement and accumulation.

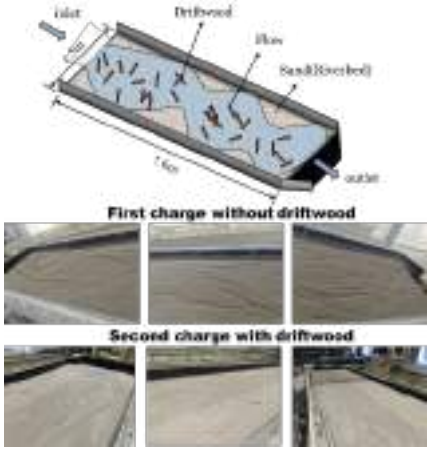

Fig. 2 Flume experiment of driftwood

LiDAR Data Acquisition

To acquire high-precision data on driftwood distribution and riverbed morphology, this study employed a handheld Revopoint MIRACO Pro laser scanner, for three-dimensional mapping of the experimental flume. The scanner performed precise pre- and post-experiment scans of the sandy riverbed and debris deposition zones, enabling detailed analysis of topographical changes and debris distribution.

The scanning system offered precision of ±0.1-1 mm with an effective range of 0-1 m, making it ideal for laboratory-scale experiments. Output data was stored in LAS format, containing XYZ coordinates, RGB color values, and normal vector data. The handheld free-scanning methodology allowed flexible movement around the experimental setup to ensure complete coverage of complex geometries while minimizing occlusion effects.

The scanning covered an area of 8 m × 1.5 m, resulting in a dense point cloud dataset containing 81,251,496 points. As shown in the visualization of Fig. 3, the scanning process successfully captured the complex three-dimensional topography of the riverbed and driftwood accumulation patterns with exceptional detail.

Dataset

The dataset used in this study consists of high-resolution point cloud data obtained from indoor flume experiments under controlled conditions. Each point contains XYZ coordinates, RGB color values, and surface normal vectors. The final dataset includes 81,251,496 points, representing both driftwood and riverbed elements.

The dataset is structured for a binary semantic segmentation task and includes two primary classes: driftwood and non-driftwood. The driftwood class refers to all recognizable woody debris, including both individual logs and aggregated accumulations, while the non-driftwood class encompasses the background, such as exposed sand, sediment surfaces, and riverbed features. Manual annotation was performed to assign class labels based on geometric shape, color, and surface continuity. The resulting class distribution is highly imbalanced, with driftwood representing only 1.58% of all points. This skewed distribution poses a significant challenge for model training, as standard loss functions tend to favor the dominant background class, potentially leading to poor segmentation of driftwood regions.

Data Augmentation

To enhance model generalization ability, we developed a dataset augmentation by multi-scale geometric feature approach that calculated three critical geometric characteristics at multiple scales:

(1) Roughness: For a point p with neighborhood points $\{p_1, p_2, ..., p_k\}$, roughness is calculated as Eq.1:

$$R(p) = \frac{1}{k}\sum_{i=1}^{k} \left\| (p_i - p) - \left((p_i - p) \cdot \hat{n}\right)\hat{n} \right\| \quad (1)$$

where, p_i represents neighboring points, k is the number of points in the neighborhood, $\hat{n}$ is the unit normal vector at point p.

(2) Surface Variation: Computed as the ratio of the smallest eigenvalue to the sum of all eigenvalues of the local covariance matrix, as shown in Eq.2:

$$SV(p) = \frac{\lambda_3}{\lambda_1+\lambda_2+\lambda_3} \quad (2)$$

where, $\lambda_1 \geq \lambda_2 \geq \lambda_3$ are the eigenvalues of the covariance matrix.

(3) Anisotropy: Characterizes the directional dependence of point distributions, as shown in Eq.3:

$$A(p) = \frac{\lambda_1-\lambda_3}{\lambda_1} \quad (3)$$

Deep Learning Models for Segmentation

For driftwood segmentation in point cloud data, three deep learning models were implemented and evaluated: PointNet++, PointNet++ with Multi-Scale Grouping (MSG), and Graph Attention Convolution Network (GACNet) [7,8].

PointNet++ employs a hierarchical structure with Set Abstraction modules that select representative points and group their local regions. Features are extracted through multi-layer perceptions applied to each group, enabling the model to capture local geometric patterns critically for distinguishing driftwood from the riverbed.

PointNet++ MSG enhances standard PointNet++ by implementing Multi-Scale Grouping, which processes each centroid at multiple scales simultaneously. This approach is particularly effective for driftwood segmentation as it captures both fine details of individual wood pieces and broader contextual information about accumulation patterns.

GACNet combines graph convolutional operations with self-attention mechanisms. It constructs a graph representation where each point connects to its k-nearest neighbors. The attention mechanism allows the model to dynamically focus on the most relevant neighboring points, which is advantageous for identifying complex driftwood structures amid varying riverbed formations.

Driftwood Volume Quantification Procedure

The point cloud data after semantic segmentation consists of discrete points, and the volume cannot be calculated directly. It is necessary to identify independent driftwood piles and apply appropriate geometric methods to calculate their volumes.

This study employs a comprehensive approach to driftwood volume quantification, as illustrated in the flowchart. The process begins with the segmentation results from the deep learning models, which separate driftwood points from the riverbed and other elements.

First, DBSCAN (Density-Based Spatial Clustering of Applications with Noise) clustering is applied to identify independent driftwood piles. This algorithm effectively groups points based on density, allowing for the separation of distinct driftwood accumulations even when they are in close proximity.

Following clustering, two parallel analytical paths are pursued:

(1) Convex Hull Method: A convex hull is constructed around each identified driftwood cluster to calculate the envelope volume (V_{convex}). This represents the maximum possible space occupied by the driftwood accumulation, including void spaces between individual pieces. The convex hull effectively creates a three-dimensional boundary that encompasses all points in the cluster, providing an upper bound for volume estimation.

(2) Voxelization Analysis: The point cloud is discretized into a three-dimensional grid of voxels (volumetric pixels) of uniform size. By counting the number of voxels occupied by driftwood points (N_d) versus the total number of voxels within the convex hull (N_c), a porosity factor (η) is calculated using the equation: $\eta = 1 - (N_d/N_c)$ This porosity factor represents the proportion of empty space within the driftwood accumulation, which is critical for accurate volume estimation.

The actual driftwood volume (V_d) is then calculated by applying the porosity correction to the convex hull volume:

$$V_d = V_{convex} \times (1 - \eta) \quad (4)$$

RESULTS AND DISCUSSION

Experimental Results And Riverbed Morphology Changes

The experimental results demonstrate significant impacts of driftwood on riverbed morphology through alterations in sediment transport, fluid dynamics, and channel configuration. After the second release of driftwood in the experiment, the riverbed morphology exhibited considerable changes compared to its initial state. The visualization of riverbed curvature (Fig. 3) clearly illustrates these morphological transformations across the experimental site.

Analysis of the spatial distribution patterns revealed a strong correlation between driftwood accumulation and areas of curvature change in the riverbed. While driftwood was observed throughout

the experimental channel regardless of curvature magnitude, the frequency of accumulation was notably higher in zones with significant curvature variations. This finding suggests that riverbed geometry, particularly abrupt changes in channel direction, serves as a primary controlling factor for driftwood deposition and retention.

A particularly noteworthy observation was that the riverbed morphology in areas of driftwood accumulation often conformed to the shape of the deposited driftwood. This phenomenon indicates a bidirectional relationship where driftwood not only responds to existing channel features but actively modifies the riverbed through localized erosion processes. The driftwood-induced scour patterns observed around accumulated pieces further support this interpretation of active morphological modification.

Qualitative assessment of curvature patterns before and after driftwood introduction showed visible increases in morphological complexity following the second release. This transformation demonstrates the substantial geomorphic impact of driftwood on channel configuration, even in controlled laboratory conditions. The most significant morphological changes occurred at locations where multiple driftwood pieces formed complex accumulation structures, creating flow obstructions that redirected erosional forces.

It should be noted that the current experimental design only permitted comparison between the first and second release conditions. Additional time-series experiments with varied flow conditions would be beneficial to further validate these observations and explore the temporal evolution of driftwood-riverbed interactions. Nevertheless, these findings provide valuable insights into the fundamental mechanisms governing driftwood accumulation and its geomorphic consequences in river systems.

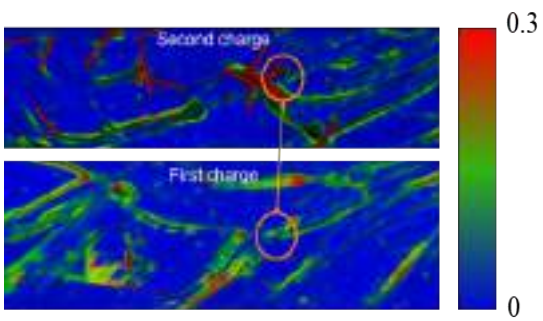

Fig. 3 Visualization of riverbed curvature

Segmentation Results

To evaluate the performance of driftwood segmentation from LiDAR point cloud data, three deep learning models—PointNet++ (PLUS), PointNet++ with Multi-Scale Grouping (MSG), and Graph Attention Convolution Network (GACNet)—were implemented. Each model was trained and tested under two configurations: with dataset augmentation (E) and without dataset augmentation (NE) the proposed dataset augmentation based on multi-scale geometric features. The evaluation metrics included Intersection over Union (IoU), Precision, and F1-score for both driftwood and non-driftwood classes, as well as their macro-averaged mean.

The quantitative results (Table 1) clearly show that dataset augmentation substantially improves model performance. For instance, GACNet(E) achieved the highest overall accuracy with a driftwood IoU of 78.07%, precision of 84.13%, and F1-score of 87.68%. In contrast, its non-augmented counterpart, GACNet(NE), showed noticeably lower performance (IoU = 64.64%, F1 = 78.52%). This trend was consistently observed across all models, confirming the effectiveness of the augmentation technique in mitigating class imbalance and enhancing feature learning.

In the case of PointNet++ (PLUS), dataset augmentation led to a significant improvement from 43.71% to 69.39% in driftwood IoU, and from 60.83% to 81.93% in driftwood F1-score. This demonstrates that even basic hierarchical point-based models benefit considerably from geometric feature enhancement. MSG, which incorporates multi-scale grouping to capture local-global context, showed a similar trend, with IoU improving from 42.97% to 70.27% and F1-score from 60.11% to 82.54%. However, compared to GACNet, both PLUS and MSG exhibited lower segmentation accuracy, likely due to their limited ability to dynamically model contextual dependencies in cluttered driftwood environment.

Among the three models, GACNet demonstrated superior segmentation capability, benefiting from its integration of graph attention mechanisms that allow dynamic context adaptation and better differentiation between driftwood and riverbed points. MSG also performed well due to its multi-scale grouping strategy, capturing both local detail and global context.

Furthermore, qualitative comparisons of the segmentation maps (Fig. 4) show that the dataset augmentation significantly sharpens the boundaries of driftwood objects and reduces the number of isolated noise points incorrectly classified as driftwood. In contrast, models trained without augmentation exhibited more blurred object boundaries and a higher frequency of false positives

scattered throughout the background. These improvements demonstrate the effectiveness of augmentation in enhancing spatial coherence and suppressing spurious classifications in challenging riverbed environments. Among the three, PLUS(E) generated smoother but more conservative driftwood regions, while MSG(E) produced more extensive coverage but included more boundary artifacts. GACNet(E) achieved the best visual clarity and spatial consistency, particularly in distinguishing intertwined driftwood clusters from adjacent sediment zones.

These results highlight the importance of geometric-aware augmentation and attention-based modeling in achieving high-accuracy semantic segmentation of driftwood under complex morphological conditions, thus providing a reliable foundation for subsequent volume estimation and disaster analysis.

Table 1 Quantitative evaluation metrics for driftwood segmentation

	IoU			Precision			F1		
	Driftwood	Non	Mean	Driftwood	Non	Mean	Driftwood	Non	Mean
PLUS(NE)	43.71	98.80	71.25	51.83	99.66	75.75	60.83	99.40	80.11
PLUS(E)	69.39	99.50	84.44	74.85	99.88	87.36	81.93	99.75	90.84
MSG(NE)	42.97	98.59	70.78	46.84	99.79	73.32	60.11	99.29	79.70
MSG(E)	70.27	99.54	84.90	78.82	99.83	89.33	82.54	99.77	91.15
GACNet(NE)	64.64	99.41	82.02	72.71	99.81	86.26	78.52	99.70	89.11
GACNet(E)	78.07	99.67	88.87	84.13	99.89	92.01	87.68	99.84	93.76

Table 2 Comparison of driftwood volume estimations across models and areas

	Actual volume (mm^3)	PLUS		MSG		GACNet	
		NE	E	NE	E	NE	E
Area 1	9608	13608.44	6481.38	13378.61	6618.29	6132.21	7443.16
Area 2	6782	4684.90	2336.51	4771.59	2532.19	2639.43	3843.60
Area 3	11304	20881.60	10713.22	20813.46	10726.56	13464.11	10997.18
Mean error (%)		+31.82%	-34.44%	+31.24%	-32.96%	-26.05%	-22.85%

Driftwood Volume Estimation Results

Table 2 presents the driftwood volume estimation results across three areas using different deep learning models with and without dataset augmentation. The volume estimation accuracy directly reflects the effectiveness of each model in practical driftwood disaster investigation scenarios.

The experimental results reveal distinctive patterns in volume estimation performance across different models and areas. Non-enhanced models PLUS(NE) and MSG(NE) demonstrated inconsistent behavior, significantly overestimating volumes in Areas 1 and 3, while unexpectedly underestimating volumes in Area 2. This inconsistency indicates poor adaptation to varying riverbed morphologies and driftwood distribution patterns. When comparing actual values to estimated volumes, the non-enhanced models showed extreme overestimation in Area 3, with values approximately twice the actual volume.

In contrast, all enhanced models consistently underestimated driftwood volumes across all areas, though with different magnitudes. GACNet(E) achieved the most balanced performance with the lowest mean error (-22.85%) among enhanced models, particularly excelling in Area 3 where its estimated volume was closest to the actual measurement. The dataset augmentation technique substantially transformed the estimation behavior of PLUS and MSG models, converting significant overestimation tendencies to underestimation.

Regional variation analysis revealed a consistent pattern among enhanced models: Area 2 presented the greatest estimation challenges with the largest volume underestimation, followed by Area 1, with Area 3 showing the closest estimates to actual volumes. This systematic pattern strongly indicates that riverbed morphology significantly influences volume estimation accuracy, with certain topographical features presenting greater challenges regardless of model architecture.

The relationship between semantic segmentation performance and volume estimation accuracy presented interesting observations. While GACNet(E) both achieved the highest IoU (78.07%) in segmentation tasks and delivered well-balanced volume estimates, GACNet(NE) with a lower IoU (64.64%) achieved a slightly lower mean error (-26.05%) than GACNet(E) (-22.85%), though with higher area-to-area variation. This suggests that while improved segmentation generally contributes to better volume estimation, other factors in the volume calculation pipeline may influence final accuracy.

The consistent underestimation observed in enhanced models may indicate systematic effects in boundary detection or voxelization processes that warrant further investigation. Nevertheless, GACNet with dataset augmentation provides the most robust approach for driftwood volume estimation.

CONCLUSIONS

This study successfully developed a LiDAR-based deep learning approach for driftwood disaster investigation through controlled flume experiments. The proposed multi-scale geometric feature augmentation technique effectively enhanced model performance, with all models achieving mIoU exceeding 80%. GACNet with dataset augmentation demonstrated superior performance in both semantic segmentation (driftwood IoU of 78.07%) and volume estimation (mean error of -22.85%). Experimental results revealed a bidirectional relationship between driftwood accumulation and riverbed morphology, where riverbed geometry influences driftwood deposition patterns, while accumulated driftwood modifies channel configurations. This research validates the integration of LiDAR technology with deep learning for driftwood disaster assessment, offering an effective approach for disaster investigation and mitigation. However, the accuracy of driftwood accumulation volume estimation was affected by challenges such as the complex morphology of riverbeds, the irregular and porous structure of driftwood piles, and the limitations of current clustering and volumetric algorithms based on point cloud. Future work should address these issues by refining volume estimation techniques and improving the handling of complex accumulation patterns.

ABSTRACT

This study aims to utilize and illustrate the potential and effectiveness of Long Short-Term Memory (LSTM) networks to predict temperature variations at the inlet and outlet of integrated energy piles with the air conditioning system, especially in a soft clay soil layer. The energy piles are gaining traction by combining structural and thermal dissipation functions, incorporated well into sustainable building designs. Their performance is reflected by the temperature at the inlet and outlet over time. Accurate prediction of temperature changes in energy piles is crucial for designing, optimizing system performance, and evaluating the effective thermal conductivity of the system by forecasting its behavior over time. The proposed LSTM model is trained by feeding normalized, time-series splitting data from inlet and outlet temperature recordings at the time sequences. The model's performance is evaluated using R-squared (R^2) combined with Root Mean Squared Error (RMSE), showing on average the confidence of 0.9270, ±0.2373°C for inlet prediction temperature, and 0.9094, ±0.2673°C for outlet prediction temperature, respectively. The model showing improvement int the accuracy as the number of LSTM layers increases from 1 to 3, the R^2 increase 0.09% and 11.96% for RMSE in inlet side, while the R^2 increase 1.81% and 4.51% for RMSE in outlet side respectively. Machine learning models such as LSTM require careful balancing between the time frame and prediction frequency to ensure reliable results. In short-term predictions, fewer layers of LSTM are more suitable, due to their greater sensitivity to data fluctuations. In contrast, adding more LSTM layers improved stability but reduced sensitivity, resulting in smoother long-term trends. The findings contribute to the development of more efficient, data-driven approaches for managing energy pile systems, advancing both the practical and theoretical understanding of thermal energy storage in geotechnical engineering applications.

Keywords: Energy pile, Ground source heat pump, Long short-term memory, Machine learning, Prediction model

INTRODUCTION

The global warming effect and urbanization in major cities have intensified the heat island effect, significantly elevated ambient temperatures, and consequently increased the demand for air conditioning systems in residential and commercial buildings. This phenomenon is particularly pronounced in densely populated metropolitan areas across Southeast Asia, where rapid population growth and limited urban space have exacerbated heat retention and energy consumption issues. Given that many of these urban centers are situated on soft marine clay deposits, deep foundation piles are routinely employed for structural support in building construction. Even though the energy piles and GSHP technology are still young and at their early stage in the Southeast Asia region, a few academic studies [1] [2] [3] [4] have been conducted. This presents an opportunity to utilize these foundational structures by integrating energy piles and Ground Source Heat Pump (GSHP) systems. Depicted in Fig.1 [2].

The system's components in cooling mode operation comprise of the geo-structure, the embedded heat exchanger, the heat pump unit, and the distribution system.

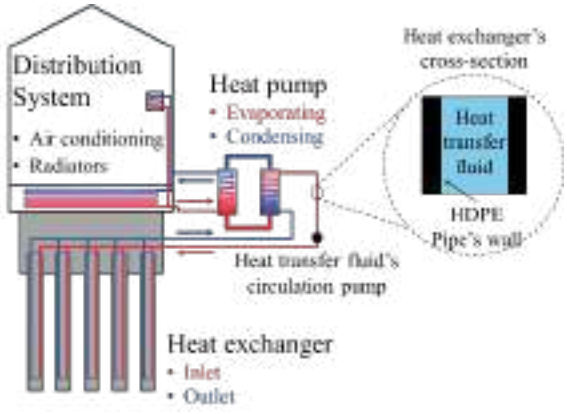

Fig.1 Schematic of the components of an energy pile for small-to-medium residential units. [2]

Energy piles provide a sustainable solution by leveraging the stable ground temperature for efficient heating and cooling, thereby helping to mitigate urban heat island effects and reduce energy consumption and reliance on conventional cooling systems. However, implementing energy piles and GSHP technology requires comprehensive analyses

of temperature distribution in soft clay, as well as accurate predictions of inlet and outlet fluid temperatures. These indexes are critical for reliable performance assessments of energy piles and GSHP systems, including the coefficient of performance (COP: ratio of heat delivered to energy input), energy efficiency ratio (EER: cooling output per unit electrical input), seasonal energy efficiency ratio (SEER: cooling efficiency averaged over a cooling season), seasonal coefficient of performance (SCOP: heating efficiency averaged over a heating season), seasonal performance factor (SPF: actual seasonal performance considering all energy inputs), long-term seasonal COP (LSCOP: COP measured over multiple seasons or years), and long-term cooling factor (LSCF: cooling efficiency ratio in long-term). Clarifying these is especially important in densely populated areas in Southeast Asia and Japan.

Integrating machine learning (ML) techniques with energy piles and GSHP systems has become a promising research frontier, enhancing predictive accuracy, system optimization, and operational efficiency. Recent advances in ML, particularly in deep learning architectures such as long short-term memory (LSTM), artificial neural networks (ANNs), simple recurrent neural networks (Simple RNN), and convolutional neural networks (CNNs), have enabled more precise thermal performance modeling and improved energy demand forecasting. Instead of relying solely on computationally intensive simulations like finite difference method (FDM), finite element method (FEM) or Multiphysics modeling, ML techniques offer an efficient alternative that reduces the need for extensive computing resources. By pretraining LSTM models, practical limitations due to high computational demand can be overcome, improving accessibility for end-users.

RESEARCH SIGNIFICANCE

This research aims to illustrate the potential and effectiveness of employing LSTM models to predict the thermal behavior of energy piles, contributing to a valuable tool for optimization in energy piles and GSHP design. Specifically, the developed LSTM model forecasts the inlet and outlet temperatures for energy piles and GSHP, particularly when these systems are situated within deep layers of soft marine deposit clay, which are common in major cities in Japan and the Southeast Asia region.

PREVIOUS STUDIES

An LSTM model, following the architecture first proposed by Hochreiter and Schmidhuber [5], was chosen for its suitability in time-series predictions. Specifically, the sequence-to-sequence (seq2seq) model illustrated in Fig.2 represents an advanced form of sequence prediction, classified as “many-to-many.” In this model, new sequences are predicted based on patterns learned from training data, offering flexibility as the predicted sequences can differ in length and timing from the inputs. The seq2seq architecture employs recurrent neural networks to map input sequences of varying lengths to similarly variable output sequences [6]. For predicting the temperatures of energy piles and GSHP systems, both input and output data are multi-step time series, making this model particularly effective for forecasting multiple future observations from historical data.

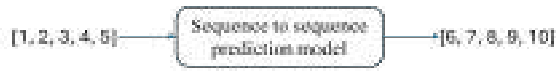

Fig.2 Depiction of a sequence-to-sequence prediction problem

Recent scholarly advances in ML applications for energy piles and GSHP systems have indicated the basic outline of how to build the ML model, such as,

Zhang [7] indicated in the outlet water temperature prediction of energy pile using the CNN–LSTM hybrid model, the superior enhancement in the accuracy of the prediction, indicated by the mean R^2 value of 96.252%, superior to the values of the individual LSTM, CNN, ANN, and Simple RNN models by 2.326%, 3.527%, 4.585%, and 5.755% respectively. By employing a hybrid modeling approach proves advantageous due to its effective integration of CNNs' capability for feature extraction with LSTMs' proficiency in sequential learning, resulting in enhanced accuracy for current-state predictions.

Chen [8] demonstrated that machine-learning-based performance prediction of energy pile heat pump systems, using a hybrid ANN model fine-tuned with particle swarm optimization (PSO), can effectively predict the output COP index. The model used readily measurable input features, including ambient and room temperature and humidity, as well as hourly power consumption. The PSO-ANN model produced predictions that closely matched the measured values, outperforming conventional empirical regression models that deviated within ±20% of the 1:1 line, as shown in Fig.3 (a) and (b). Incorporating multiple input parameters that reflect the thermal and electrical behaviors of the system enhanced the model’s generalization capability and improved prediction reliability under varying operating conditions.

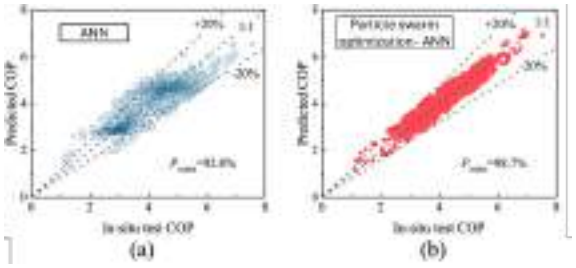

Fig.3 The stacked LSTM temperature prediction model [5]

Output temperature predictions of geothermal heat pump systems using the Improved Grey Prediction Model [9] reveal that the size of the data points, whether small or large, influences the prediction's effectiveness and accuracy. A smaller sample size during training tends to yield higher accuracy but is more sensitive to bias, whereas a larger sample size offers more consistent predictions, albeit with slightly reduced accuracy. Balancing data size is essential to avoid overfitting and ensure reliable predictions. This study successfully used only 24 data points (hours) to forecast temperatures eight hours ahead. Further experiments determined that for the GM model, particularly GM(1,1). A key model for short-term time-series prediction, sample sizes as low as six data points can be used. This underscores the need for proper data preparation, including outlier removal and ensuring a non-random, non-negative dataset, to improve model quality and prediction reliability.

Song [10] tackled the challenge of hourly heat load prediction accuracy in smart district heating, using a temporal convolutional neural network, citing the utilities beyond the temperature forecast of ML in energy piles and GSHP. The conventional regression, although commonly applied, tends to fail to leverage the nonlinear and temporal relationships characteristic of the heat load data. The researcher intends to forecast the peak cooling load of the system by proposing a temporal convolutional neural network (TCN) for hourly heat load forecasting in district heating systems (DHS). TCN fuses the feature extraction in parallel offered by CNNs with the sequence modeling capability of RNNs to better deal with complex, nonlinear, and time-varying data. The model uses both working parameters, such as supply temperatures, return temperatures, past loads, and outdoor temperature, which have been pre-processed using correlation analysis.

Chandra and Matuska [11] address critical limitations in current building energy management systems within intelligent data workflows, including data pipelines and LSTM efficiency prediction. Traditionally, data collection and performance prediction for thermal energy storage (TES) systems have been separate and static. While previous studies have applied ANNs and exergy analysis for TES-heat pump systems, significant challenges remain in accurately modeling transient behaviors during dynamic load periods, due to issues like vanishing gradients and overfitting. The authors propose an intelligent, real-time data acquisition and processing framework using Raspberry Pi hardware and LSTM-MLP models. This framework automates data curation and prediction, integrates custom exergy models for live performance assessment, and offers real-time visualization tools. Their approach improves predictive accuracy and bridges a key gap in literature, paving the way for more autonomous and efficient building energy systems.

METHOD STATEMENT

Long Short-Term Memory (LSTM) was selected for its strong ability to capture long-term temporal dependencies and nonlinear patterns typical in the thermal behavior of energy piles. Unlike Autoregressive Integrated Moving Average (ARIMA), which assumes linearity, or Support Vector Regression (SVR), which struggles with temporal dynamics, LSTM effectively models complex, multivariate time-series data without prior assumptions. While Gated Recurrent Unit (GRU) networks are more computationally efficient, other than that LSTM offers broader community support, abundant libraries, and better plugin integration, making it more accessible for beginners. It has also shown superior accuracy in modeling seasonal and delayed thermal responses in geo-energy systems.

This study's LSTM model was developed using the *TensorFlow* library [12] in *Python* to predict the inlet and outlet temperature behavior of energy piles based on the non-negative and non-random inlet, outlet, and time parameter sequences, the key factors in assessing the performance of energy piles and GSHP systems. The model was trained using full-scale experimental datasets from the previous study on energy piles in Bangkok by Jotisankasa [13]. The proposed model employs a stacked LSTM neural network architecture for seq2seq temperature prediction, as illustrated in Fig. 4. During preprocessing, these data are segmented into sequences with a length of 25-time steps. The model comprises up to 3 hidden LSTM layers, each containing 64 nodes, and is trained over 200 epochs (calculation cycle) with a batch size (number of data points) of 64 to optimal balance between computational efficiency and prediction accuracy. The output layer generates predictions for inlet and outlet temperatures.

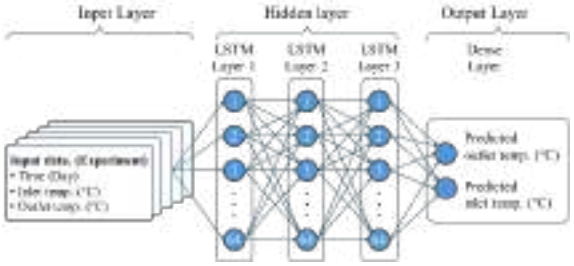

Fig.4 The stacked LSTM temperature prediction model

RESULT AND DISCUSSION

The LSTM Prediction Model's Verification

The LSTM prediction model's verification was performed using parity diagrams shown in Fig.5, which compare the predicted and actual inlet and outlet temperatures for models with 1, 2, and 3 LSTM layers. The data points largely aligned along the 1:1 line and the ±5% reference line, indicating strong agreement between predicted and measured values. The R^2 values were 0.9280, 0.9257, and 0.9272 for outlet temperature and 0.9181, 0.9082, and 0.9018 for inlet temperature, respectively. The relatively low RMSE values of 0.2547, 0.2298, and 0.2275 for outlet temperature and 0.2783, 0.2573, and 0.2663 for inlet temperature suggest reliable predictions with minimal error fluctuation.

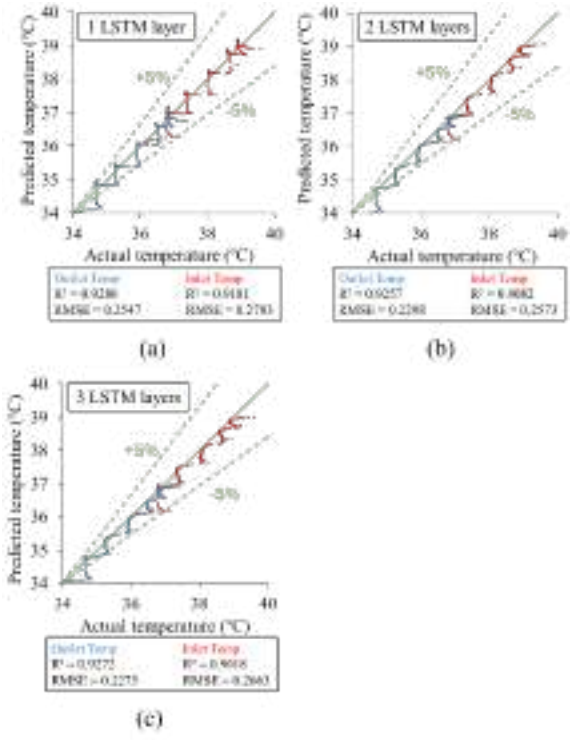

Fig.5 Parity diagram of predicted versus actual inlet and outlet temperatures using a-layer LSTM model

Each of the LSTM model architectures, ranging from a single layer to three layers, presents unique advantages and disadvantages. The suitability of each model depends on the specific application, whether for short-term or long-term predictions. These aspects will be discussed in more detail in the following section.

Inlet and Outlet Temperature Prediction

Although the single-layer LSTM model yielded slightly lower accuracy compared to models with higher layer counts, it is not without practical value. Specifically, as depicted in Fig.6, the single-layer model can be effectively utilized for short-term predictions due to its greater sensitivity, as demonstrated by its better capacity to closely replicate the shape and fluctuations of actual data.

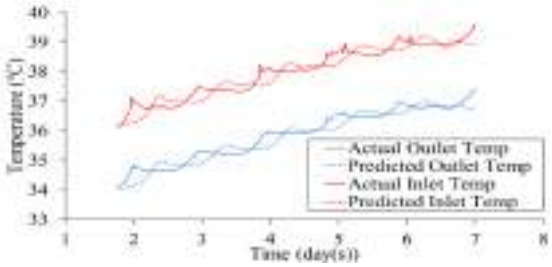

Fig.6 Short-term temperature simulation over time using the 1-layer LSTM model

In contrast, increasing the number of LSTM layers tends to improve prediction stability but reduces sensitivity, leading to smoother outputs that capture fewer short-term fluctuations. Fig.7 presents the predicted inlet and outlet temperatures of energy piles over 10 years (3650 days), revealing a near-linear stable temperature in the long run. Although such stability is rare due to seasonal changes in ground and air temperatures, using year-long datasets can enhance prediction accuracy. This is seen in Fig.8 and Fig.9, where even within the first six months or years 1 to 2, minor temperature fluctuations persist. These results indicate that the input data influences the model, suggesting potential for further accuracy improvement.

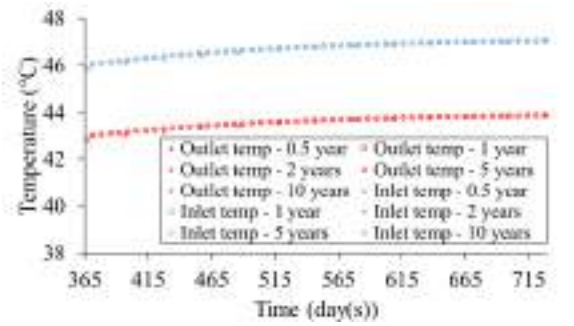

Fig.9 Long-term temperature simulation over time using the 3-layer LSTM model, including a detailed view of the 1 to 2 years

Impact of LSTM Layers

The results from varying the number of 1, 2, and 3 layers of the LSTM model showed marginal differences in prediction accuracy for both inlet and outlet temperatures, as summarized in Table 1. For inlet temperature, the average R^2 are at 0.9270, a slight improvement of 0.0863 % (0.0008) over time. while the average RMSE is at 0.2373, indicating a 11.956 % (±0.0272°C) improvement. Similarly, the outlet temperature's average R^2 values around 0.9094, improving by 1.8075 % (0.0163) over time, while the average RMSE is at 0.9094 reflecting a 4.5062 % (±0.0120°C). An increase in R^2 signifies that the predicted values are more closely aligned with the observed data, indicating tighter grouping of data points around the regression line. Consequently, this improved alignment naturally results in narrower range of fluctuation in the RMSE, as prediction errors become smaller, more consistent, and numerically closer to the observed values.

Even from a practical perspective, the improvement indicated by average RMSE values ±0.2373°C for inlet and 0.2673°C for outlet temperature predictions may appear marginal, with improvements of only 11.956% (±0.0272°C) and 4.5062% (±0.0120°C), respectively. However, it would be premature and potentially misleading to dismiss these results based solely on the current dataset, as valuable insights might be overlooked. At this stage, it is clear that increasing the number of LSTM layers tends to enhance predictive accuracy, albeit modestly. Nevertheless, it should also be noted that as the dataset expands in future analyses, the observed incremental accuracy improvements could diminish or plateau.

Table 1 Comparison of prediction accuracy (R^2 and RMSE) for inlet and outlet temperatures with varying numbers (1, 2, and 3) of LSTM layers.

Source	Index	Number of LSTM layer(s)			Avg value	Avg improvement per 3 layers , %
		1 layer	2 layers	3 layers		
Inlet temp	R^2	0.9280	0.926	0.927	0.9270	0.0008, 0.0863%
	RMSE	0.255	0.23	0.228	0.2373	0.0272, 11.956%
Outlet temp	R^2	0.918	0.908	0.902	0.9094	0.0163, 1.8075%
	RMSE	0.278	0.257	0.266	0.2673	0.0120, 4.5062%

CONCLUSIONS

The development of a multi-layer LSTM model demonstrated its potential for large-scale systems. While the single-layer model offered slightly lower accuracy, it remains valuable for short-term predictions due to greater sensitivity to data fluctuations. Adding layers improved stability but reduced sensitivity, smoothing long-term trends at the expense of short-term detail. Model performance heavily depends on the quality and comprehensiveness of input data.

Balancing prediction frequency and timeframe is crucial when using machine learning models like LSTM. For example, predicting hourly or half-day intervals over a year can strain the model and decrease accuracy. Thus, selecting appropriate prediction intervals aligned with dataset resolution is vital to maintain meaningful and reliable outcomes without overwhelming the model.

Future research should expand beyond time, inlet and outlet temperatures by incorporating parameters such as thermal load, active length, flow rate, connection types, and operational cycles. A comprehensive, year-long dataset covering all seasonal variations and operational scenarios will enhance the model's ability to generalize and accurately reflect real-world conditions. Including diverse scenarios will strengthen predictions of thermal performance and capture complex system interactions.

Lastly, the more sophisticated algorithms or combining multiple algorithms could further enhance prediction accuracy. Ensuring that the model's underlying architecture supports scalability and

integration with additional data sources will help maintain reliability and accuracy as new data emerges.

ABSTRACT

This study investigates the performance enhancement of an evaporative cooling system by integrating thermosyphon heat pipes to improve dehumidification efficiency in hot and humid climates. The experimental setup comprised a thermally insulated cubic test chamber (100 × 100 × 100 cm³) fitted with a cellulose-based cooling pad, axial flow fans, and five copper heat pipes (9.5 mm in diameter and 40 cm in length) charged with R-134a refrigerant. The heat pipes were positioned upstream of the cooling pad to passively extract latent heat and reduce moisture content in the incoming air prior to evaporative cooling. Experiments were conducted under two levels of natural solar radiation, averaging approximately 600 W/m² and 750 W/m², respectively, recorded using a pyranometer at 30-minute intervals. Measured parameters included dry-bulb temperature and relative humidity, collected using calibrated K-type thermocouples and digital hygrometers. The results indicate that the heat pipe system effectively reduced the relative humidity of supply air by approximately 6% to 10%, with maximum reductions reaching 12.5% under high solar intensity. This pre-conditioning process not only lowered the latent cooling load but also enhanced overall cooling performance. While the dry-bulb temperature increased slightly, thermal comfort improved significantly. The findings highlight the potential of this passive hybrid approach to enhance indoor environmental quality and energy efficiency in tropical buildings. Future work should focus on airflow optimization and the use of alternative refrigerants to refine system applicability in real-world scenarios.

Keywords: Heat Pipe, Evaporative Cooling, Dehumidification, Energy Efficiency, Tropical Climate

INTRODUCTION

In tropical countries like Thailand, where annual temperatures average between 32°C and 35°C and relative humidity regularly exceeds 70%, the demand for thermal comfort in buildings leads to high energy consumption, particularly through air-conditioning systems. Conventional vapor compression air conditioners not only consume large amounts of electricity but also rely on refrigerants that contribute to ozone depletion and global warming [1-3]. These environmental and economic concerns have driven the search for alternative, energy-efficient cooling technologies that can function effectively in humid climates. Evaporative cooling systems have emerged as a promising solution due to their simplicity and low energy consumption. They operate by taking advantage of the latent heat of water evaporation to cool incoming air, making them suitable for dry and semi-arid environments. However, in hot and humid regions such as Southeast Asia, their cooling capacity becomes limited as the ambient air approaches saturation, reducing the temperature differential between the dry-bulb and wet-bulb temperatures [4-5]. To address this limitation, researchers have explored hybrid cooling systems that incorporate passive and active dehumidification technologies. Heat pipes, particularly thermosyphon heat pipes, have gained attention for their ability to transfer heat efficiently without moving parts. These devices can extract latent heat from moist air by condensing water vapor on a cooled surface, thus reducing humidity before the air enters the evaporative cooling stage.

Several studies have demonstrated the potential of integrating heat pipe systems into air conditioning and agricultural applications. Van Den Bulck et al. introduced rotary heat exchangers to improve dehumidification in HVAC systems [6], while Lazzarin and Gasparella investigated combined heat and cooling systems for enhanced energy efficiency [7]. In Thailand, Watcharodom et al. examined the performance of thermosyphon heat pipes in residential-scale air conditioners, showing energy savings and improved indoor climate control [8-10]. Srihajong et al. applied heat pipe systems to regulate moisture in aeroponic plant environments [11], and Meena et al. studied the role of oscillating heat pipes in moisture reduction during agricultural drying processes [12].

Despite these efforts, limited research has focused on directly integrating thermosyphon heat pipes with evaporative cooling systems to enhance dehumidification under naturally hot and humid conditions. There is a knowledge gap in evaluating how such hybrid systems perform under real environmental fluctuations without mechanical

assistance. This study aims to address that gap by experimentally assessing the performance of an evaporative cooling system enhanced with thermosyphon heat pipes, focusing on its effectiveness in reducing humidity and improving overall thermal comfort in tropical climates.

RESEARCH SIGNIFICANCE

This study proposes a hybrid cooling system that integrates thermosyphon heat pipes into an evaporative cooling configuration to pre-condition incoming air by reducing its moisture content. This approach enhances the system's latent cooling performance and makes it suitable for hot and humid tropical climates. By operating without additional electrical input for dehumidification, the system provides a passive, energy-efficient, and environmentally friendly solution that contributes to sustainable indoor climate control. The findings from this study are expected to support the design of future hybrid cooling systems that reduce dependence on high-energy mechanical air conditioning.

EXPERIMENTAL SETUP

This experiment was conducted using a custom-designed hybrid cooling system that integrates evaporative cooling with thermosyphon heat pipes. The entire setup was installed on an open rooftop to simulate natural ambient conditions (Fig. 1). At the core of the system is a thermally insulated cubic test chamber with internal dimensions of 100 × 100 × 100 cm^3. The chamber structure comprises a steel frame with double-layered plywood walls, internally lined with 5 cm thick thermal insulation to minimize heat transfer from the surroundings. A 60-watt incandescent bulb was installed inside the chamber to simulate internal heat gains typically found in small residential spaces. At the upstream section of the chamber, a centrifugal fan was installed to draw ambient air through a pre-conditioning unit composed of five vertically arranged thermosyphon heat pipes. These copper pipes, each with a diameter of 9.5 mm and a length of 40 cm, were filled with R-134a refrigerant and equipped with aluminum fins to enhance heat dissipation. The heat pipes operate passively and are arranged in parallel at the system's front end to extract latent heat from the incoming humid air before it reaches the evaporative cooling pad. The evaporative unit uses a cellulose-based cooling pad measuring 33 × 33 × 10 cm^3, assisted by two 12-volt axial flow fans that force air through the wetted pad. This allows for both sensible and latent heat exchange. The conditioned and dehumidified air then enters the test chamber. Environmental parameters, including dry-bulb temperature and relative humidity, were measured at four key locations: ambient air, before and after the heat pipe section, and inside the test chamber. Calibrated K-type thermocouples (±0.5°C accuracy) and digital hygrometers were used to collect data. Solar radiation was monitored using a pyranometer to track natural irradiance fluctuations during the experiment. The experiment was conducted in an open-air environment without mechanical control of solar intensity. Instead, testing was carried out over two separate days to reflect natural solar variation: one day with moderate radiation averaging 600 W/m^2, and another with higher radiation averaging 750 W/m^2. Measurements were recorded every 30 minutes between 12:00 and 15:30. Although solar intensity was not entirely constant, the selected intervals showed sufficiently consistent patterns to enable meaningful comparison. Grouping the results based on average daily irradiance allowed for performance evaluation of the system under two distinct environmental conditions without relying on active solar control mechanisms.

Fig.1 Experimental setup of the hybrid evaporative cooling system integrated with heat pipes

ANALYZE DATA

The analytical framework for evaluating the evaporative cooling system integrated with thermosyphon heat pipes was developed based on the principles of steady-state mass and energy conservation. In this system, the airflow and thermal interactions were considered under quasi-adiabatic conditions, assuming minimal heat loss to the environment due to the insulated test chamber and short processing time. The predominant processes occurring within the system were heat and moisture exchanges between the ambient air, the evaporative medium, and the heat pipe assembly. As the ambient air enters the system, it first passes through the heat pipe array, where a portion of the water vapor is condensed due to the refrigerant's phase change within the pipes. This process reduces the moisture content of the incoming air through latent heat

extraction, resulting in a slight increase in dry-bulb temperature. Following this stage, the pre-conditioned air flows through the evaporative cooling pad, where both sensible and latent heat exchanges occur, lowering the dry-bulb temperature while increasing the humidity ratio.

To analyze these thermal phenomena, the energy balance was applied to the moist air stream, which includes both the dry air component and the associated water vapor. The enthalpy change of the moist air was used as a performance indicator to quantify system behavior and energy transfer across each stage. The total enthalpy was calculated based on psychrometric properties, combining sensible heat and latent heat contributions. The conceptual diagram illustrating the mass and energy exchanges across the system, which includes both the heat pipe section and the evaporative pad (Fig.2). This diagram provides a visual summary of the airflow pathway, component interactions, and measurement points used in the experiment. It serves as a reference for interpreting the performance results in the following section.

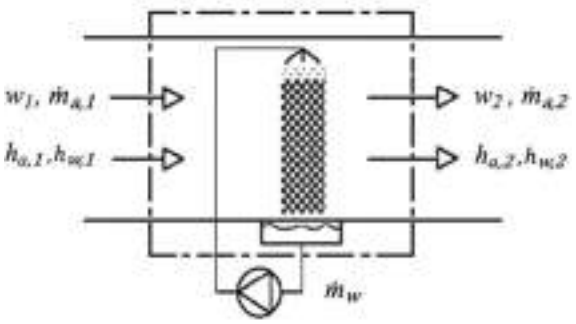

Fig. 2 Schematic diagram of mass and energy balance in evaporative cooling process

To determine the mass of evaporated water, the conservation of mass for water vapor is written as:

$$\dot{m}_w = \dot{m}_a (W_1 - W_2) \quad (1)$$

Where $\dot{m}_w$ is the rate of water evaporation (kg/s), $\dot{m}_a$ is the mass flow rate of dry air (typically 0.05 kg/s in this experiment), and W_1 and W_2 are the humidity ratios ($kg_{water}/kg_{dry\ air}$) at the inlet and outlet of the cooling section, respectively.

The total enthalpy of moist air at any point is calculated as the sum of the enthalpies of dry air and water vapor:

$$h_{total} = C_{p,a}T + W(h_{fg} + C_{p,v}T) \quad (2)$$

Where $C_{p,a}$ = 1.006 kJ/kgC is the specific heat of dry air, $C_{p,v}$ = 1.84 kJ/kgC is the specific heat of water vapor, T is air temperature (°C), h_{fg} = 2450 kJ/kg is the latent heat of vaporization, and W is the humidity ratio at the respective state.

For the moisture-laden air entering the cooling media, the rate of heat transfer from the air to the water (which facilitates evaporation) is derived from the energy balance as:

$$Q = \dot{m}_a (h_1 - h_2) \quad (3)$$

where h_1 and h_2 are the total enthalpies of the air stream before and after the evaporative process, respectively.

The performance of the cooling process was evaluated by calculating the evaporative cooling effectiveness, given by:

$$\varepsilon = \frac{T_{db,in} - T_{db,out}}{T_{db,in} - T_{wb,in}} \quad (4)$$

Here, $T_{db,in}$ and $T_{db,out}$ are the dry-bulb temperatures before and after the evaporative section, and $T_{wb,in}$ is the inlet wet-bulb temperature. This ratio quantifies the cooling performance relative to the maximum potential defined by wet-bulb depression.

The dehumidification efficiency of the heat pipe system was also analyzed by comparing relative humidity measurements before and after the heat pipe section. This is expressed as:

$$\eta_{dehum} = \frac{RH_{in} - RH_{out}}{RH_{in}} \times 100\% \quad (5)$$

RESULTS AND DISCUSSION

This experimental evaluation was conducted to examine how the integration of thermosyphon heat pipes into an evaporative cooling system can enhance both temperature regulation and indoor humidity control. This section presents the findings through analysis of measured dry-bulb temperatures, relative humidity levels, and calculated performance indicators, as defined in the analytical framework and equations provided in the preceding section. Prior to the installation of heat pipes, the standalone evaporative cooling system demonstrated a moderate capacity to reduce indoor air temperature but showed limited effectiveness in managing relative humidity. As presented in (Table 1) and (Fig.3), indoor air temperatures fluctuated between 26.5°C and 31.0°C, while inlet air temperatures ranged from 26°C to 30°C during the experimental period. These results indicate that the evaporative cooling system provided sensible cooling by lowering the dry-bulb temperature; however, the indoor environment remained vulnerable to heat accumulation, primarily due to solar radiation and internal thermal loads. The limited humidity control observed in the baseline system is consistent with the known constraints of conventional evaporative cooling, which tends to introduce additional moisture into the space through constant evaporation. If this added moisture is not properly managed, it can impair thermal comfort,

reduce system efficiency, and potentially encourage microbial growth in enclosed spaces. Therefore, enhancing such systems with a passive dehumidification mechanism such as thermosyphon heat pipes may offer a promising solution for buildings located in hot and humid climates where both cooling and dehumidification are critical to indoor environmental quality.

Table 1 Hourly variation of outdoor, inlet and indoor temperatures before heat pipe installation

Time	Outside temperature	Temperature before entering the room	Room temperature
12:00	33	26	27
12:30	31	27	26.5
13:00	33	28	29
13:30	32	29	30.5
14:00	33	30	30
14:30	33.5	29.5	30.5
15:00	34	29.5	30
15:30	34.5	29	31

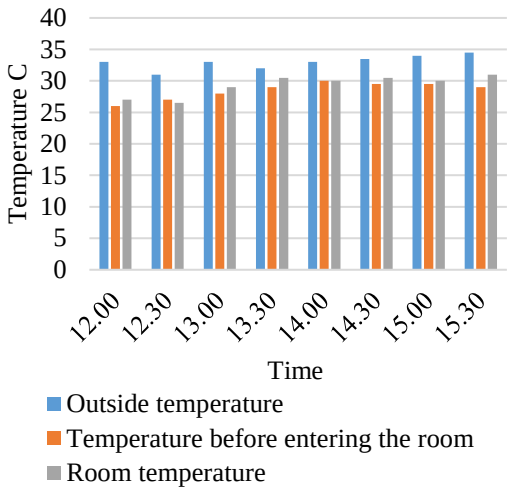

Fig.3 Temperature profiles before the installation of heat pipes

In parallel, (Table 2) and (Fig.4) show that the relative humidity inside the room consistently exceeded outdoor levels, reaching up to 80% at peak periods. This can be attributed to continuous water vapor saturation introduced by the evaporative pad. Such elevated humidity not only compromises thermal comfort but also limits the evaporative effectiveness, as defined in Eq. (4).

After the installation of the thermosyphon heat pipe section, a significant shift in both temperature and humidity behavior was observed. Under moderate solar intensity (600 W/m²), as shown in (Fig.5), the room temperature remained stable between 28°C and 30°C. Under higher solar radiation (750 W/m²), (Fig.6) shows a similar trend with peak room temperature approaching 31°C, yet still below the outdoor temperature range (33–34.5°C), demonstrating consistent thermal buffering.

Table 2 Hourly variation of outdoor and indoor relative humidity

Time	Outdoor humidity	Indoor humidity
12:00	57	77
12:30	53	80
13:00	55	75
13:30	54	67
14:00	55	68
14:30	58	66
15:00	57	68
15:30	59	64

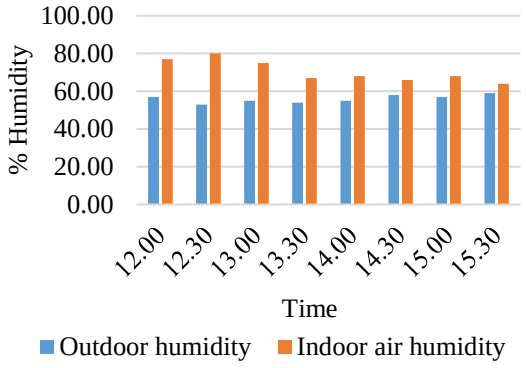

Fig.4 Relative humidity trends before the installation of heat pipes

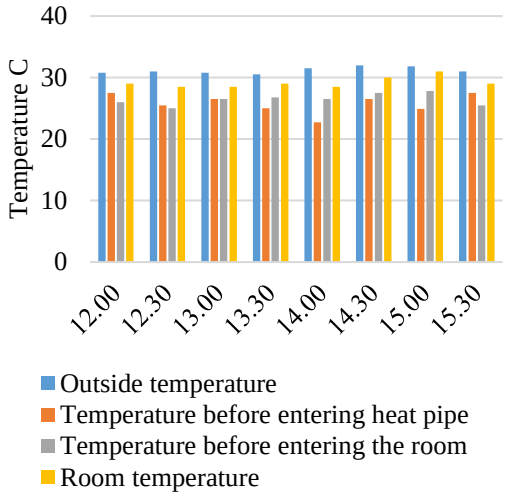

Fig.5 Temperature trends under 600 W/m² solar intensity

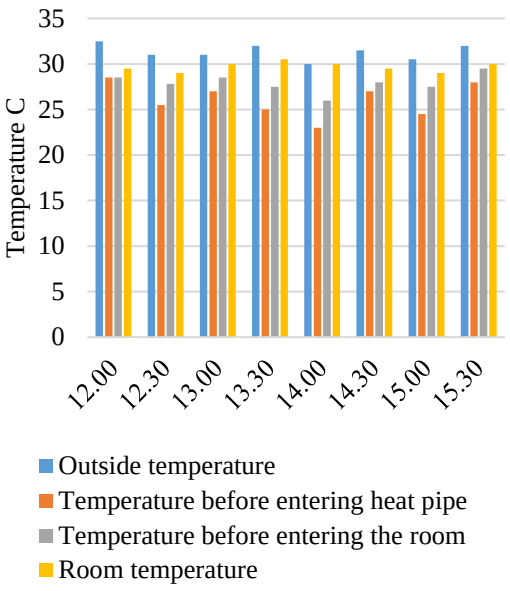

Fig.6 Temperature trends under 750 W/m² solar intensity

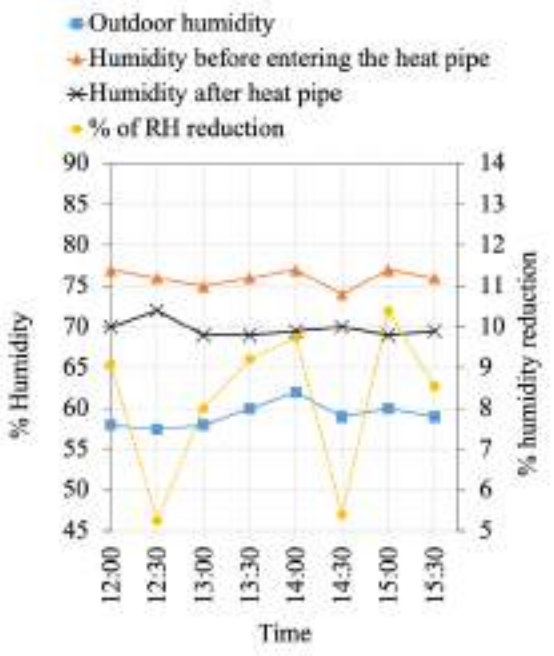

Fig.7 Trends of Relative Humidity and Dehumidification Efficiency Before and After Heat Pipe under 600 W/m² Solar Radiation

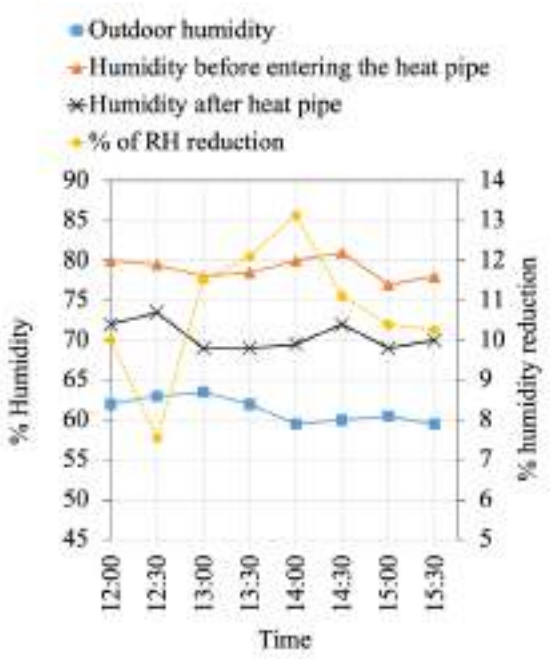

Fig.8 Trends of Relative Humidity and Dehumidification Efficiency Before and After Heat Pipe under 750 W/m² Solar Radiation

The experimental results reveal a consistent reduction in relative humidity across both test conditions, demonstrating the effectiveness of the thermosyphon heat pipe system in enhancing latent heat management. The air entering the heat pipe section exhibited noticeably higher relative humidity than the air exiting the system, confirming the successful extraction of moisture through the phase-change mechanism, as described by Eq. (1). Under moderate solar radiation at approximately 600 W/m², relative humidity values declined from 74–77% at the inlet to 66–69% at the outlet; similarly, under higher radiation at 750 W/m², humidity levels decreased from 76–82% to 67–70%. These reductions, referenced in Figures 7 and 8, correspond to a dehumidification efficiency reaching up to 12.5%, based on Eq. (5).

This enhanced performance under elevated radiation levels is primarily attributed to the increased thermodynamic activity of the R-134a refrigerant, where higher ambient temperatures facilitate more intensive latent heat absorption and subsequent vapor condensation inside the heat pipes. As a result, the humidity ratio of the incoming air is significantly reduced before it reaches the evaporative cooling medium, thereby alleviating the latent cooling load. This pre-conditioning effect not only improves evaporative cooling effectiveness but also contributes to improved thermal comfort, as the system achieves a more substantial temperature drop with less residual indoor humidity. The integration of thermosyphon heat pipes thus proves to be a valuable passive enhancement for evaporative systems operating in humid tropical climates.

This pre-conditioning step alleviated the latent load on the evaporative pad, leading to an improved cooling effect with lower moisture saturation in the room. As a result, the evaporative cooling effectiveness, calculated using Eq. (4), increased in comparison to the baseline system. The air felt drier

and more comfortable, particularly during afternoon hours with peak solar radiation.

CONCLUSION

This study demonstrates the potential of integrating thermosyphon heat pipes with an evaporative cooling system to enhance indoor comfort in hot and humid climates. By pre-conditioning the incoming air, the system passively reduces moisture content before it reaches the evaporative pad, improving overall cooling efficiency. The hybrid design responded well to natural environmental conditions without the need for mechanical control, supporting its applicability in real-world settings. This passive approach offers a sustainable alternative to conventional air conditioning and holds promise for future use in energy-efficient building design.

A STUDY ON FLOOD INUNDATION ANALYSES AND HAZARD MAPPING APPROACHES FOR SMALL-SIZED RIVERS

Shengping Zhnag[1] and Jie Qi[2]

[1]Faculty of Urban Science, Meijo University, Japan;
[2] School of International Studies, Utsunomiya University, Japan

ABSTRACT

As global warming intensifies, heavy rainfall disasters have become dramatically more frequent. Although various mitigation strategies exist, disaster management experts almost unanimously assert that evacuation remains the most effective way to safeguard human lives. Consequently, accurate and reliable flood inundation data is essential for ensuring efficient evacuations. In Japan, flood hazard maps based on meticulous inundation analyses have been developed, disseminated, and widely used for major river basins to provide critical information. However, in smaller river basins, flood conditions are often influenced by runoff from larger downstream rivers, and the development of comprehensive watershed databases has lagged. As a result, performing precise flood inundation analyses is challenging, and dependable hazard maps are frequently unavailable. This study employs the iRIC (International River Interface Cooperative) model—a reliable and user-friendly tool for flood inundation analysis—to investigate the behavior of small-sized rivers and develop detailed 3D hazard maps. Verification of the analysis results and the resulting hazard maps confirmed their reliability. Ultimately, the proposed approach to flood inundation analysis and hazard mapping is expected to be a practical and highly effective asset for designing evacuation strategies and reducing casualties during flood disasters.

Keywords: Global Warming, Inundation Analyses, Evacuation Planning, Hazard Map, iRIC (International River Interface Cooperative)

INTRODUCTION

In recent decades, Japan has witnessed increasingly severe extreme weather events attributed to climate change, including record-breaking heavy rainfall occurring almost annually [1]. These events have caused widespread flooding and inundation exceeding urban flood control standards, as well as serious landslides, resulting in substantial economic losses and human casualties [2].

To mitigate damage from flood inundation, the reinforcement of hard infrastructure flood control measures is essential. However, such developments require significant financial investment and extended timelines, limiting their immediate effectiveness. Consequently, evacuation strategies have gained increased attention. Numerous cases demonstrate that timely evacuation can prevent fatalities, whereas delays or failures in evacuation exacerbate harm, highlighting the critical role of effective evacuation planning [2]. However, Japan is facing a pronounced demographic challenge, with individuals aged 65 and older constituting 29.1% of the population in 2023, projected to rise to 40% by 2050 [3]. This unprecedented aging population presents considerable obstacles to rapid evacuation.

To ensure efficient and reliable evacuation, local governments have developed evacuation plans supported by hazard maps that provide essential information such as inundation depths and extents, possible evacuation facilities and routes for various flood scenarios. While hazard map development is advanced in major river basins and metropolitan areas, smaller river basins have lagged behind. Often, disaster prevention plans for tributaries depend on finalized plans for downstream major rivers, resulting in numerous basins without adequate hazard maps [4].

This study employs the reliable and user-friendly iRIC (International River Interface Cooperative) flood simulation model to analyze inundation in small river basins [5]. Using the simulation results, we develop a three-dimensional flood hazard map aimed at securing smooth and rapid evacuation routes during floods. Finally, evacuation scenarios are simulated to enable virtual pre-experience of evacuation routes, thereby assessing the feasibility of prompt evacuation behavior.

RESEARCH SIGNIFICANCE

This study applies a comprehensive methodology for developing three-dimensional hazard maps for small- to medium-sized river basins, where obtaining reliable and detailed flood information is particularly challenging. The 3D hazard maps produced through this process enable users to identify suitable evacuation shelters, determine optimal evacuation routes, and estimate required evacuation time, thereby supporting the development of feasible and effective evacuation plans. Moreover, the application

of these 3D hazard maps facilitates the implementation of online evacuation drills, which are expected to make a significant contribution to reducing human casualties in the event of flooding. Furthermore, Combining the traditional inundation analysis model with the 3D mapping technology makes the hazard map generation procedure more reliable and easier.

INUNDATION ANALYSES

Inundation Analysis Model iRIC

iRIC (International River Interface Cooperative) is a free software platform designed for inundation analysis and numerical simulation of rainfall-runoff processes. Developed by the International River Interface Cooperative [5], iRIC supports a diverse range of computational solvers addressing various problems in water science and engineering [6]. Originally created as a tool for river flow and morphodynamic analysis, the software has since evolved to encompass a broad spectrum of applications, including flood prediction, rainfall-runoff modeling, tsunami propagation, debris flow simulation, habitat assessment, and other hydrological and hydraulic phenomena.

iRIC is widely used in Japan, and its reliability, flexibility, and user-friendly interface have been demonstrated through numerous reported case studies [7]. It is currently recognized by the Japanese government as one of the approved inundation analysis models that can be utilized in the formulation of river management plans [4]. Therefore, this study adopts the iRIC model for inundation analyses.

The specific hydrological and hydraulic details implemented within iRIC model are omitted here; readers are referred to the official iRIC manual for further information. The manual is available for download from the iRIC official website [6].

The Watershed for Inundation Analyses

This study has chosen the Oiwagawa River watershed located in Toyama Prefecture, Japan for inundation analyses. The location of the Oiwagawa watershed is shown in Fig.1. The Oiwagawa River is a tributary of the Shiraiwa River and is a small river with a total length of 12 kilometers. Originating from Takamine Mountain, which stands at an elevation of 958 meters, the river descends while forming deep V-shaped valleys and large waterfalls, eventually converging with the Shiraiwa River. Several settlements have developed around the small basin areas along the river. Repeated flooding of this river poses significant threats to the lives and properties of these inhabitants [8]. The Oiwagawa basin was selected as the subject of analysis with the aim of providing essential information for the evacuation of residents.

Fig.2 illustrates the specific inundation analysis area within the Oiwagawa watershed. The inundation analysis region encompasses a rectangular area measuring 1.3 kilometers in width and 8.0 kilometers in length, covering nearly the entire upstream watershed from the confluence with the Shiraiwa River to the exit of the Takamine Mountain valley.

The rectangular analysis area does not include four tributaries of the Oiwagawa River (Shioya River, Kakenana River, Futaguchi River, and Suyama River) and the very upstream segment of the Oiwagawa River that flows down the Takamine Mountain valley. The inflows from all the five rivers are inputted directly into the corresponding segments of Oiwagawa River with careful considerations of the runoff time in each river segment. Also shortened names of the five rivers are used for simplicity in this paper as Shio, Kake, Futa, Suya and Oiwa, respectively.

Fig.1 The location of the Oiwagawa River watershed

Fig.2 The inundation analysis area within the Oiwagawa River watershed

Setting Up the Analysis Conditions

To apply the iRIC model to the target river basin, it is essential to define both the basin conditions and the analysis parameters in advance.

First, topographic data of the study area is required. For this purpose, data provided by the Geospatial Information Authority of Japan (GSI) through its GPS system was utilized [9]. The GSI data was selected due to its high reliability.

Next, the river basin was discretized into a rectangular grid (cells) based on the topographic data described above. The grid comprises 200 cells along the river flow direction and 50 cells across the river width, resulting in individual cell dimensions of approximately 40.3 meters in length and 26 meters in width. This grid resolution was chosen in consideration of the trade-offs among topographic data accuracy, analysis duration, and computational cost.

A key parameter used to represent the hydrological characteristics of the river channel is Manning's roughness coefficient. The values adopted here are those traditionally used by Toyama Prefecture in previous flood analyses of the Oiwagawa River [10]. This choice allows for direct comparison and validation against prior results.

Furthermore, rainfall intensity must be specified as input for the flood inundation model. In the flood mitigation planning for this basin, Toyama Prefecture has already established standard design rainfall based on a 1-in-50-year return period. The rainfall intensity associated with this probability rainfall is defined by the following equation [11]:

$$\mathbf{r} = \frac{\mathbf{2019.92}}{\boldsymbol{t}^{\mathbf{0.76}} + \mathbf{7.680}} \quad (1)$$

where t is time in minutes and r is the rainfall intensity in mm/hr. The corresponding hyetograph for this design rainfall is presented in Fig. 3.

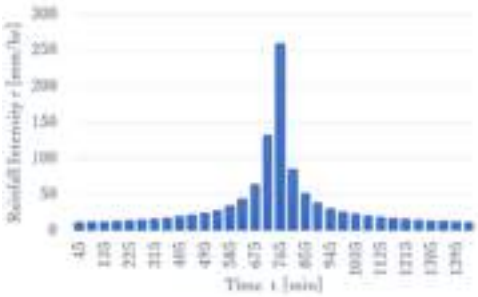

Fig.3 The hyetograph of the design rainfall

Finally, the study area receives inflows from several tributaries, including the upstream portion of the Oiwagawa River. The inflows from these tributaries must be predefined as input for the iRIC model. To estimate these inflows, the well-known Rational Method was employed:

$$\mathbf{Q} = \frac{\mathbf{1}}{\mathbf{3.6}} \boldsymbol{frA} \quad (2)$$

In this equation, Q represents the flow rate from a tributary (in m^3/s), f is the runoff coefficient (dimensionless), r is the rainfall intensity (mm/hr) as defined in Eq.(1), and A is the drainage area of the tributary (in hectares).

Using Eq. (2), the flow rates for five tributaries—Oiwa, Futa, Suya, Shio, and Kake—were calculated. The resulting hydrographs are presented in Fig. 4.

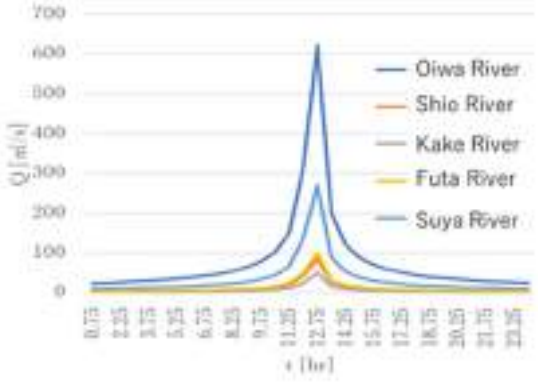

Fig.4 The hydrographs of the five inflowing tributaries

Inundation Analysis Results

Using the analysis conditions established in the previous section, the iRIC model was applied to the target watershed. As a result, the extent and depth of inundation caused by the design rainfall were obtained.

Fig.5 illustrates the inundation depth at the time of peak discharge (t = 46,800 seconds) at the downstream end of the simulation domain. The areas where inundation water depths are less than 0.01m are not shown in this figure because these water depths are considered will not cause any more problems for evacuation activities than the heavy rainfall itself. Fig.6 shows the maximum inundation depth recorded in each computational cell during the whole design rainfall event. It should be noted that the timing of these peak depths varies across cells. Nevertheless, the maximum inundation depth is particularly important when considering evacuation planning.

Fig.7 shows the planned inundation scenario for the target river basin currently published by Toyama Prefecture [12]. It has already been confirmed that this published scenario contains calculation errors [13], and a reassessment is currently being conducted by the prefectural authorities to evaluate the impact of those errors. In comparison, the flood assessment conducted in the present study reveals a wider inundation extent and greater inundation depths, indicating a more severe flood scenario than previously reported.

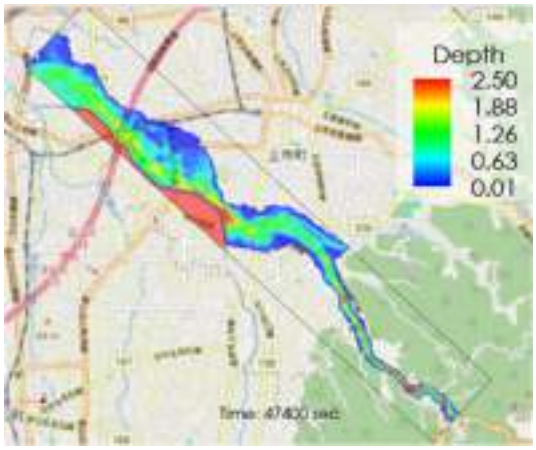

Fig.5 The inundation depth(m) when the downstream discharge reached the maximum

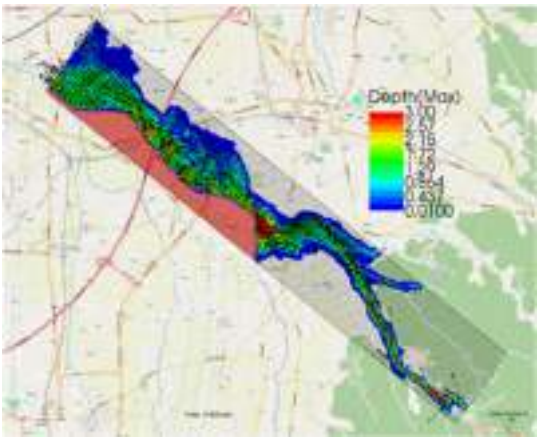

Fig.6 The maximum inundation depth(m) during the whole runoff process.

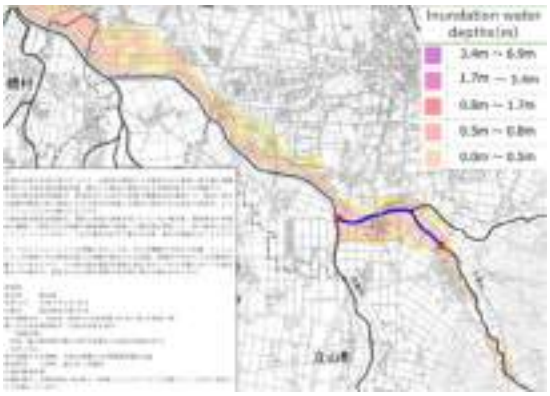

Fig.7 The current inundation scenario for Oiwagawa watershed published by Toyama Prefecture [12] (The analysis river segment for this study is between the two red dots.)

GENERATE INUNDATION HAZARD MAPS

2-Dimentional Hazard Map

By overlaying the inundation depth results obtained from the flood simulation described in the previous section with various digital maps, it is possible to generate different types of hazard maps tailored to specific purposes.

First, a two-dimensional hazard map was created by superimposing the maximum inundation depths during the design rainfall event (as shown in Fig.6) onto Google Maps. Fig.8 presents an image illustrating the overlay process, and Fig.9 shows the base version of the resulting two-dimensional hazard map. Naturally, to complete this hazard map, additional information—such as the locations of evacuation facilities—should be overlaid as well. However, such information is already well-maintained by local governments in Japan, and thus that step is omitted in this discussion.

3-Dimentional Hazard Map

Next, the creation of a three-dimensional hazard map is described. Similar to the 2D map, the 3D hazard map is produced by overlaying the flood simulation results onto digital map data. In this case, however, Google Earth is used as the base platform, and Google Street View is also incorporated to enhance the spatial context. Fig.10 and Fig.11 show examples of 3D hazard maps for two different locations.

Results and Discussion

This three-dimensional hazard map generated above allows users to visually assess the extent of inundation in specific areas, including around evacuation facilities, offering an intuitive understanding of the flood situation at points of interest. Additionally, users can evaluate the inundation conditions along potential evacuation routes, which aids in selecting safer paths. Once the evacuation facilities and routes are identified, the 3D hazard map can be used to estimate evacuation times, enabling the development of more realistic and effective evacuation plans.

The primary advantage of this 3D hazard map lies in its use of familiar platforms—Google Earth and Google Street View—which are widely used in daily life. While many disaster-specific systems have been developed, historical evidence has repeatedly shown that unfamiliar systems are often ineffective during actual emergencies.

Moreover, the 3D hazard map holds great promise as a tool for disaster education. Traditional 2D hazard maps were typically used only for passive viewing. In contrast, the 3D map, combined with Google Street View, offers high interactivity, allowing users to

engage directly with the data and explore affected areas more actively. This interactivity is especially promising for engaging younger generations, who have consistently shown lower disaster awareness in various public surveys.

Fig. 8 Generate 2-dimentional inundation hazard map

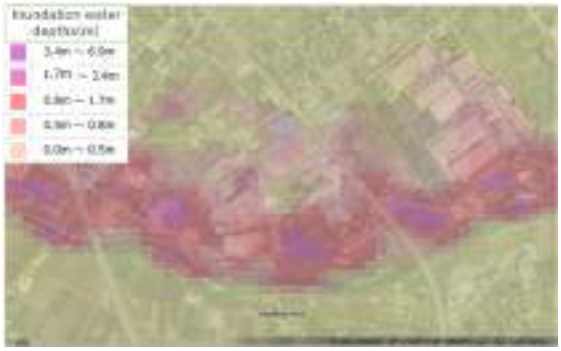

Fig.9 The final 2-dimentional inundation hazard map

Fig.10 The 3-dimentional inundation hazard map at Street-A where the water depth is 1.68m.

Fig.11 The 3-dimentional inundation hazard map at Street-B where water depth is 1.21m.

CONCLUSIONS

This study has been conducted to provide reliable and detailed flood hazard information for small- to medium-sized river basins. These basins are typically located upstream of major rivers and are often treated merely as tributaries within the broader flood management systems of major river basins. As a result, disaster-related information for these areas is frequently generalized, with data often presented as single-point or single-segment information. Such limited granularity makes it nearly impossible to formulate reliable and feasible evacuation plans. Consequently, preventable damages have occurred in many cases.

This study has also utilized the versatile runoff analysis model iRIC to simulate flood inundation extents and water depths under designed rainfall scenarios specifically for small- to medium-sized river basins. The simulation results were overlaid onto digital maps to enhance traditional two-dimensional hazard maps. Furthermore, we developed three-dimensional hazard maps by integrating these results with Google Earth and Google Street View, thereby offering a more immersive and spatially intuitive representation of flood risk.

These enhanced hazard maps provide residents living in small-sized river basins with more detailed and accessible flood risk information. This facilitates easier selection of evacuation shelters and routes, confirmation of evacuation timing, and ultimately supports the development of more reliable and actionable evacuation plans. The approach is expected to contribute significantly to the reduction of avoidable disaster damage.

The methodology employed in this study establishes a practical framework for generating hazard maps tailored to small-sized and medium-sized river basins. Future work will focus on gathering feedback from local residents using these hazard maps to identify areas for improvement. Additionally, the potential of these 3D hazard maps as effective tools for disaster education will be further explored through practical applications.

ACKNOWLEDGMENTS

The authors would like to express their sincere gratitude to the International River Interface Cooperative for generously providing the iRIC runoff analysis software free of charge. Through the course of this study, the authors were able to confirm the reliability of the iRIC model and the user-friendliness of its interface. The authors also wish to extend their appreciation to Mr. Teruma Nakamura, a student in the Laboratory of Water Resource Planning at Meijo University, Japan, for his significant contributions to the collection, organization, and analysis of relevant

data and materials.

ENHANCING FLOOD RESILIENCE THROUGH UPDATED IDF CURVES: LESSONS LEARNED FROM RECENT EXTREME RAINFALL EVENTS IN THE UAE

Khalid B. Almheiri[1] and Rabee Rustum[2]

[1]School of Energy, Geoscience, Infrastructure and Society, Dubai Campus, Heriot-Watt University, Dubai, United Arab Emirates

ABSTRACT

Sharjah in the United Arab Emirates (UAE) has experienced unprecedented extreme rainfall, exposing vulnerabilities in its urban drainage systems. This study recalibrates Intensity–Duration–Frequency (IDF) curves based on extended and refilled rainfall data from 1992 to April 2024, and employs a Kohonen Self-Organizing Map (KSOM) to reconstruct missing sub-daily data. Extreme-value distributions were fitted via non-stationary frequency analysis to incorporate climate covariates, including cloud-seeding activity. The revised curves show peak intensities up to 41 percent higher for 10-year return periods and increased short-duration sensitivity. Benchmarking against Kuwait and Qatar confirms that Sharjah's rainfall intensification exceeds neighboring trends, underscoring the inadequacy of old design storms. Infrastructure evaluations identify capacity deficits under updated conditions. Recommended measures include five-year IDF recalibration, integration of sustainable urban drainage systems, deployment of real-time monitoring networks, and establishment of a Gulf-wide data-sharing consortium. The methodology offers a repeatable framework for dynamic stormwater design and management. These actions will align design standards with evolving hydro-climatic realities and strengthen flood resilience across arid urban environments.

Keywords: cloud-seeding; comparative study; Intensity-Duration-Frequency (IDF) Curves; rainfall; Sharjah.

INTRODUCTION

Urban flooding has emerged as a major hydrometeorological challenge in arid and semi-arid regions, where rainfall events tend to be infrequent but intense. The United Arab Emirates (UAE), and particularly the Emirate of Sharjah, has witnessed increasingly irregular and extreme rainfall events over the past decade. These events have exposed critical vulnerabilities in the stormwater management systems of many rapidly urbanizing cities. Sharjah, characterized by its flat topography, high degree of surface impermeability, and dense built environment, has been especially prone to urban flooding when short-duration, high-intensity storms exceed the design capacity of existing drainage infrastructure, and in many urbanized areas, stormwater networks are either non-existent or only partially implemented.

Intensity-Duration-Frequency (IDF) curves are among the most fundamental hydrological and urban infrastructure design tools. They are used to estimate the expected intensity of rainfall over varying durations and recurrence intervals, guiding the sizing of culverts, storm drains, storage basins, and flood protection measures [1]. Conventional IDF curves are often derived from limited historical data, emphasizing daily rainfall totals rather than short-duration, high-intensity events. This neglects the critical need for actual and accurate records that reflect the true nature of storm events, which in arid urban environments like Sharjah often last just a few hours and are the main contributors to urban flooding [2]. Moreover, these curves usually assume climatic stationarity, which is an increasingly outdated premise due to the growing influence of climate change and cloud-seeding interventions. In the UAE, cloud-seeding operations have increased rainfall, but also unintentionally altered precipitation patterns, making traditional IDF models less reliable.

Recent flooding events, including those in March 2016, January 2020, and most notably April 2024, have demonstrated the consequences of using outdated IDF data that do not reflect the current or future precipitation regime. These events caused widespread urban disruption, economic losses, and safety hazards. For instance, the April 2024 event overwhelmed Sharjah's existing stormwater system within the first hour of rainfall, causing severe road and property inundation, as shown in figures 1(a) and 1(b) and figures 2(a) and 2(b).

Fig.1(a) and 1(b) Partial and Total Vehicle Submersion.

Fig.2(a) and 2(b) Rainwater Flooding of Major Roads.

These failures underscore the necessity for a more adaptive and precise approach to rainfall estimation and drainage system design, supported by updated IDF curves that reflect the local context's specific climatic and environmental conditions.

This paper addresses these challenges by recalibrating Sharjah's IDF curves using extended and corrected rainfall records from 1992 to 2024. It employs Kohonen Self-Organizing Maps (KSOM) to reconstruct missing data and validate the results against hourly records from the nearby Dubai Airport weather station, supplemented by archived photographs capturing flooded roads and inundated properties throughout Sharjah. The objective is to demonstrate how revised IDF models can enhance flood resilience and inform a new generation of policy and planning interventions aligned with emerging climatic and urban development realities.

Research Significance

This study highlights the urgent need to update IDF curves in the UAE following recent rainfall extremes and evolving hydrometeorological conditions. By revealing the inadequacy of existing drainage infrastructure under revised intensities, it emphasises the critical role of accurate rainfall characterization in urban flood mitigation planning and resilient infrastructure design.

METHODOLOGY

This study follows a structured three-stage methodology: first, data acquisition and enhancement; second, IDF curve derivation; and third, regional benchmarking. The aim is to update IDF curves and assess their implications for urban flood resilience in the Sharjah Emirate.

Description of the Study Area

Sharjah, the third-largest emirate in the United Arab Emirates, covers 2,564 km² along the southern shore of the Arabian Gulf, and is geographically bounded by latitudes 25.2° N to 25.4° N and longitudes 55.4° E to 55.6° E [3]. As shown in Figure 3, it is bordered by Ajman and Al Umm Al Quwain to the north, Fujairah and Ras Al Khaimah to the east and southeast, and Dubai to the south.

Fig.3 Sharjah Emirate location and its three regions within the UAE [4].

Although the emirate includes both rugged mountain terrain in the east and broad central plains, the western urban core, Sharjah City, now contains the bulk of its residential and commercial development.

Sharjah City has become a compact metropolitan area with extensive impermeable surfaces and occasional yet intense convective storms. Urban expansion has exceeded the capacity of the city's drainage system, substantially increasing its flood vulnerability and underscoring the urgent need for adaptive, resilience-focused stormwater management strategies.

Data Acquisition and Enhancement

Rainfall records from January 1992 to April 2024 were compiled from the UAE National Centre of Meteorology (NCM) and Sharjah municipal archives, as consolidated by [1], [2]. To address missing observations, particularly during the 1990s, short-interval gaps were infilled using Kohonen Self-Organizing Maps (KSOM), trained on both local Sharjah gauge data and concurrent hourly records from the Dubai Airport station. This unsupervised neural network technique projects high-dimensional datasets onto a lower-dimensional grid while preserving topological relationships among data points. The algorithm identifies similarity patterns within the available data, enabling robust infilling of incomplete time series.

In this study, KSOM was applied to reconstruct missing sub-daily rainfall records from the 1990s and early 2000s. Previous regional applications have

demonstrated its validity and effectiveness for hydrological datasets, particularly in data-sparse environments [5], [6]. Its integration in this analysis supported the development of more accurate IDF curves by extending the historical rainfall record with statistically consistent values.

The dataset employed in this study was initially developed by the authors [1], [2]. The complete rainfall series was then divided into pre-seeding (1992–2009) and post-seeding (2010–2024) periods to isolate the effects of cloud-seeding operations. Validation of the reconstructed dataset involved statistical comparison with Dubai Airport hourly measurements to ensure quantitative accuracy and physical corroboration against archived photographs, confirming that extreme events were accurately represented over time [2].

IDF Curve Derivation

Annual maximum rainfall depths were extracted from 10 minutes to 24 hours at each station. Frequency analyses employed the Generalized Extreme Value (GEV) distribution, with parameters estimated via Maximum Likelihood Estimation. Model adequacy was assessed using Kolmogorov–Smirnov and Anderson–Darling goodness-of-fit tests to ensure robust extreme-value characterization. Separate intensity-duration-frequency points for return periods of 2, 5, 10, 25, 50, and 100 years were fitted to continuous parametric equations through nonlinear regression. Daily maxima were temporally disaggregated for design-level applications using standardized reduction factors from the Sharjah Storm Drainage Manual. This approach ensured consistency across timescales and enhanced the practical utility of the revised curves. For full procedural details, refer to [1].

Regional Benchmarking

Published IDF datasets for Kuwait [7] and Qatar [8] were standardized to match Sharjah's revised curves over 10 minutes to 24 hours and return periods of 2 to 100 years. Comparative metrics of intensity ratios at each return period, curve steepness, and short-duration sensitivity were calculated, and paired t-tests determined the significance of observed differences. This regional benchmarking validates the internal consistency of Sharjah's updated IDF values against neighbouring standards and highlights how cloud-seeding has altered rainfall extremes in the UAE relative to other Gulf countries.

RESULTS

This section provides the quantitative foundation for this study. Section 3.1 compares old (1992–2020) and revised (2021–April 2024) IDF curves across multiple durations and return periods, quantifying peak-intensity variation. Section 3.2 then benchmarks Sharjah's updated curves against published datasets for Kuwait and Qatar, employing paired t-tests to confirm statistically significant regional differences. These findings explore the accuracy of old IDF curve values relative to the recently updated values and assess the necessity of further regional calibration.

Revised IDF Curve Characteristics

The recalibration incorporates additional rainfall data from January 2021 through April 2024, extending the record used in the original 2020 analysis. Table 1 compares the (OLD) IDF values, derived from January 1992 to December 2020 records, and the revised (NEW) values updated with data through April 2024. Across all combinations of storm duration (10 - 120 minutes) and return period (2 -10 years), the updated intensities exceed the old values by (37 - 41) %, with the most significant relative increases occurring at the shortest durations, as compared in Table 1.

Table 1 Comparison of Old and New IDF Curves for Sharjah

Return Period	Duration Minutes	IDF OLD* (mm / h)	IDF NEW** (mm / h)	Percent Increase
2-year	10	25.09	34.96	39.3
	20	17.50	24.38	39.3
	30	13.88	19.34	39.3
	60	9.11	12.70	39.4
	120	5.85	8.15	39.3
3-year	10	39.32	55.46	41.0
	20	27.42	38.68	41.1
	30	21.75	30.68	41.1
	60	14.28	20.14	41.0
	120	9.16	12.93	41.2
5-year	10	55.42	78.30	41.3
	20	38.65	54.60	41.3
	30	30.66	43.31	41.3
	60	20.13	28.43	41.2
	120	12.92	18.25	41.3
10-year	10	77.70	106.99	37.7

20	54.19	74.61	37.7
30	42.98	59.18	37.7
60	28.22	38.85	37.7
120	18.11	24.94	37.7

Notes:
** OLD: Based on January 1992–December 2020 records.*
*** NEW: Includes additional rainfall data from January 2021 to April 2024.*

Comparative analysis of the updated and old IDF curves for Sharjah City reveals a clear upward shift in rainfall intensity across all durations and return periods, with the most pronounced relative increases occurring at shorter durations and lower return periods.

At the 2-year return period, the 10-minute intensity climbed from 25.09 to 34.96 mm/h, a 39.3 % increase, while the 60-minute intensity rose from 9.11 to 12.70 mm/h (39.4 %) as illustrated in Figure 4.

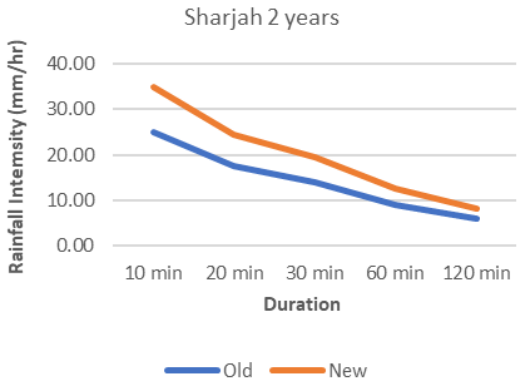

Fig.4 Increase in IDF Curve Values for Sharjah City's 2-Year Return Period.

For the 10-year return period, the 30-minute intensity increased from 42.98 to 59.18 mm/h, representing a 37.7 % rise, as illustrated in Figure 5.

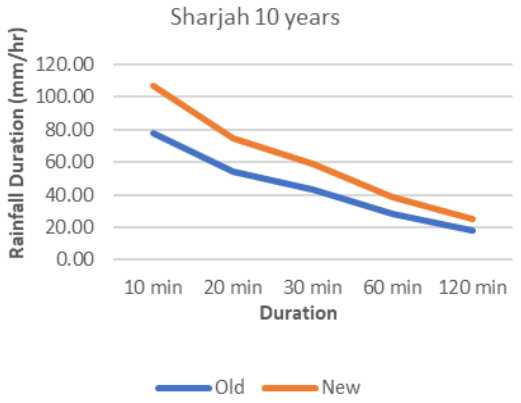

Fig.5 Increase in IDF Curve Values for Sharjah City's 10-Year Return Period.

At the 100-year return period, the 30-minute intensity grew from 83.37 to 108.88 mm/h, representing a 30.6 % increase, as shown in Figure 6.

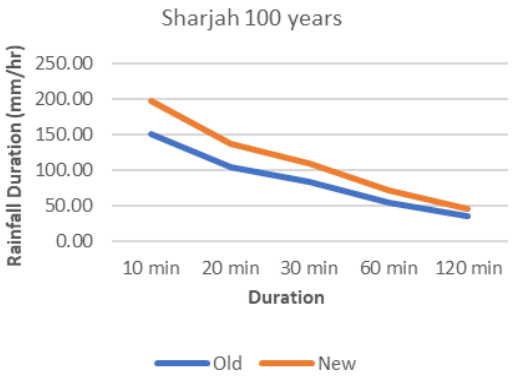

Fig.6 Increase in IDF Curve Values for Sharjah City's 100-Year Return Period.

Overall, these upward trends signal more frequent and intense rainfall events in Sharjah City, underscoring evolving regional climate patterns and the urgent need to reinforce flood-resilience measures across the urban landscape.

Regional Benchmarking

Sharjah's revised IDF characteristics were compared directly with recent curves for Kuwait [7] and Qatar [8]. All datasets were aligned to durations of 10 minutes, 1 hour, 24 hours, and return periods of 2 to 100 years. Three key metrics were evaluated: absolute intensities at selected durations, the GEV shape parameter (α), and a short-duration sensitivity index (10 min / 1 h intensity), as shown in Table 2.

Table 2 Comparison of Sharjah's Metrics with Kuwait and Qatar

Metric	Sharjah	Kuwait	Qatar
10-min, 10-yr intensity (mm/h)	78.39	70.50	74.20
1-hr, 10-yr intensity (mm/h)	51.50	45.90	48.70
24-hr, 10-yr intensity (mm/h)	101.20	90.30	93.60
GEV shape parameter (α)	0.28	0.24	0.26
Short-duration sensitivity index *	0.85	0.74	0.78

** Short-duration sensitivity index = (10 min intensity) / (1 hr intensity)*

Statistical paired t-tests on the matched 10-year return-period intensities show that Sharjah's mean rainfall values are significantly higher than those of Kuwait ($p = 0.012$) and Qatar ($p = 0.028$).

DISCUSSION

This section interprets the implications of the updated IDF curves and regional benchmarks across five themes: storm intensification, urbanization impacts, cloud-seeding influences, non-stationary modelling, and integrated management.

Intensification of Short-Duration Storms

The updated IDF curves reveal marked increases in peak intensities for the shortest durations, fundamentally altering Sharjah's storm hazard profile. For Sharjah City, comparing NEW (2021–April 2024) against OLD (1992–2020) values shows:

In the two-year return period, the 10-minute intensity rose from 25.09 mm/h to 34.96 mm/h (39.3 %), the 20-minute intensity increased from 17.50 mm/h to 24.38 mm/h (39.3 %), and the 30-minute intensity climbed from 13.88 mm/h to 19.34 mm/h (39.3 %).

At the ten-year return period, the 10-minute intensity jumped from 77.70 mm/h to 106.99 mm/h (37.7 %), the 20-minute intensity rose from 54.19 mm/h to 74.61 mm/h (37.7 %), and the 30-minute intensity increased from 42.98 mm/h to 59.18 mm/h (37.7 %).

This concentration of rainfall into shorter events drastically reduces available warning times. These storms formerly peaked over an hour, now reach maxima in under 30 minutes, and can overwhelm drainage systems designed for lower peak rates.

Across Sharjah City, short‑duration rainfall intensities rose by an average of 36.76%, signalling a shift toward storms with greater urban flood potential. These steeper peaks require updating design storm parameters and enhancing early warning and emergency response protocols to accommodate these more extreme events.

Urbanization and Runoff Dynamics

The transformation of Sharjah over recent decades from sparsely developed desert landscapes to a densely built urban environment has markedly increased surface impermeability. With expansive paved streets, compacted yards, and rooftops covering much of the city, rainfall that once percolated into the ground is routed immediately into storm drains. When paired with the substantially higher short-duration intensities revealed by the revised IDF curves as discussed earlier, this land-use shift exposes a critical mismatch between rainfall inputs and drainage capacity [9].

Existing networks were originally engineered using old IDF values that underestimate peak intensities by up to 41% for 10-year return period storms. Under current conditions, runoff volumes during a 30-minute design storm exceed conduit capacity within the first 20 minutes, leading to rapid surcharge and surface flooding [2]. Field inspections after the April 2024 event confirmed that although structurally sound, major culverts and open channels were hydraulically overwhelmed by inflows far beyond their design thresholds.

This deficit underscores two imperatives. First, drainage design must be recalibrated using the updated IDF curves so that pipe diameters, invert slopes, and detention requirements reflect actual peak flows. Second, urban planners and infrastructure managers should combine on-site stormwater retention including green roofs that capture and slowly release rainfall, permeable pavements that allow infiltration, rain gardens that store and naturally filter runoff, and underground reservoirs that hold excess water with staged-release controls and real-time flow monitoring to replace the buffering once provided by natural soils. On-site retention captures and stores stormwater at its source, staged-release controls temporarily detain runoff in basins or vaults before discharging it at measured intervals, and real-time flow monitoring uses sensor networks to track conveyance flows instantaneously and adjust release rates as needed. Together, these measures smooth out peak flows and help prevent sudden surges of stormwater runoff. By aligning network design and operational procedures with enhanced rainfall intensities and the prevailing high-impermeability land cover, Sharjah can substantially improve flood resilience.

Cloud-Seeding Influences

After 2010, cloud-seeding in the UAE increased significantly, altering rainfall characteristics by intensifying convective storms and changing intensity-duration profiles. A prior study found that cloud-seeding increased peak rainfall intensities in Sharjah and advised regular re-evaluation of urban stormwater drainage and updating IDF data for changing precipitation trends [1].

Building on earlier analyses, this study employed segmented IDF derivation to assess the impact of intensified cloud-seeding operations on rainfall

behaviour. The rainfall series was divided into two distinct periods: 1992 to 2009 (pre-seeding) and 2010 to 2024 (post-seeding) to isolate potential anthropogenic influences. Analysis of the recalibrated IDF curves revealed an approximate 36.8 % increase in average short-duration rainfall intensities during the post-seeding period. This trend is consistent with previous findings [2], which reported statistically significant intensification of convective storm events in the UAE following the escalation of cloud-seeding activities. The results highlight the importance of integrating cloud-seeding parameters as dynamic covariates in future IDF modeling frameworks.

To maintain infrastructure resilience, IDF recalibration protocols should quantify cloud-seeding contributions by incorporating seeding activity records as covariates in non-stationary extreme-value models. These protocols should also align curve updates with seeding program schedules. By integrating cloud-seeding influences into the IDF methodology, design standards can adapt to both natural climatic variability and cloud-seeding consequences.

Climatic Non-Stationarity and Uncertainty

Rainfall patterns in the UAE have changed significantly, rendering traditional stationary models and old IDF curves unreliable due to their assumption of a stable climate. The April 2024 floods, the most severe on record, highlighted this disconnect and showed that historical data can no longer bound future risks.

Two interconnected challenges lie at the heart of this issue. First, extreme rainfall events are non-stationary: as temperatures rise and convective systems evolve, peak intensities' statistical parameters shift over time. Using fixed-parameter fits may result in lower estimates of critical design storms, potentially affecting safety margins. Second, although the study records now run from 1992 to April 2024, sub-daily measurements remain sparse outside recent years. Limited availability of sub-daily rainfall observations undermines the reliability of extreme-event intensity estimates. This increased uncertainty complicates the selection of appropriately conservative design storms, thereby increasing infrastructure vulnerability to severe future rainstorms.

Overcoming these challenges requires a modernized approach to IDF curve development. Frequency analyses must be non-stationary, with extreme-value distribution parameters linked to measurable climate covariates such as temperature trends or cloud-seeding activity. Robust uncertainty quantification techniques, such as Bootstrap or Bayesian methods, can be applied to define confidence bounds on design intensities. IDF curves should then be updated every three to five years in accordance with World Meteorological Organization guidance. Embedding non-stationarity and quantified uncertainty into design tools will enable engineers and planners to develop infrastructure capable of withstanding both current extremes and those projected in the future.

Integrated Management and Policy Recommendations

To translate the insights from updated IDF curves into lasting resilience, Sharjah’s flood management framework must evolve along four complementary dimensions. First, municipal drainage regulations should be revised to require the use of the 1992–2024 dataset with adjustments for cloud-seeding effects in all new infrastructure projects and major rehabilitations. A formal five-year review cycle will align IDF curves with the latest climatological observations and seeding records.

Second, real-time monitoring and adaptive operations are essential. Deploy a network of IoT-enabled rain gauges and flow sensors across critical watersheds, integrated into an automated platform that continuously recalibrates short-duration intensity estimates. When observed rainfall rates exceed design thresholds, the system would issue alerts, adjust detention basin controls and activate emergency response protocols.

Third, expansion of sustainable urban drainage systems (SuDS) must be enforced for all new developments. On-site detention and infiltration measures such as permeable pavements, green roofs, and bio-retention swales should be sized to reduce at least the one-hour, 10-year design storm. Existing corridors can be modified with modular storage units or shallow infiltration trenches designed to reduce peak flows to the maximum capacity available in the corridors.

Finally, institutional capacity and regional coordination must be strengthened. Establish a Gulf-wide IDF consortium to harmonize data sharing, benchmarking, and best-practice exchange. Provide

workshops on extreme-value analysis and cloud-seeding for municipal engineers and embed these topics both in university degree programs and in the certification and continuing education requirements for licensed engineers to enhance flood resilience across the region.

Summary of Key Findings

The analysis yielded several critical findings with direct implications for rainfall characterization, infrastructure planning, and flood resilience in Sharjah.

Intensification of Short-Duration Rainfall

The revised IDF curves for Sharjah revealed substantial increases in short-duration rainfall intensities compared to the 1992–2020 dataset. Peak values rose by up to 41%, particularly for the 10-minute duration and return periods between 2 and 10 years, which are crucial for urban drainage design and risk management.

Concentration of Rainfall and Infrastructure Overload

Short-duration storm events have become more intense, with average rainfall intensification reaching 36.76%. This compression of storm durations reduces available warning time and has exceeded the design thresholds of pre-existing drainage systems, resulting in more frequent surcharging and surface flooding.

Regional Comparisons and Statistical Significance

Benchmarking against updated IDF datasets for Kuwait and Qatar confirmed that Sharjah's intensification trend exceeds regional norms. Paired t-tests at the 10-year return period demonstrated statistically significant differences ($p = 0.012$ for Kuwait; $p = 0.028$ for Qatar), underscoring the localized impact of urban densification and cloud-seeding activities, and the need for emirate-specific design standards.

Cloud-Seeding and Modeling Enhancements

In the period after 2010, rainfall intensities increased markedly in alignment with expanded cloud-seeding operations in the UAE, indicating a significant anthropogenic influence on Sharjah's evolving intensity–duration profile. This shift underscores the importance of incorporating cloud-seeding activity records as covariates in non-stationary modeling frameworks. Additionally, the use of KSOM for rainfall reconstruction, alongside climate-based extreme-value analysis, provided a more accurate and dynamic representation of present and future storm hazards than traditional stationary approaches.

POLICY RECOMMENDATIONS

Building on the empirical findings presented in Section 4 and expanding upon insights from the author's previous studies (2021; 2024), the following policy actions are proposed to enhance flood resilience and guide infrastructure adaptation strategies in Sharjah. These recommendations reflect both new contributions from the present analysis and a combination of best practices from the wider hydrological literature.

The first step is institutionalizing regular IDF recalibration. Every five years, the NCM and Sharjah Municipality should jointly review and update IDF curves using the latest sub-hourly rainfall records, including cloud-seeding data and non-stationary extreme-value methods. This five-yearly process will keep design parameters aligned with current and emerging precipitation patterns and prevent infrastructure from falling behind evolving climatic risks.

Complementing recalibration, an expanded real-time monitoring network will capture critical sub-hourly rainfall and runoff data across urban and peri-urban catchments. Deploying IoT-enabled rain gauges and flow sensors linked to a centralized open-access platform, integrated with GIS-based forecasting and early-warning systems, can allow dynamic calibration of design storms and rapid operational adjustments during extreme events.

Stormwater design codes should be rewritten to focus on performance. Engineering teams and relevant departments must update their standards so that all hydraulic models use the revised IDF values. They must also set clear limits on how much water can back up in pipes (surcharge depths) and collect on surfaces (ponding) during 10-year and 50-year storms. By tying code compliance to these measurable criteria, both new pipelines and retrofitted systems will reliably handle more intense peak flows while preserving required safety margins.

Urban zoning regulations must evolve in response to changing climate conditions. Planning authorities should employ scenario-based IDF simulations to identify flood-prone areas and limit development in those high-risk zones. At the same time, they can

incentivize the use of green infrastructure such as permeable pavements and retention basins that capture and reduce peak runoff.

Finally, capacity building and regional collaboration are essential for sustaining adaptive flood resilience. Ministries of Water Resources, universities, and engineering societies across the Gulf are encouraged to establish a consortium for hydro-meteorological data sharing, joint benchmarking, and coordinated updates. Supporting graduate research fellowships and professional workshops on advanced hydrological modeling, such as non-stationary frequency analysis and KSOM reconstruction, will develop the technical expertise and institutional frameworks needed to confront future extremes.

CONCLUSIONS

Revised IDF curves for Sharjah reveal up to 41 percent higher peak intensities at short durations, directly exposing critical design gaps in existing drainage infrastructure that contributed to the rapid failures of the system during the April 2024 flood. By integrating non-stationary extreme-value analysis, KSOM-based reconstruction of missing observations, and Gulf-wide benchmarking, this study establishes a robust, repeatable framework for dynamic IDF updates.

Statistical analysis confirms that rainfall intensities in Sharjah have risen significantly since 2010. Moreover, pronounced spatial differences across the local gauge network show that relying on regional or uncertain rainfall records can misrepresent actual conditions, underscoring the need for site-specific calibration. When set against IDF curves from Kuwait and Qatar, Sharjah's rate of intensification is higher, reinforcing the case for adapted, city-specific design standards rather than uniform regional models.

These findings have significant consequences for urban communities and infrastructure resilience, as undersized drainage conduits can transform even moderate storms into severe flood events that trigger costly road closures, property damage, and emergency response operations. Regularly updating IDF curves to reflect observed extremes will ensure design storms align with reality and help prevent system failures. Embedding the study's methodology in a formal review cycle can institutionalize adaptive drainage standards and accelerate their regulatory adoption. In contrast, the integration of updated IDF curves with sustainable urban drainage systems, real-time monitoring networks, and performance-based design codes will create multiple layers of protection and redundancy against urban floods.

Resilient urban drainage systems must evolve through iterative, data-driven processes. This begins with continuous real-time monitoring via IoT-equipped rain gauges and flow sensors that feed into automated platforms. This allows design storms to be recalibrated as new extremes are observed. Quantifying uncertainty with bootstrap or Bayesian techniques will provide confidence bounds on those design intensities, supporting decisions that appropriately balance risk and cost.

Adaptive modelling frameworks that integrate climate covariates, such as rising temperature trends or records of cloud-seeding activity, will further strengthen future infrastructure planning. At the same time, a Gulf-wide consortium for hydro-meteorological data sharing, joint benchmarking, and coordinated updates will bind regional expertise and resources. By moving away from static design storms and toward ongoing, science-driven updates, Sharjah and other arid cities can better protect critical infrastructure, protect vulnerable communities, and maintain flexible planning in the face of a changing climate.

AKNOWLEDGMENTS

The authors gratefully acknowledge Sharjah Municipality, the National Centre of Meteorology, and Heriot-Watt University Dubai for providing essential data, modeling support, and collaborative opportunities.

HEAVY METAL CONCENTRATIONS OF CICADA SHELL AND CICADA ADULT IN JAPAN

Hiroyuki Ii[1]

[1]Faculty of Systems Engineering, Wakayama University, Japan

ABSTRACT

Japan has many heavy metal mines and many abandoned waste disposal sites, so heavy metal contamination of soils has become a major problem. Heavy metals in soils are either soluble or insoluble, and not all heavy metals in soils are available to living organisms. Plants collect heavy metals from soils and accumulate them mainly in their roots, with low concentrations in the above ground parts. Cicada larvae live in the soil by sucking sap from the roots. It is believed that the larvae and the above ground cicada shells concentrate heavy metals, so the heavy metal characteristics of cicada shells were investigated. The concentrations of Fe, Mn, Ni, As, Pb, and Ag in cicada shells were higher than those of adults, and it was found that cicadas discard Fe, Mn, Ni, As, Pb, and Ag into their shells when molting. Zn was higher in adults, and Cu was almost the same. The concentrations of Ni, As, Pb, and Ag in cicada shells vary greatly depending on geology and soil conditions, and no differences were observed between species, so they are thought to be excellent indicators of soil contamination. The concentrations of Fe, Mn, Zn, and Cu in cicada shells do not reflect geology or soil conditions. There are interspecific differences in Cu, Zn, and Mn, with the large brown cicada tending to have significantly higher Cu and lower Mn and Zn than other species. No interspecific differences were found in Fe.

Keywords: Cicada shell, Cicada adult, Heavy metal, Metal mine, Contamination

INTRODUCTION

Excessive heavy metals found in factory and mine sites are toxic to living organisms, so in order to investigate the effects of heavy metals on native organisms such as plants, insects, and animals, soil must be excavated and the heavy metal concentrations in the soil measured, as shown in Figure 1. Generally, heavy metals in soil are either soluble or insoluble, but organisms only utilize soluble metals, and insoluble metals gradually become soluble. Not all heavy metals in soil are utilized by organisms, and metal concentrations in soil are not necessarily useful as an indicator of the impact of heavy metals on life. Therefore, in order to monitor heavy metal concentrations in organisms, it is necessary to show the actual transfer of heavy metals from soil to organisms. Ii [1,2] shows that the heavy metal concentrations of collected mosses fluctuate greatly and increase depending on the heavy metal contamination situation. Therefore, mosses were considered to be a good indicator of soil heavy metal contamination. However, mosses do not have deep roots, so their heavy metal concentrations are only affected by the heavy metal concentrations in the surface soil.

Trees get nutrients from their roots and take root in deep soil. In general, the heavy metal concentrations in tree roots are much higher than those in tree leaves and trunks [3,4]. Meanwhile, cicada larvae obtain nutrients from tree roots. Therefore, the heavy metal concentrations in cicadas depend on the heavy metal concentrations in tree roots, and ultimately on the heavy metal concentrations in deep soil [5,6,7,8], as shown in Figure 2. Cicada shells can be easily collected from trees above the soil. Therefore, the purpose of this study is to confirm that the heavy metal concentrations in cicada shells depend on heavy metal contamination in soil and that cicada shells are effective for soil heavy metal contamination.

RESEARCH SIGNIFICANCE

When investigating the impact of soil contamination on ecosystems in areas where contamination is a concern, cicada shells can be used to carry out a completely non-destructive evaluation without the need for disintegrating soil excavation or plant collection. Soil evaluation using cicada shells is a first, and this study clarified what metals accumulate in cicada shells depending on the geology, soil conditions, and species. The concentrations of Ni, As, Pb, and Ag contained in cicada shells vary greatly depending on the geology and soil conditions, with no differences observed between species, making them an excellent indicator of soil contamination.

METHOD

In this study, firstly cicada shells and adults were sampled at various geological and land use places with different heavy metal contamination conditions to compare each heavy metal concentrations.

Fig.1 Relationships between soil, plants, and heavy metals.

Fig.2 Relationships between soil, plants, cicadas, cicada shells, and heavy metals.

Sampling points

As shown in Figure 3, cicada shells were collected from mines, basalt, volcanic areas, limestone, serpentine, urban parks, and old factory sites throughout Japan. The cicada species were the black cicada, the large brown cicada (including the minmin cicada), the evening (including the tsukutsukuboshi), the platy cicada, the spring cicada (including the ezoharuzemi), and the ezo cicada.

The mines are Teine (As, Cu) and Chitose (Ag, Pb, Zn) in Hokkaido, Nishinomaki (As) in Gunma Prefecture, Rendaiji (Ag, Cu, Pb, Zn, Mn) in Shizuoka Prefecture, Tada (Ag, Pb, Zn, Cu) and Ikuno (As, Ag, Cu, Pb, Zn) in Hyogo Prefecture, Waidani (As, Cu, Zn, Pb) in Okayama Prefecture, Iwami (Ag, Pb, Mn) in Shimane Prefecture, and Naganobori Mine (As, Cu) in Yamaguchi Prefecture [9]. The basalt area is the southeastern foot of Mt. Fuji where lava of Mt. Fuji is distributed. The volcanic hot spring area is Kusatsu hot spring in Gunma Prefecture. The limestone areas are Shuri Castle in Okinawa Prefecture and the Akiyoshidai in Yamaguchi Prefecture. Serpentine (Ni) area is Kamogawa in Chiba Prefecture, Ogose in Saitama Prefecture, Ryumonzan in Wakayama Prefecture, and Nakase Mine (Sb, As) in Hyogo Prefecture. Generally, serpentinite is rich for Ni (Ni > 0.1%) [9]. Urban parks are in Tokyo (Ueno, Kasai Rinkai, Tokyo University, Higashi Ojima, Takasago), in Osaka (Shirasagi, Osaka Castle, Nagai, Suminoe, Sumiyoshi), and in Wakayama (Wakayama Castle, Wakayama University, Akibasan, Wakaura). The factory (Ni, Pb, Fe) is the former site of a wire factory in Nishikinohama in Osaka Prefecture.

Fig.3 Sample points for cicada shell and cicada adult.

Treatment

In the laboratory, the sampled cicada adults and shells were first rinsed with ultrapure water and then desiccated by a dryer. After drying, they were dissolved with concentrated nitric acid and filtered with a membrane filter with a 0.45 micrometer pore size. After filtering, the Fe, Mn, Ni, Ag, Pb, As, Zn and Cu concentrations in cicada adults and shells were measured by ICP-OES (AMETEK, Inc., SPECTRO ARCOS) in the laboratory at Wakayama University. The actual detection limit of ICP-OES is 0.001ppm for Fe, Mn, Ni, Ag, Pb, As, Zn and Cu.

RESULTS AND DISCUSSION

Ni concentration of cicada shells and adults

Ni, As, Pb, Ag, Fe, Mn, Zn and Cu concentrations in cicada shells and adults were measured for studying the difference in metal concentrations in cicada shells and cicada adults comparing metal contaminated and non-contaminated areas.

Figure 4 shows the Ni concentration in cicada shells and adults. The Ni concentration in cicada shells ranged from 0.01 to 100 mg/kg, and in adults

ranged from a few 0.01 to several tens of mg/kg. The Ni concentration in cicada shells was more than 10 times that of adults. Therefore, it is thought that cicadas release Ni into their shells during molting, maintaining a high Ni concentration in the shell.

The Ni concentration in cicada shells in Kamogawa, Nakase mine, Ogose, and Ryuumon, which are serpentine rocks expected to have high Ni, exceeds 10 mg/kg, more than 10 times higher than other areas [9]. In addition, even in former factory sites where Ni contamination is expected, the Ni concentration is more than 1 mg/kg, reaching several tens of mg/kg. On the other hand, the Ni concentration in Iwami, Teine, and Chitose mines, which are not Ni mines, is less than 1 mg/kg, and in Syuri and Akiyoshidai, which are limestone rocks with low Ni content, it is low at less than a few mg/kg. Therefore, it is thought that the Ni concentration in cicada shells changes according to the geological and soil conditions. Even within the same species, there were large regional differences in concentration, and the differences between species were not clearly found.

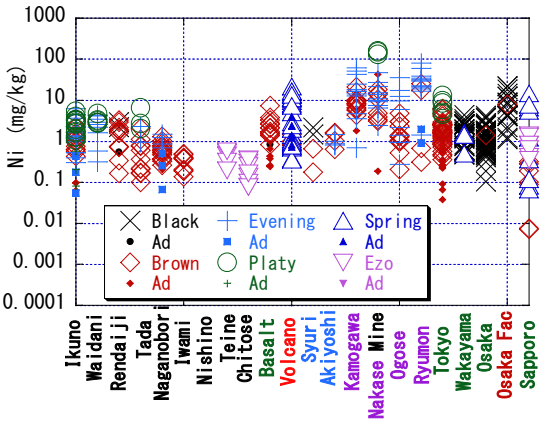

Fig.4 Ni concentrations in cicada shells and adults.

As concentration of cicada shells and adults

Figure 5 shows the As concentration in cicada shells and adults. In cicada shells, the concentration ranged from several 0.01 to several thousand mg/kg, and in adults, the concentration ranged from several 0.1 to several tens of mg/kg. The As concentration in cicada shells was more than 10 times that of adults. Therefore, it is thought that cicadas release As into their shells during molting, and maintain high As concentrations in the shells. Cicada shells from the Ikuno, Waidani, Nakase, Naganobori, Teine, and Nishinomaki mines, where As minerals expected to have high As concentrations are found [9], have concentrations of 10 mg/kg or more, reaching a maximum of several thousand mg/kg. In urban parks in Tokyo and Osaka and volcanic hot spring area, As concentrations reach several tens of mg/kg. These areas may be affected by urban pollution and hot spring water. On the other hand, the As concentrations in the Renndaiji, Tada, Iwami, and Chitose mines, where no As minerals were found, limestone areas (Syuri, Akiyosidai), serpentine areas (Kamogawa, Ogose, Ryumon), and parks in Wakayama and Sapporo were low at less than 10 mg/kg. Therefore, it is thought that the As concentration in cicada shells varies according to the geology and soil conditions. Even within the same species, there were large regional differences in concentration, and the differences between species were not clearly found.

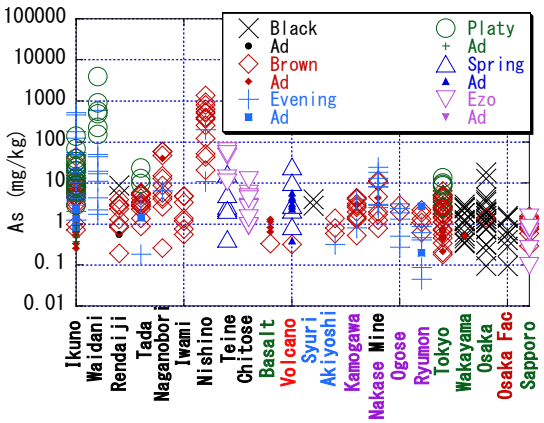

Fig.5 As concentrations in cicada shells and adults.

Pb concentration of cicada shells and adults

Figure 6 shows the Pb concentration in cicada shells and adults. In cicada shells, the concentration ranged from 0.01 to 100 mg/kg, while in adults it ranged from 0.1 to 100 mg/kg. The Pb concentration in cicada shells was more than 10 times that of adults. Therefore, it is thought that cicadas release Pb into their shells during molting, maintaining high Pb concentrations in the shells.

Cicada shells from the Ikuno, Waidani, Renndaiji, Tada, Iwami, Chitose, and Nakase mines, where Pb minerals expected to have high Pb concentrations are found [9], have Pb concentrations of 10 mg/kg or more, reaching a maximum of several hundred mg/kg. In addition, Pb concentration of cicada shells at former factory site ranges from several mg/kg to several hundred mg/kg. Meanwhile, urban parks in Tokyo and Osaka also have high levels, exceeding a maximum of several tens of mg/kg. On the other hand, the Teine and Nishinomaki mines, where no Pb minerals were found, limestone areas (Syuri, Akiyosidai), serpentine areas (Kamogawa, Ogose, Ryumon), and parks in Wakayama and Sapporo had low Pb concentrations of less than 10 mg/kg. Therefore, the Pb concentration in cicada shells is thought to vary according to the geological and soil conditions. Even within the same species, there were large regional differences in concentration, and the

differences between species were not clearly found.

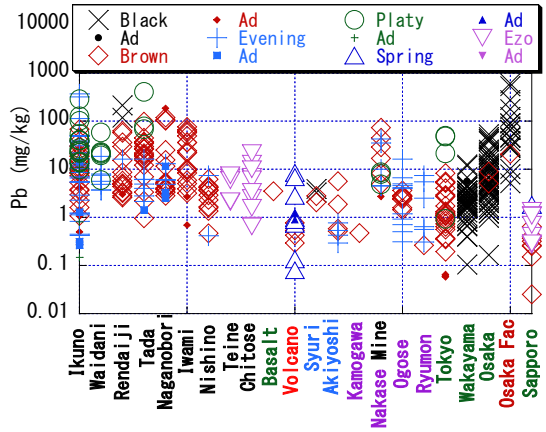

Fig.6 Pb concentrations in cicada shells and adults.

Ag concentration of cicada shells and adults

Figure 7 shows the Ag concentration in cicada shells and adults. The Ag concentration in cicada shells ranged from 0.1 to several tens of mg/kg, while that in adults ranged from several 0.01 to several 1 mg/kg. The Ag concentration in cicada shells was more than 100 times that of adults. Therefore, it is thought that cicadas release Ag into their shells during molting, maintaining a high Ag concentration in the shells.

The cicada shells of Ikuno, Waidani, Renndaiji, Tada, and Iwami mines, where Ag minerals expected to have high Ag concentrations are found [9], show values exceeding 1 mg/kg. However, although the Chitose mine is an Ag mine, the Ag concentration is less than 1 mg/kg, and all other areas are less than 1 mg/kg. Even for the same black cicada, Rendaiji has a concentration of more than several tens of mg/kg, while the city park has a concentration of less than 1 mg/kg. Therefore, it is thought that the Ag concentration in cicada shells varies according to the geological and soil conditions. There are large regional differences in concentration even for the same species, and the differences between species were not clearly found.

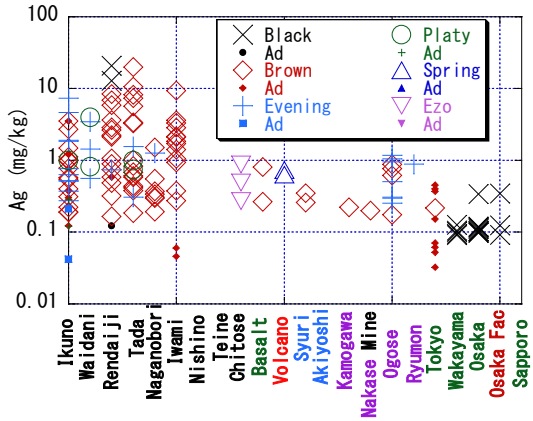

Fig.7 Ag concentrations in cicada shells and adults.

Fe concentration of cicada shells and adults

Figure 8 shows the Fe concentration in cicada shells and adults. The Fe concentration in cicada shells ranged from 100 to several tens of thousands of mg/kg, while the Fe concentration in adults ranged from several tens to several thousands of mg/kg. The Fe concentration in cicada shells was more than 100 times that of adults. Therefore, it is thought that cicadas release Fe into their shells during molting, maintaining a high Fe concentration in the shell.

The Fe concentration in cicada shells from metal mines rich in Fe sulfides such as pyrite (Ikuno, Waidani, Renndaiji, Tada, Naganobori, Iwami, Nishinomaki, Teine, Chitose, Nakase mines) [9], basalt area and serpentine areas, which contain a lot of Fe, is not particularly high compared to limestone and urban parks, which contain little Fe, and shows a similar range of variation. Therefore, the Fe concentration in cicada shells does not change according to the geological or soil conditions. There were large regional differences in the concentration even within the same species, and the inter-species differences were not clearly found.

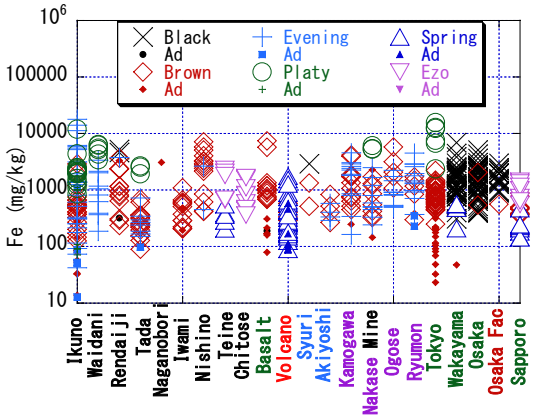

Fig.8 Fe concentrations in cicada shells and adults.

Mn concentration of cicada shells and adults

Figure 9 shows the Mn concentration in the shells and adults of cicadas. In the shells, the concentration was 100 to several thousand mg/kg, and in the adults, the concentration was several tens to 1,000 mg/kg. The Mn concentration in the shells of cicadas was about 10 times that of the adults. Therefore, it is thought that cicadas release Mn into their shells during molting, thereby maintaining a high Mn concentration in the shells.

The Renndaiji and Iwami mines, where Mn minerals are found [9] and Mn concentrations are expected to be high, are not necessarily high, and other locations have roughly the same concentration range. Therefore, the Mn concentration in the shells of cicadas does not change in line with the geological

and soil conditions. Overall, the Mn concentration of the large brown cicada is lower than that of other cicadas.

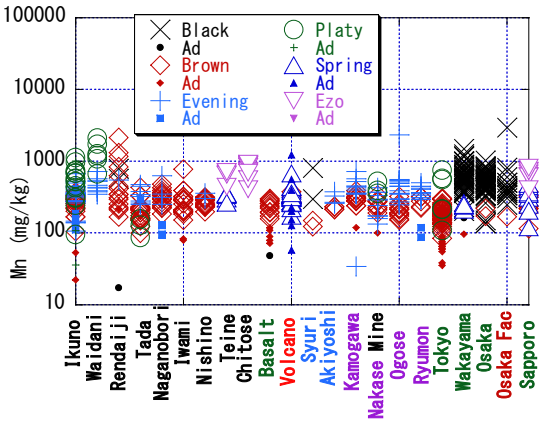

Fig.9 Mn concentrations in cicada shells and adults.

Zn concentration of cicada shells and adults

Figure 10 shows the Zn concentration in the shells and adults of cicadas. The Zn concentration in the shells ranged from several 1 to several thousand mg/kg, while the Zn concentration in the adults ranged from several hundred to 100 mg/kg. The Zn concentration in the shells of cicadas was less than one-tenth of that in adults. Therefore, it is thought that cicadas do not release Zn into their shells during molting, and maintain high Zn concentrations in their bodies. Since Zn is necessary for cell division and an essential component for maintaining life, it is thought that it is stored in the body rather than released into the shell [10, 11].

Zn minerals are found in all mines, and the metal mines expected to have high Zn concentrations are particularly high at Ikuno, Waidani, and Rendaiji, exceeding 1000 mg/kg, while the other mines are not high at 100 mg/kg or less, while the city park reaches 1000 mg/kg, and other locations have roughly the same concentration range. Therefore, the Zn concentration in the shells of cicadas does not change in line with the geological and soil conditions. Overall, the Zn concentration of the large brown cicada is lower than that of other cicadas.

Cu concentration of cicada shells and adults

Figure 11 shows the Cn concentration in the shells and adults of cicadas. The concentrations ranged from 1 to 1000 mg/kg in the shells and several tens to several hundreds of mg/kg in the adults. The Cu concentration in the shells of cicadas was less than one-tenth of that in the adults. Therefore, it is thought that cicadas do not release Cu into their shells during molting, and maintain high Cu concentrations in their bodies. Because insect blood is hemocyanin and contains copper and Cu is a necessary component for insect, it is thought that it is stored in the body rather than released into the shell [10, 11].

Metal mines where Cu minerals are found and Cu concentrations are expected to be high include the Ikuno, Waidani, Rendaiji, Tada, Naganobori, Iwami, and Teine mines, which exceed 100 mg/kg, while the Nishinomaki and Chitose mines, where no Cu minerals are found, have low Cu concentrations of several tens of mg/kg or less. However, the Cu concentrations of large brown cicadas in other non-mining areas exceed 100 mg/kg, and the Cu concentrations in cicada shells do not change in line with the geological and soil conditions. The Cu concentration of the large brown cicada ranges from 10 to 1,000 mg/kg, which is higher than the 1 to several tens of mg/kg of other cicadas, and there is a clear species difference. In particular, comparing Figures 10 and 11, a clear species difference can be seen in that the large brown cicada has a low Zn concentration and a high Cu concentration.

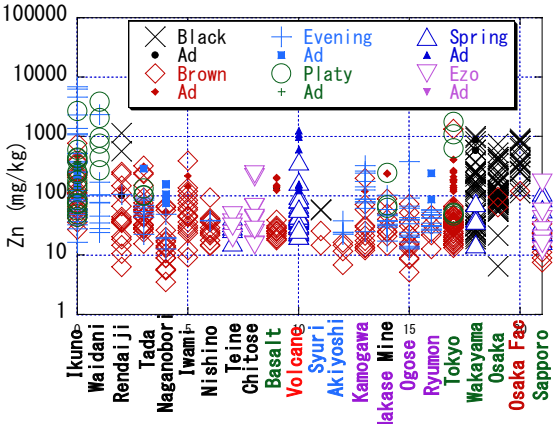

Fig.10 Zn concentrations in cicada shells and adults.

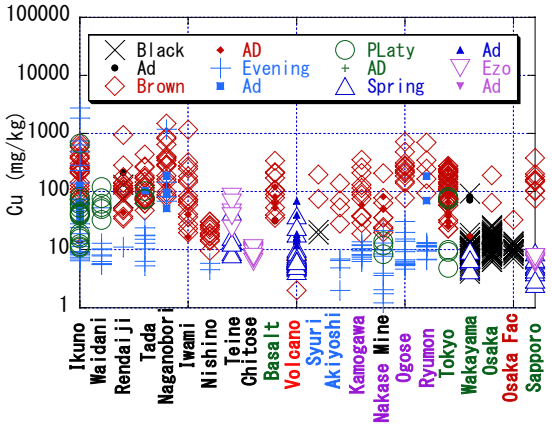

Fig.11 Cu concentrations in cicada shells and adults.

CONCLUSIONS

Cicada larvae live in the soil, sucking sap from tree roots, and it is thought that heavy metals are concentrated in the shells of cicada larvae and cicadas

that have emerged above ground. Therefore, in this study, we investigated the heavy metal characteristics of cicada shells to determine whether they could be used as a new indicator of heavy metal pollution in soil. Cicada shells were collected from mines, basalt area, volcanic areas, limestone areas, serpentine areas, urban parks, and former factory site throughout Japan. The cicada species were the black cicada, the large brown cicada (including the minmin cicada), the evening (including the tsukutsukuboshi), the platy cicada, the spring cicada (including the ezoharuzemi), and the ezo cicada.The concentrations of Fe, Mn, Ni, Ag, Pb, and As in cicada shells are higher than in adults, and it is thought that cicadas discard Fe, Mn, Ni, Ag, Pb, and As in their shells during molting, lowering the Fe, Mn, Ni, Ag, Pb, and As concentrations in adults. These elements are thought to be components that tend to be excessive in cicadas. The Zn concentration of cicadas is higher in adults than in their shells, and Cu is about the same, so the shells are not necessarily higher.

The Ni, Ag, Pb, and As concentrations in cicada shells vary greatly depending on the geology and soil conditions, and no differences between species were observed. Therefore, it was found that the Ni, Ag, Pb, and As concentrations in cicada shells are good indicators of soil pollution. On the other hand, the Fe, Mn, Zn, and Cu concentrations in cicada shells do not reflect the geology and soil conditions.

There are species differences in Mn, Zn, and Cu, with the brown cicada and the Minmin cicada tending to have significantly higher Cu levels and lower Mn and Zn levels than other species. No species differences are seen in Fe.

Insect blood uses hemocyanin, which uses Cu, and Zn is necessary for cell division, so Cu and Zn are thought to be important elements for cicadas. Therefore, it is thought that the concentrations are higher in adults than in the shell, and that the Cu and Zn concentrations are also higher than other elements.

ACKNOWLEDGMENTS

I am grateful to Mr. Kazuto Futsuta and Mr. Kazuki Nakajima of Eco-management Corporation for showing us around the premises when collecting cicada shells at the Teine and Chitose mines.

STABILIZATION OF KHON KAEN LOESS FOR THE PAVEMENT STRUCTURE USING RICE HUSK ASH AND KAOLIN CLAY

Stanley Emeka Ovuta[1] and Ratamanee Nuntasarn[2]

[1,2]Faculty of Engineering, Khon Kaen University, Thailand

ABSTRACT

Loess which is a wind deposited soil in Khon Kaen, Thailand, is extremely compressible, weak, and prone to erosion, making it unsuitable for pavement construction. This research investigates the effect of cement and geopolymer-based binders on loess soil. Specific gravity, sieve and hydrometer, Atterberg limit, compaction, Unconfined Compressive Strength (UCS), California Bearing Ratio (CBR), and wet-dry durability test were conducted to evaluate soil performance. The stabilization was carried out using 5% cement and combination of RHA and kaolin clay (calcined to metakaolin) in varying ratios, with sodium hydroxide and sodium silicate as alkaline activators for the geopolymer mixes. Results showed that RHA and MK generally reduced the maximum dry density (MDD) and slightly increased the optimum moisture content (OMC) due to their low specific gravity and porous nature of the additives. The UCS results indicated that the 1% RHA + 4% MK mix achieved the highest strength, even surpassing the 5% cement. Durability assessment under wet-dry cycles revealed that the geopolymer-stabilized loess exhibited lower mass loss and high strength retention (>90%), confirming its long-term stability. The CBR values further supported its suitability for use as a pavement subgrade and subbase material. These findings highlight the potential of geopolymer stabilization as an effective and sustainable alternative to conventional cement treatment for loess soils while promoting waste recycling in civil engineering construction. Further research is recommended for field- scale validation to assess long-term performance.

Keywords: Stabilization, Loess soil, Rice husk ash, Kaolin clay, Pavement structures.

INTRODUCTION

Loess, a wind-deposited silty soil commonly found in regions like Khon Kaen, Thailand, presents significant challenges for construction due to its high compressibility, collapsibility, and moisture sensitivity. When used as subgrade material, unstabilized loess often leads to pavement deformation, reduced service life, and costly maintenance. Traditional stabilization using cement or lime has been effective in improving soil strength and durability but these methods are associated with high costs and environmental concerns due to CO_2 emissions during production [1].

In response to the environmental impact of cement, geopolymer technology has emerged as a sustainable alternative. Materials such as rice husk ash (RHA) and kaolin clay (to be calcined to metakaolin, MK) have been increasingly used as sustainable alternatives to cement due to their pozzolanic reactivity and ability to improve soil structure and strength [2, 3]. RHA is rich in silica, which aids in the formation of cementitious compounds, while metakaolin contributes to a high content of alumina [2, 4]. Despite their individual promise, limited research exists on the combined effect of rice husk ash (RHA) and metakaolin (MK) in stabilizing loess, particularly under mechanical and durability conditions relevant to pavement structures. This study investigates the compaction behavior, Atterberg limit, sieve and hydrometer, unconfined compressive strength (UCS), durability under wet-dry cycling, and California Bearing Ratio (CBR) of Khon Kaen loess stabilized with cement and various combinations RHA and metakaolin. The objective is to determine the effectiveness of these alternative binders in improving the geotechnical performance of loess while promoting the reuse of agricultural and industrial by-products for sustainable road construction and equally to establish a good percentages and aspect ratios of each stabilizing materials that can be utilized in many years to come.

RESEARCH SIGNIFICANCE

This study demonstrates the viability of using rice husk ash (RHA) and metakaolin (MK) as sustainable stabilizers for improving the engineering properties of loess. The findings shows that these materials significantly enhanced the strength, durability, and moisture resistance of the soil, offering a cost-effective and environmentally responsible alternative to cement. This research supports the reuse of agricultural waste in geotechnical applications, promoting sustainable construction practices, and provides practical insights for improving pavement performance in loess-prone regions.

MATERIAL PREPARATIONS AND METHODS

Materials

The loess soil used in this study was collected in a land near College of Local Administration (COLA), Khon Kaen University, Thailand. The top soil was stripped and the underlying loess was manually excavated. The basic properties of the loess are shown in table 1. The kaolin clay was calcined to form metakaolin (MK) at different temperatures (650, 700, 750, 800, and 850˚c) and heating time (30, 60, 90, and 120 minutes) at a heating rate of 10˚c/mins. The rice husk ash used was bought from the KPS Goods shop, Kampaeng Saen, Nakhon Pathom, Thailand. It was further blended and sieved through sieve No. 200 to obtain a finer, more uniform ash. The geopolymer activator was prepared using sodium hydroxide (8M) and sodium silicate in a 1:2 ratio.

Table 1: Basic properties of Khon Kaen loess

Properties

% of Sand	55.22
% of Silt	27.23
% of Clay	17.55
USCS classification	SM

Sample Preparation and Mix Design

The loess was oven-dried, sieved through a 4.75 mm mesh and mixed with stabilizers as shown in table 2. A total of eight mix combinations were tested as presented in table 2. The alkaline activator was incorporated into the geopolymer mixes as the total moisture content. Compaction was conducted using a 4x4'' mold. UCS and durability samples were prepared in a mold of 50 mm x 100mm dimensions.

Table 2: Mix Ratios

Sample ID.	Soil (%)	Binder material for geopolymer		Cement (%)
		RHA (%)	Kaolin Clay /MK (%)	
Unstabilized loess	100	0	0	
Soil cement	95			5
Soil geopolymer	95	5	0	
	95	4	1	
	95	3	2	
	95	2	3	
	95	1	4	
	95	0	5	

TEST METHODS

Sieve and hydrometer test was performed in accordance with ASTM D421 and D422. Compaction characteristics were evaluated using Modified Proctor test (ASTM D1557). UCS test were performed after 7days of curing following ASTM D1633. Durability was assessed under wet-dry cycles (ASTM D559), with UCS testing conducted after 1st, 3rd, 6th, 9th, and 12th cycles. Mass loss and physical damages were monitored. CBR test followed ASTM D1883 and AASHTO T193, with penetration values recorded at 2.5 and 5.0 mm for soaked and unsoaked conditions.

RESULTS AND DISCUSSIONS

Sieve and Hydrometer Test

The sieve test showed that Khon Kaen loess consist of 55% of sand, 27% of silt and 18% of clay. Based on USCS, the soil was classified as silty sand (SM). This aligns with [5, 6], who identified Khon Kaen loess as fine-grained and weakly plastic.

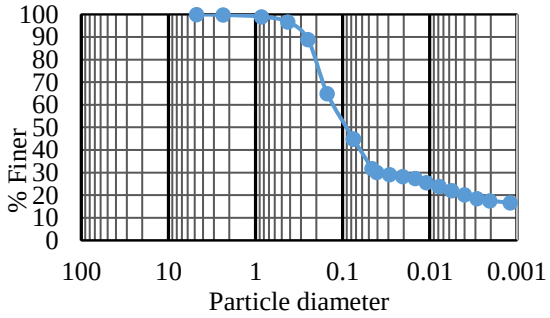

Fig 1: Sieve and Hydrometer Curve for Khon Kaen Loess showing silt-dominated structure.

Compaction Test

The unstabilized loess as shown on table 3 and figure 2 exhibited a maximum dry density (MDD) of 21.150 kN/m³ and optimum moisture content (OMC of 6.84%. The inclusion of RHA and MK resulted in a general fluctuation in MDD as shown in table 3 and figure 4 – 6 due to the lower specific gravity and porous structure of RHA [7] while MK improves particle packing and densification at an increased ratio [2]. Conversely, OMC varied slightly, attributing to the higher water absorption capacity of RHA and MK. The 5% cement mix recorded a modest reduction in MDD to 20.94 kN/m³, while the 1% RHA +4%MK mix showed 20.88 kN/m³. These results are consistent with previous findings that geopolymer binders reduces density while improving reactivity and structure [11].

Table 3: The MDD and OMC values for each compacted mix ratio of Khon Kaen loess

Samples	Symbol	Maximum dry density (kN/m³)	Optimum moisture content (%)

Unconfined Compressive Strength (UCS)

The UCS test samples was compacted in a mold of 50 mm x 100 mm at 95% of the maximum dry density at the wet-side of the compaction curve, extruded from the mold and cured for 7 days before testing. Then, a strain rate of 1mm/minutes was applied on the samples until failure occurred. In each mixture, 5 samples were tested. The results as shown in tables 4, 5, and figures 7 and 8 revealed a significant improvement in strength for all stabilized mixes. The unstabilized loess had a UCS of 87.94 kPa. The stress-strain curve showed the strain softening. Meanwhile, the 5% cement mix had a brittle mode failure accompanied with a sudden cracking sound at the peak load as shown in figure 8. The UCS of stabilized sample with 5% cement is higher than the unstabilized at about 40.6 times. However, the 1R4M mix exhibited a more ductile behavior as shown in figure 8 achieving the highest strength, which is about 2.3 times increase in strength from the 5% cement loess. The 1R4M mix had the lowest coefficient of variation (COV = 6%) as shown in table 5, based ACI 214R-11 guidelines, confirming the reliability of the high UCS, elastic modulus (E), and energy absorption (E_A) values presented in table 4. In addition, table 6 shows the initial, final moisture content, and dry density of all mixes. Dry density decreased slightly in RHA and MK stabilized mixes compared to cement-stabilized loess, due to their specific gravity and porous nature [2, 3]. This strength gain is attributed to the formation of additional geopolymer gel and strong interparticle bonding from aluminosilicate

activation [8]. The samples indicated consistent strength development especially for the geopolymer mix, suggesting good repeatability.

1R4M	5.05	3.70	19.33
0R5M	4.72	3.17	18.93

California Bearing Ratio (CBR)

The CBR test was oven-dried, pulverized, and sieved via 4.75mm sieve. Each mix was prepared using the moisture content as obtained from the 95% MDD (wet-side) of modified proctor compaction test. Then, the samples were compacted using 56 blows per layer (5 layers). The geopolymer materials were cured for 7 days with plastic wrapping before soaking for 96 hours, for the soaked samples. The samples were tested on the CBR machine with penetration of 1.25mm/minutes. The adopted CBR values for both soaked and unsoaked condition (Table 7) followed ASTM D1883 procedures, taking the higher value from 2.5 mm or 5.0 mm penetrations. As shown in figure 9, the unstabilized loess exhibited very low CBR values, classifying it as poor subgrade material per AASHTO T193. In contrast, the 5% cement mix showed a soaked CBR meeting base course standards, with only 0.018% swelling, highlighting cement's strong binding capacity [9]. The highest improvement of unsoaked CBR was 1R4M as same as soaked CBR, which increased about 83 and 73 times by the unstabilized samples, respectively.

Swelling potential results for the soaked condition is presented in table 7. The untreated loess exhibited the highest swelling at 0.0585%, while the 5% cement and 5% RHA-stabilized mixes showed reduced values of 0.018% and 0.0138%, respectively. All other geopolymer-stabilized mixes, including the optimal 1R4M, recorded zero swelling, indicating strong volume stability. The superior performance of the 1R4M mix is attributed to the optimal balance of reactive silica and alumina, which promotes aluminosilicate gel formation (N-A-S-H), improving bond strength and reducing porosity [2, 4]. Figure 10 illustrates the CBR loss or gain due to soaking. While most mixes lost strength, three exhibited negative loss (i.e., strength gain): 4% RHA + 1% MK, 5% cement, and 5% MK. This behavior is attributed to extended hydration or geopolymerization under moist conditions [4, 10]. Overall, all stabilized mixes exceeded 198% soaked CBR making them suitable for subbase or base course applications. Among them, the 1% RHA + 4% MK stood out for combining high

strength and stability, reinforcing the effectiveness of geopolymer binders.

Table 7: The adopted CBR, percentage loss or gain values, and the swelling potentials.

Mix Design	Adopted CBR unsoaked (%)	Adopted CBR soaked (%)	Loss or Gain (%)	Swelling (%)
Un	14.12	13.64	3.40	0.0585
5C	533.31	642.89	-20.55	0.018
5R0M	224.04	198.00	11.62	0.0138

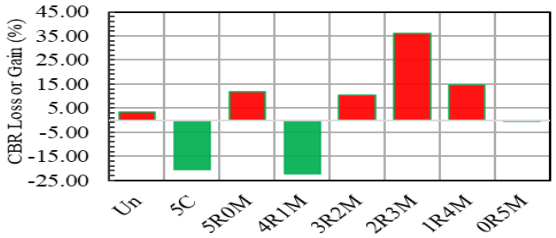

Fig.10: Percentage change in adopted CBR values after soaking showing loss or gain.

Wet-Dry Durability

The durability of stabilized loess was evaluated using UCS retention and mass loss across 12 wet-dry cycles (ASTM D559). The samples (2 samples per cycle) were compacted at the 95% MDD (wet-side) of the compaction curve using mold 50mm x 100mm. After compaction, the samples were cured for 7 days in a plastic wrap simulating early-stage curing conditions prior to durability testing. Upon completion of curing, the samples underwent wet-dry cycles by soaking for 24 hours then oven drying at 105˚c for 24 hours and cooling at room temperature for at least 2 hours. At the end of each cycle, the samples were tested with the UCS machine at the strain rate of 1mm/mins to obtain the compressive strength as shown in table 8 and 9. The 5% cement mix showed strength gain up to cycle 6, retaining 2.7 times of its original UCS followed by later cycles exceeding machine capacity limits as shown in table 8 and figure 12, indicating continued hydration of the cement material [11]. The 1% RHA + 4% Mk mix showed exceptionally high initial UCS and maintained over 100% strength up to cycle 6 (Table 9 and figure 12) and then retained 91.39% at cycle 12, confirming excellent durability caused by continued reaction, leading to gel formation filling the micro-voids [12]. However, the UCS increase at cycle 12 may be due to continued geopolymer gel formation and matrix densification, which outweighed early microcracking effects. Mass loss analysis (Table 9 and figure 11) values represent the average of two specimens tested per cycle. The RHA-MK mix ranged from 3.60-4.49%, lower than the cement mix (5.99% - 4.85%) as shown in table 8 and figure 11. Table 10 confirms the RHA-MK mix as “Excellent” in durability, supported by minimal surface damage and strong structural integrity [8].

Table 8: Individual UCS results, Retained UCS, and mass loss for 5% cement per cycle

Cycles	Sample 1 UCS (kPa)	Sample 2 UCS (kPa)	Avg. UCS (kPa)	Retained UCS (%)	Mass Loss (%)
0	–	–	3574.62	100.00	–

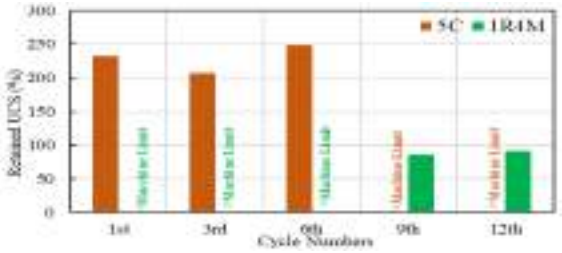

Fig. 12**:** Retained compressive strength of stabilized loess across wet-dry cycles.

CONCLUSION

This study examined the stabilization of Khon Kaen loess using cement and geopolymer binders (RHA and MK). The inclusion of RHA and MK reduced MDD and slightly increased OMC due to their lower specific gravity. UCS results showed that 1% RHA + 4% MK achieved the highest strength of about 2.3 times outperforming cement stabilized loess which served as the baseline for comparison. In wet-dry cycles, geopolymer mixes retained over 90% of their UCS with minimal mass loss, indicating excellent durability. The CBR values for all stabilized mixes exceeded subbase and base requirements under both soaked and unsoaked conditions. The study confirms that 1R4M mix achieved the highest strength and durability at only 7 days of curing, demonstrating its suitability for time-sensitive construction scenarios. These findings support the use of RHA-MK geopolymer binders as an effective, sustainable alternative to cement for loess soil stabilization.

ACKNOWLEDGMENTS

My acknowledgement goes to the department of Civil Engineering, Faculty of Engineering, in Khon Kaen University for their extreme support for this research.

ABSTRACT

This study aimed to develop a bio-enhanced compost fertilizer by incorporating *Azotobacter* sp., *Bacillus* spp., and *Azotobacter vinelandii* to promote the growth of Red Cos lettuce. A Box-Behnken Design within the Response Surface Methodology (RSM) framework was applied to optimize microbial formulations. The results showed that the bio-enriched compost significantly increased plant dry weight ($p < 0.0001$), with *A. vinelandii* contributing the most, followed by *Azotobacter* sp. and *Bacillus* spp. The optimal formulation—0.19% *Azotobacter* sp., 1.84% *Bacillus* spp., and 0.39% *A. vinelandii*—yielded the highest observed dry weight (2.14±0.04 g), consistent with model predictions. ANOVA confirmed the model's robustness ($R^2 = 0.9973$, Adjusted $R^2 = 0.9925$), and the lack-of-fit was insignificant. Contour and 3D surface plots further supported the significant interactive effects among microbial factors. The optimized compost formulation was validated through confirmation experiments, demonstrating its potential as an eco-friendly and effective alternative to chemical fertilizers. This research highlights the feasibility of using microbial consortia in compost to enhance crop performance, supporting the future development of sustainable biofertilizer products.

Keywords: Bio-coated clay, Azotobacter, Bacillus, Response surface methodology, Sustainable agriculture

INTRODUCTION

Modern agriculture is evolving to incorporate eco-friendly practices, focusing on optimizing plant growth substrates. Traditional growth media such as peat moss pose environmental concerns, prompting the need for sustainable alternatives [1]. When enriched with beneficial microorganisms, high-porous clay granules [2] can serve as an efficient plant growth medium, enhancing nutrient availability and reducing chemical fertilizer dependency [3].

Beneficial microorganisms added to clay materials promote plant growth and soil health. These microbes include nitrogen-fixing bacteria (e.g., *Azotobacter* sp.) [4], phosphate-solubilizing bacteria (e.g., *Bacillus* spp.) [5], and growth-promoting rhizobacteria that enhance nutrient uptake [6], stimulate root development, and improve resistance to environmental stress [7]. Integrating these microbes into clay granules ensures their prolonged viability and effectiveness in plant cultivation, making bio-coated granules a viable alternative to conventional fertilizers [8].

Microorganism-enriched bio-coated clay granules provide an innovative solution by integrating microbial strains that promote plant growth. This study employs Response Surface Methodology (RSM) to optimize the formulation of microbial bio-coated clay granules. RSM is a statistical and mathematical approach that helps develop, improve, and optimize processes by evaluating the relationships between multiple independent and response variables [9]. Using the Box-Behnken Design within RSM allows efficient experimentation by reducing the number of required trials while ensuring accurate model predictions [10]. Our previous research shows that fired clay granules can be eco-friendly carriers for nitrogen-fixing bacterial cells, promoting microbial viability and plant growth efficiency [8]. Moreover, further advancements have explored the incorporation of additional microbial species and nutrient-enriched coatings to enhance the performance of these bio-coated granules in various agricultural settings. This study leverages RSM to determine the optimal microbial concentrations and their interactions to maximize plant growth efficiency while ensuring environmental sustainability. The findings contribute to advancements in sustainable agriculture, offering an alternative plant growth medium with enhanced microbial benefits.

MATERIALS AND METHODS

The Experimental Design

This study investigates the effects of microbial supplementation in compost powder on

plant growth when cultivated in clay granules. The independent variables are the concentrations of *Azotobacter* sp. (0.13–0.67 %w/w), *Bacillus* spp. (0.07–0.33 %w/w), and *A. vinelandii* (1.3–2.7 %w/w), while plant dry weight is the dependent variable. Controlled factors include compost composition, plant type, environmental conditions (light, water, temperature, humidity), clay granule properties (size, porosity, water-holding capacity), and experiment duration. The variable ranges are summarized in Table 1.

Table 1 Levels, actual and coded experimental independent variables for microbial supplementation in compost powder on the growth of Red Cos lettuce

Variables	Coding	Unit	Levels		
			-1	0	+1
Azotobacter sp.	X_1	%w/w	0.4	0.13	0.67
Bacillus spp.	X_2	%w/w	0.07	0.2	0.33
A. vinelandii	X_3	%w/w	1.3	2	2.7

The Statistical Analysis

Statistical analysis was performed using a Box-Behnken Design (BBD) under Response Surface Methodology (RSM) to evaluate interactions among three variables. Design-Expert® Version 13 was used for A one-way Analysis of Variance (ANOVA), response optimization, and visualization via contour and 3D surface plots, providing insights into how the inputs influenced plant growth (Table 2). The regression analysis resulted in a second-order polynomial equation, which was used to predict plant growth based on the levels of microbial supplementation. This equation takes the general form:

$$y = \beta_0 + \sum \beta_i X_i + \sum \beta_{ii} X_i^2 + \sum \beta_{ij} X_i X_j \quad (1)$$

where y represents the predicted response (dry weight), X_1, X_2, and X_3 The coded levels of the independent variables, and the coefficients represent the quadratic and interaction effects. This model enabled precise evaluation of the individual and combined effects of the microbial inputs on plant growth.

The Confirmation Experiments

A set of seven confirmation experiments was conducted to validate the predictive accuracy of the response surface model. These included: (1) a control without microbial addition, (2–5) low and high levels of individual microbial inputs, (6) a center point representing average values, and (7) an optimized formulation derived from numerical optimization. Each treatment involved precise concentrations of *Azotobacter* sp., *Bacillus* spp., and *A. vinelandii* incorporated into compost powder and applied to high-porosity clay granules as the plant growth medium.

Table 2 Desing matrix of the experiments along with the corresponding experimental and predicted values for the growth of Red Cos lettuce.

Run	Variables			Response*	
	X_1	X_2	X_3	Dry weight (g)	
	(%w/w)	(%w/w)	(%w/w)	Observed value	Predicted value

*Note: *The dry weight data of Red Cos Lettuce after 60 days of planting*

Red Cos lettuce seedlings were grown in a regulated environment for 60 days. Each treatment was replicated three times. When it came time to harvest, the growth performance of the plants was evaluated through the measurement of the plant dry weight (g). Statistical evaluations were carried out to analyze the means of the treatments. ANOVA accompanied by Tukey's Honestly Significant Difference (HSD) test was employed to identify notable differences between treatments, using a 95% confidence level ($p < 0.05$).) [11].

High Porous Clay Granule Preparation

High-porous clay granules were prepared following the method described in [8], incorporating 15% (w/w) sawdust waste into the raw clay mixture. A water solution containing 30-35% water was added to improve plasticity for shaping. The granules were manually formed using the soft-mud paving technique, resulting in diameters of 1.0-1.5 cm. The formed granules were sun-dried for three days before being fired at 900°C to enhance their structural integrity and porosity.

Microbial Preparation

The selected microbial strains, including

Azotobacter sp., *Bacillus* spp., and *A. vinelandii*, were cultured in 6000 mL fermentation vessels containing 1800 mL of sterilized nitrogen-free media supplemented with Potassium Metabisulfite (KMS). The cultures were incubated under shaking conditions at room temperature for five days. The bacterial suspensions were adjusted to an optical density (OD_{600}) of 1 before being used for bio-coating applications.

Compost Powder Production

The compost was formulated from food waste (40–55%), cricket manure (15–25%), dried rain tree (Samanea saman) leaves (15–20%), and molasses (8.5–15%) to maintain a balanced carbon-to-nitrogen (C/N) ratio and stimulate microbial activity. This blend of nutrient-rich and carbon-based materials served as an ideal substrate for microbial enrichment.

Composting was carried out in a 3×5 meter chamber for 60 days. The mature compost was air-dried in the shade for three days, then shredded and sieved to obtain a fine powder. The final product was analyzed for pH, organic matter, C/N ratio, salinity, moisture content, electrical conductivity (EC), and key macronutrients (N, P, K, Ca, Mg, and S) to ensure compliance with the 2007 Fertilizer Act and the 2014 Organic Fertilizer Criteria set by the Department of Agriculture [12]. A total of 16 compost powder formulations—including a non-microbial control—were developed according to a Box-Behnken Design. Fig. 1 presents the characteristics of each microbial-enriched formulation.

Fig. 1 Characteristics of microbial-enriched compost powder formulations based on the Box-Behnken Design

RESULT

Regression Model Fitting Using the Box-Behnken Design (BBD)

The analysis of variance (ANOVA) summarized in Table 3 demonstrates that the fitted quadratic regression model is highly statistically significant, with a *p*-value of the model less than 0.0001. This indicates that the observed variation in the dry weight of Red Cos lettuce is primarily attributable to the effects of the selected microbial input variables and their interactions, rather than random experimental error. The high *F*-value further reinforces the strength of the relationship between the model and the response variable.

Table 3 Analysis of variance (ANOVA) for the model regression representing.

Source	Sum of Squares	df	Mean Square	*F*-value	*P*-value
Model	0.22	9	0.0245	207.31	< 0.0001
X_1	0.01	1	0.0157	132.61	< 0.0001
X_2	0.01	1	0.0108	91.21	0.0002
X_3	0.03	1	0.0265	224.04	< 0.0001
$X_1 X_2$	0.0100	1	0.0100	84.51	0.0003
$X_1 X_3$	0.0020	1	0.0020	17.11	0.0090
$X_2 X_3$	0.0064	1	0.0064	54.08	0.0007
X_1^2	0.0652	1	0.0652	551.25	< 0.0001
X_2^2	0.0728	1	0.0728	615.22	< 0.0001
X_3^2	0.0513	1	0.0513	433.85	< 0.0001
Residual	0.0006	5	0.0001		
Lack of Fit	0.0003	3	0.0001	0.8125	0.5929
Pure Error	0.0003	2	0.0001		
Cor Total	0.2214	14			
R^2	0.9973				
Adjusted R^2	0.9925				

The model's coefficient of determination implies that approximately 99.73% of the total variation in plant dry weight can be explained by the fitted model. This exceptionally high R^2 value signifies a near-perfect fit between the predicted and actual data points, confirming that the model captures the key trends and effects of the independent variables on the growth response. All three main effects—*Azotobacter* sp. (X_1), *Bacillus* spp. (X_2), and *A. vinelandii* (X_3)—were statistically significant ($p < 0.0002$), with *A. vinelandii* contributing the most substantial impact ($F = 224.04$, $p < 0.0001$). Significant two-way interaction effects were observed between X_1X_2 and X_2X_3. At the same time, the quadratic terms (X_1^2, X_2^2, and X_3^2) exhibited highly significant effects ($p < 0.0001$), indicating curvature in the response surface and supporting the appropriateness of the second-order model. Moreover, the lack-of-fit test was insignificant ($p = 0.5929$), confirming that the model fits the data adequately and that the residual variance can be attributed primarily to pure error rather than model misspecification.

Optimization of Compost Powder Formulation For Microbial-Enriched Compost Powder Formulations

To examine the interaction effects of the three

microbial components—*Azotobacter* sp. (X_1), *Bacillus* spp. (X_2), and *A. vinelandii* (X_3)—on the dry weight of Red Cos lettuce, contour plots and three-dimensional response surface plots were generated from the quadratic regression model. The visualizations confirm a well-defined optimum region and demonstrate the synergistic impact of the microbial formulations on plant biomass (Fig.2). Fig. 2a illustrates the interaction between *Azotobacter* sp. and *Bacillus* spp., while *A. vinelandii* was fixed at its central value (2.0% w/w).

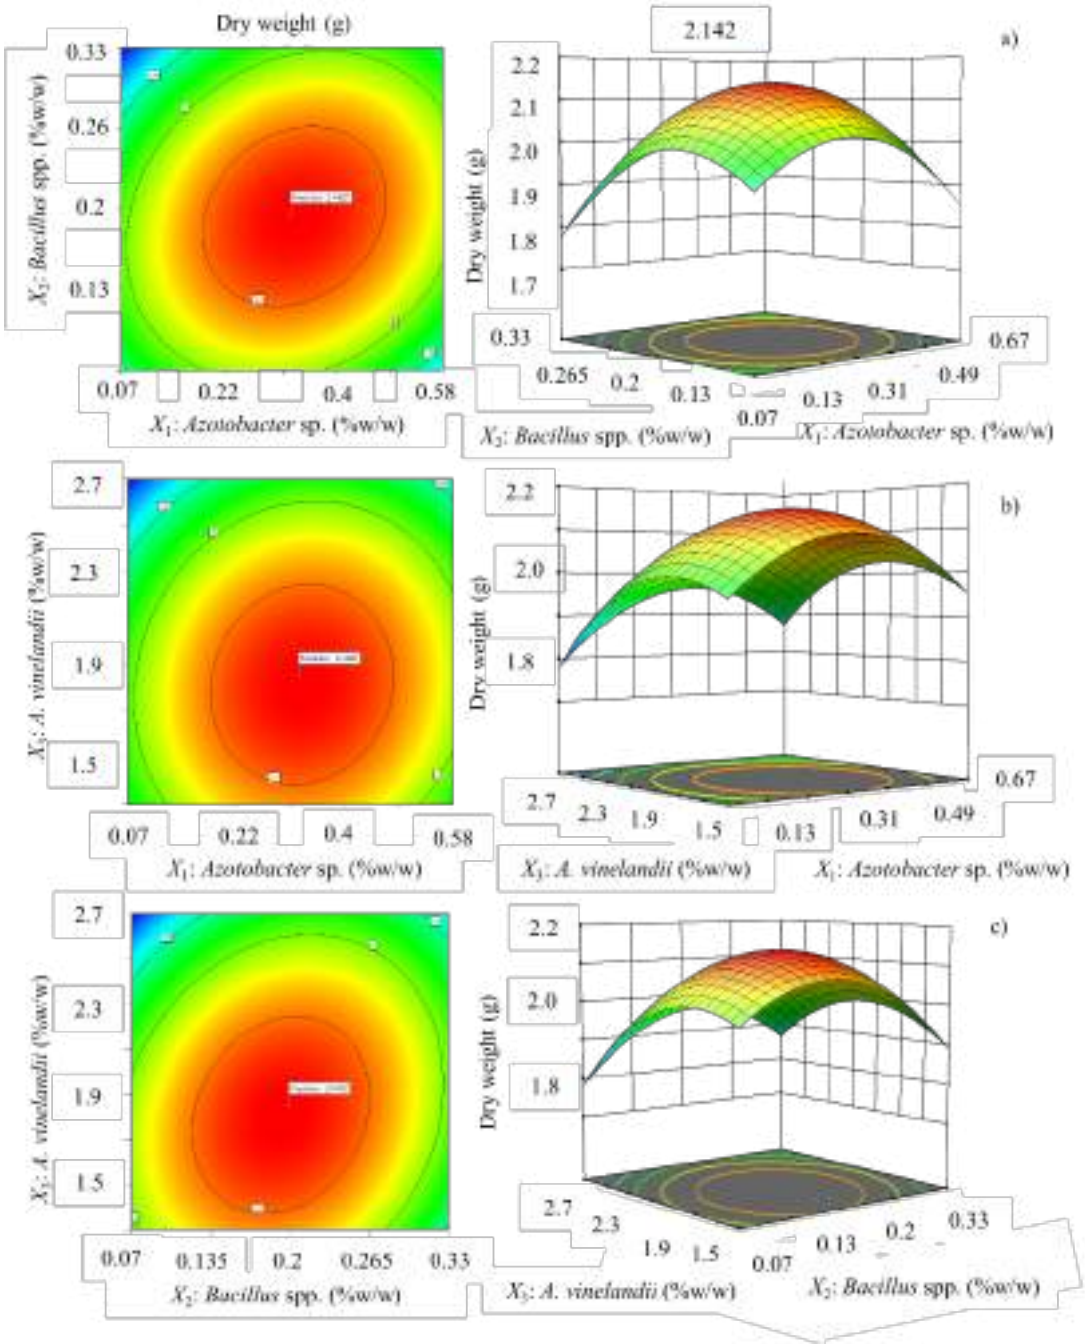

Fig. 2. Contour and 3D response surface plots illustrate microbial inputs' interactive effects on the dry weight of Red Cos lettuce: (a) *Azotobacter* sp. (X_1) × *Bacillus* spp. (X_2); (b) *Azotobacter* sp. (X_1) × *A. vinelandii* (X_3); (c) *Bacillus* spp. (X_2) × *A. vinelandii* (X_3).

The results show that increasing both *Azotobacter* sp. and *Bacillus* spp. Concentrations up to their mid-range significantly enhance dry weight. The predicted maximum dry weight in this interaction was approximately 2.14 g, confirming a strong synergistic effect. Fig. 2 b presents the interaction between *Azotobacter* sp. and *A. vinelandii*, with *Bacillus* spp. held constant. Similar to the previous interaction, a convex surface is evident, with the optimum

occurring at mid-range concentrations of both X_1 and X_3. This indicates that *Azotobacter* sp., a nitrogen-fixer, and *A. vinelandii*, another diazotroph with biofilm-forming capacity, complement each other in promoting plant growth. Fig. 2c depicts the interaction between *Bacillus* spp. and *A. vinelandii* while keeping *Azotobacter* sp. constant. The plots

Confirmation of The Optimized Microbial-Enriched Compost Powder Formulation

Seven treatments were conducted under defined microbial conditions to validate the regression model, as summarized in Table 4. The optimized formulation (Treatment 7: 0.19% *Azotobacter* sp., 1.84% *Bacillus* spp., and 0.39% *A. vinelandii*) yielded the highest dry weight (2.14±0.04 g), which was statistically equivalent to the center point (Treatment 6: 2.14±0.06 g) and significantly higher than all other treatments ($p < 0.05$).

Treatments 2 and 5, which included either low or excessive levels of one or more microbial components, resulted in the lowest dry weights (1.89±0.01 g and 1.85±0.05 g, respectively), emphasizing the need for a balanced microbial formulation. Treatments 1, 3, and 4 showed no significant differences among themselves, with dry weights ranging from 1.97 to 1.98 g, indicating moderate effectiveness. The strong agreement between predicted and observed optimum responses supports the accuracy of the RSM model and confirms the practical efficacy of the optimized microbial-enriched compost formulation.

Table 4 The confirmation experiments for the growth of Red Cos lettuce.

Treatment	Variables			Response
	Azotobacter sp. (%w/w)	*Bacillus* spp. (%w/w)	*A. vinelandii* (%w/w)	Dry weight (g)
1	0	0	0	1.98±0.02^{ab}
2	0.4	0.07	2	1.89±0.01^{c}
3	0.13	0.07	1.3	1.98±0.02^{ab}
4	0.67	0.33	2	1.97±0.07^{ab}
5	0.13	0.33	2.7	1.85±0.05^{c}
6	0.13	0.2	2	2.14±0.06^{a}
7	0.19	1.84	0.39	2.14±0.04^{a}

DISCUSSION

This study demonstrates the effectiveness of microbial-enriched compost powder in promoting the growth of Red Cos lettuce, with significant increases in plant dry weight observed under optimized formulations. The high predictive accuracy of the regression model ($R^2 = 0.9973$, Adj. $R^2 = 0.9925$) was confirmed by experimental validation. The optimal mix—0.19% *Azotobacter* sp., 1.84% *Bacillus* spp., and 0.39% *A. vinelandii*—achieved the highest dry weight (2.14 g), consistent with model predictions and superior to other treatments.

Among the microbial inputs, *A. vinelandii* showed the most substantial effect ($p < 0.0001$), likely due to its nitrogen-fixing and biofilm-forming capacity. *Azotobacter* sp. and *Bacillus* spp. also contributed through nitrogen fixation and phosphate solubilization, respectively, resulting in synergistic growth enhancement. This supports earlier findings that microbial consortia outperform single strains in improving nutrient uptake and plant resilience [14,15].

The response surface plots highlighted strong interactions among the variables, confirming the importance of optimizing both individual concentrations and their ratios. The model's good fit (lack of fit $p = 0.5929$) further supports its use for formulation scaling and development.

Practically, the optimized formulation may be extended to other leafy vegetables like romaine or butterhead lettuce. The fired porous clay granules provide structural stability and allow dry storage, suggesting good shelf-life potential. Future research should examine storage longevity and application across diverse crops and field conditions.

CONCLUSIONS

This study successfully developed and optimized a microbial-enriched compost powder formulation that significantly enhances plant biomass in Red Cos lettuce. Through Response Surface Methodology and Box-Behnken Design, the optimal combination of *Azotobacter* sp., *Bacillus* spp., and *A. vinelandii* was identified and validated. The model exhibited strong predictive accuracy ($R^2 = 0.9973$) and demonstrated reliable agreement with experimental results.

The findings highlight the potential of incorporating microbial consortia into compost-based carriers to improve plant growth efficiency while supporting sustainable agriculture. The use of fired porous clay granules offers both microbial stability and ease of dry storage, suggesting good shelf-life potential. The optimized formulation also shows promise for broader application in similar leafy crops. Future studies should explore field-scale validation, crop-specific adaptation, and long-term effects on soil health and nutrient cycling.

To build upon these findings, future research should focus on multi-season and field-scale trials to validate efficacy under variable environmental

conditions. Studies should also investigate crop-specific formulation adjustments, compatibility with organic farming practices, and the long-term impacts on soil microbiota, fertility, and carbon sequestration.

DEVELOPMENT OF NEW BASE MATERIALS FOR SEAWEED BEDS USING PROBLEMATIC SOILS, RECYCLED MATERIALS AND RICE BRAN AND ITS VERIFICATION MONITORING IN THE SEA

Kentaro Yamamoto[1], Kazumasa Fukuda[1], Takehito Negami[2], Mizuki Hira[3] and Yoshihisa Tsurunari[1]

[1]Oita, University, Japan; [2]Saga University, Japan; [3]Kagoshima University, Japan

ABSTRACT

The area of seaweed beds along Japanese coasts has decreased by approximately 40% in the last 40 years due to climate change and human activity. In addition, there are similar concerns regarding coastlines worldwide. Thus, it is critical to recover seaweed communities quickly to maintain marine plants and environments. On the other hand, the treatment of disaster waste like decomposed granite and Shirasu in Kyushu region is getting a big problem when a disaster due to heavy rain has occurred. Large amounts of waste material such as scrap ceramics and gypsum are discharged from the ceramics industry in the Saga and Nagasaki Prefectures of Kyushu, Japan. The effective use of disaster and industrial wastes (problematic soils, flow medium sand used for woody biomass power generation, scrap ceramics and gypsum) represents an important problem that must be solved in the Kyushu region of Japan. The objective of this study is to develop environment-oriented base materials for seaweed beds with a low environmental load using several recycled materials from disaster and industrial wastes and rice bran. The developed base materials were placed into the actual sea since June 2024, and monitoring has started. A discussion of the results of short-term monitoring is presented.

Keywords: Seaweed beds, Recycled materials, Industrial waste, Low environmental load, Short-term monitoring

INTRODUCTION

Seaweed beds have been reduced due to the increase of seawater temperatures and changes in the marine environment. They are essential to ecosystems and coastal fisheries because of their multiple effects as fish reefs [1]. Coastal engineering efforts such as reclamation and the phenomenon known as barren ground (called “isoyake” in Japanese) have led to the deterioration of coastal environments. Figure 1 shows a photo of “isoyake” in the sea of Sasebo, Nagasaki Prefecture. There is no seaweed or marine species except sea urchins. These sea urchins have no edible body parts.

In addition, it has been pointed out that iron and other nutrients, which are necessary for the growth of seaweed and the promotion of photosynthesis and chlorophyll synthesis, are becoming scarce in the sea due to river improvement and dam construction [2]. Thus, it is important to provide iron and amino acids in the sea. From a geotechnical point of view, Japan has a variety of problematic soils with each region having its own unique geotechnical characteristics. These problematic soils are often the cause of natural disasters and the problem of increasing the size of disasters [3]. Therefore, it is important from the point of view of disaster prevention and natural resources to indicate a new method of using problematic soils. Based on the above, we have developed and verified environment-friendly base materials of seaweed beds that effectively utilizes recycled industrial waste, with the aim of promoting the conservation and restoration of seaweed beds and underwater greening [4]. In this study, the seaweed beds with a low environmental load was produced by varying the amount of rice bran containing amino acids for the base materials consisting mainly of recycled gypsum, scrapped ceramics, decomposed granite, Shirasu and flow medium sand. The results of monitoring the seaweed beds in the sea are described.

Figure 2 shows the carbon fixation and environmental restoration produced by the base materials for seaweed beds in this study. As shown in this figure, seaweed beds are an important part of the marine food system through their photosynthetic activities, carbon dioxide absorption and oxygen discharge. Furthermore, seaweed beds play a vital role in the ecology of the aquatic ecosystems, serving as buffers of seawater quality.

Fig.1 Isoyake at Sasebo (Date: 2017.6.4)

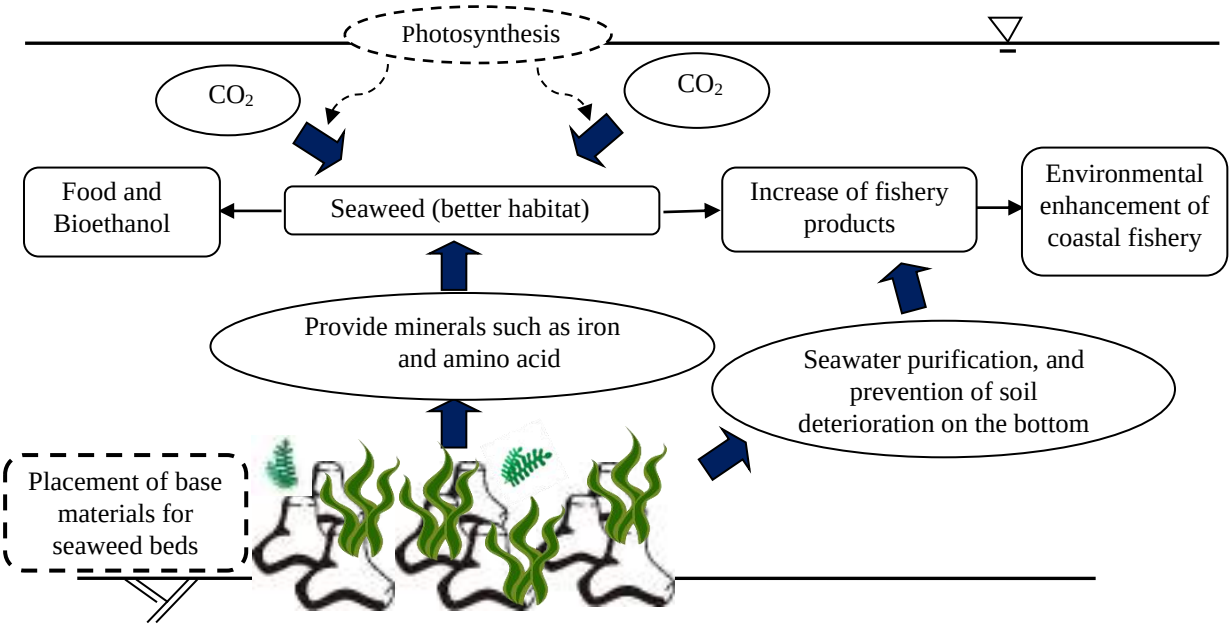

Fig.2 Carbon fixation and environmental restoration produced by base materials for seaweed beds

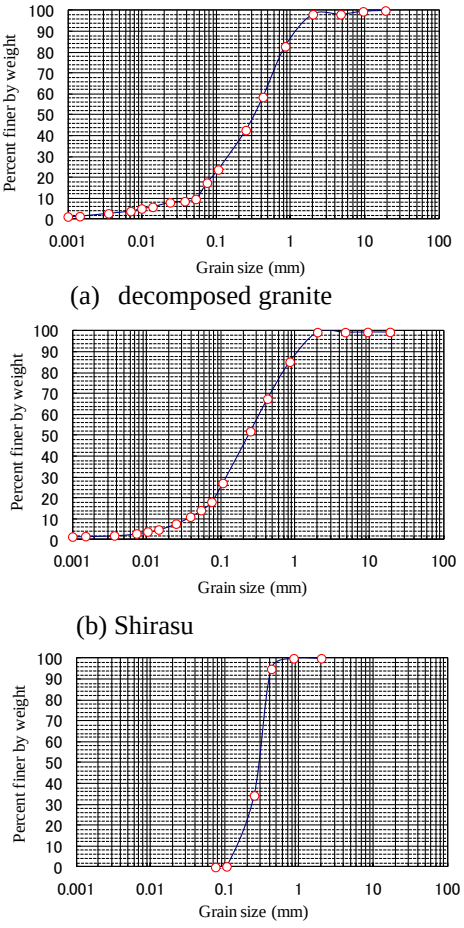
MATERIAL PROPERTY

Figure 3 shows the grain size distribution curves of the main three materials used in the seaweed beds (decomposed granite, Shirasu and flow medium sand). The decomposed granite and Shirasu passed through a 4.75 mm sieve. It can be seen that the grain size distribution of the flow medium sand is not good, and the fine-grained content of the decomposed granite and Shirasu is high. In addition to the main three materials, recycled gypsum, scrapped ceramics, water, blast-furnace slag cement type B, Portland cement, iron power (disposable heating pad), and rice bran were used. As shown in Table 1, eleven types of base materials were produced, consisting mainly of recycled gypsum, scrapped ceramics, decomposed granite, Shirasu and flow medium sand. Rice bran which contains amino acids, was mixed for the main three materials in different amounts per batch. When the amount of 3000 cm3 of rice bran was mixed, the surface was easily broken even during demolding.

TEST RESULTS OF BASE MATERTIALS FOR SEAWEED BEDS

Table 1 shows the test results of the unconfined compression test for the base materials of seaweed beds. The unconfined compressive strength is the result of the test of the specimens after 28 days of curing. The base materials of No.1-No.5 are mainly constituted of recycled gypsum and scrapped ceramics. The Portland cement is used only for the base materials of No.4-No.5. Although the base materials of No.4-No.5 are made by changing the water-cement ratio at the same mixing ratio of the



(a) decomposed granite

(b) Shirasu

(c) flow medium sand

Fig.3 Grain size distribution curve

Table 1 Results of the unconfined compression test (28 days curing)

Specimen		No.1	No.2	No3	No.4	No.5	No.6	No.7	No.8	No.9	No.10	No.11

	rice bran （cm^3）						2000	3000	2000	3000	2000	3000
Unconfined compressive strength (MPa)		11.1	7.2	15.1	2.3	1.9	6.8	0.7	6.5	0.5	1.1	0.3

Table 2 CO_2 reduction for each specimen when recycled gypsum is used as a solidification material

Specimen	No.1	No.2	No3	No.4	No.5	No.6	No.7	No.8	No.9	No.10	No.11
CO_2 reduction (Kg-CO_2/Kg)	0.2	0.1	0.0	0.3	0.2	0.1	0.1	0.1	0.1	0.1	0.1

recycled gypsum and scrapped ceramics, the unconfined compressive strength was much lower than that of No.1-No.3 base materials by the non-homogeneity of used materials. The unconfined compressive strength was the highest for No.3 base material and the lowest for No.11 base material due to the amount of recycled gypsum, cement and rice bran added.

The base materials of No.6-No.11 contain approximately 24% of the main materials (problematic soils), with approximately 19% of recycled gypsum, 14% of scrapped ceramics, 15% of blast-furnace slag cement type B, and 8% of iron powder by referring to previous research [4]. For the base materials, the unconfined compressive strength decreased considerably when the amount of 3000 cm^3 of rice bran was mixed. This is due to the fact that rice bran is an organic material with a significantly low unit volume weight, which may have influenced the decrease in unconfined compressive strength. Furthermore, the dissolution test was conducted according to the method of Notification No. 13 of the Environment Agency [5], and the dissolution of hazardous elements such as mercury and hexavalent chromium was not detected. The ratio of base materials used in this study was calculated based on the results of previous studies [4].

Table 2 shows the CO_2 reduction for each base material when recycled gypsum is used as a solidification material. The amount of CO_2 emitted at the production of Portland cement and blast-furnace slag cement type B is reported to be 0.80 kg-CO_2/kg and 0.50 kg-CO_2/kg, respectively [6]. The amount of CO_2 emitted during gypsum production was reported to be 0.07 kg-CO_2/kg [7]. We calculate the amount of CO_2 reduction when recycled gypsum and blast-furnace slag cement type B are used to make the base material for seaweed bed, comparing with the case of cement only is used as the solidification material in the present mixing ratio. For the calculation of No.4-No.5, the use of Portland cement is assumed.

Since the amount of the recycled gypsum and blast-furnace slag cement type B are the same for the base materials from No.6 to No.11, it can be seen that there is CO_2 reduction of approximately 0.1 kg-CO_2/kg of the produced base material. The use of recycled gypsum also results in a slightly lower pH, which has a smaller environmental load than that of blast furnace slag cement type B only. In Table 2, the CO_2 reduction was the highest for No.4 base material and the lowest for No.3 base material due to the amount of recycled gypsum and Portland cement.

MONITORING ROOTING AND GROWTH OF SEAWEED

We conducted the short-term monitoring by diving into the sea with an underwater digital camera in the summer and autumn seasons and underwater drone only in the winter and spring season. Tables 3-4 show a summary of the monitoring dates and sea quality data from September 2024 to April 2025. These tables shows that the temperature and salinity of the sea water were high in September, 2024. The pH was approximately 8.08-8.29. The of electrical conductivity was over 40 mS/cm throughout the year. The salinity was around 1.0-1.7 except in September 2024. In general, the temperature of the sea water in Kagoshima Bay is higher than that of Wakinoura due to these locations and oceanic currents.

The developed base materials for seaweed bed (diameter: 40cm, height: 14cm, weight: approximately 26.0kg, disk-shaped type) was set in the sea at Matsushima, Karatsu in June 2024 (No.1-No.5 in Table 1), and at Wakinoura, Kitakyushu and Kagoshima Bay, Kagoshima in late September 2024 (No.6-No.11 in Table 1). Figure 4 shows the changes in the properties of the base materials for seaweed beds (No.1-No.3) placed in the sea at Matsushima, Karatsu. Figures 4(a) and (b) show the base material for seaweed beds after 4 and 6 months passed. From these figures, the rooting of the green alga family could be seen on the surface of base materials. There was no significant differences among the three materials (No.1-No.3), regarding the rooting of seaweed. It is noted that the breakage of the base materials (No.4-No.5) was progressing after 2 months of the installation into the sea due to the low unconfined compressive strength.

Figures 5 and 6 show the changes in the properties of the base materials for seaweed beds (No.6- No.11) placed in the sea at Wakinoura, Kitakyushu and Kagoshima Bay, Kagoshima. When the amount of 3,000 cm3 of rice bran was mixed, some of the seaweed beds were slightly broken during their transportation. Figures 5(a) and 6(a) were taken immediately after the base materials for seaweed beds were placed in the sea, Figs. 5(b) and 6(b) after 2-2.5 months, and Figs. 5(c) and 6(c)-(d) after 4-6 months. Although Figs. 5(b)-5(c) and 6(b)-6(d) do not show all of the base material, Figs. 5(b) and 6(b) indicate that the rooting of algae could be observed on the entire surface of the base materials. Also, Figs. 5(c) and 6(c)-(d) show that seaweeds (perforated sea lettuces and gulfweeds) are growing on the surface of the base material. The short-term monitoring so far has shown no significant differences among the main materials (No.6-11) or the amount of rice bran added.

CONCLUSIONS

Base materials for seaweed beds that reduce the environmental load were developed using several recycled materials from disaster and industrial wastes with rice bran. The developed base materials were set into Matsushima, Wakinoura and Kagoshima Bay since June 2024, and a short-term survey was conducted to monitor the rooting and growth of seaweed on the surface of base materials at fixed intervals.

The conclusions drawn in this paper are summarized as follows:

1. We could develop the base materials for seaweed beds which would return to nature gradually over time, not permanent base materials.
2. A large amount of rice bran made the base materials fragile, so that a moderate amount of rice bran was preferable. In addition, the fish attracting effect was also observed because water-soluble substances were easily released immediately.
3. The main group of observed seaweed in Wakinoura and Kagoshima Bay was the green alga family, perforated sea lettuces and a small family of brown algae: gulfweeds and sea fans, respectively.

In future work, we would like to consider the evaluation method for the rooting of seaweeds and the CO_2 fixation of seaweeds rooted for the base materials to verify the effectiveness of blue carbon.

VIBRATION ANALYSIS OF AN AC MOTOR FOR PREDICTIVE MAINTENANCE AND ENVIRONMENTAL IMPACT ASSESSMENT

Suphattharachai Chomphan[1]

[1]Faculty of Engineering at Sriracha, Kasetsart University, Thailand

ABSTRACT

Electric machinery serves as a fundamental driving force in various industrial production processes. The three-phase synchronous motor is the most widely recognized type of electric machinery used in industrial plants due to its robust structure, high power output, and ease of maintenance. However, unexpected motor failures can lead to production disruptions. Since one of the key factors contributing to motor failure is vibration, this article presents an analysis of the vibration characteristics of an AC motor and examines its environmental impact. Since moving machinery inherently generates vibrations, this study specifically investigates the vibrations occurring both at the motor itself and at its mounting base. These vibrations can significantly affect the surrounding physical environment, including the buildings and facilities where the motor is installed. Experimental comparisons of vibration levels reveal that the vibration characteristics of an AC motor vary at different positions, including drive end, non-drive end, and motor base. Measurements indicate that the non-drive end exhibits the highest vibration levels under all load conditions, since the rotor shaft extends the farthest from the stator at the non-drive end, leading to increased oscillations. In contrast, the motor base experiences the lowest vibration levels since it is not directly attached to the motor. The findings from this study will contribute to the development of predictive maintenance strategies. The failures are typically detected after they occur, resulting in repair delays, downtime, and production losses. Identifying potential motor failures in advance can reduce operational disruptions, minimize maintenance costs, and improve overall efficiency.

Keywords: AC motor, Synchronous motor, Environmental impact, Vibration signal analysis, Fast Fourier transform

INTRODUCTION

Vibration and noise are inherent byproducts of manufacturing processes, primarily originating from the operation of machinery and moving components. These phenomena not only reduce equipment lifespan but also impact the surrounding environment and operator well-being. Vibrations often stem from transient forces within mechanical systems, while noise emissions are typically linked to structural vibrations and mechanical defects. As a result, research efforts increasingly focus on understanding and mitigating noise generation, transmission, and radiation [1].

AC motors are widely utilized across diverse sectors, including automotive, energy, aerospace, construction, and semiconductor manufacturing, due to their ability to provide reliable, continuous motion with controllable speed and torque. Common applications include conveyor systems, HVAC units, industrial fans, pumps, compressors, and robotic arms. AC motors are favored for their robustness, energy efficiency, and ease of maintenance. However, their operation inherently produces mechanical vibrations and acoustic emissions, which may lead to equipment wear, environmental noise, and user discomfort particularly in sensitive environments such as laboratories or cleanrooms.

The magnitude of these effects depends on factors such as motor design, load characteristics, mounting configuration, and interfacing materials. To address these challenges, recent engineering studies emphasize optimizing motor structure, selecting suitable materials, and improving spatial integration within industrial systems to reduce noise and vibration, thereby enhancing performance, longevity, and environmental compatibility [1, 2].

Dynamic characterization and vibration analysis have long served as fundamental techniques for diagnosing and assessing the operational condition of machine tools. In a study conducted by Zapciu et al. [3], these methods were employed with the primary objective of establishing a systematic procedure for determining the natural frequencies of machine tool components. By identifying these dynamic properties, the study aimed to enhance the stability and performance of machining operations, particularly in cutting processes involving machine tools or lathe systems. Accurate knowledge of natural frequencies enables engineers to mitigate resonance-related issues, improve cutting precision, and extend the lifespan of mechanical components within the machining environment.

Garcia-Perez et al. introduced a novel method for fault detection in induction motors by analyzing acoustic signals [4]. Utilizing the multiple signal

classification algorithm, the study achieved high-resolution spectral analysis to identify specific fault conditions through sound data. This approach offers a non-invasive alternative to traditional vibration and current monitoring techniques, enhancing the reliability of fault detection in industrial settings. The findings highlight the potential of acoustic analysis as a complementary tool for condition monitoring of induction motors.

In the recent years, Hu et al. focused on reducing electromagnetic vibration and noise in permanent magnet motors [5]. By analyzing radial electromagnetic forces and conducting modal analysis, the researchers proposed design optimizations to mitigate vibration acceleration and sound pressure levels. The study underscores the significance of structural design in minimizing noise emissions, particularly in applications where acoustic performance is critical. The proposed methods contribute to the development of quieter and more efficient permanent magnet motors.

Dai et al. examined the vibration and noise characteristics of high-speed magnetic suspension motors used in rock wool centrifuges [6]. The research involved modeling the motor using Maxwell software and analyzing radial force density waves to identify primary harmonic sources. By implementing a short-range double-layer winding optimization, the study achieved a reduction in vibration and noise without compromising electromagnetic performance. This work demonstrates the effectiveness of targeted design modifications in enhancing the acoustic behavior of high-speed motors.

Moreover, Chantal et al. presented a thorough review focusing on vibration analysis and control methodologies for dual-driven feed systems [7]. The study systematically examined vibration control technologies, parameter identification techniques, and system modeling frameworks while critically assessing the respective advantages and limitations of each method. Furthermore, the authors provided an in-depth discussion on the asymmetrical relationship between dual-driven and single-driven feed systems, emphasizing their dynamic characteristics within the context of computer numerical control (CNC) machine tools.

In the past years, Chomphan conducted a study to analyze the vibration and sound signals of motorcycle engines [8]. This research focused on the vibration signals transmitted through four primary contact points between the rider and the motorcycle body. In addition to analyzing these vibration and noise signals to distinguish between LPG-powered engines and conventional 2,200-cc gasoline engines, Chomphan et al. [9] introduced several fault simulations. Another notable study by Chomphan et al. [10] explored intrinsic factor analysis using a Fast Fourier Transform (FFT) adapted for the correlation analysis of vibration and noise signals in gasoline-powered vehicles. The signal processing techniques employed in these studies have shown significant potential and are effectively applied in the present work.

RESEARCH SIGNIFICANCE

This study examines the vibrations that occur at both the motor and its mounting base, as these vibrations can significantly impact the surrounding physical environment, including nearby buildings and infrastructure. The proposed signal processing methodology is adapted from established techniques reported in [8–11], which primarily focus on intrinsic factor analysis. The main objective is to quantify the vibration transmitted to the building structure by measuring signals from the AC synchronous motor, thereby evaluating the effectiveness of the developed technology. The measurement results provide insight into the environmental impact caused by forces generated from moving mechanical components. Focusing on the signal processing approach, the FFT was selected as the primary analysis tool. This method is enhanced with customized feature extraction techniques, drawing on successful implementations in prior studies on vibration and acoustic signal analysis [9–13].

MATERIAL AND METHODS

Operating Principle of AC Synchronous Motor

The operation of an AC synchronous motor is governed by the interaction between a rotating magnetic field generated by the stator and a stationary magnetic field established in the rotor via direct current (DC) excitation. When a balanced three-phase alternating current is applied to the stator windings, a rotating magnetic field (RMF) is produced, which rotates at a constant angular velocity referred to as the synchronous speed. The stator's RMF intersects with the rotor, which is excited by a DC source through either slip rings and brushes or a brushless excitation system, thereby establishing a constant magnetic field within the rotor reference frame [14].

Due to the alternating polarity of the stator's magnetic field at standstill, the rotor is subjected to a rapidly reversing torque, which results in no net starting torque. Consequently, synchronous motors are not inherently self-starting. To initiate rotation, auxiliary starting methods are employed to accelerate the rotor close to synchronous speed. Common starting techniques include the use of damper windings or external prime movers. Once the rotor speed approaches the synchronous value, the rotor's magnetic field synchronizes with the stator's rotating field through magnetic locking. This condition, known as synchronism, enables the rotor to rotate at precisely the same speed as the stator field [14].

In steady-state operation, the rotor maintains a constant speed equal to the synchronous speed, operating with zero slip. This characteristic renders the synchronous motor particularly advantageous for applications requiring precise and constant speed

Fig.1 The synchronous motor used in the experiment.

(a) (b) (c)

Fig.2 Sensor's allocation: (a) the drive end, (b) the non-drive end, and (c) the motor base.

operation, independent of load fluctuations. Additionally, by adjusting the level of DC excitation, the motor's power factor can be controlled, making synchronous machines well-suited for industrial applications where both speed regulation and reactive power compensation are critical [14].

Vibration Phenomena in AC Synchronous Motors

Vibrations in AC synchronous motors can arise from both electrical and mechanical sources, and their presence often indicates underlying issues affecting the motor's performance, efficiency, or lifespan. Unlike induction motors, synchronous machines are more sensitive to perturbations in load, excitation, and alignment due to their inherent operational rigidity at constant speed. The most prominent forms of vibration in synchronous motors include hunting, rotor unbalance, eccentricity, misalignment, and electromagnetic forces arising from asymmetries or faults [15].

Rotor unbalance is the most frequent source of vibration, especially in large or high-speed synchronous motors. This is due to: mechanical wear and tear over time, imperfect manufacturing or assembly tolerances, accumulation of dust, oil, or mechanical residue on the rotor. Even a small mass imbalance at high RPM leads to significant centrifugal forces, resulting in noticeable vibration. Because rotor unbalance directly affects both the vibration amplitude and mechanical stress, it is typically the first aspect monitored in vibration diagnostics [15].

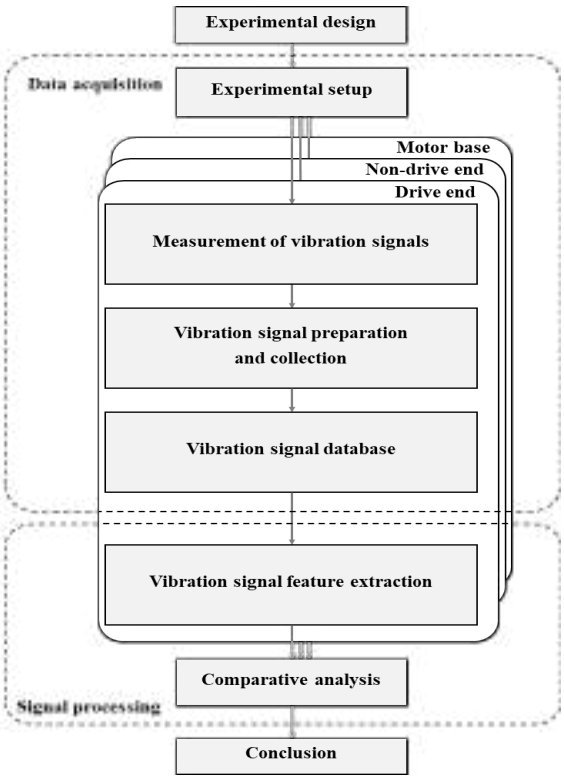

Fig.3 Experimental Procedure.

Sensor's Allocation

In a synchronous motor as depicted in Fig. 1, the part most susceptible to vibration in terms of both frequency and impact is typically the rotor assembly, particularly the shaft and bearings. In vibration diagnostics and condition monitoring, sensors are typically mounted near the motor bearings. The sensors that measure vibration generated by the motor, as explained earlier, and transmitted to the environmental surroundings were chosen to be located at three critical locations: the drive end, the non-drive end, and the motor base, as illustrated in Fig. 2.

Experimental Procedure

The experimental procedure was structured into two primary phases: data acquisition and signal processing, as illustrated in Fig. 3. The experimental design was initiated from the setup stage, where a high-frequency sensor system, along with associated accessories, was connected to a data acquisition computer. In the data acquisition phase, vibration signals were simultaneously recorded from the motor's drive-end surface under six distinct load conditions. The signals were first captured under no-load conditions at a voltage of 380 V and a current of 3.5 A, with a total of 50 measurement instances. Subsequently, signals were recorded under the other five different load conditions of 20%, 40%, 60%, 80%, and 100% at the same voltage. The corresponding electrical currents for these load levels were 4.16 A, 4.48 A, 5.48 A, 6.14 A, and 6.80 A, respectively. All data collection was carried out using the DigivibeMx M20 software.

Subsequently, a comprehensive vibration signal database was constructed through a systematic signal measurement protocol. The sensors operated at a fixed sampling frequency of 24,000 Hz. During the signal preparation and collection phase, signal segmentation was performed at the input port to ensure temporal consistency and synchronization across samples.

In addition to the drive-end measurements, vibration data were also collected at two additional sensor locations: the non-drive end of the motor and the motor base. This multi-point sensing configuration enabled a more holistic characterization of the motor's vibrational behavior under varying mechanical loads.

Following the data acquisition phase, the collected data were categorized into six distinct segments corresponding to the predefined load conditions. In the signal processing phase, a feature extraction procedure was implemented to characterize the vibrational behavior under each load. Specifically, the FFT was applied to each segmented signal to convert the time-domain data into the frequency domain, yielding corresponding frequency spectra.

From the resulting spectra, five significant peaks along the frequency axis were identified and used to determine the dominant frequencies and their associated magnitudes. These peaks represent the primary frequency components of the vibration or acoustic signals generated by the motor's internal moving parts. To enhance reliability and reduce signal variability, the extracted features were subjected to an averaging process across multiple measurements for each load condition.

After feature extraction, a comparative analysis examined the relationship between motor load conditions and corresponding spectral characteristics by means used in [11-13]. The implications of these findings, along with in-depth interpretations, are presented and discussed comprehensively in the conclusion section of this paper.

EXPERIMENTAL RESULTS

The comparative analysis methodology utilizes features derived from spectral analysis to compute statistical averages. To facilitate visual interpretation, a comparative bar chart has been developed [16, 17].

Specifically, the comparative analysis of vibration involves evaluating the average magnitudes of the first through fifth peaks in the frequency spectrum of vibration signals recorded under varying load conditions, as illustrated in Figs. 4-6.

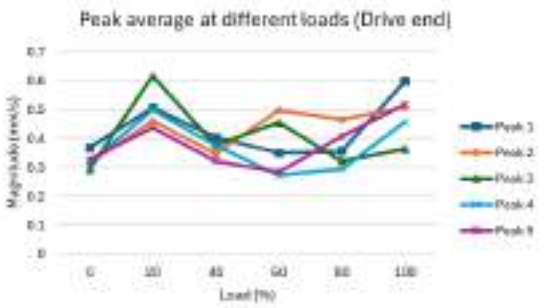

Fig.4 The averaged magnitudes of the 1st to 5th peaks of the frequency spectrum of the vibration signal at the motor's drive end with distinct load conditions.

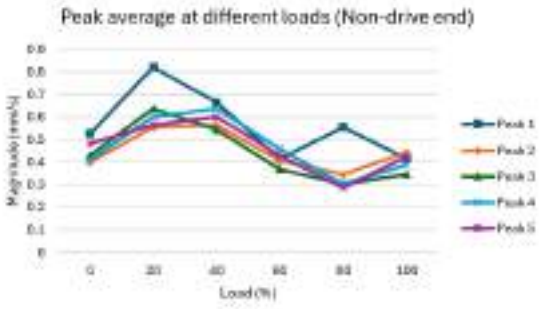

Fig.5 The averaged magnitudes of the 1st to 5th peaks of the frequency spectrum of the vibration signal at the motor's non-drive end with distinct load conditions.

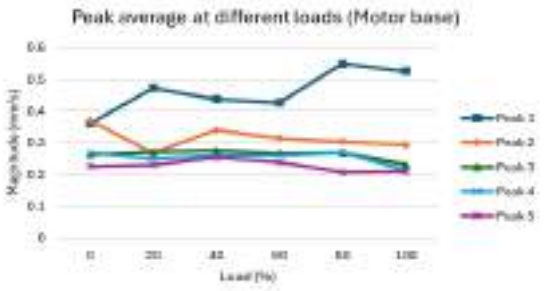

Fig.6 The averaged magnitudes of the 1st to 5th peaks of the frequency spectrum of the vibration signal at the motor base with distinct load conditions.

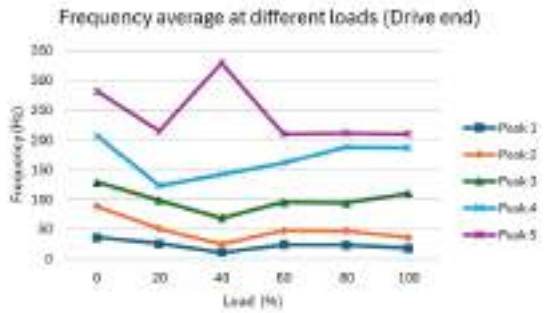

Fig.7 The averaged frequencies of the 1st to 5th peaks of the frequency spectrum of the vibration signal at the motor's drive end with distinct load conditions.

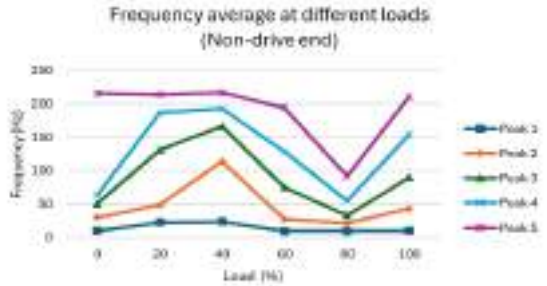

Fig.8 The averaged frequencies of the 1st to 5th peaks of the frequency spectrum of the vibration signal at the motor's non-drive end with distinct load conditions.

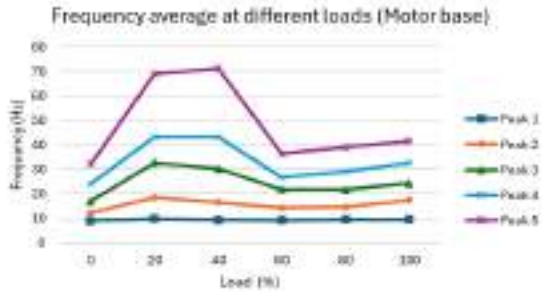

Fig.9 The averaged frequencies of the 1st to 5th peaks of the frequency spectrum of the vibration signal at the motor base with distinct load conditions.

Additionally, Figs. 7-9 present a comparison of the average frequencies corresponding to the first through fifth spectral peaks of the vibration signals under the same load conditions.

The analysis of vibration amplitude at the drive-end position of the motor. The results indicate that the peak amplitude tends to vary with increasing load levels, exhibiting its maximum value at 100% load. Notably, an anomalously high peak amplitude is observed at 20% load, which is significantly greater than those at adjacent load levels as presented in Fig. 4.

The vibration amplitude analysis at the non-drive end of the motor. It is observed that the peak amplitude reaches its highest value at 20% load. Subsequently, the amplitude demonstrates a decreasing trend as the load increases as illustrated in Fig. 5.

Furthermore, Fig. 6 shows the vibration amplitude analysis at the motor base. The amplitude of the first spectral peak exhibits a trend of increasing magnitude with higher load levels, whereas the amplitudes of the remaining peaks remain relatively stable, with some exhibiting a slight downward trend.

The dominant frequency analysis at the drive end of the motor. The frequencies of the first to third peaks remain relatively constant regardless of load conditions. In contrast, the frequencies of the fourth and fifth peaks fluctuate with changes in load, displaying no consistent pattern as seen in Fig. 7.

The dominant frequency analysis at the non-drive end of the motor. Only the frequency of the first peak remains relatively constant across varying load levels. The frequencies of peaks two through five, however, demonstrate significant fluctuations in response to load variations as shown in Fig. 8. Additionally, it is noteworthy that a clustering of peak frequencies occurs at 80% load.

The dominant frequency analysis at the motor base. The frequencies of peaks one through four remain stable across all load levels. However, the fifth peak exhibits load-dependent variability, with its frequency changing irregularly as the load varies as displayed in Fig. 9.

Overall, the experimental results presented in Figs. 4–6 indicate that the non-drive end consistently exhibits the highest vibration amplitudes under all loading conditions. This trend is primarily attributed to the extended length of the rotor shaft beyond the stator at the non-drive end, which increases the susceptibility to oscillatory motion. In contrast, the motor base consistently records the lowest vibration levels, owing to its mechanical decoupling from direct motor attachment.

CONCLUSIONS

This study presents a comprehensive experimental investigation into the vibrational characteristics of an AC synchronous motor operating under varying load conditions. The experimental procedure encompassed two principal phases: data acquisition and signal processing. The results indicate that vibration behavior is sensitive to both load condition and sensor location. These findings underscore the complex interplay between mechanical loading and vibrational response, highlighting the diagnostic value of multi-point vibration analysis in assessing motor condition and performance. The results serve as a foundation for further studies in predictive maintenance and fault detection using vibration signal analysis.

ACKNOWLEDGMENTS

This study was conducted with extensive utilization of laboratory facilities and technical resources provided by the Mechanical System and Signal Processing Research Group. Additional operational support was contributed by laboratory personnel. Financial support for this research was provided by the Faculty of Engineering at Sriracha, Kasetsart University, Sriracha Campus.

AI-BASED GEOTECHNICAL INFORMATION PREDICTION AND LIQUEFACTION HAZARD MAPPING FOR THE TOKYO METROPOLITAN AREA

Arisa Katsuumi [1], Koutaro Takasuna [1] and Shinya Inazumi [1]

[1] Shibaura Institute of Technology, Japan

ABSTRACT

This study presents an AI-based framework for predicting subsurface geotechnical conditions and mapping liquefaction hazards across the Tokyo metropolitan area. A comprehensive dataset of 13,926 borehole logs and elevation data was used to train a two-level stacking model integrating Random Forest, Gradient Boosting, and Support Vector Machine algorithms. The model accurately predicted SPT N-values, soil classifications, and groundwater levels at un-surveyed locations. These predictions were incorporated into the Potential Liquefaction (PL) method, enabling a quantitative evaluation of liquefaction risks. A high-resolution (200 m × 200 m) hazard map was generated, revealing enhanced spatial granularity compared to existing public maps (500 m × 500 m). The proposed approach successfully identified localized high-risk areas, especially in reclaimed coastal zones such as eastern Tokyo. Comparative analysis demonstrated that the AI-based method provided superior detection sensitivity and predictive continuity even in data-scarce regions. The integration of ensemble learning and geotechnical engineering knowledge offers a scalable, data-efficient solution for urban hazard assessment. This framework contributes to improving disaster mitigation strategies and infrastructure planning in earthquake-prone urban environments. Future work will refine missing data estimation and extend the method to handle complex soil stratifications, further enhancing its practical applicability to large-scale geotechnical risk evaluations.

Keywords: Liquefaction, Ground Condition Prediction, Ensemble Learning, Hazard Map, AI

INTRODUCTION

Liquefaction, a phenomenon in which saturated soils lose their strength and stiffness in response to earthquake shaking, has long been recognized as a critical cause of structural damage in seismic regions [1]. The 1964 Niigata and Alaska earthquakes notably brought this hazard to the forefront, prompting extensive field investigations and laboratory experiments. These studies have since contributed to a deeper understanding of liquefaction mechanisms and have informed the development of engineering-based prediction and mitigation strategies widely used today.

In recent years, increasing concern over the potential occurrence of large-scale seismic events, such as the anticipated Nankai Trough earthquake, has highlighted the importance of precise and spatially comprehensive ground investigations in urban areas. Liquefaction risk is particularly significant in densely populated and infrastructure-heavy regions like the Tokyo metropolitan area, where the consequences of ground failure could be catastrophic. Thus, the need for accurate and high-resolution liquefaction hazard assessment is more pressing than ever.

However, conventional ground investigation methods, while reliable, are inherently constrained by substantial time, financial, and logistical costs. As a result, survey data are often limited in both spatial density and coverage. This poses a major challenge for hazard mapping, especially in complex urban terrains where ground conditions can vary considerably over short distances. The resulting lack of detailed subsurface data makes it difficult to conduct precise risk evaluations at the local scale.

To address these limitations, advanced data-driven techniques such as artificial intelligence (AI) and machine learning (ML) have emerged as promising tools for geotechnical analysis [2,3]. These approaches enable the extraction of meaningful patterns from limited datasets, allowing for the inference of subsurface properties in un-surveyed locations. These methods significantly enhance the spatial resolution and reliability of ground condition predictions across large areas.

The objective of this study is to construct a predictive framework for estimating ground conditions throughout the Tokyo metropolitan area by leveraging AI-based techniques. Specifically, the predicted subsurface properties are applied within the PL method, an established engineering procedure for liquefaction hazard evaluation, to generate detailed hazard maps. This integrated approach aims to improve the granularity of hazard assessments and to enhance their accuracy, particularly in areas with sparse direct survey data. Through this, the study contributes to the advancement of data-efficient methodologies for disaster prevention and infrastructure resilience planning in urban

environments.

METHODOLOGY

Construction of the AI-Based Predictive Model

Artificial intelligence, particularly machine learning, has become an increasingly valuable tool in geotechnical engineering due to its ability to handle large, complex, and often incomplete datasets. In this study, an ensemble learning approach, specifically, a stacking methodology, was employed to construct a strong predictive model for subsurface geotechnical properties [3,4]. Ensemble learning combines multiple base models to improve generalization performance, reduce overfitting, and capture complex nonlinear relationships within the data.

As schematically illustrated in Fig. 1, the stacking model operates in two stages. In the first stage, three base learners, Random Forest, Gradient Boosting, and Support Vector Machine, are trained independently using the same input dataset. Each of these algorithms contributes distinct strengths: Random Forest is effective in handling high-dimensional data and mitigating variance through averaging; Gradient Boosting improves predictive accuracy by sequentially correcting errors from prior models; and Support Vector Machine excels in managing nonlinear boundaries in both classification and regression tasks.

In the second stage, the outputs of these base models serve as input features to a meta-model, which is also constructed using Gradient Boosting. This hierarchical structure allows the model to effectively learn from the complementary strengths of the base learners, thereby achieving enhanced prediction performance while controlling for bias and variance. The combined use of tree-based and margin-based methods ensures the ensemble is both accurate and generalizable to unseen data, which is critical for applications involving geospatial variability in urban regions.

Liquefaction Hazard Assessment Using the PL Method

The Potential Liquefaction (PL) method provides a quantitative framework for evaluating the likelihood of soil liquefaction during seismic events [5]. It operates by integrating the factor of safety (FL) across relevant soil layers, assigning appropriate weights to compute a PL value for each location. The mathematical procedures and threshold-based hazard classifications are outlined in Table 1 and expressed in Eqs. (1) and (2).

$$P_L = \int_0^{20} (1 - F_L)(10 - 0.5x)dx \quad (1)$$

$$F_L = \frac{R}{L} \quad (2)$$

$5 < P_L \leq 15$	Liquefaction Risk: Medium
$0 \leq P_L \leq 5$	Liquefaction Risk: Small

Fig. 2 Spatial distribution map of groundwater levels in the Tokyo metropolitan area

Where F_L is the liquefaction resistance, x is the depth from ground surface, R is the dynamic shear strength, and L is the seismic shear stress ratio.

This method targets subsurface layers that meet specific liquefaction-susceptible conditions, including:

- Groundwater table located within 10 meters of the ground surface, and saturated layers present within a depth of 20 meters.
- Fines content (FC) of 35% or less, or FC greater than 35% provided the plasticity index (Ip) does not exceed 15.
- Median grain diameter (D50) less than or equal to 10 mm and 10% grain diameter (D10) less than or equal to 1 mm.

The soil parameters used in the PL method evaluation were selected based on typical values for each soil type commonly found in the Tokyo metropolitan area, following established geotechnical engineering practice and previous liquefaction studies [5]. These standardized parameters ensure consistency in the evaluation process and compatibility with the PL method requirements.

These criteria reflect widely accepted empirical correlations between soil characteristics and liquefaction potential. For this study, spatial

Table 2 Soil classification parameters used in PL method evaluation (parameters selected based on typical values for Tokyo area soils following established geotechnical practice)

Soil Type	Unit Weight Below Groundwater Table (t/m^3)	Unit Weight Above Groundwater Table (t/m^3)	Median Particle Diameter D_{50} (mm)	Fines Content (%)
Gravel	2.1	1.9	0.6	0
Sand	1.9	1.7	0.25	10
Silt	1.7	1.5	0.02	80
Clay	1.5	1.3	0.025	75

groundwater level data were obtained and interpolated as visualized in Fig. 2, while soil parameter classifications used in PL evaluation are listed in Table 2. By applying the PL method to AI-predicted subsurface profiles, the study produces hazard assessments that integrate both geotechnical engineering knowledge and data-driven prediction.

Data Collection and Prediction Framework

Geotechnical data used in this study were derived from publicly available borehole logs provided by the Tokyo Metropolitan Government. As shown in Fig. 3, the dataset includes location information (latitude and longitude), SPT N-values, and soil classification data from 13,926 sites. In addition, surface elevation data were incorporated from the Geospatial Information Authority of Japan to enhance the spatial resolution of the input dataset.

One of the key challenges was the presence of missing groundwater data in many of the borehole records. To address this, spatial interpolation was applied using surrounding valid data, resulting in a comprehensive groundwater distribution map as shown in Fig. 2. This step was essential for ensuring consistent PL evaluation across the study area.

For the prediction of N-values, the model treated the N-value at each depth from 1 to 20 meters as the target variable, with explanatory variables including location coordinates, elevation, and known N-values at other depths. In the case of soil classification, a similar set of explanatory variables was employed. Where borehole logs indicated mixed soil types within a single layer, the dominant material type was used to ensure consistency in prediction and compatibility with the PL method. Due to the lack of direct laboratory data for predicted soil types, soil property parameters from Table 2 were applied based on the classification results.

RESULTS AND DISCUSSION

Using the ensemble learning model constructed as described in the previous section, key subsurface geotechnical parameters, namely SPT N-values, soil classification, and groundwater level, were predicted across the entire Tokyo metropolitan area. These predicted values served as input for the PL method,

Fig. 3 Sample borehole log extracted from Tokyo metropolitan dataset

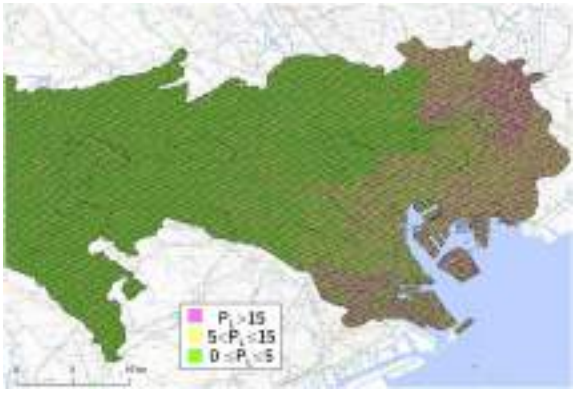

Fig. 4 High-resolution liquefaction hazard map generated by this study (200 m × 200 m)

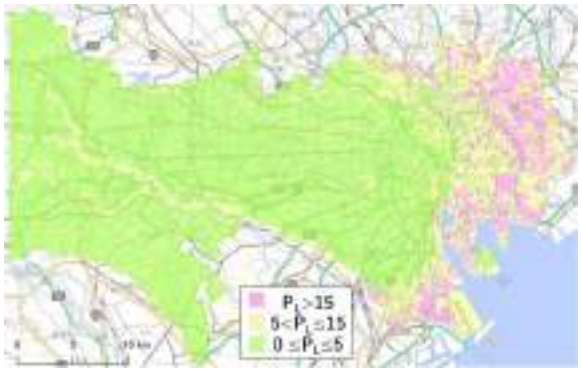

Fig. 5 Publicly available liquefaction hazard map (500 m × 500 m) for comparison

enabling the calculation of liquefaction potential for each mesh point.

The resulting liquefaction hazard map is presented in Fig. 4, which depicts the PL value distribution on a 200 m × 200 m mesh. Each mesh cell is color-coded based on its computed PL value, allowing for the identification of areas with differing degrees of liquefaction susceptibility. The fine resolution of this map facilitates a more localized assessment of hazard, which is crucial for urban-scale disaster mitigation planning.

Model accuracy analysis reveals distinct geographical patterns across the study area. High prediction accuracy ($R^2 > 0.85$) is achieved in eastern Tokyo, particularly in Koto Ward ($R^2 = 0.88$) and surrounding reclaimed coastal areas such as Sumida Ward ($R^2 = 0.86$) and Edogawa Ward ($R^2 = 0.84$). These regions benefit from dense borehole data coverage and relatively uniform geological conditions. Conversely, moderate accuracy ($R^2 = 0.70$-0.80) is observed in western Tokyo's mountainous areas and peripheral regions where data density is lower. The high accuracy in Koto Ward is particularly significant given its elevated liquefaction risk, providing confidence in hazard assessments for this critical area.

To evaluate the performance and practical utility of the proposed method, the generated map was compared with the publicly available liquefaction hazard map, shown in Fig. 5, which is based on a coarser 500 m × 500 m mesh. This comparative analysis provides insights into the added value of the AI-based approach in terms of spatial granularity and predictive fidelity.

The comparison reveals that in the western part of Tokyo, where ground conditions are generally more stable and data density is lower, both maps show similar hazard classifications. However, significant differences emerge in eastern Tokyo, particularly in reclaimed coastal zones such as Koto Ward. In these areas, the AI-generated map identifies a broader extent of zones categorized as "medium" or higher risk (PL = 5–15), indicating greater sensitivity to localized ground conditions. Specifically, Koto Ward demonstrates both high liquefaction risk and high prediction confidence, making it a priority area for detailed investigation. This outcome underscores the ensemble model's ability to extrapolate ground conditions in data-sparse regions while preserving spatial accuracy [6].

The improved resolution and accuracy of the proposed approach are attributed to several key factors. Regional accuracy assessment shows that eastern reclaimed areas, including Koto Ward, consistently achieve higher prediction reliability due to dense data coverage and uniform geological conditions, while western mountainous regions show moderate accuracy reflecting more complex terrain and sparser data distribution.

- Finer mesh size: The 200 m resolution enables the detection of subtle variations in soil conditions that would be obscured in coarser mesh.
- Integration of interpolated groundwater data: As visualized in Fig. 2, spatial interpolation fills data gaps and enhances the completeness of the input dataset for the PL method.
- Strong predictive modeling: The ensemble learning approach effectively captures nonlinear interactions between location, soil type, elevation, and existing N-values, enabling reliable predictions beyond observed locations.

Furthermore, the denser geotechnical data distribution in eastern Tokyo contributes to higher model reliability in these areas, which is evident from the hazard distribution patterns. Conversely, in regions with fewer boreholes, the model still maintains predictive continuity due to its ability to generalize from surrounding data.

These findings demonstrate that the integration of AI-based prediction with the PL method yields a high-resolution hazard map that offers enhanced insight into urban liquefaction risk. The explicit accuracy assessment, particularly highlighting high-confidence predictions in critical areas like Koto Ward, provides valuable guidance for practitioners to prioritize areas for detailed investigation and mitigation planning. This is particularly valuable for local governments and infrastructure planners who require detailed spatial information to guide seismic risk mitigation strategies, land-use planning, and emergency response frameworks.

CONCLUSIONS

This study developed and applied an AI-based geotechnical prediction framework to assess liquefaction hazard across the Tokyo metropolitan area. By integrating ensemble learning with established engineering methodologies, the proposed approach offers a data-efficient and spatially detailed solution for urban seismic risk evaluation. The main findings and contributions of this study are summarized below:

(1) An ensemble learning model combining Random Forest, Gradient Boosting, and Support Vector Machine was successfully constructed using a stacking approach, allowing for high-accuracy prediction of key geotechnical parameters such as N-values, soil classification, and groundwater level across un-surveyed areas.

(2) The predicted subsurface information was effectively incorporated into the PL (Potential Liquefaction) method, enabling quantitative liquefaction hazard evaluation that accounts for depth-dependent safety factors and soil susceptibility conditions.

(3) A high-resolution (200 m × 200 m) liquefaction hazard map was generated, providing improved

spatial granularity compared to publicly available maps (e.g., Fig. 5) and enabling more localized risk assessments, particularly beneficial for urban infrastructure planning.

(4) The AI-based model demonstrated strong predictive reliability even in data-scarce regions, by leveraging spatial interpolation and nonlinear pattern recognition to estimate missing or incomplete geotechnical data (e.g., groundwater levels as shown in Fig. 2).

(5) Comparative analysis revealed that the proposed method identifies a broader extent of high-risk zones in vulnerable areas, such as the reclaimed lands of eastern Tokyo, highlighting its effectiveness in capturing localized hazard variations that may be underestimated by conventional methods.

This research provides a scalable and transferable framework that can be adapted to other urban regions facing similar challenges in liquefaction risk assessment. Future work will focus on improving prediction accuracy by refining the estimation of missing geotechnical parameters, incorporating more diverse data sources, and extending the methodology to account for mixed soil properties in greater detail.

APPLICATION OF SROI FRAMEWORK IN COST-EFFECTIVENESS ANALYSIS FOR THE ENVIRONMENTAL PROTECTION INVESTMENTS OF QUARRY MINES

Ngwu Tochukwu[1], Somprasong Komsoon[2] and Chanapol Charoentanaworakun[3]

Faculty of Engineering, Chiang Mai University, Thailand

ABSTRACT

Environmental Protection Plans (EPPs) are mandatory components of regulatory compliance for quarry mining operations in Thailand. However, the challenges in quantifying the environmental and social values generated by these interventions hamper the evaluation of their cost-effectiveness, potentially hindering optimal resource allocation. This study addresses this gap by applying a Social Return on Investment (SROI) framework to evaluate the environmental benefits of EPPs in two selected quarry mines. This was achieved by using the benefit from reduced pollution and environmental improvements and monetary proxies for each EPP category to quantify the cumulative social and environmental values, which are compared to the operational expenditures (OPEX) involved in the implementation. Results indicate that Mine A generated a value of $320,528.11 from an investment of $200,734.75, yielding an SROI of 1.60, and Mine B generated $115,050.00 from $77,908.25, with an SROI of 1.50. The higher SROI obtained in Mine A is attributed to a more systematic EPP implementation and pollution reduction and larger land degradation, which requires remediation. These findings justify the cost-effectiveness of the EPP investments, emphasizing the capacity of SROI as a tool for evidence-based environmental decision-making. The study supports the integration of SROI into regulatory benchmarking and sustainability reporting frameworks, enabling stakeholders to assess the value generated from investments in environmental stewardship in mining.

Keywords: Social Return on Investment, Mining, Environmental Protection Plans, Theory of Change

INTRODUCTION

The quarry industry has played a significant role in Thailand's economy for several decades, driven by economic demands and industrialization [1]. However, quarrying activities also generate significant environmental impacts, which necessitate the implementation of regulatory frameworks and protection schemes to ensure a harmonious balance between economic benefit and environmental sustainability. These environmental impacts of quarrying operations vary due to the type of mineral production, scale of operation, and other geologic factors. Environmental Impact Assessment (EIA) has therefore become a crucial tool for evaluating the potential environmental impacts of quarrying activities [2], serving as the foundation for developing Environmental Protection Plans (EPPs) aimed at mitigating these impacts. Quarrying, like other mining activities in Thailand, is regulated by comprehensive environmental regulations aimed at curbing negative impacts such as air, noise, and water pollution and alterations to the natural landscape. According to the Enhancement and Conservation of National Environmental Quality Act B.E. 2535 (1992) in Thailand, mining operations are required to implement an Environmental Impact Assessment (EIA) and set up Environmental Protection Plans (EPPs) prior to receiving project approval. This plan takes into account cumulative expected environmental impacts of the operations and a corresponding protective plan to mitigate each impact [3].While these measures ensure compliance with environmental policies, there has been limited focus on the quantification of the generated environmental benefits relative to the cost of implementation. This prompts an inquiry into the cost-effectiveness of these measures and their capacity to deliver measurable and optimum value to stakeholders. Furthermore, an apparent challenge in evaluating the cost-effectiveness of EIAs and environmental protection measures is that it is difficult to quantifiably define their environmental outcomes or benefits [3, 4]. In response to this challenge, literature such as [5] recommends further studies with a focus on advancing ideas for measurable and evidence-based methods for evaluating environmental outcomes of EIA interventions. In addition, [6] have applied SROI in quantifying the social benefits of EIA intervention projects in monetary terms and further evaluating their effectiveness compared to the financial investments. To address these gaps, this study evaluates the cost-effectiveness of these environmental protection plans of quarries by evaluating their environmental protection schemes using the existing framework of Social Return on

Investment (SROI). This decision is due to the ability of SROI to measure the environmental benefits of EIA programs and EPPs relative to the financial cost of implementation, thereby effectively capturing environmental and social outcomes as well as the economic costs in a single metric [7, 8]. This study facilitates the evaluation and implementation of environmental protection measures that are both economically viable and environmentally sustainable in quarry mines.

RESEARCH SIGNIFICANCE

As part of regulatory compliance and sustainability efforts, quarry mines in Thailand are mandated to invest in the implementation of Environmental Protection Plans (EPPs). However, there is a lack of tools or frameworks to assess and quantify the environmental benefits generated by these investments. This gap presents a critical challenge in determining the actual impact and cost-effectiveness of EPPs, resulting in inefficient resource allocation and suboptimal performance. This research addresses this gap by applying a systematic approach to evaluate the environmental benefits of EPPs in quarries using SROI principles to support cost-effective and evidence-based investment in EPPs.

METHODOLOGY

The study follows a structured, multi-phase approach designed to assess the cost-effectiveness and social-environmental value of Environmental Protection Plans (EPPs) implemented by selected quarry operations. Two quarry sites were purposively selected as case studies based on the availability of Environmental Impact Assessment (EIA) reports and Environmental Protection Plan documentation. Relevant secondary data were collected through a comprehensive literature review, including publicly available EIA reports, corporate sustainability reports, and peer-reviewed publications related to environmental management in mining. Based on the collected documentation, key mitigation measures were identified and systematically categorized into four main environmental domains: air quality control (e.g., dust suppression, emission filters), water quality management (e.g., sedimentation ponds, recycling systems), noise reduction (e.g., acoustic barriers, limited blasting schedules), and land rehabilitation and reforestation (e.g., planting programs, soil restoration). Each mitigation measure was documented with technical specifications, implementation timelines, and associated costs. The identified mitigation strategies were used to develop a set of inputs for the Social Return on Investment (SROI) analysis. Following the Theory of Change model. For each outcome identified, financial proxies were assigned to represent the environmental and social value generated. These proxies were derived from market prices, shadow pricing, benefit transfer techniques, and previous SROI studies [9, 10]. The total investment cost of implementing each EPP was then compared against the monetized social and environmental benefits to calculate the SROI ratio (i.e., the value generated per unit of investment). This analysis allowed for a direct comparison between the two quarries.

Quarry Site Selection and Cost Assessment of Environmental Protection Plans

Two limestone quarries in Thailand were selected for this study based on differences in production scale and concession area, as outlined in Table 1. Quarry A, a medium-scale operation in central Thailand, produces about 100,000 tons per year, while the smaller quarry in the same region produces around 32,000 tons annually. The Environmental Protection Plans (EPPs) were drafted through a systematic review of Environmental Impact Assessment (EIA) reports and field observations. Mitigation measures from each potential environmental impact served as the foundation for the EPPs at each quarry. The environmental monitoring reports were used to assess compliance with these plans. Data from the Thai Department of Primary Industries and Mines (DPIM), field observations, industry documents, and EIA documents of each quarry were used to estimate investment costs in Environmental Protection Plans (EPPs), as shown in Table 1 for Mines A and B.

Defining Theory of Changes

This study uses a Theory of Change (ToC) approach to assess the environmental and social impacts or outcomes of EPPs in quarry operations. ToC serves as the conceptual basis for impact valuation using the Social Return on Investment (SROI) methodology. ToC enables the mapping of causal pathways linking environmental interventions to expected outcomes, using empirical evidence drawn from observations and data analysis [11]. Determining the theory of change and selecting appropriate financial proxies are key steps in estimating the environmental and social value of each EPP at the selected mines.

Quantifying Impacts and Assigning Financial Proxy

In this study, the benefits generated by EPPs are quantified based on the nature and objectives of each Environmental Protection Plan (EPP). To assign monetary value to the environmental and social outcomes of the EPPs that were identified through the Theory of Change, this adopts a systematic approach

to determine appropriate financial proxies. Financial proxies represent the estimated monetary value of non-market outcomes, enabling a standardized comparison between costs, effectiveness, and benefits using the SROI framework [12-15].For air pollution reduction, benefits were calculated by multiplying the amount of reduced emissions by the social cost per unit of emission. Reforestation benefits were derived by estimating the economic value of ecosystem services, which is carbon sequestration. Noise abatement benefits were calculated as the reduction in noise levels from baseline to post-intervention scenarios and multiplied by willingness to pay (WTP) for noise pollution reduction in the region. The benefits for water quality improvement were estimated based on the volume of pollutants removed, the amount of treated wastewater, and the market price of removal per volume. Overall, the value/benefits of each EPP correspond to the damage avoided or reduced through its implementation. Table 2 summarizes the calculated social and environmental outcomes in monetary terms.

Economic Outcome from Environmental Value E_v and Social Value S_v

This approach integrates environmental economic valuation techniques with data derived from ToC and financial proxies, providing a monetary valuation of the benefits of the intervention. Due to the available data, the valuation method applied in this study is the benefit from reduced pollution and environmental improvements and monetary proxies for each EPP category to quantify the cumulative social and environmental values. The general equation for determining economic outcome in monetary terms from environmental and social values generated is defined as Equation (1) and Equation (2), respectively.

$$E_v = \sum_{i=1}^{n}[Q_i \times FP_i \times (1 - \sum D_i)] \quad (1)$$

$$S_v = \sum_{i=1}^{n}[Q_j \times FP_{ij} \times (1 - \sum D_j)] \quad (2)$$

Where E_v refers to environmental value and S_v represents social value created. Q_i is the representative of quantity or magnitude of the environmental outcome (e.g., tons of CO_2 reduced, hectares reforested). FP_i is the parameter of financial proxy for each environmental outcome per unit. D_i indicates the rate at which a specific environmental outcome declines over a given period, expressed as a percentage and calculated in relation to a baseline or the initial state of environmental conditions.

Valuation of SROI

SROI is a form of cost-benefit analysis that extends traditional financial accounting to include non-market social and environmental outcomes. The aim is to express the total social value generated per unit of investment, which is illustrated as equation (3):

$$SROI = \frac{NPV_{B-EPP}}{NPV_i} \quad (3)$$

NPV_{B-EPP} is the Net Present Value representing the sum of total value of anticipated outcomes, expressed in monetary terms and adjusted to reflect relevant factors specific to the EPPs., while NPV_i accounts for all associated costs, including capital investments, operational expenses, and expenditures related to environmental or social mitigation measures.

Evaluation of Cost-Effectiveness Using Social Return on Investment (SROI) Framework

The Social Return on Investment (SROI) framework presents a viable methodology for conducting cost-effectiveness analysis (CEA) of Environmental Protection Plans (EPPs), as it integrates both financial and non-financial evidence-based outcomes into an evaluation model [18-20]. SROI is obtained by dividing the social and environmental value generated by an intervention by the financial cost of implementation. This ratio signifies the social and environmental values generated per unit of financial investment, offering an apparent measure of the impact relative to the resources allocated. The aim of the analysis is to assess the efficiency of investment in EPPs by comparing the total monetized value of social, environmental, and economic outcomes against the costs incurred. This allows decision-makers to determine which EPP strategies deliver the most optimum value relative to their financial input. Equation (4) demonstrates the formula applied in this study to determine the cost-effectiveness of EPP plans.

$$C_{Eff} = \frac{\sum(S_V + E_v)}{\sum(CAPEX_{EPPS} + OPEX_{EPPs} + E_{xi})} \times 100 \quad (4)$$

Where C_{Eff} is the percentage of cost effectiveness in the investment of EPPs. S_V stands for the social value generated by the EPPs , $while\ E_v$ represents the environmental value generated by the EPPs. The $CAPEX_{EPPS}$ and $OPEX_{EPPs}$ is the capital cost and operation cost of the EPPs, respectively. In addition, the E_{xi} term refers to auxiliary expenditure related to EPPs including additional technology and fees.

RESULTS AND DISCUSSION

Evaluating Investments in EPPs

The total investments in EPPs are $200,734.75 and $77,908.25 for mine A and B, respectively, as shown in table 1. This consists of investments in air

quality management, water quality management, noise and vibration control, reforestation, extra EPPs, and reclamation and environmental funds.

Table 1 Summarized EPPs Investments/OPEX for Mine A and B.

Category	Mine A	Mine B
Production Size (tons/month)	100,000	32,000
Concession Area (sq.km)	0.928	0.538
EPPs OPEX/Investments (USD)		
Air Quality Management	52,600.00	15,900.00
Water Quality Management	3,771.56	976
Noise & Vibration Control	0	0
Reforestation	6,183.61	2,495.54
Extra EPPs	5,000.00	0
Reclamation and environmental Funds	133,179.58	58,536.71
TOTAL OPEX	**200,734.75**	**77,908.25**

Quantifying Benefits of the EPPs in Monetary Terms

The quantified monetary outcomes generated by the Environmental Protection Plans (EPPs) show a cumulative value of $320,528.11 and $115,050.00 for Mine A and Mine B, respectively, as shown in table (2) below.

Table 2 shows the monetary outcomes generated by the EPPs

Category	Mine A (USD)	Mine B (USD)
Air Quality Management	55,080.00	45,900.00
Water Quality Management	32,435.00	8,567.00
Noise & Vibration Control	22,032.00	7,908.00
Reforestation	12,852.00	4,613.00
Extra EPPs	45,900.00	16,475.00
Environmental Fees & Funding	206,695.53	74,188.00
Total	**320,528.53**	**115,050.00**

This reflects the extensive economic and social benefits derived from the implementation of EPPs in mining operations. The higher monetary outcome for Mine A is primarily due to more systematic application of EPPs, which results in more reduced pollution and degradation. Additionally, a larger land concession area, which necessitates extra remediation efforts, also contributes to the higher monetary outcome in Mine A, and vice versa for Mine B. Reclamation and environmental funds contributed to higher monetary outcomes in both quarries, underscoring the significance of these investments in the restoration of degraded landscapes. Other significant aspects include extra EPPs (such as advanced filtration systems) and water and air quality management, which shows the direct benefits of pollution control measures in community and environmental sustainability. The variations in the quantified monetary outcomes of the two quarries show that production scale and population density play a crucial role in determining potential value generated by EPPs.

Interpretation of Net Present Value (NPV) and SROI

The analysis of Net Present Values (NPVs) and Social Return on Investment (SROI) shows that Mine A achieved an SROI value of 1.60 from an investment of $200,734.75. In comparison, Mine B yielded an SROI of 1.50 from an investment of $77,908.25. This indicates that for every dollar invested in EPPs, Mine A and Mine B returned $1.60 and $1.50, respectively. This ratio highlights the cost-effectiveness of the EPPs and the investments, as shown in Tables (3) and (4). The marginally higher SROI observed in Mine A indicates enhanced efficiency in the deployment of Environmental Protection Plans (EPPs), particularly in domains such as air quality management, reclamation funds, and additional EPPs (like advanced filtration systems), which substantially amplified generated value without an equivalent increase in cost. This highlights the capacity of innovative, targeted interventions to significantly improve generated values. In contrast, the lower generated values for Mine B can be attributed to a lower OPEX and potentially less intensive EPP implementation, which may be due to lesser systematic EPP implementation, a lesser concession area for reclamation, or financial/resource constraints. These discrepancies highlight the necessity for context-driven environmental investment, where site-specific characteristics such as land use and ecological sensitivity are factored into the planning of EPPs. Environmental fees and funding accounted for almost 50% of the total environmental and social values generated in both quarries, highlighting that land restoration not only mitigates environmental degradation but also delivers high community and ecological benefits, making it a high-impact, high-value EPP. Generally, the SROI ratio justifies the cost-effectiveness of the investments in EPPs, with both quarries exceeding a 1:1 return on investment, which is in correlation with [16, 17].Therefore, the findings illustrate that governments and regulatory agencies can use SROI values to benchmark performance, design incentive schemes, or structure environmental taxes/funds, while mining companies can integrate these findings into sustainability reporting and ESG disclosures,

showing shareholders and communities the value generated through responsible operations.

Table 3 Social return on investment (SROI) of Mine A

Category	Total OPEX (USD)	Value of Impact (USD)
Air Quality Management	52,600.00	55,080.00
Water Quality Management	3,771.56	32,435.00
Noise and Vibration Control	–	22,032.00
Reforestation	6,183.61	12,852.00
Extra EPPs	5,000.00	45,900.00
Environmental Fees & Funding	133,179.58	206,695.53
Total	**200,734.75**	**320,528.53**
SROI	–	**1.6**

Table 4 Social return on investment (SROI) of Mine B

Category	Total OPEX (USD)	Value of Impact (USD)
Air Quality Management	15,900.00	45,900.00
Water Quality Management	976	8,567.00
Noise and Vibration Control	–	7,908.00
Reforestation	2,495.54	4,613.00
Extra EPPs	–	16,475.00
Environmental Fees & Funding	58,536.71	74,188.00
Total	**77,908.25**	**115,050.00**
SROI	–	**1.5**

CONCLUSION

This study illustrates the capacity of applying Social Return on Investment (SROI) in the evaluation of the cost-effectiveness of Environmental Protection Plans (EPPs) in quarry mines. The findings indicate that strategic investments in EPPs yield returns that exceed the investment cost, highlighting their cost-effectiveness. Key contributors to the generated monetary values comprised reclamation and environmental funding and innovative pollution control technologies, which delivered substantial community and ecological benefits. The marginally higher SROI obtained by Mine A emphasizes the significance of strategic EPP implementation and pollution reduction capacity, particularly in quarries with significant environmental degradation in the concession area and host community. On the contrary, the lesser ratio observed in Mine B can be attributed to a lower OPEX and potentially less intensive EPP implementation and lesser pollution reduction capacity. These findings underscore the need for context-based environmental planning that considers local ecological and financial variables. Conclusively, SROI proves to be a robust tool for aligning environmental and social sustainability with economic performance, enabling policymakers and mining companies to make informed, evidence-based investment decisions that promote long-term environmental and social well-being while ensuring safe and sustainable operations. Future work will expand the application of the SROI framework to different scales of mining operations and incorporate Monte Carlo simulations for robust economic modeling and sensitivity analysis. This will enhance decision-making by accounting for variability and uncertainty in environmental and financial outcomes.

PERFORMANCE OF ENVIRONMENTALLY FRIENDLY SOLIDIFIERS UTILIZING WASTE GLASS AND BLAST FURNACE SLAG FOR LIQUEFIED STABILIZED SOIL

Koki Shinohara [1], Kohei Maru [1] and Shinya Inazumi [1]

[1] Shibaura Institute of Technology, Japan

ABSTRACT

This study contributes a novel understanding of the dual-phase hardening behavior in eco-binders through systematic microstructural evaluation, expanding on previously suggested models by incorporating quantitative analysis of the Ca/Si ratio and its morphological implications. In response to growing environmental concerns associated with conventional soil stabilization techniques, this study investigates the development and performance of eco-friendly solidification binders utilizing industrial by-products, specifically waste silica powder and blast furnace slag, activated with slaked lime. Two experimental series were designed to evaluate the influence of slaked lime content on the rheological properties, mechanical performance, and hydration mechanisms of the developed binders when mixed with Kasaoka clay, a highly plastic cohesive soil. The binders were formulated with varying lime contents (0–10%) and tested for flowability, bleeding, and unconfined compressive strength (UCS) over curing periods of 3, 7, and 28 days. Advanced analytical techniques including X-ray diffraction (XRD) and scanning electron microscopy with energy-dispersive X-ray spectroscopy (SEM–EDS) were employed to characterize hydration products and elucidate the microstructural evolution. Results indicated that a 5% slaked lime content optimally balanced early flocculation-driven strength gain and long-term pozzolanic reactivity, yielding superior UCS compared to both lower- and higher-lime mixtures, including the Portland cement control. Microstructural analysis confirmed the formation of dense, fibrous calcium silicate hydrates (C-S-H) at lower Ca/Si ratios, which correlates with the observed increase in 28-day compressive strength. Excess lime, by contrast, led to less favorable hydrate morphologies and reduced strength at 28 days. A two-stage hardening mechanism is proposed: (1) an initial physical flocculation phase enhancing early stability and cohesion; followed by (2) a chemically governed pozzolanic phase generating strength through the formation of C-S-H. The findings demonstrate the feasibility of replacing cement with low-carbon industrial by-products, offering a technically and environmentally viable alternative for sustainable ground improvement.

Keywords: eco-friendly binder, waste silica powder, blast furnace slag, ground improvement

INTRODUCTION

In the context of global efforts to reduce environmental burdens associated with civil engineering works, the development of sustainable ground improvement techniques has gained significant importance. Conventional binders such as Portland cement, although highly effective in stabilizing soft soils, emit substantial amounts of CO_2 during production, approximately 798.1 kg per ton [1]. Moreover, concerns persist regarding the environmental toxicity of cement-treated soils, particularly due to potential leaching of hexavalent chromium [2]. These environmental issues have prompted the search for alternative solidification materials that can provide equivalent or superior mechanical performance while minimizing ecological impact.

Industrial by-products such as waste silica powder, generated during glass cullet processing, and blast furnace slag, produced as a residue in the steelmaking process, are abundant, underutilized resources with latent pozzolanic activity. When combined with chemical activators such as slaked lime, these materials may form hydration products similar to those generated by cement, such as calcium silicate hydrates (C-S-H), but with significantly reduced carbon emissions. Despite this potential, the relatively slow setting and strength development of these alternative binders have limited their practical application in rapid-construction contexts.

The present study addresses this challenge by investigating the mechanical properties and hardening mechanisms of eco-friendly binders composed of waste silica powder, blast furnace slag, and slaked lime. Two complementary experimental series were conducted to evaluate the influence of slaked lime content on the binder's physical behavior, strength development, and hydration products. In addition to verifying engineering performance parameters such as flowability, bleeding, and unconfined compressive strength, this study emphasizes the microstructural and chemical changes that occur during curing. By elucidating the

interaction between material composition, particularly the Ca/Si (C/S) molar ratio, and hydration behavior, the research provides critical insights into the design and optimization of sustainable ground improvement materials.

MATERIALS AND METHODS

Materials and Mix Composition

The soil employed in all mixtures was Kasaoka clay, a representative cohesive soil known for its fine particle size distribution and high plasticity. The solidification binder was designed using industrial by-products to promote sustainability. It consisted of a silica-based activator formulated by blending waste silica powder, an alkali additive, and slaked lime ($Ca(OH)_2$). This silica activator was further combined with blast furnace slag to form the complete binder system. Under alkaline conditions, the silica and slag components are expected to undergo pozzolanic and latent hydraulic reactions, respectively, leading to the formation of cementitious hydrates such as calcium silicate hydrate (C-S-H). For comparison, ordinary Portland cement (OPC) was employed as a control binder.

Two series of experimental conditions were established. In both, the total binder dosage was fixed at 200 kg/m³. The main variable of interest was the slaked lime content in the silica activator. In Series A, slaked lime was added at 2.5%, 5%, and 7.5% by mass, corresponding to Cases 1 to 3, respectively. In Series B, the lime contents were set at 0%, 5%, and 10%. In both series, Case 4 served as the control and consisted solely of Portland cement, without any industrial by-products.

The detailed mix proportions used in the experimental program are summarized in Table 1. As the lime content increased, the amount of silica activator also increased proportionally, while the amounts of blast furnace slag, Kasaoka clay, and water were kept constant to ensure comparability. In the cement-only Case 4, a total of 200 kg/m³ of cement was used without silica activator or slag. The mix designs were selected to isolate the effects of lime content on physical behavior and hydration reactions.

Sample Preparation and Curing

All mixtures were prepared by thoroughly blending the binder components with Kasaoka clay and deionized water to obtain a uniform and homogenous slurry. Mixing was performed mechanically to ensure even distribution of binders and to activate the pozzolanic components. The resulting fresh mixtures were cast into cylindrical molds (dimensions per standard UCS testing procedures) and immediately sealed to prevent moisture loss.

Curing was conducted under controlled laboratory conditions, with all specimens placed in hermetically sealed containers maintained at a relative humidity of 98% or higher and at room temperature (~20°C). The curing durations were set at 3, 7, and 28 days to investigate both the early and long-term mechanical behavior of the binders.

Testing Methods

To evaluate the engineering performance of the mixtures, a series of physical and mechanical tests were conducted. Flowability was assessed by measuring the average of two orthogonal spread diameters on a horizontal plate immediately after mixing. The target flow value was set at 140 mm or greater, in accordance with the requirements for fluidized soil applications.

Bleeding behavior was evaluated based on the measurement of the volume of separated water 20 hours after casting. The bleeding ratio was calculated as the ratio of separated water volume to the total volume of the sample. A threshold of less than 1% was adopted to ensure sufficient water retention and mixture stability.

Mechanical properties were examined through unconfined compressive strength (UCS) testing at curing ages of 3, 7, and 28 days. The UCS tests were performed under displacement-controlled loading at a constant rate, and peak strength values were recorded for comparison across cases.

In addition to the macroscopic performance tests, chemical and microstructural evaluations were carried out to elucidate the underlying mechanisms of strength development. X-ray diffraction (XRD) analysis was conducted to identify crystalline hydration products, with particular attention to the formation of C-S-H and ettringite. Furthermore,

Table 1 Mix Proportions of solidification materials in each case

Case	Slaked Lime Addition (%)	Solidification Binder (kg/m^3)			Slurry Components (kg/m^3)	
		Silica Activator	Blast Furnace Slag	Cement	Clay	Water
1	2.5	23				
2	5	28	181	0	818	313
3	7.5	33				
4	0	0	0	200	828	305

Note: For Cases 1–3, the total binder content is fixed at 200 kg/m^3, composed of the silica activator and blast furnace slag. In Case 4 (control), only Portland cement is used at 200 kg/m^3 with no industrial by-products.

scanning electron microscopy coupled with energy-dispersive X-ray spectroscopy (SEM–EDS) was employed to observe the morphology and elemental composition of hydration products, especially focusing on the spatial distribution of calcium, silicon, oxygen, and aluminum. These advanced analyses provided critical insights into the structure–property relationships of the developed eco-friendly binders.

RESULTS

Flowability and Bleeding Behavior

The flowability and bleeding characteristics of each mixture are summarized in Table 2, which presents the measured spread diameters and corresponding bleeding ratios for Cases 1 through 4. All mixtures exceeded the target flow value of 140 mm, indicating sufficient workability for field application. However, a distinct trend was observed in bleeding behavior depending on the slaked lime content.

As shown in Table 2, Cases 2 and 3, which contained 5% and 7.5% slaked lime respectively, exhibited bleeding ratios well below the 1% threshold. This indicates a clear stabilizing effect induced by the lime addition. Conversely, excessive bleeding was observed in Case 1 (low-lime eco-binder) and Case 4 (cement-only control), where the absence or minimal use of lime likely failed to suppress free water migration.

These results suggest that the addition of slaked lime promotes early-stage flocculation among clay particles. This flocculation phenomenon, induced by the electrostatic neutralization of negatively charged clay surfaces by divalent Ca^{2+} ions, effectively traps pore water within the agglomerated structure. As a result, segregation is minimized, and water retention is enhanced. Such behavior plays a critical role in regulating the rheology of the fresh mixture, especially in slurry-based applications where water-to-solid ratios are moderate.

Compressive Strength Development

The unconfined compressive strength (UCS) results at curing ages of 3, 7, and 28 days are illustrated in Fig. 1. The eco-friendly binder mixtures exhibited notable strength development across all timeframes, consistently surpassing the minimum performance requirement of 200 kN/m².

Compressive strength results for each case. Case 3 (7.5% lime) exhibited the highest early strength, while Case 2 (5% lime) achieved the highest long-term strength.

At 3 days, compressive strength increased proportionally with the lime content. Case 3, containing 7.5% lime, achieved the highest early strength, suggesting that higher lime dosage accelerates initial flocculation (particle binding) and possible early-stage hydrate formation. This early strength development aligns with the reduction in bleeding previously discussed, both of which are driven by enhanced particle binding and lime-induced aggregation.

Table 2 Results of flow test and bleeding ratio

Case	Flow Value (mm)	Bleeding Ratio (%)
1	478	2.4
2	375	0.0
3	368	0.7
4	550	3.5

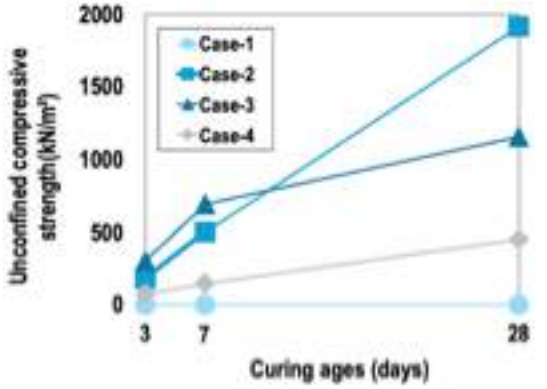

Fig. 1 Unconfined compressive strength at 3, 7, and 28 days

At 28 days, however, the trend deviated. Case 2, with 5% lime, exhibited the highest long-term strength, even surpassing the cement-based Case 4 and the higher-lime Case 3. This reversal implies that while higher lime content may promote early stiffness, it does not necessarily benefit long-term hydration. The likely explanation lies in the balance between calcium and silica availability: excess lime may lead to a higher Ca/Si (C/S) molar ratio, which can hinder the formation of structurally optimal calcium silicate hydrates or induce microstructural porosity due to incomplete reactions.

These results highlight the importance of optimizing the lime content to simultaneously achieve rapid initial strength and superior long-term mechanical performance. The data suggest that 5% slaked lime represents a favorable balance point in this regard.

Microstructural and Chemical Analysis

To elucidate the strength development mechanisms observed in the previous section, detailed microstructural and mineralogical analyses were conducted on specimens from Case 2 (5% lime eco-binder) and Case 4 (cement-only control). The XRD profiles shown in Fig. 2 reveal distinct differences in hydration product formation between the two binder systems.

XRD analysis confirms the presence of C-S-H in both binders. Ettringite is additionally detected in the cement-based mix (Case 4), indicating a difference in the hydration mechanisms.

In Case 2, peaks associated with C-S-H are clearly evident, supporting the hypothesis that pozzolanic reactions between blast furnace slag and the silica activator under alkaline conditions are responsible for strength development. In Case 4, in addition to C-S-H, peaks corresponding to ettringite were detected, reflecting the sulfate-aluminate reactions typical of Portland cement hydration.

Microstructural observations obtained via SEM are shown in Figs. 3 and 4. The eco-friendly binder in Case 2 exhibits fibrous and cotton-like hydration products, which are characteristic morphologies of C-S-H with a low C/S ratio. These structures appeared densely packed, with minimal porosity, contributing to the high compressive strength observed at 28 days.

Fibrous and cotton-like C-S-H morphologies observed. EDS confirms high concentrations of Ca and Si, consistent with pozzolanic hydrate formation.

In contrast, Fig. 4 depicts the microstructure of Case 4, where needle-like ettringite crystals and amorphous phases dominate. The spatial distribution of these products was less uniform, and visible micro-voids were more prevalent, indicating a comparatively less dense matrix.

Needle-like ettringite and less compact hydrate phases are observed. The structure suggests lower packing density than in the eco-binder.

Energy-dispersive X-ray spectroscopy (EDS) analyses confirmed that the primary elements in the hydration products were calcium (Ca), silicon (Si), and oxygen (O), with traces of aluminum (Al) in both binders. The higher Si content in Case 2 aligns with the usage of silica powder in the activator and supports the lower C/S ratio identified in the morphological interpretation.

The integration of mineralogical and microstructural results provides strong support for a chemically distinct hardening mechanism in the eco-binder system. Specifically, the low C/S ratio in the pozzolanic matrix of Case 2 favors the development of fibrous C-S-H, which is mechanically superior to the crystalline or amorphous hydrates found in traditional cement systems. These findings align with the observed compressive strength trends and confirm that optimized lime content and silica-rich conditions are key to achieving high-performance, environmentally sustainable ground improvement binders.

DISCUSSION

Unlike earlier studies which conceptually proposed dual-phase hardening, this research substantiates the mechanism through detailed SEM-EDS analysis and identifies the critical role of silica availability in optimizing hydrate morphology.

The experimental results presented in the preceding sections clearly demonstrate that the

performance of the developed eco-friendly solidification material is closely governed by the amount of slaked lime incorporated into the mixture. From a physical standpoint, the addition of slaked lime was found to play a significant role in promoting the flocculation of clay particles. This flocculation process enhances the structural coherence of the slurry at an early stage and effectively reduces bleeding, as evidenced by the results in Table 2. The observed improvement in bleeding resistance in Cases 2 and 3 is attributed to this early particle aggregation, which immobilizes pore water and suppresses its upward migration.

At the chemical level, the amount of slaked lime directly influences the availability of calcium ions (Ca^{2+}), which are essential for initiating pozzolanic reactions. These reactions occur between Ca^{2+} and the amorphous silica and alumina provided by the waste silica powder and blast furnace slag. A key factor in this process is the resulting Ca/Si molar ratio (C/S ratio) within the hydration products. The morphology, crystallinity, and binding capacity of calcium silicate hydrate (C-S-H), the primary strength-giving hydrate, are all known to be sensitive to this ratio.

An important observation from both Series A and Series B was that the mixture containing 5% slaked lime (Case 2) consistently achieved the best balance between early strength development and long-term compressive strength. Although higher lime contents (e.g., 7.5% or 10%) promoted greater early strength, they did not result in superior 28-day strength. This can be explained by considering the C/S ratio: excess calcium relative to silica may lead to the formation of less polymerized or more crystalline C-S-H structures, which are generally associated with lower mechanical integrity and greater porosity.

On the basis of these results, a two-stage hardening mechanism is proposed, which integrates both physical and chemical processes. This mechanism is conceptually illustrated in Fig. 5, which outlines the sequential transformation of the mixture from a flocculated state to a hardened matrix.

Stage I: Flocculation induced by the electrostatic interaction between Ca^{2+} and clay particles enhances early cohesion and reduces bleeding. Stage II: Under alkaline conditions, pozzolanic reactions between calcium and silica/alumina components lead to the formation of C-S-H and other hydration products, contributing to long-term strength development [3,4].

In Stage I, the rapid flocculation process is initiated immediately upon mixing, as slaked lime dissociates to release Ca^{2+} into the pore water. These ions neutralize the surface charges of negatively charged clay minerals, promoting particle flocculation (particle binding) and improving the initial consistency of the mixture. This process accounts for the observed reduction in bleeding and the early strength gain in the high-lime cases.

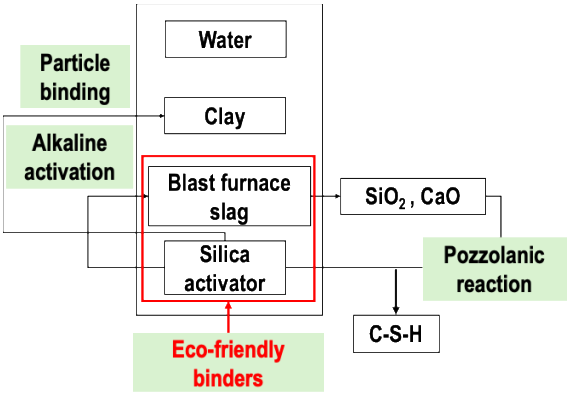

Fig. 5. Schematic illustration of the proposed two-stage hardening mechanism

In Stage II, the presence of reactive silica and alumina in the blast furnace slag and waste silica powder initiates slower pozzolanic reactions in the alkaline environment. These reactions result in the formation of C-S-H, which binds soil particles together and fills voids, thereby enhancing long-term strength. The characteristics of the resulting C-S-H gel, particularly its density, morphology, and degree of polymerization, are governed by the C/S ratio. A lower C/S ratio, promoted by a silica-rich matrix, tends to favor the formation of fibrous C-S-H with high binding efficiency, as observed in the SEM-EDS images of Case 2 (see Fig. 3).

This two-stage mechanism aligns well with the microstructural findings. In Case 2, the fibrous morphology and dense matrix contributed to superior compressive strength at 28 days, whereas in Case 4, the presence of ettringite and needle-like structures suggested a different, less effective hydration pathway. These morphological differences also underscore the role of mix design, especially the lime-to-silica ratio, in governing both early and long-term performance.

The findings of this study further highlight that the eco-friendly binders in some cases surpassed the mechanical performance of the cement-based control in every tested parameter, with the exception of bleeding in the lowest-lime condition (Case 1). This validates the technical feasibility of replacing cement with industrial by-products, resulting in reduced environmental impact without compromising, and indeed improving, structural performance. However, the sensitivity of hydration behavior to lime content also implies that mix design optimization is crucial. Precise control over the lime dosage is essential to ensure that the hydration reactions proceed in a manner that favors the development of high-quality, low-porosity C-S-H structures.

The results of this investigation underscore the critical role of slaked lime not merely as a chemical activator, but as a functional regulator of the physical and microstructural evolution of the binder system

[3]. The dual contributions of flocculation and pozzolanic activity must be strategically balanced to achieve the full performance potential of eco-friendly solidification materials in ground improvement applications.

CONCLUSIONS

This study has demonstrated the development and mechanistic understanding of eco-friendly solidification materials incorporating waste silica powder, blast furnace slag, and slaked lime. Through a systematic evaluation of physical properties, compressive strength, and microstructural features, the following conclusions can be drawn:

(1) The addition of slaked lime to mixtures of waste silica powder and blast furnace slag significantly improved early strength development and reduced bleeding by promoting flocculation of clay particles. A lime addition of 5% was found to be optimal for achieving a balance between early flocculation (particle binding) and efficient long-term pozzolanic activity.

(2) Microstructural analyses confirmed the formation of calcium silicate hydrate (C-S-H) in all eco-binder mixtures. Scanning electron microscopy revealed fibrous morphologies in mixtures with lower Ca/Si ratios, indicating the formation of dense and effective binding structures. These structural characteristics were directly associated with enhanced compressive strength at 28 days. Excessive lime addition was found to be counterproductive for long-term strength development, likely due to the formation of less favorable hydrates or the persistence of unreacted lime.

(3) A two-phase hardening mechanism was proposed. In the first phase, lime-induced flocculation and particle aggregation dominate the early setting behavior. In the second phase, a pozzolanic reaction between lime, slag, and silica powder under alkaline conditions leads to the formation of C-S-H, contributing to long-term strength gain. This model is consistent with both the observed strength trends and microstructural findings.

(4) The eco-friendly binders developed in this study outperformed conventional cement-based mixtures in terms of long-term compressive strength, while also meeting practical performance criteria for flowability and bleeding control. This indicates their technical feasibility and potential applicability in sustainable ground improvement projects.

Future work should focus on the quantitative evaluation of Ca/Si ratios in the reaction products and further investigation into the field applicability and long-term durability of these eco-binders under various environmental and loading conditions.

TROPICAL SOIL BEYOND THE TROPICS: THE INFLUENCE OF PALEOENVIRONMENTS ON ENGINEERING PROPERTIES

John Victor Smith[1,2]

[1]School of Engineering, RMIT University, Australia
[2]CMW Geosciences, Australia

ABSTRACT

Tropical soils are known to be a distinct class of soils with predicable engineering properties. The definition of the range of such soils is typically linked to the distribution of current global environmental conditions. However, at previous times, most notably the Eocene Epoch, conditions that we consider tropical today covered much of the Earth's surface. Consequently, there are soils with a tropical weathering imprint present at latitudes beyond the tropics as defined today. Such soils can be called paleosols, however that term is commonly applied to soils buried within a sequence of sediment or rock that may not be considered as soil in the engineering sense. The ancient overprint of high temperature and wet conditions on soils in temperate regions can be removed by burial by later sediments or can be removed by erosion. Therefore, the relict tropical soils occur in localized places. Since large parts of Australia have been relatively stable tectonically the amount of sediment deposition and erosion has been less than some other parts of the globe. The current arid and temperate conditions can preserve soils developed in tropical conditions. Selected examples of such soils are presented to illustrate that the tropical soil paradigm can be extended to engineering properties of some soils beyond the tropics.

Keywords: Tropical residual soil, Paleosol, Paleoeclimate, Basalt soils, Slope stability

INTRODUCTION

Engineering properties of soils relate to the environment in which they formed, for example, arid, temperate or tropical [1]. Tropical soils are known to be a distinct class of soils with particular engineering properties. The definition of the range of such soils is typically linked to the distribution of current global environmental conditions. However, at previous times, most notably the Eocene and Miocene Epochs, conditions that we consider tropical today covered much of the Earth's surface [2].

It is observed that there are soils with a tropical weathering imprint present at latitudes beyond the tropics as defined today. Such soils can be called paleosols, however that term is commonly applied to soils buried within a sequence of sediment or rock that may not be considered as soil in the engineering sense. The ancient overprint of high temperature and wet conditions on soils in temperate regions can be obscured by burial with later sediments or can be removed by erosion. Therefore, the relict tropical soils occur in localized places.

Since large parts of Australia have been relatively stable tectonically the amount of sediment deposition and erosion has been less than some other parts of the globe. The current arid and temperate conditions can preserve soils developed in tropical conditions. Selected examples of such soils are presented to illustrate that the soil types, depths and engineering characteristics are those of the tropical soil type as a result of the past environmental conditions influencing the soil's development.

This paper shows how the tropical soil paradigm can be extended to engineering properties of some soils beyond the tropics in temperate southeastern Australia.

RESEARCH SIGNIFICANCE

The assumption that tropical soils are restricted to present day tropical locations can result in mis-interpretation of soil types and the missed opportunity to apply the well developed paradigm of tropical residual soils to other locations where previous climatic conditions have produced equivalent soil types.

TROPICAL RESIDUAL SOIL

The significance of tropical residual soils has been recognized by the International Society for Soil Mechanics and Geotechnical Engineering which has established a global technical committee on the topic: Tropical Residual Soils (TC107).

According to the Handbook of Tropical Residual Soils Engineering [3], the majority of researchers in that field defined residual soils as a highly weathered in situ material with >50% soil. It also notes that large expanses of residual soils occurring to great depths are normally found in tropical humid regions, e.g. Northern Brazil, Ghana, Malaysia, Nigeria, Southern India, Sri Lanka, Indonesia and Philippines, due to active weathering leading to residual soil

formation. The depth of tropical soil can vary but 30 m of residual soil development in tropical conditions is not uncommon [3,4].

According to [3] soil development in the tropics may have begun over 2–3 million years ago and the prolonged process of soil development over geological time. These climatic changes mean that areas under more temperate climates at present can have experienced the development of tropical soil profiles [3].

There are many soil science terms and concepts but not all of these relate to engineering properties of soils. Three terms related to the fate of iron in residual soils have been beneficial in clarifying types of residual soils [3]. The term fersiallitisation describes weathering that occurs in a subtropical climate with a marked dry season. The dominant clay minerals formed are the 2:1 clays, such as the smectite group including montmorillonite. In this process most of the silica and cations released by the weathering are retained within the soil profile. These soils also develop kaolinite clay as a minor component. The Fe^{2+} liberated by mineral weathering in these soils is rapidly oxidised and precipitated as ferric (Fe^{3+}) oxide and hydroxide such as hematite and goethite. These soils can develop distinctive red (or hues of orange and yellow) colors as the iron oxides coat clay particles. This process is equivalent to weak to moderate leaching (Fig.1).

Ferrugination occurs in a tropical climate that is more humid than fersiallitic conditions and with a less pronounced dry season. The dominant clay minerals are the 1:1 clays such kaolinite and its related kandites. Smectite may also be present. Fe oxides are also formed but may or may not form red colored coatings on the clay particles and mottled coloring is common. This process is equivalent to intense leaching (Fig.1).

Ferrallitisation is the most intense stage of leaching (Fig.1) where almost all primary minerals are weathered leaving quartz (if present in the parent rock), newly formed kaolinite and Fe and Al oxides for example, goethite, hematite and gibbsite.

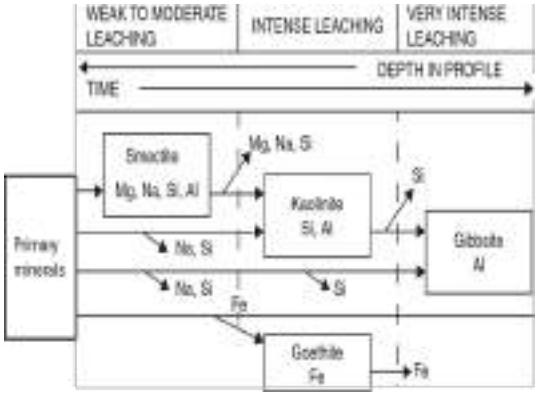

Fig.1 Summary of chemical and mineralogical changes in tropical weathering [3]

MIOCENE BASALT IN VICTORIA

Context

The case study presented is located in southeastern Australia in the La Trobe Valley of Victoria. This region has produced significant brown coal resources in the past. The brown coal was used for electric power throughout the state and significant electricity infrastructure such as high voltage powerlines are present. As coal mining is phased out the surrounding region is of interest for renewable energy installation to benefit from the existing infrastructure.

Geology

Basalt lava flows of the Thorpedale Volcanics form a plateau to the southwest of the brown cola deposits. The brown coal deposits formed in the Oligocene to late Miocene periods. Fluvial sediment of the Childers Formation underlies the basalt and is exposed on the west of the Thorpedale Volcanics and has a maximum thickness of 35 m. To the east of the Thorpedale Volcanics is the Miocene to Pliocene age Haunted Hills Gravel which contains ferruginous sand which overlies the basalt (Fig. 2).

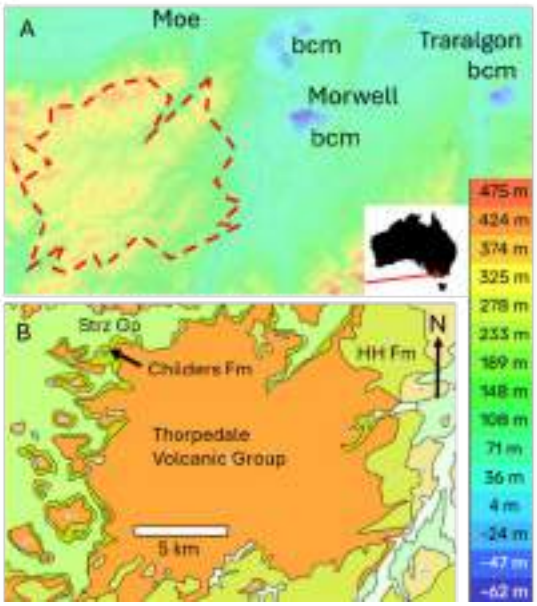

Fig.2 A) Regional context of brown coal mines (bcm) and basalt plateau and ridges of the Thorpedale Volcanic Group (red dashes) and elevation key. B) The main part of the Thorpedale Volcanic Group (orange), underlying Childers Formation and Cretaceous sedimentary rocks to the west (Strz Gp = Strzelecki Group) and overlying Plio-Pleistocene sedimentary deposits to the east (HH = Haunted Hills Formation). Fig.3 Typical pathways of formation of secondary minerals in weathering profiles [5]

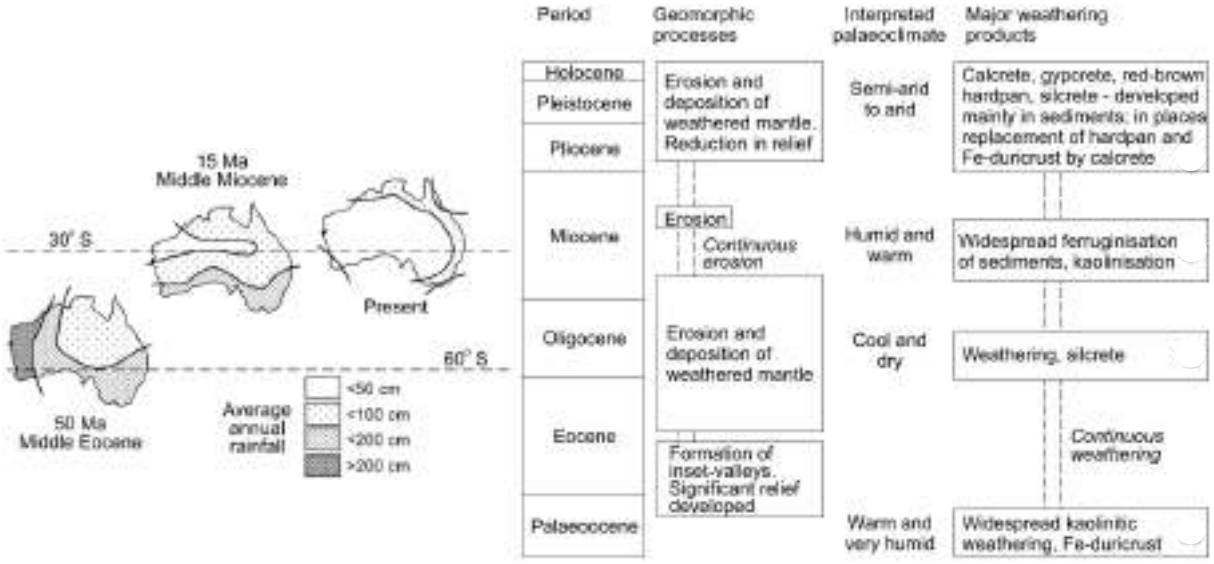

Fig.4 Australia's changing latitude through time (left) and a summary of climate and weathering (right) [5]

Soil Mineralogy

One of the most diagnostic indicators of soil formation conditions within a soil profile is the minerals present in the soil (Fig.3). Mineralogy is typically assessed by X-ray diffraction [6]. A study on slope stability found that the Thorpedale Volcanics and underlying Childers Formation were dominated by kaolinite and halloysite (Table 1). Halloysite is a clay similar to kaolinite in composition but with a distinctive rolled-up form rather than the platy form of most other clay particles [3]. The Childers

Formation soils were found to have quartz as a relict of their original primary mineralogy whereas the basalts were quartz free. The Cretaceous age Strzelecki Group soils were found to be dominated by smectite clays and quartz (Table 1).

Table 1 Summary of soil mineralogy in the study area [7]

Strata	Type	Color	Mineralogy
Thorpedale Vocanics	Clay	Red-brown, yellow, gray	Kaolinite, Halloysite
Childers Fm	Sandy silty clay	Brown, gray, red-brown, yellow	Kaolinite, Halloysite, Quartz
Strzelecki Group	Sandy silty clay	Brown, gray, yellow-brown	Montmorillonite, Quartz

Note: hematite, goethite detected as minor components are potentially under-detected due to fine grainsize.

According to a study of engineering behaviour of soils in the area [7] the soils are classified the soils derived from the Older Volcanics in the Krasnozem pedological group or Ferrosols and described as acid friable porous soils in which the texture generally increases with depth. These soils are usually deep soils with a dark red A1 horizon of friable clay with a strong crumb structure. The A1 horizon grades through a redder and more clayey A-B into a red or dark red medium or heavy clay B horizon. These are moderately plastic clays and often rather compact in place, but highly structured, very permeable and friable when moist. Very fine, red and sometimes black, ferro-manganiferous nodules are common. The B horizon continues with little change for many feet, finally grading through a B-C horizon of yellow-red; or red-brown more plastic clay into a C horizon of weathering rock. In wetter environments the B-C is somewhat mottled red, light gray and yellow-gray clay grading into a thick C horizon of weathering rock which may be partially saturated with water.

Palaeoclimate

At the present, only the most northerly parts of Australia are considered to have tropical climates (Fig.4). The west Gippsland region has a Mediterranean climate Grazing, mostly dairy and beef cattle, and cropping [8]. Over earlier times Australia moved from higher southern latitudes toward its present position. The global temperature conditions in the Eocene and, to a lesser extent, the Miocene were what would be considered tropical today (Fig.4).

The record of paleoclimate through Cenozoic time has been developed principally from oxygen isotope studies (Fig.5A) [2]. The Thorpedale Volcanics formed as one of the last phases of volcanism known as the Older Volcanics in Victoria (Fig.5B) [9,10].

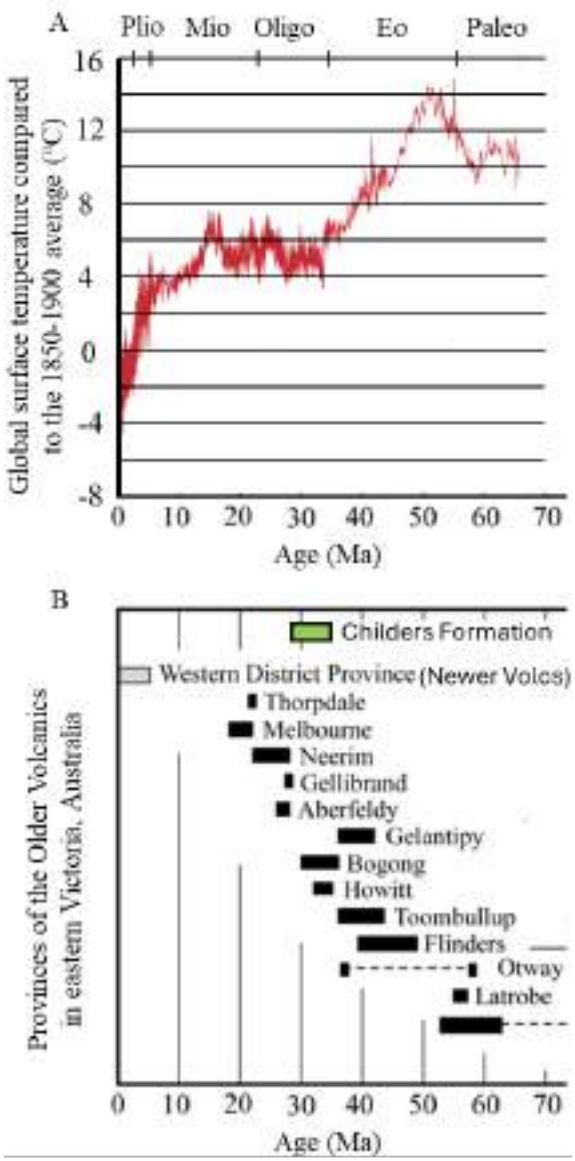

Fig.5 A) Summary of global temperature during the Cenozoic [2] and B) The age of Cenozoic basalts in Victoria [9] (Childers Formation added)

Consequently, the Thorpedale Volcanics were exposed to weathering conditions which can be considered at least equivalent to present day tropical conditions even though the latitude of formation and presently would not qualify as tropical. The sediments of the Childers Formation underlying the Thorpedale Volcanics were also potentially weathered in the high temperature conditions of the Miocene after their deposition in the Oligocene (Fig.5B).

The Thorpedale Volcanics indeed have a deeply developed red soil which is greater than 20 m thick in many places (Fig.6).

Fig.6 Roadside exposure of the Thorpedale Volcanic soil [8]

Landscape Evolution

In order to form and then preserve the soils formed in the Miocene the evolution of the landscape must prevent excessive erosion at the location. The Thorpedale Volcanics are understood to have formed as valley-fill basalt flows [9]. With later erosion the basalts can become plateau and ridges a process called topographic inversion (Fig.7)[5].

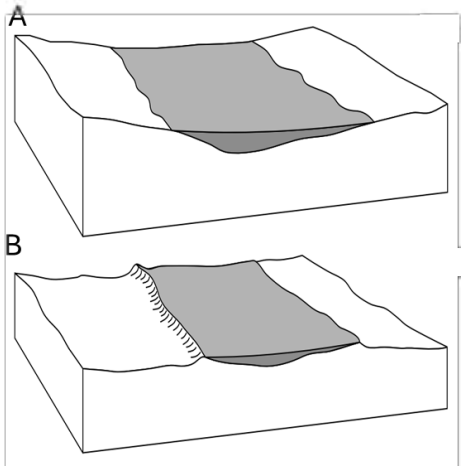

Fig.7 Conceptual representation of the inversion of topography of valley-filling basalt lava (gray) [5]

Soil would be expected to begin forming once the basalts are emplaced but soil development would continue throughout the evolution of the landscape. The proposition is that in the area of the Thorpedale Volcanics residual soil developed during the tropical conditions of the Miocene and was not significantly eroded subsequently. One contributor to the preservation of the tropical residual soil could be the presence of the Haunted Hills Formation. These sediments were deposited during the Pliocene-Pleistocene i.e. after the Miocene. The Haunted Hill Formation presently covers the eastern part of the Thorpedale Volcanics and may have covered more of the volcanics in the past. The later sedimentary cover may have preserved the thick residual soil that had developed in the Thorpedale Vocanics and Childers Formation.

Engineering Properties

Slope stability of tropical residual soils is a distinctive engineering issue due to the typical deep weathering of these soils and the presence of various mineral cementing agents [11].

Slope stability has been a significant issue in the area of this study site [7]. The soils are associated with well-drained sites on hilly uplands and plateaux. The soils were formed by strong weathering and leaching of the basalt. The basaltic clays in the study area typically have high plasticity and are locally friable and permeable.

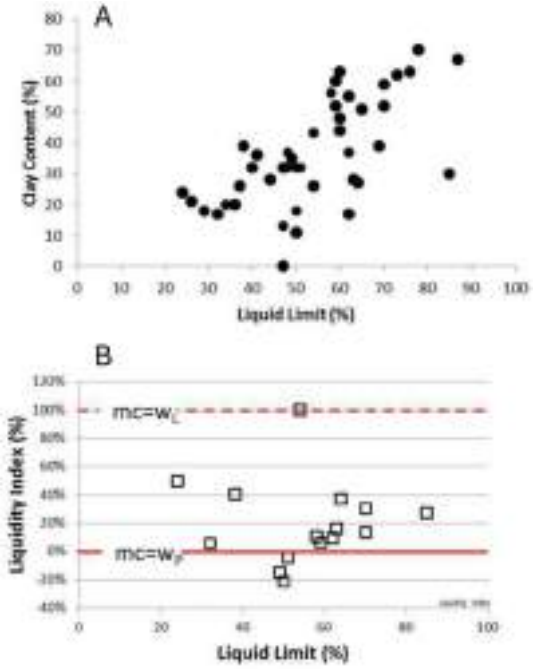

Fig.8 Summary of selected soil properties in the Thorpedale Volcanics area [7]

In engineering terms, the soils are clays with silty, sandy and/or gravelly components consisting of partly weathered rock and mineral particles and occasional iron oxide nodules and ferruginized concretions. The clays are mainly classified as high plasticity (CH) type soils, but the weathered rock content of some samples gives the soil a silty or sandy texture and an MH or SC classification. In these cases the clays have lower plasticity and are usually friable. Low plasticity CL type soils also occur. The overall high plasticity is illustrated by a medium plasticity index of 32% with a range of 20% to 46%. The liquid limit has a medium valley of 69% and a range of 54% to 87%. The in-situ winter moisture content was estimated in the field to be generally greater than the plastic limit and this was confirmed by laboratory tests. In some cases the in-situ moisture content approaches the liquid limits (Fig.8).

Fig.9 The toe of a complex earth flow in the Thorpedale Volcanics [7]

The central Thorpdale area has topography that is gently undulating whereas at the margins of the Thorpedale Vocanics the topography is mainly steeply undulating. Significant landslides have occurred within the areas of steeply undulating terrain (Fig.9) [7].

Halloysite can make these leached soils sensitive to drying methods. (Fig.9) [7]. Air-drying rather than oven-drying is recommended to avoid destruction of the clay fabric.

CONCLUSIONS

The evolution of landscape in former climatic conditions can play an important role in determining the engineering properties of soils. The study site in southeastern Australia currently has a temperate climate but the soils developed are more typical of tropical conditions and can be attributed to the warmer and wetter conditions in the Miocene Epoch.

WATER QUALITY CHARACTERISTICS OF THE TRADITIONAL WATER MANAGEMENT FACILITY "MANBO" IN HOKUSEI CHUO PARK, MIE PREFECTURE

Maki Oyagi, Rion Ito, Toyokazu Hirozumi

Environmental and Information Sciences, Yokkaichi University, Japan

ABSTRACT

Manbo is an underground agricultural irrigation system consisting of vertical and horizontal shafts, constructed as a hand-dug tunnel. In Hokusei Chuo Park, a Manbo has long been used for agricultural irrigation. However, no prior studies have examined its water quality. Therefore, this study aims to investigate the water quality characteristics of the Manbo and to assess the changes in water quality as water flows from an upstream pond into the Manbo. The results indicated that the electrical conductivity of the pond water was below 100 µS/cm. In contrast, the Manbo exhibited a significantly higher value of 250 µS/cm, exceeding typical river water levels. It suggests that dissolved impurities increase as water flows from the pond into the manbo. To investigate the factors contributing to this increase, an analysis of total nitrogen was conducted. The findings revealed that nitrogen levels were higher in the Manbo than in the pond. Specifically, while the total nitrogen concentration in the pond remained below 2 mg/L throughout the year, the Manbo exhibited concentrations of approximately 3 mg/L. On average, dissolved and suspended nitrogen accounted for about 50% of the total nitrogen in the pond, whereas dissolved nitrogen constituted nearly all the nitrogen in the Manbo. Based on these findings, it was inferred that one of the primary factors contributing to the elevated electrical conductivity in the Manbo is the increase in dissolved nitrogen. This study has enhanced the scientific understanding of traditional water facilities and provided valuable insights for modern water resource management.

Keywords: Manbo, Water management facility, Water quality, Nitrogen

INTRODUCTION

A manbo is a culverted, hand-dug groundwater irrigation system used in agriculture, consisting of both vertical and horizontal shafts. These structures are typically excavated by a single person and measure approximately 0.5 to 1 meter in width and 1 to 2 meters in height. Some extend more than 1 kilometer in length. The primary water source is usually groundwater, and its origin is believed to date back to the late Edo period (1603–1867). As for the name, he concludes that “manbo” is a derivative of the mining term *mabu*, which refers to a horizontal tunnel excavated for ore extraction [1].

In Japan, manbos are commonly found on alluvial fan plains and plateaus composed of sandy and gravelly sediments, particularly in the Chubu and Kansai regions, where surface water is scarce and difficult to use for irrigation [2]. They are especially concentrated in the eastern foothills of the Suzuka Mountains in Mie Prefecture. Several reports have documented individual manbos in the Utsube River fan region [3], while others have examined them from agricultural, geographical, and historical perspectives [4]. Recent research on manbo in Mie Prefecture includes studies on its relationship with humans [5], its role in regional landscapes [6], and reports recognizing it as an agricultural engineering heritage [7]; however, the number of such studies remains limited.

Existing studies on manbos can be broadly categorized into four areas: (1) agronomic irrigation methods, (2) water use in rural communities, (3) civilization theories—including the origin and etymology of the term *manbo*—and (4) general studies on water use and water resources[8].

Despite being water infrastructure for agricultural irrigation, there have been very few studies focusing on the water quality of manbos. This lack of attention is noteworthy and underscores the significance of this study, which aims to address that gap.

RESEARCH SIGNIFICANCE

Mie Prefectural Hokusei Chuo Park is situated in the Inabe River watershed, northwest of Yokkaichi City. The park features two agricultural reservoirs, Kami-ike and Shimo-ike, built during the Edo period, as well as manbos that draw water from these reservoirs. These traditional irrigation systems have been used for farming purposes for many years and continue to supply around 8 hectares of farmland. However, few systematic studies have been conducted on their water quality characteristics or how they change over time.

This study focuses on the manbos and their upstream agricultural reservoirs (Upper Pond and Lower Pond) in Hokusei Central Park, aiming to clarify the current state of water quality and investigate the factors contributing to its variation as

water flows from the ponds to the manbos. Special attention is given to changes in electrical conductivity and nitrogen concentration to scientifically evaluate the influence of the subsurface environment on water quality.

METHODS

Study Area and Observation Dates

Hokusei Chuo Park, located on a plateau between the Inabe River and the Asaake River in the northwestern part of Yokkaichi City, Mie Prefecture, was selected as the study site (Fig.1). Surveys were conducted at two agricultural reservoirs (Kami-ike and Shimo-ike; Fig. 2) and three vertical shafts in manbos (Fig. 3) within the park. The culverted section of the manbo has a total length of 286 meters, with water flowing at a depth of approximately 2.5 meters below the ground surface. Water sampling was conducted at a vertical shaft located midway along the culvert. Field investigations were carried out five times: on July 2, 2023; October 17, 2023; February 15, 2024; June 25, 2024; and September 10, 2024.

Analytes of Water Quality

Dissolved oxygen (DO) and water temperature were measured immediately after water sampling using a multi-parameter water quality meter (WQ-310J, HORIBA). In contrast, pH and electrical conductivity (EC) were measured using a portable field-type meter (D-200-2, HORIBA). fter sampling, the water was stored in plastic bottles, transported to the laboratory under chilled conditions, and immediately subjected to suction filtration to determine suspended solids (SS). GF/F glass fiber filters (pore size 0.7 μm, Whatman) were used, and the filtrate was treated as representing the dissolved fraction.

Total phosphorus (TP) and total dissolved phosphorus (TDP) were analyzed in the laboratory using the molybdenum blue method [9]. Particulate organic phosphorus (POP) was calculated as POP = TP − TDP. Total nitrogen (TN) and total dissolved nitrogen (TDN) were measured by UV absorption spectrophotometry [9]. Particulate organic nitrogen (PON) was calculated as PON = TN − TDN.

RESULT AND DISCUSSION

Field Measurements of Water Quality

Fig. 4 shows that water temperatures averaged 10.3°C in the Upper and Lower Ponds and 11.0°C in the manbo during winter (February). In summer (June), the temperatures were 25.65°C in the ponds and 22.0°C in the manbo, showing that both were strongly affected by ambient air temperature (fig.5). However, because of the subsurface culvert structure of the manbo, water temperatures tended to be lower in summer and higher in winter compared to the ponds. This pattern is similar to the thermal behavior typically seen in groundwater.

Dissolved oxygen (DO) concentrations averaged 11.3 mg/L in the ponds and 8.6 mg/L in the manbo during winter (Fig.4), and 9.9 mg/L in the ponds and 6.0 mg/L in the manbo during summer (Fig.5). Oxygen saturation levels averaged 104% in the ponds and 81% in the manbo in winter, and 123% in the ponds and 70% in the manbo in summer. These results show that the ponds were generally supersaturated and well-oxygenated throughout the year, while the manbo experienced higher oxygen consumption.

The pH averaged 7.5 in the ponds and 7.0 in the manbo during winter, and 9.4 in the ponds and 6.4 in the manbo during summer (Fig.6). The higher pH levels in the ponds during summer are probably due to carbon dioxide uptake through photosynthesis, as indicated by the high DO concentrations.

Electrical conductivity (EC) averaged 51.9 μS/cm in the ponds and 159.1 μS/cm in the manbo during winter, and 89.2 μS/cm in the ponds and 162.3 μS/cm in the manbo during summer (Fig.7). The manbo consistently exhibited high electrical conductivity (EC) throughout the year, distinctly differing from the values observed in the pond. EC is a key indicator of water quality, influenced by both natural and anthropogenic factors, and is considered to reflect the overall water environment of the region [10]. Therefore, the elevated EC in the manbo suggests that additional ionic constituents were incorporated into the water during its subsurface flow from the pond.

Despite the inflow of water from the ponds into the manbo, notable differences in water quality parameters were observed, indicating distinct environmental characteristics between the two water bodies.

Laboratory Analysis of Chemical Water Quality

Fig.8 shows that suspended solids (SS) averaged 10.2 mg/L in the upper pond, 20.4 mg/L in the lower pond, and 2.6 mg/L in the manbo throughout the year. Seasonal variation was minimal compared to other parameters.

Total phosphorus (TP) concentrations averaged 0.36 mg/L in the upper and lower ponds and 0.16 mg/L in the manbo during winter (February), and 0.13 mg/L in the ponds and 0.07 mg/L in the manbo

during summer (June). The composition of TP indicated that particulate organic phosphorus (POP) accounted for 50–85% of the total in both the ponds and the manbo (Fig.9 and 10).

Total nitrogen (TN) averaged 2.4 mg/L in the ponds and 3.2 mg/L in the manbo during winter, and 1.1 mg/L in the ponds and 1.8 mg/L in the manbo during summer. In terms of composition, particulate organic nitrogen (PON) accounted for 30–70% of TN in the ponds, while it was less than 10% in the manbo. (Fig.11 and 12)

Fig. 13 shows that, regarding these results, the N/P ratio in the pond sometimes exceeded 10 but generally remained within the range of 7 to 10, which is considered favorable for algal growth [11]. Blue-green algae blooms were visually observed from spring to summer. The high SS concentration in the pond is presumed to be due to algal proliferation, as both nitrogen and phosphorus were predominantly present in suspended form.

According to the environmental standards for preserving the living environment (lakes and ponds) established by the Ministry of the Environment, the pond falls into Type V, the lowest water quality category (Types I–V), based on its nitrogen and phosphorus concentrations. Compared to nearby ponds [12][13], this pond exhibited higher concentrations of both nitrogen and phosphorus.

In the manbo, nitrogen concentrations tended to be significantly higher than phosphorus, which is attributable to elevated total dissolved nitrogen (TDN) levels. The high electrical conductivity (EC) observed in the manbo also appears to be closely related to the presence of TDN. Additionally, dissolved oxygen (DO) levels in the manbo remained relatively stable throughout the year, suggesting ongoing microbial decomposition processes.

Although water from the pond flows into the manbo, the results of water quality measurements revealed distinct characteristics between the two. The park studied is situated on a plateau composed of sedimentary rock, and geological factors were taken into consideration. However, since the manbo in question is located in a shallow layer (approximately 2.5 meters deep) and exhibited consistent trends throughout the year, the influence of geological conditions was considered to be limited.

Other contributing factors may include inflows from sources other than the pond, as well as the influence of organisms inhabiting the manbo. Due to its relatively enclosed structure, the manbo is less susceptible to external contamination and is therefore considered to be a stable source of agricultural water. In this study, although changes in water quality were observed along the subsurface flow path, a stable supply of dissolved oxygen and active microbial decomposition were also confirmed, indicating the ecological health of the manbo. These findings suggest that traditionally managed water facilities like the manbo can still function effectively in modern water management contexts.

Future challenges include identifying the specific factors contributing to increased electrical conductivity (EC) through cation and anion analysis, as well as quantitatively assessing the dynamics of water movement from the ponds to the manbo and further downstream. This study provided a scientific reevaluation of traditional water facilities such as the manbo as regional water resources and presented foundational insights that may contribute to the development of sustainable water use strategies.

EXTRACTION OF SLOPE VARIATION EXTENT USING OPTICAL SENSORS AND SAR FOR THE MANASLU CIRCUIT TRAIL, NEPAL

Hijiri Shimojima[1]

[1] Faculty of Regional Environment Science, Tokyo University of Agriculture, Japan

ABSTRACT

Frequent slope failures induced by intense monsoonal rainfall in Nepal threaten trekking routes and local infrastructure, especially in high-altitude regions like the Manaslu Circuit Trail. This study evaluates the effectiveness of satellite-based landslide detection methods using both optical and synthetic aperture radar (SAR) data. Two optical-based techniques (land cover change classification and NDVI-GSI differencing) and five SAR-based approaches (texture analysis, NDPI differencing, dual-polarisation image interpretation, coherence difference analysis, and interferogram interpretation) were applied to pre- and post-monsoon Sentinel-1 and Sentinel-2 datasets. A field survey conducted in September 2024 provided ground-truth data for validating remote sensing results. Optical methods yielded more reliable results, with NDVI-GSI differencing achieving the highest detection accuracy. SAR-based techniques faced challenges due to terrain-induced distortions and coherence loss, though coherence difference analysis showed relative promise. Limitations in optical imagery, such as misclassification caused by seasonal land use changes, suggest that SAR data can complement optical analysis to improve reliability. This study concludes that a hybrid approach integrating optical and SAR datasets enhances landslide detection in mountainous regions.

Keywords: landslide, SAR, Optical Sensor, Trail, Manaslu Conservation Area, Nepal

INTRODUCTION

Nepal, a mountainous country in South Asia, attracts tourists from around the world for Himalayan mountaineering and trekking in its foothills. These activities constitute a vital opportunity for foreign currency acquisition and significantly contribute to the economic development of local communities. The Himalayan Mountain region represents one of the country's most important tourism assets.

However, Nepal experiences frequent natural hazards such as floods, landslides, and debris flows triggered by heavy rainfall during the monsoon season [1]. Landslides often interrupt key transportation routes, disrupting logistics networks and causing considerable economic losses that have become a major societal issue.

Such slope disasters frequently occur in the Higher Himalaya region, located north of the Main Central Thrust (MCT). Trekking trails traversing this area are also susceptible to landslides. Due to narrow and rugged terrain and the absence of well-developed roads, these trails serve as the sole means of transportation not only for trekkers but also for local residents. When a landslide occurs along a trail, it hinders mobility for both community members and goods transportation.

Accurately identifying the location and extent of trail-based slope failures is essential for sustainable trail maintenance and management. Various satellite-based approaches have been shown to be effective in detecting landslides adjacent to road networks. Previous studies have applied optical sensor imagery, such as Landsat, to identify landslide sites [2] and used ensemble learning models on aerial photographs [3]. However, these optical systems are weather-dependent and often face challenges acquiring high-quality data during unfavourable conditions.

To address this issue, Synthetic Aperture Radar (SAR) data, which can observe the earth's surface regardless of atmospheric conditions or time of day, has emerged as a promising tool for disaster monitoring. Especially since the 2015 major earthquake in central Nepal, numerous studies—such as that of David et al. [4]—have investigated slope failure detection using SAR imagery. Nevertheless, research specifically focusing on landslides occurring along trekking trails remains limited.

This study aims to evaluate the effectiveness of existing landslide extraction methods for accurately delineating slope deformation areas using optical and SAR data, specifically along trekking routes in Nepal.

METHODOLOGY

Study Area

The target area for this study is the Manaslu Circuit Trail located in the Gorkha region, approximately 200 km northwest of Kathmandu, the capital of Nepal. This circular trekking route encircles Mount Manaslu, which stands at an elevation of 8,156 meters. The high-altitude section of the trail is designated as the Manaslu Conservation Area (Fig. 1).

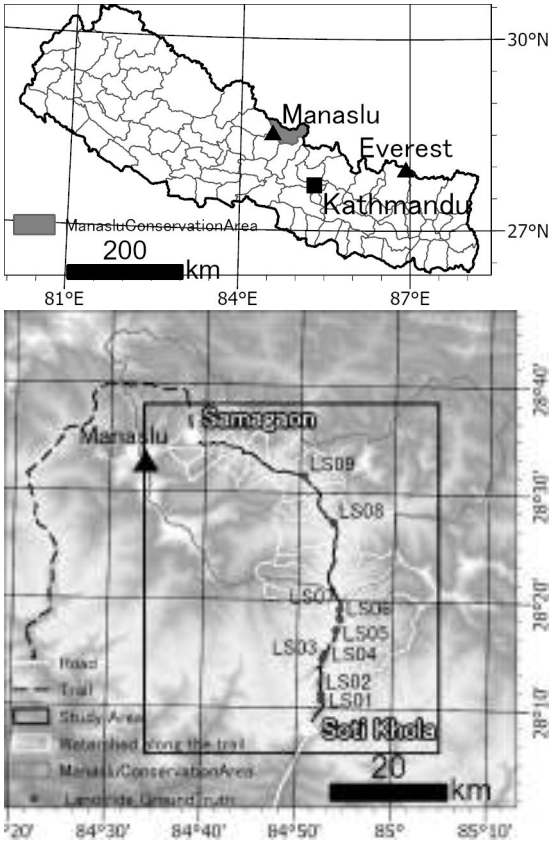

Fig.1 Study area map

Table 1 DATA SOURCES

Type	Satellite name	Acquisition date	Orbit	Polarization
Optical Satellite Imagery	Sentinel-2	2024.4.29	—	—
		2024.10.21	—	—
SAR Imagery	Sentinel-1	2024.5.03	Ascending	VV, VH
		2024.5.27		VV, VH
		2024.10.06		VV, VH
		2024.4.17	Descending	VV, VH
		2024.5.11		VV, VH
		2024.9.20		VV, VH

Data Sources

To extract landslide-affected areas along the Manaslu Circuit Trail, optical and SAR sensor data were utilised. Specifically, Sentinel-2 optical imagery and Sentinel-1 SAR imagery were selected. To capture slope deformation dynamics, one pre-monsoon and one post-monsoon scene were selected for each sensor. For Sentinel-2 imagery, cloud-free scenes within the study area were preferentially selected. The specifications of the datasets used in the analysis are summarised in Table 1.

Landslide Extraction Methods

To identify slope failures occurring along the trail, two spatial scopes were defined: (1) catchment areas adjacent to the trail, and (2) buffer zones of 50 meters from the trail route. Multiple approaches were applied to both optical and SAR data.

RGB-NDVI Colour Composite for the Land Cover Distribution Chart (LCDC)

This method identifies landslide areas by detecting changes in vegetation between two periods. NDVI values before and after the monsoon were calculated from Sentinel-2 data. A colour composite image was created by assigning pre-monsoon NDVI to red, post-monsoon NDVI to green, and pre-monsoon blue band reflectance to blue [5][6]. The resulting image was classified into five colours (red, yellow, green, blue, black), with red regions interpreted as landslide-affected areas. A supervised classification using the Maximum Likelihood Method was then applied using training areas extracted from these colour classes.

NDVI-GSI Differential Analysis

This method identifies landslide areas as regions that transitioned from vegetated surfaces Normalized Difference Vegetation Index (NDVI) before the monsoon to bare surfaces Gray Size Index (GSI) afterward [7]. GSI was calculated using the formula (Equation1):

$$GSI = \frac{(R - B)}{(R + G + B)} \quad (1)$$

Where *R*, *G*, and *B* represent the reflectance of red, green, and blue bands from Sentinel-2 imagery. Thresholds for NDVI and GSI were determined through visual inspection of false-colour satellite images (The NDVI threshold pre-monsoon is 0.2, and post-monsoon is 0.3. The GSI threshold pre-monsoon is 0.1, and post-monsoon is 0.06).

SAR Intensity Texture Analysis

Texture analysis using SAR intensity data was conducted to delineate sediment disaster zones, which typically exhibit rough surface textures due to disrupted land cover. Pre-monsoon VV-polarized SAR images were converted to backscatter coefficients (σ^0) and filtered with a 5×5 Lee filter to suppress speckle noise. Landslide-prone areas were identified based on the standard deviation of σ^0, as such regions show significantly elevated SD values. Thresholds were statistically defined using the mean and standard deviation of the SD values, with five levels set: $\mu + 1.0\sigma$ to $\mu + 3.0\sigma$. Given the radar

illumination geometry, ascending scenes captured west-facing slopes and descending scenes east-facing slopes. To ensure comprehensive extraction, both datasets were merged, and the same procedure was applied throughout the analysis.

NDPI Differential Analysis

Normalized Difference Polarization Index (NDPI) was applied to detect changes in surface scattering characteristics using pre- and post-monsoon VV and VH polarization backscatter data [10]. NDPI is defined as (Equation2):

$$NDPI = \frac{(\sigma^0 VV - \sigma^0 VH)}{(\sigma^0 VV + \sigma^0 VH)} \quad (2)$$

In this study, σ^0VV and σ^0VH represent the backscatter coefficients (σ^0) of VV and VH polarizations, respectively. The NDPI, ranging from −1.0 to 1.0, was used to distinguish volume scattering (e.g., vegetation) from surface scattering (e.g., bare ground). NDPI was calculated from pre- and post-monsoon SAR data, and the absolute difference between the two was derived. Areas affected by sediment-related disasters typically show a shift from volume to surface scattering, resulting in high absolute NDPI difference values. However, contributions from snow and ice scattering complicate threshold selection. Therefore, five statistical thresholds were defined: $\mu + 1.0\sigma$ to $\mu + 3.0\sigma$.

Dual-Polarisation SAR Image Interpretation

A colour composite image was created using VV and VH polarisations before the monsoon and VV polarisation after the monsoon. Bare landslides, which exhibit increased VV reflectance over time, were interpreted as purple regions [11][12].

Coherence Difference Analysis

Coherence Values (CV) are generated during the interferometric SAR processing and represent the correlation coefficient between intensity data acquired at two different times, ranging from 0 to 1.0. Low CV indicate weak temporal correlation in land cover, suggesting that surface conditions have changed between acquisitions [13][14].

In this study, coherence was calculated separately from pre-monsoon and post-monsoon SAR image pairs. The coherence derived from the post-monsoon pair was subtracted from that of the pre-monsoon pair on a pixel-by-pixel basis. Areas affected by sediment-related disasters are typically characterized by a transition to bare ground, resulting in low coherence difference values relative to the overall distribution.

Therefore, five threshold levels were defined based on the statistical distribution of the coherence differences: $\mu - 1.0\sigma$, $\mu - 1.5\sigma$, $\mu - 2.0\sigma$, $\mu - 2.5\sigma$, and $\mu - 3.0\sigma$.

Ground Truth Survey

To validate the remote sensing-derived landslide detection results, a field survey was conducted along the Manaslu Circuit Trail between September 8–21, 2024. Landslide sites were verified visually and recorded with photographs and GPS coordinates. Interviews with local residents were also conducted to gather temporal data on disaster occurrences. These records served as ground truth data for evaluating the accuracy of satellite-based extraction methods.

RESULTS AND DISCUSSION

Landslide Extraction Using RGB-NDVI Colour Composite for the LCDC

The results of landslide extraction based on land cover change classification using optical sensor data are shown in Fig. 2. Within the trail buffer zone, a total of 213 landslide sites were extracted, covering an area of 40.7 hectares. Of the nine ground truth sites, two were correctly extracted. The remaining seven sites were not detected, which suggests that no landslide events occurred at those locations in 2024. Subsequently, 141 random points were generated within the extracted landslide areas. Using post-monsoon Sentinel-2 imagery and satellite images from Google Earth as reference data, the proportion of correctly matched points (accuracy) was calculated (Table3). The accuracy was 78.0%; however, due to a high number of points being classified outside actual landslide areas, both the F-measure and Cohen's kappa coefficient yielded relatively low values. Misclassified areas included farmland, livestock grazing zones, riverbanks, and residential settlements. These errors are presumed to have resulted from changes in NDVI values between the two observation periods, leading to false positives in the extraction process.

Landslide Extraction Using NDVI-GSI Differential Analysis

The NDVI-GSI differential analysis results are

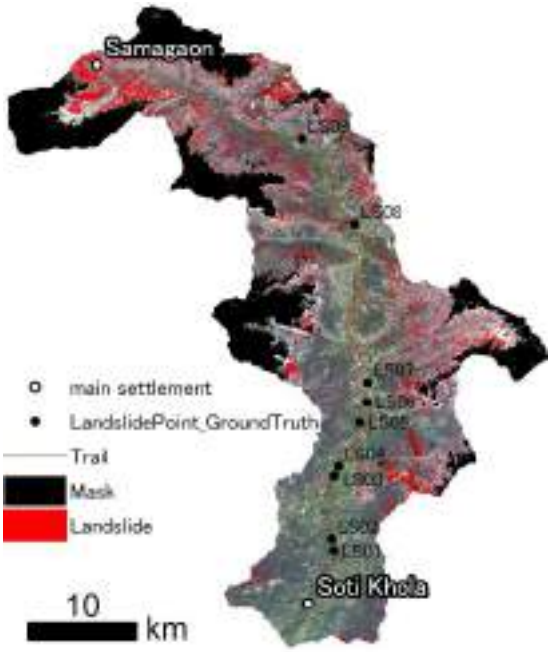

Fig. 2 Landslide-Affected Areas Identified by Land Cover Distribution Chart

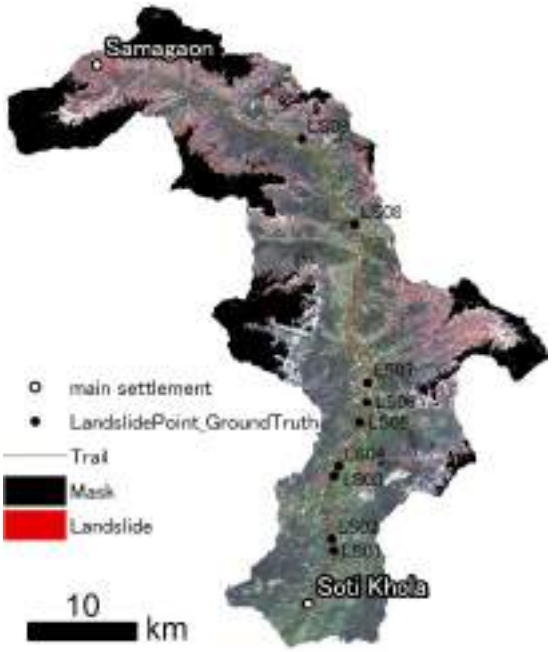

Fig. 3 Landslide-Affected Areas Extracted Using NDVI–GSI Differential Analysis

presented in Fig. 3. A total of 99 landslide-affected sites were extracted within the trial buffer zone, encompassing an area of 13.0 hectares. Of the nine ground truth sites, two were correctly identified. The remaining seven sites were not detected, which suggests that no landslide events occurred at those locations in 2024.

The accuracy was 81.3%, which was higher than that obtained by any other method (Table3). However, due to a large number of points being classified outside actual landslide areas, both the F-measure and Cohen's kappa coefficient yielded relatively low values. Misclassified areas were similar to those observed in the land cover change classification map, including farmland, livestock grazing zones, riverbanks, and residential settlements. Compared to the land cover change classification map, the total extracted area was smaller. This underestimation is presumed to be a result of the threshold values set for NDVI and GSI, which may have led to conservative extraction of landslide-affected regions.

Landslide Extraction Using SAR Intensity-Based Methods

Texture analysis and NDPI differential analysis results, based on SAR backscatter coefficients, are shown in Fig. 4 and Fig. 5, respectively. The texture analysis tended to highlight ridge and valley regions based on thresholding, while NDPI-based results showed extensive and fragmented patterns that were difficult to interpret as landslide zones [15].

These challenges are likely due to geometric distortions in SAR imagery, such as layover and shadowing. In comparison with ground truth data, texture analysis correctly identified four out of nine sites, while NDPI analysis detected only two. The accuracy was 68.0% for the texture-based analysis method and 60.7% for the NDPI differential analysis (Table 3).

Landslide Extraction Using Dual-Polarisation SAR Image Interpretation

Fig. 6 presents the results derived from dual-polarisation SAR imagery. Similar to other SAR-based approaches, the image interpretation was hindered by layover and radar shadow effects, resulting in unreliable detection. Only one of the nine ground truth sites was correctly identified, indicating the limitations of this method in mountainous terrain. The accuracy was 74.0% (Table 3).

Landslide Detection Using Coherence Difference Analysis

Landslide extraction results from coherence difference analysis are shown in Fig. 7. Although spatial patterns were scattered, five of the nine ground truth sites were successfully matched. The accuracy was 64.0% (Table 3). This suggests that coherence-based methods may offer relatively better results than SAR intensity analyses, although some matches may have occurred coincidentally.

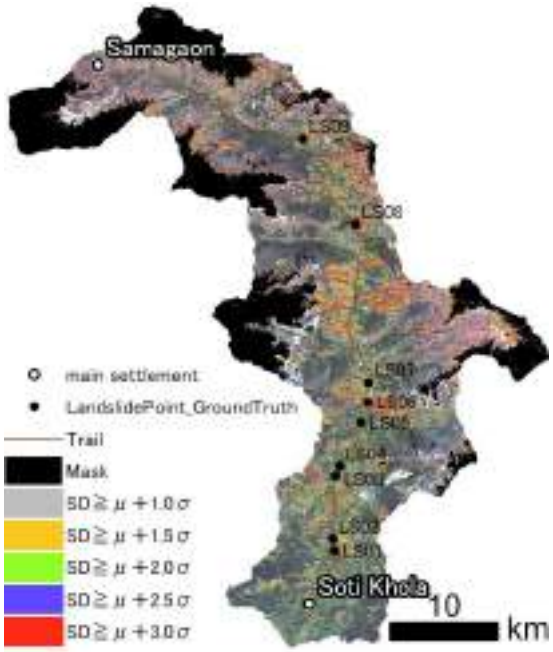

Fig. 4 Landslide-Affected Areas Extracted by SAR Intensity-Based Texture Analysis

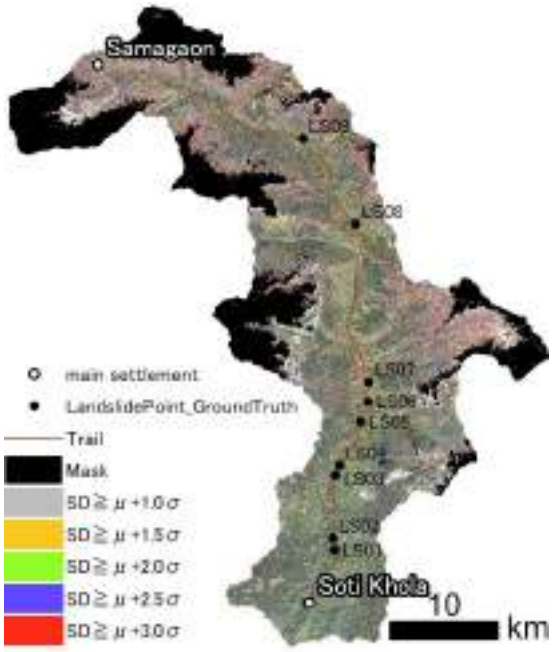

Fig. 5 Landslide Detection Based on NDPI Differential Analysis

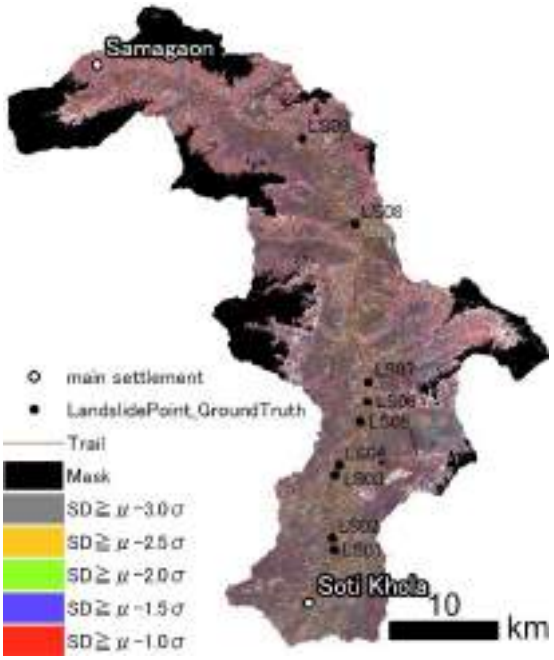

Fig. 7 Landslide-Affected Areas Detected by Coherence Difference Analysis

Landslide Extraction Results Based on Ground Truth Comparison

Table 2 presents a comparative evaluation of the results obtained from various analytical methods concerning nine ground-truth locations (LS01–LS09). At LS01, no landslide area was detected by either optical or SAR datasets, suggesting that no slope deformation occurred at this site in 2024. LS02 yielded a small-scale landslide detection using optical sensor analysis; SAR-based methods indicated partial detection, but layover and radar shadow effects likely reduced data reliability.

LS03 showed consistent detection across both data sources, although slight spatial mismatches were observed. Optical data did not detect LS04, but SAR-based methods identified slope failure to some extent, again with limitations due to terrain-induced distortion. LS05 yielded similar results to LS04.

Table 2 Comparison Between Ground Truth Locations and Landslide-Affected Areas Extracted by Each Method

No	Photo of Landslide	LCDC	NDVI-GSI	Texture Analysis	NDPI Difference Analysis	DPSII	Coherence Difference Analysis
LS01							LS02							
LS03							LS04							LS05							LS06							
LS07							
LS08							LS09							
LS06 was detected by both optical and SAR data and corresponded to the most extensive landslide in the study area, with an estimated width of approximately 100 meters and a length of 400 meters. This was the only site where interviews with nearby residents were conducted, confirming that heavy rainfall in August 2024 triggered the slope failure.

Table 3 Results of Landslide Detection for Nine Ground-Truth Locations Across Multiple Analytical Methods

		Optical Satellite Imagery						SAR Imagery											
		LCDC			NDVI-GSI			Texture Analysis			NDPI DA			DPSII			Coherence DA		
		L	O	T	L	O	T	L	O	T	L	O	T	L	O	T	L	O	T

Kappa Coefficiant		0.054			0.082			0.116			-0.153			0.155			0.028		

Legend: L: Landslide, O: Others, T: Total

At LS07, no landslide was detected using either data source, indicating the absence of deformation. LS08 revealed a small-scale landslide using optical data and partial detection through SAR, but terrain distortions compromised accuracy. LS09 produced similar results to LS08, and both sites are unlikely to have experienced slope failure in 2024.

These findings suggest that when slope deformation is observed by both optical and SAR datasets, the site can be reliably classified as a landslide area. In contrast, SAR-only detection in mountainous regions should be interpreted cautiously due to layover and radar shadowing effects. Optical-only detections may reflect land use changes, such as seasonal agricultural activity, and cannot be unequivocally identified as landslides. Therefore, a combined approach using both optical and SAR data is essential for accurate landslide extraction in complex mountain environments.

CONCLUSION

In this study, we applied two optical-based and four SAR-based methods to extract landslide-affected areas along the Manaslu Circuit Trail in Nepal. Each method was evaluated in terms of its capacity to delineate slope failure zones, and its effectiveness was validated using ground truth data.

Consistent with previous findings, the complex topography of the Himalayan region poses significant challenges for SAR-based landslide detection due to layover, shadowing, and coherence loss. Among the SAR approaches, coherence difference analysis yielded comparatively better results, although its accuracy remained limited.

On the other hand, the NDVI-GSI differential analysis using optical sensor data demonstrated the most promising performance, effectively identifying landslide sites with fewer false positives. However, its susceptibility to seasonal land cover changes, particularly agricultural activities, highlights limitations in discriminating between genuine landslides and anthropogenic surface changes.

For landslide detection in mountainous regions, it is considered effective to primarily utilize optical sensor data while minimizing misclassification through time-series analysis of NDVI fluctuations. Furthermore, by incorporating SAR imagery to differentiate between actual landslides and land use changes, more detailed and accurate extraction of landslide-affected areas can be achieved.

In this study, the SAR dataset was limited to C-band Sentinel-1 imagery. To enhance the potential for landslide detection, a key challenge lies in incorporating SAR data acquired in the L-band, which, due to its longer wavelength, can penetrate vegetated areas more effectively. This would allow for improved observation of surface deformation and facilitate the identification of optimal image pairs for interferometric SAR (InSAR) analysis.

These findings contribute to improved understanding of remote sensing-based disaster monitoring in high-altitude regions, supporting more effective trail management and community resilience in Nepal's mountainous landscapes.

ACKNOWLEDGMENTS

This field survey was made possible through a sponsored research donation from Mr. Yoichi Nakata. I would like to take this opportunity to express my sincere gratitude. I thank Mr. Ram Raj Rijal(Executive Director) and staff from Himalaya Research Expeditions(P) LTD., who have totally supported our fieldwork in Manaslu Base Camp and Manaslu Conservation Area, Nepal. This work was supported by JSPS KAKENHI Grant Numbers JP22K12623, JP25K03332.

HEAVY METAL CONCENTRATIONS OF PLANTS GROWING AROUND MINES IN VICTORIA, AUSTRALIA

Daiki Yamamoto

Graduate School of Systems Engineering, Wakayama University, Japan ;

ABSTRACT

Some plants can grow even in areas where the soil is rich in heavy metals, such as mines. Some of them can contain large amounts of toxic heavy metals in their bodies. They are called hyperaccumulators and are expected to be used for the remediation of contaminated sites. There are many gold and antimony mines in Australia, and some areas are contaminated by antimony, arsenic, copper, and other metals. In this study, plants native to mining areas in Victoria and South Australia, were surveyed to determine which plants were present. Heavy metal concentrations in plants were measured and compared between heavy metal contaminated and non-contaminated areas. As a result, antimony was detected in the plants in Costar field, and some plants were found to contain 100 ppm of antimony in their roots. Most of the plants contained more heavy metals in the roots, with concentrations in the leaves and stems ranging from one-tenth to one-hundredth of those in the roots. Blackberry and grass plants were found in many mines and non-contaminated areas, and their concentrations differed.

Keywords: Heavy metals, Victoria, Plant, Antimony

INTRODUCTION

By the 1860s, De Saussure, von Sacks, and Knop had shown that C, H, O, N, P, S, K, Ca, Mg, and Fe were essential for plant growth. C, H, O, N, P, S, K, Ca, Mg, and Fe are essential for plant growth. Subsequently, 17 essential elements for plant growth were listed by 1987 [1]. Since heavy metals and other soil contaminants are absorbed together during the absorption process, plants in general cannot grow in areas with high concentrations of soil contaminants. However, some plants prefer to grow in areas with high concentrations of contaminants, especially heavy metals, and absorb and accumulate heavy metals at high levels. These plants are called mine plants or hyperaccumulators in Japanese.

Australia boasts one of the world's largest gold production volumes. Since the gold rush of the 19th century, there have been numerous gold mines in Australia. Antimony (Sb), which is produced alongside gold (Au), also has one of the world's largest production volumes, and there are Sb mines centered around Costerfield in Victoria. Rocks that were mined in the past remain on the slopes of the mountains around the mines, and it is believed that the soil contains heavy metals that have dissolved from the ore deposit.

The purpose of this study is to investigate plants growing naturally in mines in Victoria and measure the heavy metal concentrations in the collected plants. Furthermore, we will investigate whether there are plants that absorb and accumulate high concentrations of heavy metals, and discuss the differences in heavy metal concentrations between the locations of the plants and the collection sites.

RESEARCH SIGNIFICANCE

Metals in the soil can be a source of nutrition for plants or toxic, depending on their type and quantity. Therefore, it is important to understand the role of metals in plants. By studying plants that grow naturally in Au and Sb mines, we can investigate how plants in nature process Sb and other heavy metals.

METHODS

Study Site

Fig.1 Location of study sites

The locations of plant collections in this study are shown in figure 1. The survey sites are four mines and two non-contaminated areas in Victoria.

Point (1) is Costerfield, known for its antimony mines. At this site, samples were collected from two locations, designated as Site (1) and Site (2). Figure 2 shows a photograph of Site (1), where mined ore was

piled up in a specific location, and the ore contained a large amount of stibnite (Sb_2S_3). Figure 3 shows a photograph of Site (2), which is a pile of ore located several hundred meters away from Site 1. The ore at this site also contained a large amount of stibnite (Sb_2S_3).

Fig.2 Photograph of the ore storage at site (1)

Fig.3 Photograph of the ore storage at site (2)

Both Point (2) and Point (3) were areas where gold was mined, and ore was piled up along the slopes of the mountains. The minerals were mainly quartz, and arsenopyrite (FeAsS) was also found.

Fig.4 Photograph of the sampling point at point (4)

Point (4) is the location where tungsten minerals were found, and Figure 4 shows the condition of the collection site. Ferberite ($FeWO_4$) was observed at this location. Based on past mining history and the types of minerals found at survey sites, points (1) through (4) were designated as contaminated areas.

Points (5) and (6) are areas free of heavy metal contamination, and samples were collected to compare the heavy metal concentrations in plants from the mines. These two points are designated as non-contaminated areas. Point (5) is located in an igneous rock area, while Point (6) is located in a sedimentary rock area.

Analysis Method

After pretreatment, the collected plants are measured for heavy metal concentrations in the plants using an ICP optical emission spectrometer (ICP-OES). ICP-OES is a method that introduces a solution sample into plasma to emit element-specific spectra, identifies the presence of elements from the wavelengths of these lights, and determines the concentration of elements from the intensity of the light. This method was chosen because it allows multiple elements to be measured at once.

Pretreatment consists of cleaning the plants and preparing samples. First, the collected plants are separated into root, leaf, and stem parts as much as possible. The soil is washed because it contains a large amount of heavy metals, which can cause large errors in the measurement results. After the soil is removed, the specimens are placed in the dryer for one or two days to dry.

A solution sample of heavy metals extracted from plants is prepared for ICP emission spectrometry. First, dried plants are placed in a screw tube and concentrated nitric acid is added. Nitric acid has the effect of oxidatively decomposing organic matter in the sample and extracting heavy metals. After approximately two weeks of standing, the heavy metals in the plants are extracted and a yellow solution is obtained. Fine impurities remain in the screw tube, so these are removed using a filter and syringe.

The analysis was performed using an ICP optical emission spectrometer to measure the concentration of heavy metals in the prepared samples. The heavy metals measured were antimony (Sb), arsenic (As) and tungsten (W).

From the above steps, the concentration of heavy metals is measured. Since the concentration measured is the concentration in the sample solution, it must be converted to the concentration of heavy metals in the dried plant sample using the following equation

$$a\ (mg/kg) = \frac{b\ (mg/kg) \times c(g)}{d\ (g)} \quad (1)$$

a Heavy metal concentrations in plant samples
b Concentration of solution
c Weight of solution
d Dry weight of sample

RESULTS

In this study, the concentration of three elements were measured: antimony (Sb), arsenic (As) and tungsten (W). The concentrations of each heavy metal detected are shown in the graphs for each sampling point and site.

Table 1 Collected plants and sampling point

Numbers	Scientific names	Sampling points
Grass A	*Avena barbata*	①②④⑥

Shrub B	*Ulex europaeus*	① ③

Sb Concentration

Figure 5 shows the concentration of antimony (Sb) per dry weight per plant at sampling point (1). Overall, concentrations of Sb were higher in roots, leaves, and stems, in that order. The roots of Glass A at Site (1) had the highest antimony concentration, containing 238 mg/kg. Glass C and Herb A at Site (1) had higher antimony concentrations in their leaves than in their roots, both contained an average of about 20 mg/kg. When comparing the sampling sites, the plants at Site (1) contained more antimony than those at Site (2).

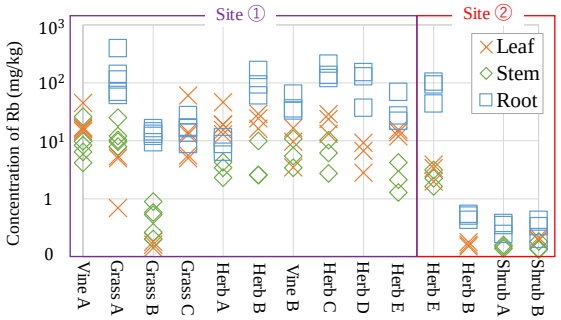

Fig.5 Measurement results for Sb

As Concentration

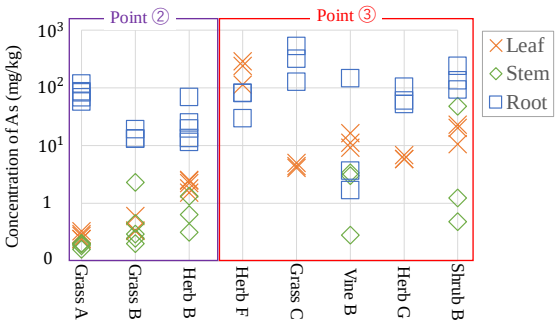

Fig.6 Measurement results for As

Figure 6 shows the concentration of arsenic (As) per dry weight of plants collected at points (2) and (3). Overall, it can be seen that arsenic is concentrated in the roots of plants. The highest arsenic concentration was found in grass C at point (3), which showed 530 mg/kg. On the other hand, Herb F at Point (3) showed higher concentrations of arsenic in the leaves than in the roots, with an average of 214 mg/kg of arsenic. When comparing sampling points, plants at Point (3) tend to have higher arsenic concentrations than those at Point (2).

W Concentration

Figure 7 shows the concentration of tungsten (W) per dry weight of each plant at sampling point (4). For glass A, samples were collected at two sites several meters apart, but both showed W concentrations of less than 1 mg/kg. On the other hand, glass D contained 11 to 24 mg/kg of W in the roots, 2 to 7 mg/kg in the stems, and 1 to 2 mg/kg in the leaves.

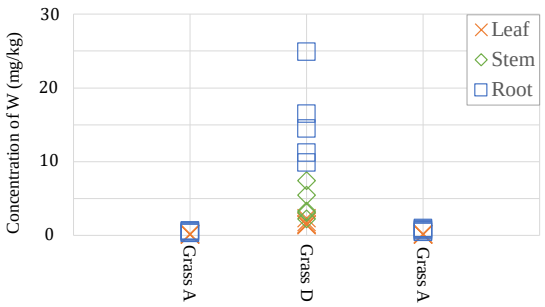

Fig.7 Measurement results for W

DISCUSSION

Comparison of Sb concentrations in the roots and leaves of contaminated and non-contaminated areas

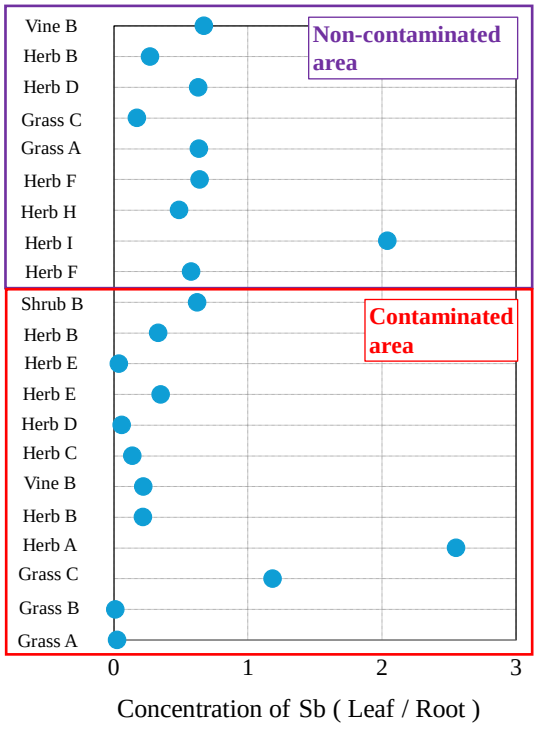

Fig.8 The ratio of Sb concentrations in roots and leaves

Figure 8 shows the antimony concentration in plant leaves collected from contaminated and non-contaminated areas divided by the concentration in the roots. The contaminated area in the figure 8 is Point (1), and the non-contaminated areas are Points (5) and (6). As mentioned in the results, many plants accumulate antimony in their roots, so the values shown in the figure are less than 1. Additionally, since the values are slightly higher in the non-contaminated areas than in the contaminated areas, it can be seen that as the amount of antimony in the soil increases, the proportion of antimony supplied to the leaves tends to decrease. However, Grass C and Herb A in the contaminated area show values greater than 1, indicating that the amount of antimony supplied to the leaves is greater than the amount accumulated in the roots.

Comparison Of As concentrations in the roots and leaves of contaminated and non-contaminated areas

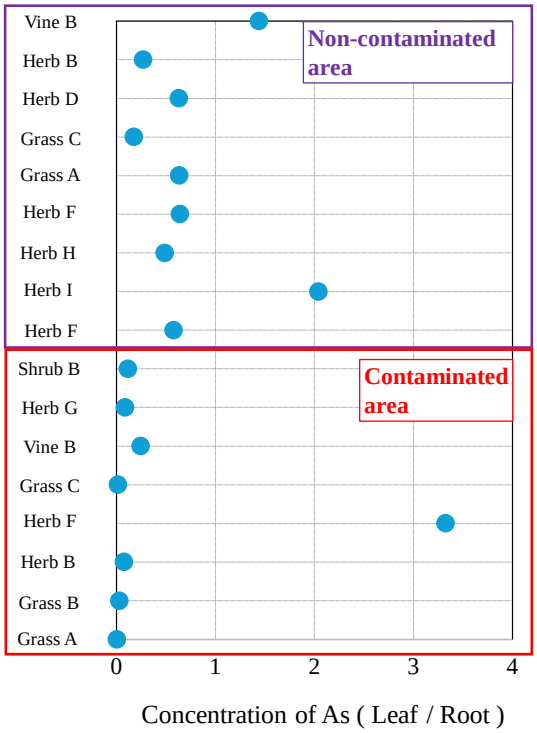

Fig.9 The ratio of As concentrations in roots and leaves

Figure 9 shows the arsenic concentration in plant leaves collected from contaminated and non-contaminated areas divided by the concentration in the roots. Note that the contaminated areas in the figure are points (2) and (3), and the non-contaminated areas are points (5) and (6). Similar to antimony, many plants accumulate arsenic in their roots, so the values shown in the figure are less than 1. Furthermore, since the values are higher in non-contaminated areas than in contaminated areas, it can be seen that as the arsenic content in the soil increases, the proportion of arsenic supplied to the leaves tends to decrease. This trend is stronger than that observed for antimony. Among the contaminated areas, only Herb F shows a value greater than 1, indicating that the amount of arsenic supplied to the leaves is greater than the amount accumulated in the roots. Even when comparing arsenic concentrations in contaminated and non-contaminated areas using the same type of

plant, such as Glass A, it can be seen that the values are higher in non-contaminated areas.

CONCLUSIONS

In this study, we conducted field surveys of plants growing naturally in gold mines, antimony mines, and other locations in Victoria, Australia, and analyzed the heavy metal concentrations in the plants. The heavy metal concentrations in all plants collected in this study ranged from 0 to 393 mg/kg for antimony (Sb), 0 to 530 mg/kg for arsenic (As), and 0 to 25 mg/kg for tungsten (W). Most of the plants collected from contaminated areas such as gold mines and antimony mines had the highest heavy metal concentrations in their roots rather than in their leaves or stems. This indicates that these plants accumulate heavy metals in their roots and reduce the amount of heavy metals supplied to their leaves and stems. Additionally, the results of comparing heavy metal concentrations in leaves and roots between contaminated and non-contaminated areas showed that as soil heavy metal concentrations increase, the proportion of heavy metals supplied from roots to leaves and stems tends to decrease. On the other hand, there were also plants, such as *Holcus lanatus* and *Marrubium vulgare* from the Costarfield Mine and *Arctotheca calendula* from the Sovereign Hill Mine, that accumulated significant amounts of antimony and arsenic in their leaves. These plants grow in ordinary soil as well. Therefore, it is possible that they have mechanisms that prevent harm to the body even when leaves and stems contain high levels of heavy metals, or that their system for supplying heavy metals from roots to leaves differs from that of other plants.

ACKNOWLEDGMENTS

In conducting this research, I would like to express my sincere gratitude to Professor Hiroyuki Ii of the Graduate School of Systems Engineering at Wakayama University and Professor John Sherwood of Deakin University for their valuable advice and guidance despite their busy schedules.

A would like to express my sincere gratitude to the members of the laboratory for their constant guidance and cooperation in laboratory analysis and data processing.

We would like to express our gratitude to all of you for your cooperation.

ABSTRACT

This study proposes a physically based framework for assessing the hazard of large woody debris (LWD) discharge in dam watersheds under extreme rainfall conditions. The method integrates rainfall return-level analysis, landslide-induced LWD recruitment modeling, and discharge simulation using a double storage function with the lumped hydrological method at a watershed scale. It was applied to five representative dam watersheds in Japan to simulate the potential minimum, maximum, and expected LWD discharge volumes under varying rainfall return periods. The results demonstrate that the framework effectively captures the variability in discharge responses across sites and identifies dam-specific rainfall thresholds for potential LWD discharge. Particularly, the use of expected initial storage conditions significantly improves the reliability of hazard estimation. The observed LWD discharge records were consistently bound by the simulated discharge ranges, validating the model's applicability. In contrast to traditional observation-based approaches, this framework enables estimation of low-frequency hazards. It offers a practical tool for risk-informed reservoir management and indicates the importance of integrating physical processes in LWD hazard prediction. These findings contribute to understanding inter-site differences in LWD storage and transport behavior, enabling more proactive hazard mitigation planning under increasing extreme weather events.

Keywords: Large woody debris, Landslide, Recruitment, Storage, Hazard assessment

INTRODUCTION

Large woody debris (LWD), generated by natural and anthropogenic processes such as mass movements and bank erosion, can be transported downstream during extreme rainfall events, threatening both ecosystems and infrastructure [1]. In mountainous regions, rainfall-induced landslides and debris flows often trigger LWD mobilization, as observed during Typhoon Lionrock in Iwate Prefecture, where transport of LWD exacerbated infrastructure damage [2]. Dam reservoirs are particularly vulnerable due to reduction in reservoir storage capacity [3].

Extensive research has been conducted on LWD recruitment and mobilization, primarily through field surveys [4]. However, due to the lack of long-term observational data on LWD dynamics, accurately predicting LWD-related hazards remains challenging. GIS-based methods that estimate LWD discharge from landslides using forest cover and land use data have also been developed [5,6], but these approaches often overestimate actual discharge volumes. To overcome such limitations, physically based modeling of LWD dynamics has emerged as a promising alternative. Komori [7] proposed a watershed-scale integrated model that incorporates landslide-induced LWD recruitment with a double storage function model using a lumped hydrological approach. The model introduces virtual tanks to represent the storage and transport of LWD within mountainous watersheds and has been successfully applied to multiple dam watersheds in Japan [8]. This study proposed the integrated framework by applying it to selected representative dam watersheds in Japan to assess LWD hazards, verify the feasibility of the approach, and examine the site-specific characteristics of LWD discharge behavior.

RESEARCH SIGNIFICANCE

This study adapted a previously developed LWD export model [7,8] for hazard assessment applications. The approach enables the simulation of potential LWD discharge volumes under varying rainfall conditions, including extreme events, by leveraging a budget framework that incorporates the key processes of recruitment, storage, and transport. It addresses the disconnect between the estimated LWD supply and its potential downstream discharge including expected volume, minimum and maximum volume.

STUDY SITES

Five dam watersheds were selected as study sites for this research, located across six prefectures in central and northeastern Japan: Nagano, Niigata, Tochigi, Yamagata, Akita, and Iwate. These watersheds were chosen to represent a range of topographic and climatic conditions characteristic of mountainous regions prone to rainfall-induced landslides and LWD transport. While geographically dispersed, the sites share similar forest coverage, slope gradients, and dam management practices, making them suitable for comparative hazard assessment under varying rainfall scenarios. The spatial distribution of Dam No. 1 to No. 5 is illustrated in Fig.1. Their key physical characteristics are summarized in Table 1.

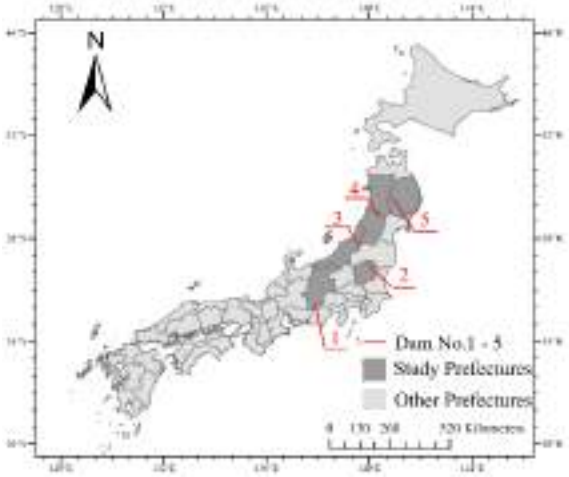

Fig.1 Locations of the five selected dam watersheds

Table 1 Basic characteristics of the five selected dam watersheds

No.	Dam	Area (km^2)	Length (km)
1	Katagiri	14.86	8.58
2	Shiobara	123.96	113.29
3	Tainaikawa	72.68	55.44
4	Kamuro	22.29	15.23
5	Yuda	577.49	512.25

Note: Area refers to total watershed area; length refers to total river length within the watershed.

Given the temporal coverage and spatial variability of the selected sites, these discharge data reflect a wide range of hydrological and geomorphic conditions relevant to LWD transport.

In Japan, local reservoir management agencies monitor the total annual volume of LWD transported into reservoirs [7]. Table 2 summarizes the highest single-year LWD discharge volume and the associated annual maximum 24-hour rainfall for each study dam during the period 1996–2021. It reflects LWD responses to extreme rainfall events, as represented by the years of maximum discharge. Despite the limited range of 24-hour rainfall (240–343 mm), it corresponds to varying rainfall intensities across sites (e.g., different return periods), which will be examined in this study.

Table 2 Highest single-year LWD discharge volumes and associated annual maximum 24-hour rainfall for each study dam (1996–2021).

No.	Max. Volume (m^3)	Max. Rainfall (mm/24hrs)
1	610	288
2	3295	343
3	397	281
4	246	242
5	2490	240

Note: Dam No. 1–5 correspond to the five study dams listed in Table 1. Max Volume indicates the highest recorded annual LWD discharge for each dam during 1996–2021. Max Rainfall refers to the maximum 24-hour rainfall over the corresponding watershed in the same year.

METHODS

The objectives of this study are two parts: (1) identify the minimum rainfall return period at which potential LWD discharge begins at each site, and (2) quantify the range of potential LWD discharge (including minimum, maximum, and expected values) under various return periods. The overall framework and methodology are presented in this section.

Rainfall Return Period and Level Analysis

Annual maximum 24-hour rainfall data (1996–2021) within five dam watersheds were extracted from the Radar-AMeDAS dataset provided by the Japan Meteorological Agency, with a spatial resolution of 1 km. For each dam watershed, the series of annual maximum was fitted to the Generalized Extreme Value (GEV) distribution to estimate rainfall intensities corresponding to different return periods [9]. The GEV distribution is widely used for hydrological hazard assessment and is defined as:

$$F(x) = \exp\left\{-[1+\xi(\frac{x-\mu}{\sigma})]^{-1/\xi}\right\} \quad (1)$$

where μ, σ, and ξ are the location, scale, and shape parameters, respectively. Parameters were estimated using the L-moments method, based on 26 years (1996–2021) of rainfall data.

From the fitted distribution, the rainfall return levels x_T within in each dam watershed were derived using the inverse of Eq. (1), expressed as:

$$x_T = \mu + \frac{\sigma}{\xi}\left[(-\log(1-\frac{1}{T}))^{-\xi} - 1\right] \quad (2)$$

Return levels for various return periods T (e.g., 3–200 years) were calculated and used as rainfall inputs for subsequent landslide modeling under different hazard scenarios. These synthetic extreme rainfall values allow comparison between observed historical conditions and potential future extremes.

LWD Recruitment Simulation

This provided two sets of outputs: annual LWD recruitment volumes based on historical rainfall, and potential recruitment volumes under different return periods. The recruitment of LWD from landslides was estimated using a previously developed analytical framework [8,10]. These results served as input to the discharge simulation process described in the next section.

Discharge Simulation and Hazard Assessment

The discharge of LWD from dam watersheds was simulated using a double storage function model based on the lumped hydrological method, following the approach of [7]. This section describes how the proposed model is used to calculate the expected, maximum, and minimum potential LWD discharge.

This section involved three steps. In the first step, dam-specific model parameters for each study site were identified by fitting the model to observe annual LWD discharge records from 1996 to 2021. For each dam, annual recruitment volumes were used as inputs, and parameter sets were determined by maximizing the Nash–Sutcliffe Efficiency (NSE) between observed and simulated discharge values [11]. The structure of the model remained fixed, and parameter optimization was conducted independently for each dam watershed. The structure of the model and its key parameters are illustrated in Fig. 2.

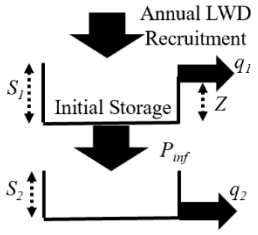

Fig.2 Conceptual framework of the double storage function model

Where S_1 and S_2 are storage volumes in first and second tank (m^3), respectively. Z is the capacity of the first tank, which is one of the model parameters determined by NSE method. Sum of q_1 and q_2 is the annual LWD discharge volume (m^3). The governing equations and parameter definitions are presented below. When $S_1 \geq Z$:

$$q_1 = S_1(n) - Z \quad (3)$$

When $S_1 < Z$:

$$q_1 = 0 \quad (4)$$

$$P_{\inf} = b \cdot S_1(n) \quad (5)$$

$$S_1(n+1) = S_1(n) + P - P_{\inf}(n) \quad (6)$$

$$\frac{dS_2}{dt} = P_{\inf} - q_2(n) \quad (7)$$

$$S_2 = k \cdot q_2^p \quad (8)$$

where b, k and p are parameters, n is time (in years). The following equation defines the NSE:

$$\text{NSE}=1-\frac{\sum_{m=1}^{N}(q_{obs}(m)-q_{sim}(m))^2}{\sum_{m=1}^{N}(q_{obs}(m)-q_{ave}(m))^2} \quad (9)$$

where N is the simulation period (year), m is a year from 1 to N, q_{obs} is the annual observed LWD discharge volume(m^3), q_{sim} is the annual simulated LWD volume (m^3), q_{ave} is the average annual observed LWD volume (m^3).

Subsequently, 10,000 annual LWD recruitment values were randomly generated for each study site. The model was run for each random value using the estimated parameters from the first step, and the resulting storage-to-capacity ratios in first tank were recorded. These ratios were then used to compute an expected initial storage-to-capacity ratios ($r= S_1/Z$) via a weighted average approach, representing the actual LWD storage conditions within dam watershed, which enables the estimation of expected potential LWD discharge. The framework for calculating the expected storage percentage is illustrated in Fig. 3.

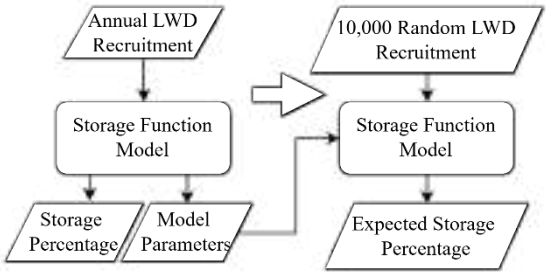

Fig.3 Schematic diagram of expected storage percentage calculation

Finally, using LWD recruitment volumes estimated under return-level rainfall conditions (mm/24 hrs), the double storage function model was run under three initial storage scenarios: empty (0%), saturated (100%), and the expected storage percentage. For each dam watershed and return period, the model produced a distribution of annual LWD discharge volumes, from which the minimum, maximum, and expected values (in m³/year) were derived. These results enabled comparative hazard assessments across sites under varying rainfall conditions.

RESULTS AND DISCCUSIONS

Model Parameters Estimation

The double storage function model described above was applied to five dam watersheds using observed annual maximum 24 hours rainfall and LWD discharge records from 1996 to 2021. Model parameters were determined independently for each site, and the simulated annual LWD discharge was compared with observations to evaluate performance by NSE. The model parameters determined by the NSE are summarized in Table 3.

Table 3 Model Parameters and NSE for each study site

No.	*Z*	*b*	*k*	*p*	NSE values
1	12,000	0.11	0.0001	100	0.900
2	14000	0.215	0.0476	2.44	0.807
3	89,000	0.17	0.0001	100	0.462
4	8,500	0.005	0.0051	9.10	0.408
5	9,000	0.47	0.0001	100	0.705

Note: Dam No. 1–5 correspond to the five study dams listed in Table 1. Z,b,k and p are model parameters in double storage function model

Expected Initial Storage Estimation

The expected initial storage-to-capacity ratios ($r = S_1/Z$) for the five dam watersheds, estimated through 10,000 stochastic simulations per site, are spatially presented in Fig. 5.

The values vary substantially among sites, ranging from 14% at Katagiri Dam to 95% at Yuda Dam. Katagiri and Shiobara Dams exhibited relatively low expected storage ratios (14% and 29%, respectively), indicating that annual LWD recruitment volumes at these sites were generally insufficient to saturate the LWD storage capcacity within in watershed. In contrast, Yuda Dam showed a markedly high value of 95%, indicating a high possibility of storage capacity exceedance. Tainaikawa and Kamuro Dams showed intermediate ratios of 78% and 52%, respectively. These differences reflect variation in modeled LWD accumulation dynamics across the study of watersheds under historical discharge conditions.

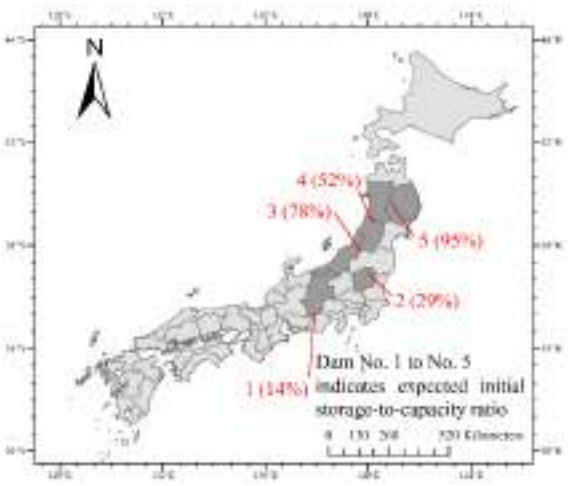

Fig.5 Spatial distribution of expected storage-to-capacity ratios (*r*) at five study dams.

Hazard Assessment Results

The results of LWD discharge simulations under rainfall return-level scenarios are presented in Fig. 6, which illustrates the estimated potential minimum, maximum, and expected discharge volumes for the five study sites. Horizontal axes represent rainfall return periods T (e.g., 3–200 years) and corresponding to different return levels (mm/24hrs), and vertical axes show LWD volumes (m³/year), including simulated potential discharges (q_{min},q_{exp} *and* q_{max}), model input potential recruitment (*P*), and observed records (q_{obs}). The black dots showed the selected LWD discharge records. As shown in Fig. 6, all black dots representing observed LWD discharge volumes fall within the modeled range of potential discharge, indicating the reliability of the hazard assessment results. Although the observational records are primarily corresponded to return periods shorter than 45 years (e.g., Fig. 6(4)), the modeling framework developed in this study enables estimation of LWD discharge for lower-frequency events beyond the observed range. This represents a significant improvement over approaches that rely exclusively on historical records, which are inherently limited in their ability to assess rare but potentially large volume LWD discharge events.

Rainfall return period and potential LWD discharge

One notable feature in Fig. 6 is the substantial variation in rainfall return levels across all sites within the same return periods. This disparity is particularly critical when determining the minimum rainfall return period at which LWD discharge is likely to occur.

Among the five study sites, the Shiobara and Katagiri dam watersheds were selected as

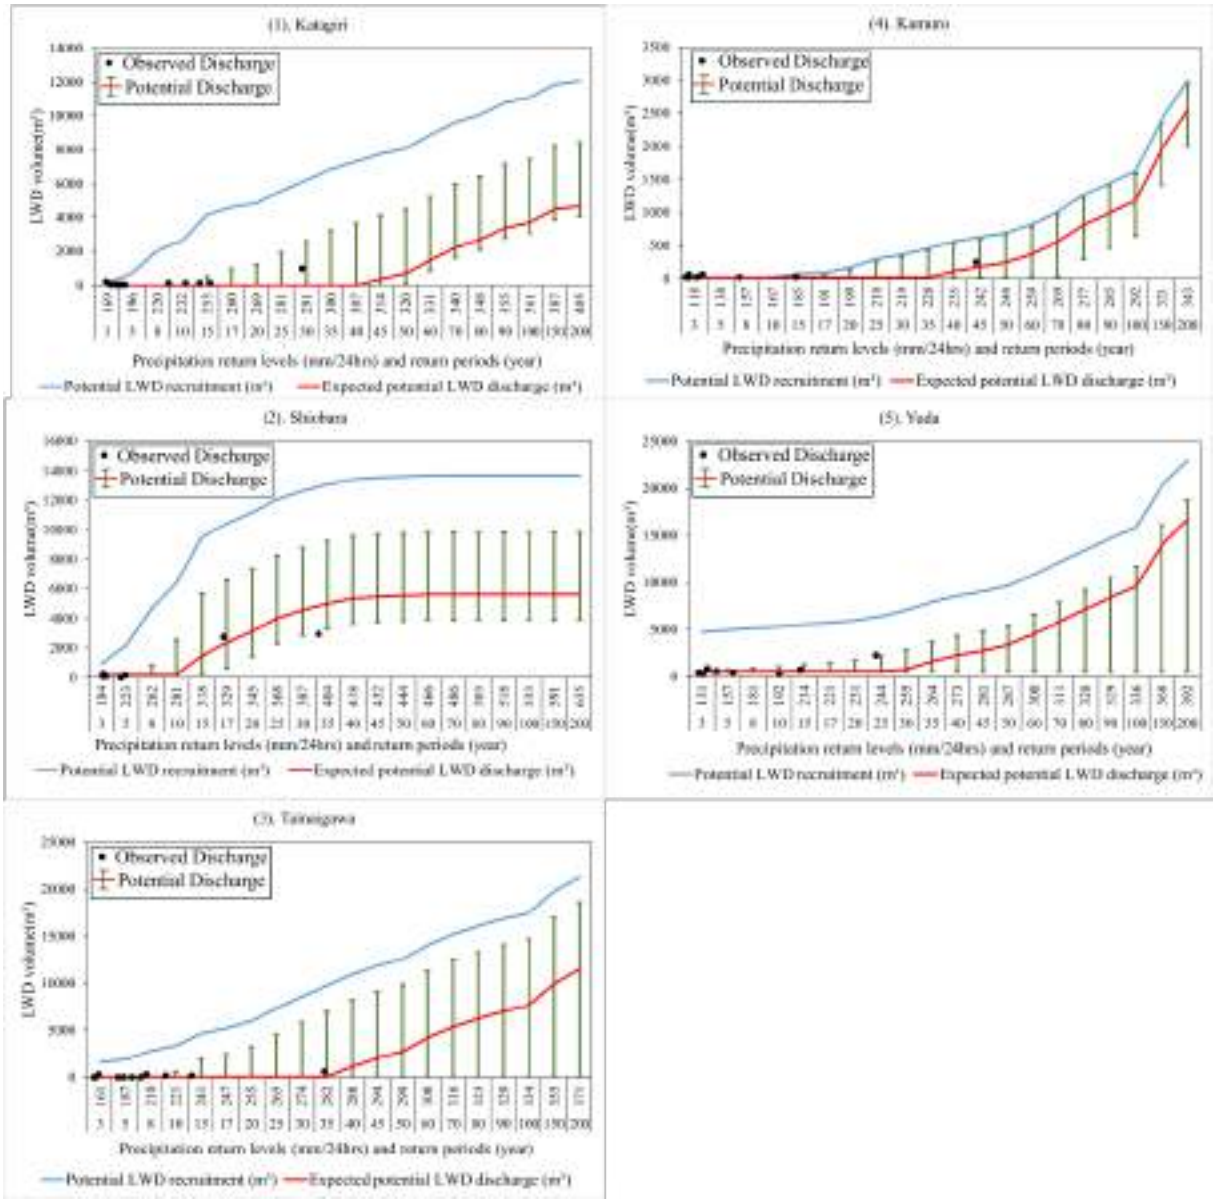

Fig.6 Simulated hazard assessment of potential LWD discharge volume under varying rainfall return periods for the five study sites.

representative cases to illustrate the contrasting responses of LWD discharge to varying rainfall return periods within each watershed.

Shiobara Dam (Fig. 6(2)) showed a rapid increase in expected discharge volume (q_{exp}) starting at a return period of 10 years (281 mm/24hrs), with q_{exp} reaching 217 m³ and q_{max} exceeding 2500 m³.

In contrast, Katagiri Dam (Fig. 6(1)) exhibited a more gradual discharge response. q_{exp} began to increase noticeably only after a 40-year return period (307 mm), reaching 4681 m³ at 200 years (405 mm), while q_{max} peaked at 8430 m³. The findings suggest that the response of LWD discharge to rainfall return periods and levels varied significantly among different dam catchments.

LWD storage characteristics of dam watershed

The results can be used to further explore LWD discharge risks from a storage characteristics perspective, based on their contrasting proportions of discharge to recruitment volume. These ratios reflect the overall capacity of each watershed to retain LWD before it is discharged, offering an additional dimension to hazard assessment. The values for catchments No.1 to No.5 were 0.62, 0.68, 0.80, 0.96, and 0.62, respectively.

Among all sites, Kamuro Dam exhibited a q_{max} to P ratio of 0.96, placing it among the highest. This suggests that under extreme rainfall, nearly the entire volume of recruited LWD may be discharged downstream. Such a condition indicates weak long-term storage capacity and frequent saturation of LWD

retention potential, increasing the likelihood of high-magnitude discharge events even under relatively moderate recurrence intervals.

In contrast, Katagiri Dam and Yuda Dam showed the lowest discharge-to-recruitment ratios among the five sites, with values of 0.62 for q_{max}. These results reflect comparatively strong LWD storage performance, where most of the recruited LWD is retained within the watershed. Consequently, the probability of sudden large-scale LWD discharge events is reduced, making this site relatively low risk from a storage-based hazard perspective.

CONCLUSIONS

This study estimated the potential discharge of large woody debris (LWD) in five dam watersheds under varying rainfall return periods, focusing on the minimum, maximum, and expected annual discharge volumes. By incorporating stochastic recruitment and evaluating discharge ranges under different storage scenarios, the expected potential discharge was successfully simulated. Simulation results revealed clear inter-watershed differences in discharge behavior and storage characteristics, with expected discharge values serving as a reliable indicator of site-specific LWD discharge risk. To further enhance the generalizability of the proposed hazard assessment framework, future studies are encouraged to include a broader range of dam watersheds with diverse geomorphological and climatic conditions. Expanding the number of study sites would enable a more comprehensive understanding of regional patterns in LWD discharge dynamics and support the development of region-specific hazard mitigation strategies.

ACKNOWLEDGMENTS

The authors would like to thank the Water Resources Environment Technology Centre and the Japanese Ministry of Land, Infrastructure and Transport (MLIT) for their assistance in providing and collecting data on LW. The authors also thank Seiki Kawagoe, Katsuhiro Nakao, and Haruka Tsunetaka for their valuable advice. This research was funded by the Ministry of Land, Infrastructure, Transport and Tourism (MLIT), according to the 'Improving the reproducibility of large wood dynamics analysis using the integrated large wood export model (PI: Daisuke Komori)' and the Grants in Aid for Fostering Joint International Research (19KK0362, PI: Daisuke Komori) from the Ministry of Education, Science and Culture, Japan.

ECOSYSTEM-LEVEL ASSESSMENT OF THE ADSORPTION AND REMOVAL CAPACITY OF CALCIA-IMPROVED SOILS USING MICROCOSM-WET TEST

Sosuke Sato[1] and Kazuhito Murakami[2]

[1]Graduate School of Engineering, Chiba Institute of Technology, Chiba, Japan; [2]Department of Life Sciences, Chiba Institute of Technology, Chiba, Japan

ABSTRACT

An ecosystem-level evaluation was conducted to assess the adsorption and removal capacity of Calcia-improved soil for eluates derived from decaying green tide algae (*Ulva* spp.) using a microcosm-based Whole Effluent Toxicity (WET) test. Calcia-improved soil, produced from steelmaking slag, is recognized as a useful recycled material; however, its environmental impact must be carefully considered before application. The microcosm (N-system) used in this study is a flask-scale model ecosystem composed of three phytoplankton species, four zooplankton species, and four dominant bacterial species, providing high reproducibility and stability. In the microcosm-WET test, dissolved oxygen (DO) levels (functional parameter) were continuously monitored, and microbial abundance (structural parameter) was observed microscopically following the addition of treated or untreated eluates containing unsolidified Calcia-improved soil. Data were statistically analyzed using branched-type ANOVA. For both parameters, the highest concentration with no significant effect was defined as the microcosm No Observed Effect Concentration (m-NOEC), and the toxicity unit (TU) was calculated as the inverse of the dilution factor. The treated eluate showed an m-NOEC of 2.5% and a TU of 40, indicating lower ecological impact compared to the untreated eluate. Considering a previously proposed safety factor of 200 for microcosm tests, these results suggest that Calcia-improved soil is unlikely to cause significant adverse effects on the actual environment.

Keywords: Calcia-improved soil, Microcosm, Microcosm-WET test, Green tide alga, Ulva spp.

INTRODUCTION

With increasing environmental awareness in Japan, Calcia-improved soil has been recognized as a recycled material that contributes to resource and energy conservation by reducing environmental burden. It is currently used as a reclamation material for bottom sediments in coastal areas [1]. Calcia-improved soil is produced by mixing Calcia-modified material with dredged sediment (Fig. 1). This material enhances the strength of bottom sediments and improves water quality, making it a promising option for sediment remediation. However, due to the specific characteristics of its raw materials, careful consideration of its potential impact on water quality is required when applying it. At present, most safety assessments rely on chemical analyses, while biological tests are primarily conducted using single-species approaches. Such tests do not account for interspecies interactions, and therefore, cannot fully reflect the material's impact under actual environmental conditions [2]. To address this limitation, microcosm-based Whole Effluent Toxicity (WET) tests, which simulate natural ecosystems and incorporate interactions among multiple species, have been proposed as an effective evaluation method [3–6]. This study is based on the conceptual framework that considers ecosystem health as a function of both structural parameters, such as species composition and abundance, and functional parameters, such as primary production and respiration. By applying this integrated approach, the potential ecological impact of Calcia-improved soil can be assessed more comprehensively than with conventional chemical or single-species tests. In this study, we focused on the adsorption and removal capacity of Calcia-improved soil and aimed to evaluate its effectiveness for bottom sediment remediation and its ecological impact in tidal flat environments affected by green tides. This research was conducted with the assumption of practical application in real-world coastal environments.

Fig.1 Overview of Calcia-improved soil

MATERIALS AND METHODS

Calcia-Improved Soil

Calcia-improved soil is a recycled material produced by mixing Calcia-modified material, derived from steel slag with adjusted particle size and composition, with dredged sediment [1]. The incorporation of Calcia-modified material enhances the strength of the mixture, and its adsorption and removal capacities for substances such as phosphorus and sulfides are expected to contribute to water quality improvement. However, due to the properties of the steel slag raw material, the mixture is known to increase pH levels, particularly in water, which must be carefully considered when applied in real environments. The typical mixing ratio for Calcia-improved soil is approximately 30% [1]. Previous dissolution experiments conducted at mixture ratios of 30%, 20%, and 10% demonstrated significant pH differences between the 30% mixture and the lower ratios. Consequently, this study focused on evaluating the 20% and 30% mixture ratios.

Microcosm

A microcosm is a simulated ecosystem in which multiple species coexist in a flask under controlled conditions (Fig. 2). Because it reproduces material cycles and interactions among organisms found in natural ecosystems, it is considered a method that enables impact assessment at the ecosystem level, compared to conventional single-species tests. Additionally, it offers advantages such as low cost and high reproducibility. In this study, we used a gnotobiotic-type microcosm (N-system) in passaged culture. All species constituting the N-system microcosm are known, including the green algae *Chlorella* sp. (1.1×10^5 N/ml) and *Scenedesmus quadricauda* (5.3×10^3 N/ml) as producers; the filamentous algae *Tolypothrix* sp. (8.0×10^2 cm/ml) and the protozoan ciliate *Cyclidium glaucoma* (6.0×10^3 N/ml) as predators; the metazoan ciliates *Lecane* sp. (1.3×10^2 N/ml), *Philodina erythrophthalma* (1.1×10^1 N/ml), and *Aeolosoma hemprichi* (1.0×10^1 N/ml); and dominant decomposer bacteria comprising four species (*Bacillus cereus*, *Pseudomonas putida*, *Acinetobacter* sp., and coryneform bacteria) totaling 1.1×10^6 CFU/ml. Numbers in parentheses indicate steady-state populations in non-additive systems. These microorganisms were self-selected through repeated culture. This system exhibits high reproducibility and stability, as reflected in the growth curves of each microorganism. Microcosms were cultured in 300 ml triangular flasks containing 200 ml of TP_{100} medium (Taub + Peptone 100 mg medium). After the addition of 10 ml of microcosm inoculum, they were incubated at 25°C under 2400 lux with a 12 h light/dark cycle for 30 days [3,7,8]. Each experimental condition was conducted in triplicate, and data were analyzed using t-tests for statistical significance. The coefficients of variation (standard deviation divided by mean, expressed as a percentage) for production and respiration rates during the first 7 days of culture were 20% or less (based on 25 independent experiments), and 5% or less from days 14 to 21. These values are consistent with previously reported results (e.g., Sugiura 2001). The results presented in the figures represent the means of three independent experiments. Differences between treated and control microcosms were evaluated using branched-type analysis of variance (ANOVA), which considers errors among samples as random variables.

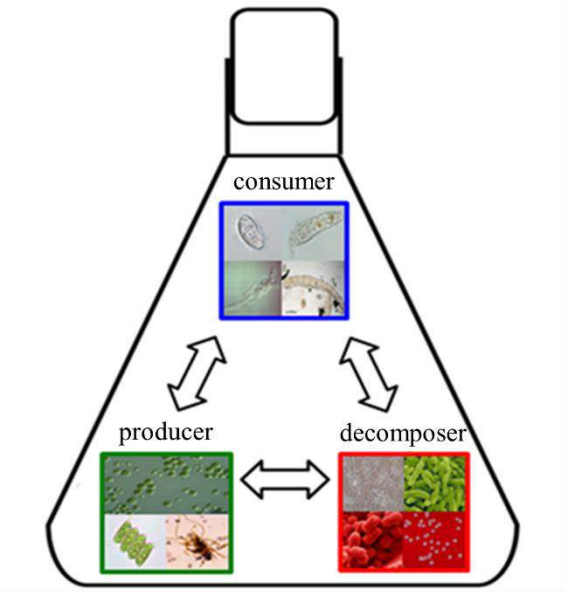

Fig.2 Outline of microcosm

Microcosm-WET Test

In the microcosm WET test, a diluted test stock solution is added as a replacement for the liquid medium in the microcosm, and the response is observed to evaluate the effects (Fig. 3). The test solution was diluted using TP_2 medium, which is adjusted for peptone content, to prevent any effects on the microcosm organisms other than those caused by the test solution itself. Prior to addition, the microcosm was transferred to a centrifuge tube and centrifuged at 250 ×g for 5 minutes. The supernatant was then removed using a micropipette to adjust the

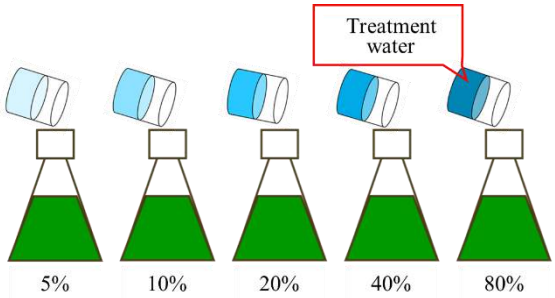

Fig.3 Outline of microcosm-WET test

biomass. After biomass adjustment, the test stock solution was diluted stepwise with TP_2 medium to concentrations of 0, 5, 10, 20, 40, and 80% for addition.

Preparation of Eluate

The experiment was conducted using *Ulva* spp. collected from the Yatsu Tidal Flat in Narashino City, Chiba Prefecture (Fig. 4). Yatsu Tidal Flat is an artificial tidal flat created through coastal land reclamation and was registered under the Ramsar Convention in 1993. It serves as an important stopover site for migratory birds, and conservation efforts, including citizen-led activities, are ongoing. In recent years, however, due to sludge outflow, the tidal flats have become saltier and sandier, leading to the large-scale proliferation of *Ulva* spp. This excessive growth has caused foul odors, degraded the landscape, and reduced the number of migratory birds

Fig.4 Location of Yatsu Tidal Flat

Fig.5 A green tide that occurred on the Yatsu tidal flat (left) and the *Ulva* spp. that makes up the green tide (right)

(Fig. 5). Consequently, there are concerns that the area's ecological value as a Ramsar wetland may be at risk [9–12]. To prepare the eluate, 2000 ml of TP_2 medium was added to the harvested Ulva spp., and the mixture was allowed to decompose for 7 days at 30°C under 2400 lux light conditions. After decomposition, solids were removed to obtain the test solution. To evaluate the adsorption capacity of ratios of 20% and 30% were placed in a funnel, and Calcia-improved soil, materials prepared with mixing the test solution was filtered through each to produce the 20% filtered and 30% filtered test solutions, respectively (Fig. 6). The Calcia-modified material was provided by the Nippon Slag Association. Water quality parameters of the test stock solution were also analyzed, including COD, T-N, NO_3-N, NO_2-N, NH_4-N, T-P, PO_4-P, Cl, pH, and H_2S-S. COD was measured using the potassium permanganate method. T-N and T-P were determined by absorbance spectrophotometry following potassium peroxodisulfate decomposition. Cl was measured using the silver nitrate titration method, and the remaining parameters were analyzed using a pack test.

Fig.6 Test stock solution preparation method

Table1 Water quality of test stock solution

	Decaying *Ulva* spp. leachate water	Filtered water with dredged soil	Filtered water with 20% calcia-improved soil	Filtered water with 30% calcia-improved soil
COD(mg/L)	76	42.4	44	58

pH	9.19	9.19	11.3	11.6
H_2S-S(mg/L)	0.1	0.1	0.1	0.1

Evaluation Method

The ecological impact of each concentration of green tide eluate was assessed based on changes in dissolved oxygen (DO) in the microcosm, which were continuously monitored using a DO meter. The transitions of production (P), respiration (R), and the P/R ratio, representing functional parameters, were calculated. In parallel, plankton samples were collected from the microcosm on days 0, 2, 4, 7, 14, 16, 18, 20, 23, and 30 after the start of the culture. The number of microorganisms was observed under a light microscope using a plankton counter to evaluate the temporal transition of structural parameters. In addition, branched-type analysis of variance (ANOVA) was performed to statistically analyze

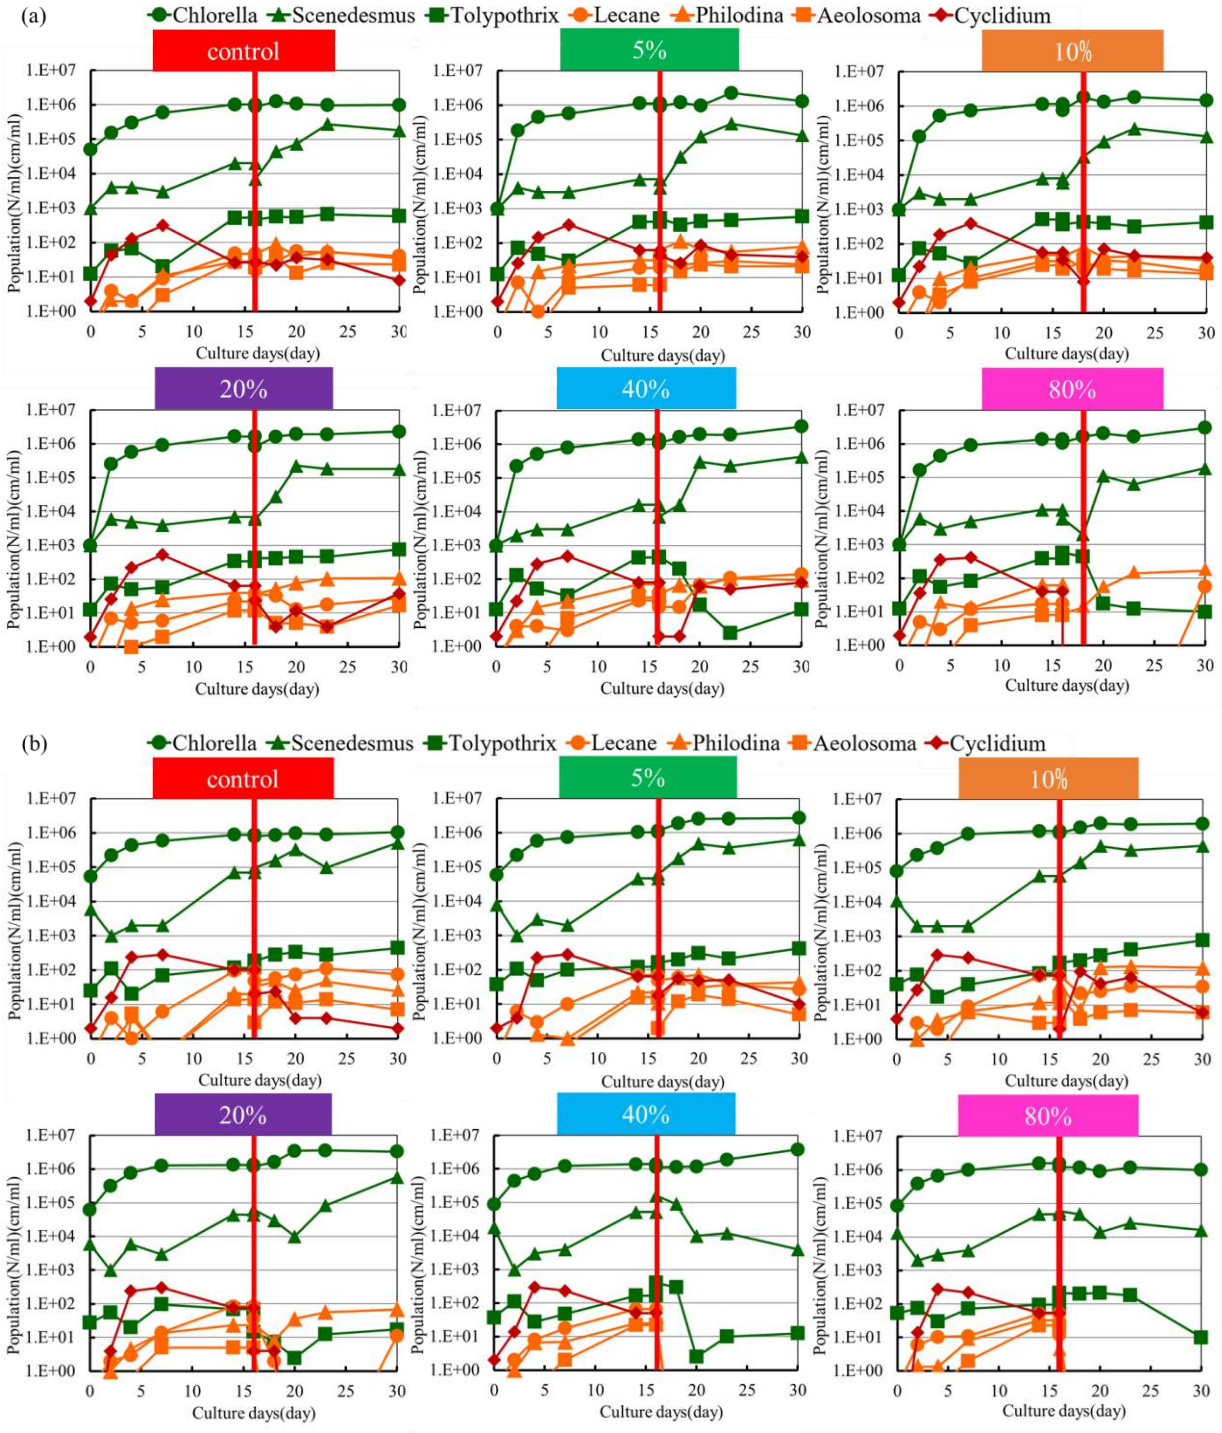

Fig.7 Changes in the population of plankton in the microcosm. (a) filtered water with 20% Calcia-improved soil added system (upper), and (b) filtered water with 30% Calcia-improved soil added system (lower). (The red vertical line indicates the date on which the test stock solution was added.)

changes in both functional and structural parameters over time. As shown in Table 2, the branched-type ANOVA evaluated two aspects: the "group" effect, representing variance among all system values, and the "interaction" effect, representing variance over time [3]. For both functional and structural parameters, the highest concentration with no statistically significant effect, based on the branched-type ANOVA results, was defined as the maximum no observed effect concentration (m-NOEC). The toxicity unit (TU) was calculated using Eq.(1). A safety factor of 200 has been proposed for this microcosm test based on previous studies [3,4,12].

$$TU = \frac{100}{m\text{-}NOEC} \quad (1)$$

RESULTS AND DISCUSSION

Improvement Effect on Water Quality

The results of the water quality analysis are presented in Table 1. Four types of solutions were analyzed: decaying *Ulva* spp. leachate, filtered water with dredged soil, filtered water with 20% Calcia-improved soil, and filtered water with 30% Calcia-improved soil. A comparison of the water quality between the decaying *Ulva* spp. leachate and the filtered water with dredged soil before the addition of Calcia-modified materials with the filtered water containing Calcia-improved soil revealed a notable decrease in T-P and PO_4-P concentrations, particularly in the filtered water samples.

Improvement Effect on Ecosystem Structure

Fig. 7 shows the changes in plankton populations within the microcosm system. In the system where filtered water containing 20% Calcia-improved soil was added, decreases or local extinction of zooplankton species such as *Cyclidium glaucoma*, *Lecane* sp., *Philodina erythrophthalma*, and *Aeolosoma hemprichi*, as well as some phytoplankton species such as *Tolypothrix* sp., were observed at higher concentrations. However, partial recovery of some species, including *Lecane* sp. and *Philodina erythrophthalma*, was also recorded. In the system where filtered water containing 30% Calcia-improved soil was added, similar decreases or extinction of species such as *Cyclidium glaucoma*, *Lecane* sp., *Philodina erythrophthalma*, and *Aeolosoma hemprichi* occurred. However, no recovery of these species was observed at the 40% and 80% concentration levels. Based on these findings, it was concluded that a Calcia-modified material mixing rate of 20% is appropriate for mitigating the ecological impacts associated with green tide events.

Improvement Effect on Ecosystem Function

Fig. 8 shows the P/R ratio in the microcosm system. In the system where filtered water containing 20% Calcia-improved soil was added, the P/R ratio converged to approximately 1 at most addition concentrations, indicating that the internal balance between production and respiration within the system was maintained. In the system where filtered water containing 30% Calcia-improved soil was added, the P/R ratio also converged to around 1 in most cases. However, in the system where the addition concentration reached 80%, both production and respiration rates decreased significantly. Based on these results, it was similarly concluded that a Calcia-modified material mixing rate of 20% is appropriate for maintaining ecosystem function. Table 2 shows the results of statistical analysis using branched-type ANOVA. The analysis indicated that all addition systems exhibited statistically significant effects. Based on these findings, the NOEC (no observed effect concentration) was defined as half of the LOEC (lowest observed effect concentration), resulting in a calculated m-NOEC of 2.5% and a toxicity unit (TU) of 40.

Steel Slag Utilization for Green Tide Influence Reduction

In terms of structural parameters, specifically the number of individuals, effects were observed at concentrations exceeding 40% in the system where filtered water containing 20% Calcia-improved soil was added, and at concentrations exceeding 20% in the system with 30% Calcia-improved soil. In particular, all zooplankton populations were suppressed at 40% and 80% concentrations in the system with 20% Calcia-improved soil. Regarding functional parameters, represented by the P/R ratio, values fluctuated significantly immediately after the addition of the test solution. However, in most of the

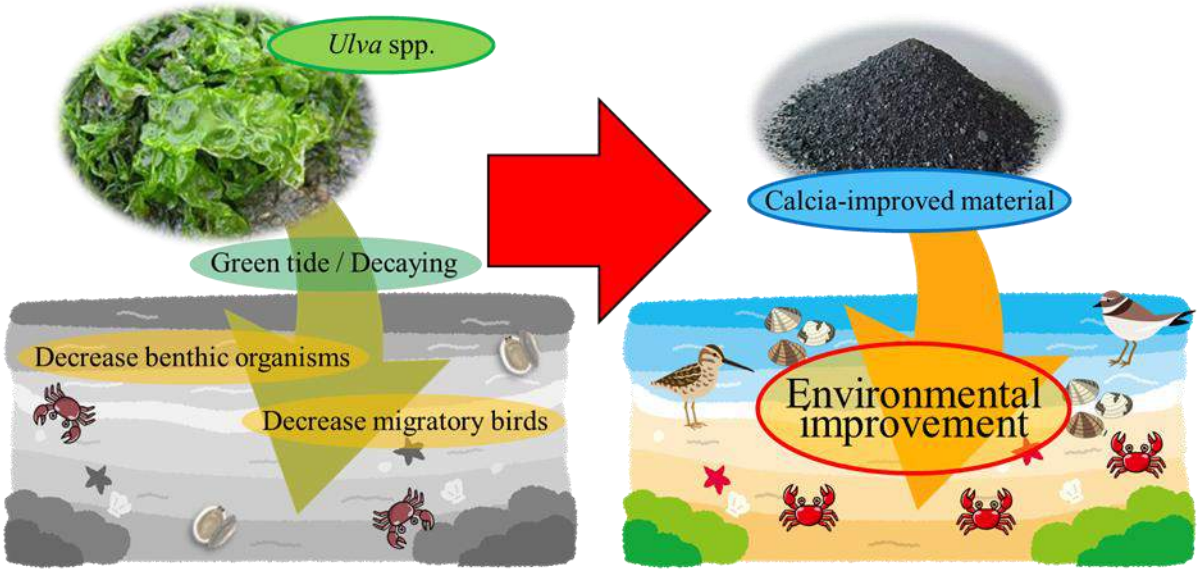

Fig.9 Conceptual diagram of the improvement of tidal flat environment through the use of Calcia-modified materials

addition systems, the P/R ratio gradually converged to approximately 1 over time, suggesting that the effects of Calcia-improved soil on ecosystem function are recoverable under these conditions. In contrast, in the system with 30% Calcia-improved soil at the 80% addition concentration, both production and respiration rates decreased significantly, and no recovery was observed. The observed effects in the high-concentration addition systems are considered to be caused by the increase in pH associated with the use of Calcia-improved soil prior to solidification. It should be noted that this experiment was conducted using a flask-scale simulated ecosystem, and the potential impacts on the actual environment may be overestimated under such controlled experimental conditions. Previous studies have shown that the extrapolation factor, or safety factor, for applying microcosm results to real environmental conditions is 200. Therefore, it is considered unlikely that Calcia-modified material would have a significant negative impact on actual aquatic ecosystems. Based on these results, it was concluded that a Calcia-improved soil mixing rate of 20% is appropriate for mitigating the effects of green tide. It is also important to note that the Calcia-improved soil used in this study was applied immediately after mixing. It is assumed that similar experiments conducted with Calcia-improved soil after solidification would yield different results. Further detailed investigation is required to determine the optimum addition concentrations and to clarify changes in eluate characteristics associated with the aging of *Ulva* spp. The application of Calcia-improved soil as a sediment improvement material has the potential to restore tidal flat environments that have been degraded by the excessive growth of green tide-forming algae (Fig. 9).

CONCLUSIONS

In the system where filtered water with 20% Calcia-improved soil was added (Fig. 7(a)), effects on structural parameters were observed at high addition concentrations of 40% and 80%. Regarding functional parameters, the P/R ratio converged to approximately 1 at most addition concentrations, indicating that the internal balance of the system was maintained. In the system where filtered water with 30% Calcia-improved soil was added (Fig. 7(b)), effects on structural parameters were observed at addition concentrations exceeding 20%. For functional parameters, the P/R ratio also converged to around 1 in most cases; however, at the 80% addition concentration, both production and respiration rates decreased significantly, and no recovery was observed. The m-NOEC was calculated to be 2.5%, and the toxicity unit (TU) was determined to be 40. It should be noted that the Calcia-improved soil used in this study was in a state immediately after mixing. It is assumed that similar experiments using Calcia-improved soil after solidification would produce different results. Therefore, further detailed investigation is required to determine the optimum addition concentrations and to clarify changes in eluate characteristics associated with the aging of *Ulva* spp.

ABSTRACT

Arsenic contamination in drinking water constitutes a significant global public health challenge, especially in areas with high arsenic groundwater. Thus, the development of cost-effective and efficient treatment methods can be imperative. This study examined the applicability of grained laterite in Hanoi, Vietnam, as an economically feasible adsorbent to treat the arsenic contaminated water. A series of laboratory experiments were conducted to examine the effects of calcination of laterite grains and heights of filtration column on the arsenic adsorption performance in the fixed-bed column adsorption system. The tested results were analyzed using adsorption models such as Adams-Bohart, Thomas, and Yoon-Nelson. Additionally, the basic physicochemical properties of both raw and calcined laterite grains were characterized using various analytical techniques such as scanning electron microscopy, energy-dispersive X-ray spectroscopy, and Brunauer-Emmett-Teller surface area analysis. The experimental findings showed that the calcined laterite grains gave higher arsenic removal than raw laterite grains at all column height conditions. Particularly, 5% breakthrough time increased from 270 min to 1230 min in 20 cm column height due to the calcination process. This observation was also supported by the Adams-Bohart model analysis, which indicated an increase in the maximum adsorption capacity from 574 to 3893 mg/L. Conversely, the calculated mass transfer zone height underscored the necessity for an adequate column length to facilitate the full development of the mass transfer zone within the column. The application of laterite grains obtained from Hanoi in Vietnam for arsenic remediation was found to be effective under the tested conditions.

Keywords: Laterite, Arsenic, Filtration, Fixed-bed column experiment, Adsorption model

INTRODUCTION

Groundwater contamination by arsenic is a severe health issue due to its widespread toxicity. It exists in nature as metalloids or chemical compounds, mainly in inorganic forms, primarily as arsenate and arsenite. Arsenite is more toxic, soluble, and mobile than arsenate [1]. About 230 million people worldwide face arsenic contamination in 108 countries across all six continents, primarily in South Asia [2]. The severity of this issue is pronounced in Bangladesh and West Bengal, India. In West Bengal, over 6 million individuals across nearly 50% of the districts are exposed to arsenic through drinking water [3]. Arsenic poisoning causes serious health effects even at low concentration, with fatal outcomes linked to excessive exposure. It damages several organs, including the lungs, liver, cardiovascular system, and central nervous system, and is highly carcinogenic [4]. Given these health risks, numerous organisations, such as the WHO and the European Union, recommend a maximum arsenic concentration of 10 µg/L in drinking water [5].

Several techniques are available for removing arsenic from water include ion exchange, chemical precipitation, adsorption, membrane filtration, and phytoremediation at present [6]. Among them, adsorption is the most cost-effective method for removing arsenic in small rural households due to its high efficiency and simple design [7]. Furthermore, the adsorbent is a key parameter of the adsorption process, and 80% of the operation cost is associated with the adsorbent [8]. Therefore, the selection of low-cost, efficient materials is the governing factor of the implementation in rural communities.

This work evaluated arsenic adsorption by laterite grains in fixed-bed column experiments in the laboratory. Previously reported that physico-chemical properties of laterite vary by location due to unequal weathering process, indicating the need for testing the material before the real application [9]. Furthermore, calcination was introduced to the laterite as a solution to the weakness of the raw material [10]. The fixed-bed column experiments were conducted to evaluate the effect of calcination and column height on breakthrough performance. Furthermore, adsorption mathematical models such as the Adams-Bohart, Thomas, Yoon-Nelson and the breakthrough service time models (BDST) were applied to predict fixed-bed column parameters,

including adsorption capacity of material.

MATERIALS AND METHODS

Preparation Of RL And CL Grains

The raw Laterite sourced from Thach That district in Hanoi, Vietnam, was utilized to produce both raw laterite (RL) and calcined laterite (CL), with a size range of 0.6 mm to 2.0 mm, for all subsequent experiments. Calcination was performed at a temperature of 550℃ for 1 hour using a muffle furnace. Finally, the calcined samples were sieved again to remove dust and fragmented particles smaller than 0.6 mm.

Spectroscopic Methods

Scanning Electron Microscopy (SEM) of X 500 magnification images with Energy-Dispersive X-ray Spectroscopy (EDS) were obtained for both RL and CL using TM4000plus (Hitachi High-Technologies Corp., Tokyo, Japan). Brunauer-Emmett-Teller (BET) multipoint graph was performed using a BET surface area analyzer (TriStar II, Micromeritics Instruments Corp., Norcross, GA, USA) for RL and CL to determine the specific surface area of the material.

Determination Of pH Zero-Point Charge

The pH zero-point charge of RL and CL grains was determined using the pH drift method, maintaining an L/S ratio of 25. The pH at which no difference between the initial and final pH was noted as the zero-point charge (pH_{ZPC}).

Fixed-bed Column Adsorption Experiments

Fixed-bed column adsorption experiments used stainless steel columns with a 3.0 cm inner diameter (upward continuous flow) and varying heights of 10, 20, and 30 cm. Experimental conditions are summarised in Table 1. Breakthrough time (t_b) and saturation time (t_s) were determined when the effluent concentration reached 5% and 95% of the influent concentration, respectively. Other breakthrough parameters calculated in this work were: arsenic removal at breakthrough (y_b), arsenic removal at saturation (y_s), mass transfer zone of column (*MTZ*), and finally, MTZ/Bed height ratio. The equations to calculate arsenic removal corresponding to the t_b and t_s are given in Eq. (1) and (2). *m* is the arsenic mass corresponding to the time considered.

$$y_b = \left(1 - \frac{m_{out,t_b}}{m_{in,t_b}}\right) x\ 100 \quad (1)$$

$$y_s = \left(1 - \frac{m_{out,t_s}}{m_{in,t_s}}\right) x\ 100 \quad (2)$$

The *MTZ* length in each column was determined by Eq. (3), where *H* is the packed column bed height, and the *MTZ* length in each column was determined [11].

$$MTZ = \left(\frac{t_s - t_b}{t_s}\right) x\ H \quad (3)$$

Table 1 Experimental conditions of fixed-bed adsorption columns

	Unit	Experiment			
		A	B	C	D

Initial As concentration	mg/L	100.0			
Flow rate	mL/min	2.0			
Initial solution pH	-	5.0			
Particle size	mm	0.6 - 2.0			

Analysis Of Breakthrough Curve Using Mathematical Models

The results obtained from laboratory scale fixed bed column adsorption tests are essential for scaling up the system for industrial applications. Therefore, a successful design of an adsorption column process necessitates accurate predictions of breakthrough curves according to the actual environmental conditions [12]. In this study, the Adams-Bohart, Thomas, and Yoon-Nelson models were applied to describe the breakthrough curves and calculate important experimental parameters.

Adams-Bohart model

Adams-Bohart model assumes that the adsorption rate is proportional to both adsorbate concentration of solute in the solution phase and the residual capacity of the adsorbent [13]. Therefore, the initial part of the breakthrough curve was utilized to evaluate this mathematical model and derive the maximum adsorption capacity of the fixed-bed column system. The linear version of the Adams-Bohart model is expressed below in Eq. (4).

$$\ln\left(\frac{C_t}{C_0}\right) = k_{AB} C_0 t - k_{AB} N_0 \frac{Z}{U_0} \quad (4)$$

where k_{AB} (L/mg· min) is the rate constant of Adams-Bohart model, Z (cm) is the bed depth, N_0 (mg/L) is maximum ion adsorption capacity per unit volume of adsorbent column, and U_0 (cm/min) is the linear velocity of the solution.

Thomas model

Thomas model is a widely used mathematical model to describe the fixed-bed column breakthrough

behavior which assumes plug flow behavior within the fixed-bed column without axial dispersion [14]. The linear form of Thomas model is expressed below in Eq. (5).

$$ln\left(\frac{C_0}{C_t}-1\right)=\frac{k_{TH}q_e x}{Q}-k_{TH}C_0 t \quad (5)$$

where k_{TH} (mL/mg.min) is the Thomas model constant, q_e (mg/g) is the predicted adsorption capacity, x (g) is the mass of adsorbent inside the column, Q (mL/min) is the flow rate, C_0 (mg/L) is the initial solution concentration, and C_t (mg/L) is effluent solution concentration with respect to time t.

Yoon-Nelson model

Yoon-Nelson model is simpler than the other models and requires no data about the characteristics of the system such as physical properties of adsorption bed, and type of adsorbent. The model is used to predict 50% saturation time. The linear version of Yoon-Nelson model is expressed below in Eq. (6).

$$\ln\left(\frac{C_t}{C_0-C_t}\right)=k_{YN}t-k_{YN}\tau \quad (6)$$

where k_{YN} (1/min) is the Yoon-Nelson rate constant and τ (min) is the time required for 50% breakthrough of adsorbate, C_0 (mg/L) is the initial solution concentration, and C_t (mg/L) is the effluent solution concentration with respect to time t.

Bed Depth Service Time (BDST) model

This model assumes that the rate of the adsorption is controlled by the surface reaction between the adsorbate and the unused capacity of the adsorbent. Consequently, this analysis facilitates rapid predictions of adsorbent performance, thereby aiding in the scalability of processes across different flow rates and concentrations of adsorbate [15]. The equation of the BDST model is given in Eq. (7).

$$t=\frac{NZ}{C_0 v}-\frac{1}{K_\alpha C_0}\ln\left(\frac{C_0}{C_b}-1\right) \quad (7)$$

RESULTS AND DISCUSSION

Surface Morphological Characterization Of Laterite Grains

The SEM image analysis of RL in Fig. 1a revealed that the material surface of RL was comparatively smoother than that of CL grains. In Fig. 1b, show SEM image of CL shows a more compact and rougher surface than that of RL. On the other hand, the cracks which were observed in RL grains were eliminated due to the calcination process.

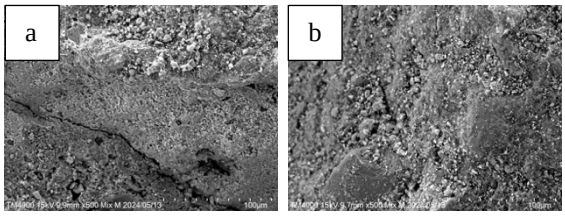

Fig. 1: SEM image of laterite. (a) RL gran and (b) CL grain

Physico-Chemical Characterization Of Laterite Grains

The surface of the tested laterite grains is mainly composed of iron, with 36.5% iron content by weight, which is within the range observed in previous studies. Except for iron, aluminium and silicon content increased after the calcination and the same scenario was observed in the previous studies [16]. The iron content in the calcined laterite sample decreased to 11.6% by weight.

The BET surface areas of raw (RL) and calcined laterite (CL) samples were 61.0 m²/g and 60.2 m²/g, respectively. Although calcination improved the laterite's physical condition, SEM analysis showed that the specific surface areas of RL and CL grains remained nearly the same. RL and CL grains had particle densities of 2.92 and 2.89 g/cm³, respectively. The decrease in particle density results from dehydroxylation and decarbonization at elevated temperatures, as noted in previous studies [16]. The pH_{ZPC} value, which represents the pH at which the net surface charge of the material is zero, was determined as 4.2 for the RL and 3.6 for the CL grains. This reduction of pH_{zpc} may be due to the dehydroxylation of the materials induced by the elevated temperature, resulting in the substantial reduction of hydroxyl groups on the laterite surface [17]. In conclusion, the unique physicochemical attributes of the laterite particulates showed significant morphological deviations from previously characterized specimens, indicating potential differences in sorption effectiveness.

Fixed-Bed Column Adsorption Experiment

Effect of calcination on adsorption performance

The effect of calcination was evaluated by testing two fixed-bed columns packed with RL and CL grains under identical conditions, as shown in Table 1. The results indicated that 5% increase in breakthrough time due to calcination. The breakthrough times were 70 and 1230 min for RL and CL grains, respectively. The saturation time, defined as the 95% breakthrough time, increased from 600 to 3,150 min. This suggests that calcination at elevated temperatures improves the adsorption performance of

laterite grains by altering the physical and chemical composition of the adsorbent. [10]. High temperatures in calcination eliminate structural water in metakaolinization, transforming kaolinite in laterite to metakaolin. The amorphous structure of metakaolin and poorly crystallized iron oxide provide ideal surface chemistry for arsenic adsorption via chemical complexation and physical adsorption mechanisms. [18].

Effect of fixed-bed column height on adsorption performance

The effect of bed height was evaluated using three fixed bed heights of 10 to 30 cm, with an initial arsenic concentration of 100 mg/L and a flow rate of 2.0 mL/min (see Table 1). Results showed breakthrough time increased from 450 to 2400 minutes with higher fixed-bed column heights. This is attributed to the system's *HRT*, as longer columns provided more time for diffusion onto the adsorbent bed, delaying breakthrough time. Similar findings were reported in previous studies [10]. The *MTZ* of the 10 cm column was 8.65 cm, while it was 12.19 cm and 12.61 cm for the 20 and 30 cm columns, respectively. The similar *MTZ* heights in the 20 and 30 cm columns, compared to the much shorter *MTZ* in the 10 cm column, imply that a 10 cm height may be inadequate for fully developing the *MTZ*.

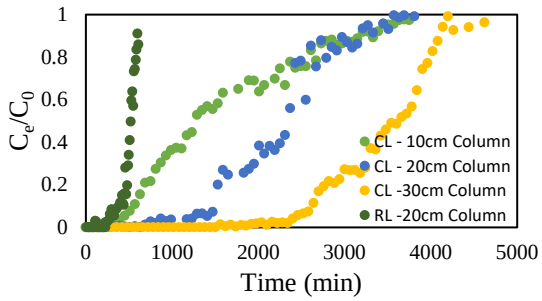

Fig. 2 Breakthrough curve of each fixed bed column

Adams-Bohart model analysis

The Adams-Bohart model, based on surface reaction theory, establishes a fundamental relationship between effluent concentration (C_t) and time (t) in continuous systems. The graphical representation of linear regression analysis of Adams-Bohart model is shown in the Fig. 3 given below. The results showed that the adsorption performance was enhanced by the calcination of laterite.

In the 20 cm column, CL exhibited a significantly higher maximum adsorption capacity (N_0) of 3893 mg/L compared to RL at 573 mg/L. Further investigation of the effect of column height on adsorption performance indicated that column height did not substantially influence the maximum adsorption capacity when sufficient length is provided to develop complete *MTZ* inside the column.

Table 2 Calculated breakthrough curve parameters

Column test		20 cm - RL	10 cm - CL	20 cm - CL	30 cm - CL
t_b	min	270	450	1230	2400
t_s	min	600	3330	3150	4140
y_b	%	99.4	98.7	98.3	99.4
y_s	%	83.0	46.4	69.6	84.5
MTZ	cm	11.0	8.7	12.2	12.6
MTZ/Bed height	-	0.55	0.87	0.61	0.42

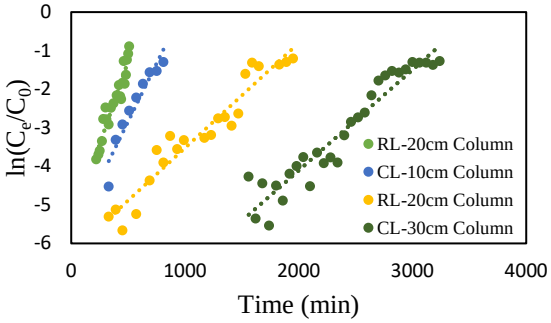

Fig. 3 Linear plot of Adams-Bohart model with experimental data

Thomas model analysis

The Thomas model analysis results assuming plug flow behavior in the fixed-bed column showed better fitting to the test data with R^2 ranging from 0.87 to 0.97. Comparative analysis of the 20 cm columns revealed that CL exhibited substantially higher equilibrium adsorption capacity than RL, with values of 2.78 mg/g and 0.54 mg/g, respectively. The observed decrease in the Thomas rate constant (k_{Th}) following calcination enhanced the equilibrium adsorption capacity, confirming the effectiveness of the calcination process in improving the arsenic adsorption performance of laterite grains. However, an inverse relationship between column height and equilibrium adsorption capacity was observed in fixed-bed column packed with CL grains. The equilibrium adsorption capacity was reduced from 3.43 to 2.60 mg/l, when increasing the fixed-bed column height from 10 to 30 cm which packed with CL grains. This phenomenon aligns with previous reported findings as well [19]

Yoon-Nelson model analysis

The experimental data closely matched the model, with R^2 values over 0.90 in all tested columns. In the 20 cm column, we observed clear differences between RL and CL. The 50% breakthrough times were 518 min for RL and 2,242 min for CL, despite of the similar BET surface areas. This highlighted the

calcination of laterite grains in improved the adsorption effectiveness. We also found that increasing the column height from 10 cm to 30 cm extended the 50% breakthrough time from 1,676 to 3,398 min. This improvement results from the increased hydraulic residence time (HRT) associated with greater column height.

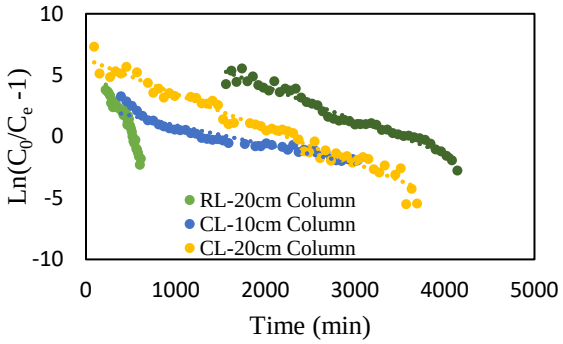

Fig. 4 Linear plot of Thomas model with experimental data

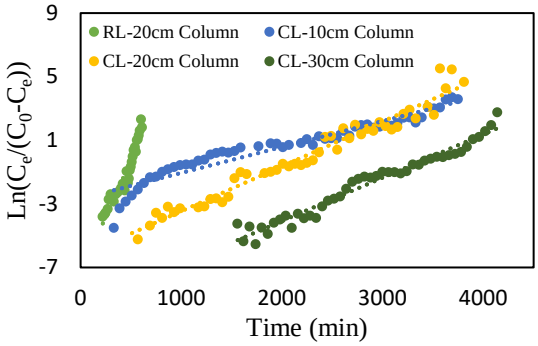

Fig. 5 Linear plot of Yoon-Nelson model with experimental data

BDST model analysis

The BDST model analyses the effect of column height at various breakthrough percentages. In this study, 5% influent concentration was set as the breakthrough point. Fig. 6 showed that breakthrough time correlates linearly with adsorbent bed height, with a correlation coefficient (R^2) of 0.99, indicating successful application of the BDST model to determine column parameter constants. The adsorbent bed capacity (N_0) and rate constant are 2759 mg/L and 0.003 L/mg.min, respectively. The minimum column height requirement to achieve the desired effluent concentration (C_t) at zero time can be calculated using the Eq. (7). Minimum column height indicated that a fixed-bed column of 6.06 cm height with 3 cm diameter is fundamentally required to ensure the effluent concentration remains at the breakthrough concentration at the initial feeding stage of the column.

$$x_0 = v/(kN_0)\, ln(C_0/C_t - 1) \quad (8)$$

CONCLUSIONS

Calcination enhanced the physical and adsorption properties of Laterite grains. SEM analysis showed increased surface roughness and elimination of cracks, while EDS revealed reduced iron content (36.5 to 11.6 wt%) and increased aluminum and silicon. CL exhibited improved rigidity and structural integrity due to dehydroxylation and decarbonization. Breakthrough time in a 20 cm column increased from 270 to 1,230 min after calcination. Theoretical models (BDST, Adams-Bohart, Thomas, Yoon-Nelson) fit the data well, confirming higher adsorption capacity in CL, with the Adams-Bohart model showing up to 3,893.36 mg/L. This increase is attributed to disordered metakaolin and poorly crystallized iron oxides, enhancing surface reactivity. Column height significantly affected performance,

with taller columns extending breakthrough and saturation times by increasing HRT and active sites.

ABSTRACT

This report presents the findings of the heat reduction performance of rooftop garden designs tailored to suit the activities of residents in four condominium buildings (Buildings A to D). The study applied four rooftop garden design types (Types 01 to 04), comprising open walkways, lawn areas, vegetative coverage, and swimming pools, respectively. Each design was installed on a concrete rooftop surface with a thickness of 0.15 meters. The rooftop area covered by Type 01 design elements was set at 80%, 60%, 40%, and 20% for Buildings A, B, C, and D, respectively. Temperature data collected from rooms and corridors beneath the rooftop gardens revealed that Building D had the lowest average indoor temperature, which was up to 2°C lower than that of Building A and up to 0.74°C below the average ambient temperature. In addition, heat flux measurements indicated a maximum reduction of 46% compared to baseline conditions prior to installation. This study underscores the influence of rooftop garden design principles, which collectively shape rooftop thermal behavior, and highlights the importance of ecological design strategies in enhancing indoor comfort and mitigating urban heat accumulation.

Keywords: Green roof, Heat Accumulation, Rooftop, Thermal Performance

INTRODUCTION

Urban expansion is progressing rapidly across various regions worldwide [1,2]. This growth is largely driven by ongoing economic, social, and infrastructural development [3–5]. A direct consequence of urbanization is the escalation of land values, primarily resulting from increased demand associated with real estate development, transportation infrastructure expansion, and population influx into urban zones. In response to spatial limitations and population density, many cities have adopted vertical urban development through the construction of high-rise buildings, aimed at maximizing land use efficiency. However, due to the high economic value of urban land, developers and investors tend to prioritize financial returns, often at the expense of urban green spaces [6,7]. Consequently, areas that might otherwise serve environmental or recreational functions are frequently replaced by built structures. The substitution of open, vegetated spaces with high-rise buildings composed of heat-retaining materials, such as concrete and glass, has significantly contributed to the Urban Heat Island (UHI) effect [8], whereby urban temperatures exceed those of surrounding rural areas. This thermal imbalance poses public health risks, especially to vulnerable populations, including children, the elderly, and individuals with pre-existing respiratory conditions [9,10]. Amidst the scarcity of accessible green areas in densely populated cities, rooftop gardens have emerged as a viable and increasingly popular solution for enhancing urban livability. These systems involve the transformation of otherwise unused rooftop surfaces into functional green spaces, offering opportunities for outdoor recreation and community engagement. The integration of rooftop gardens not only contributes to the expansion of urban greenery [11,12] but also yields multifaceted benefits across environmental, energy, health, and economic dimensions. Empirical studies have demonstrated that rooftop gardens can lower ambient air temperatures by 2–5°C [13,14], thereby mitigating UHI effects and reducing the demand for mechanical cooling, which may result in electricity savings of 20–30% [15,16]. Furthermore, these systems can sequester up to 375 grams of CO_2 per square meter per year [17], thereby supporting greenhouse gas reduction goals. In addition to reducing pollution, rooftop gardens help increase oxygen levels and enhance overall air quality. From a hydrological perspective, rooftop gardens also function as rainwater retention systems, effectively contributing to the mitigation of urban flooding risks [18,19]. On a broader scale, cities that invest in large-scale rooftop greening initiatives may also experience economic revitalization through increased tourism and local economic stimulation.

RESEARCH SIGNIFICANCE

Based on the foregoing literature review, rooftop gardens are identified as a key strategy for promoting sustainable urban development. This study investigates the design and implementation of thermally efficient rooftop spaces, utilizing rooftop garden systems as a passive solution to mitigate heat accumulation in condominium buildings. The objective of the research

is to evaluate the effectiveness of specific rooftop garden design configurations in enhancing thermal performance, improving indoor comfort, and contributing to environmental benefits in high-density urban contexts.

DEVELOPMENT OF ROOFTOP GARDEN

The rooftop garden designs were customized to accommodate the daily activities of residents in four condominium buildings to evaluate their effectiveness in reducing heat accumulation (Fig.1). Each of the four design typologies integrates distinct landscape and functional elements applied over a 0.15-meter-thick concrete rooftop slab. The first design (Type 01) consists primarily of open space and walkways, situated at an elevation of approximately 0.00 meters. The second design (Type 02) incorporates a lawn layer (0.05 meters) over soil (0.25 meters). The third design (Type 03) includes a combination of low shrubs (0.30 meters), selected tree species (2.50 meters), and planting beds (0.60 meters). The fourth design (Type 04) features a swimming pool with a depth ranging between 1.20 meters. Supporting infrastructure such as staircases, elevators, and water storage tanks, averaging 2.50 meters in height, are present but excluded from the calculation of usable rooftop area.

Fig.1 Design of Rooftop Gardens on Four Condominium Buildings to Evaluate Heat Reduction Efficiency

The rooftop spaces of the four buildings were adapted according to these design parameters, with the proportion of Type 01 coverage progressively decreasing across the buildings: Building A: 80%, Building B: 60%, Building C: 40%, Building D: 20%. A design tolerance of ±10% was applied to allow for construction variability (Table 1).

Table 1 The rooftop areas of the four buildings were modified based on the percentage allocation of the design conditions

Design conditions	Each building for rooftop areas = 100%			
	A	B	C	D
Type 01	80%	60%	40%	20%
Type 02	15%	20%	40%	20%
Type 03	5%	20%	20%	40%
Type 04	–	–	–	20%

Note: The margin of error in the design proportions is ±10%.

EXPERIMENTAL SET-UP

The performance testing of the four buildings was conducted in April,11 2025. The four rooftop garden design conditions were applied to the rooftop areas of each building, with an average rooftop area of 1,200 square meters per building. Several areas beneath the rooftop on the 8th floor were used as data collection points to compare with the ambient temperature. The experimental setup was installed under the rooftop gardens of four condominium buildings (Buildings A, B, C, and D) in a residential area in Salaya, Phutthamonthon, Nakhon Pathom, Thailand. Each building contains 23–27 residential units, with slight variations in size; corner units are larger. The central corridor in each building is 1.5 meters wide, with a floor-to-ceiling height of 2.60 meters and a 0.40-meter air gap above the ceiling for building systems. The staircase and elevator spaces have the same dimensions across all buildings, except for Building D, where part of the space is used as a mechanical room for the swimming pool system. K-type thermocouples (range: 0–1250°C, resolution: ±0.5°C) were used to measure temperatures at different positions, located in the center of the rooms, compared with ambient outdoor average temperatures. These were connected to a data logger (Hioki, Model: 8422–52, accuracy: ±0.8%). Additionally, heat flux meters (Omega HFS-3, range: 1–1400 W/m², error: ±0.5%) were installed at the ceiling surface in the rooms to record average heat transfer through the rooftop floor to the ceiling of the lower level. Doors and windows were kept closed to observe the heat transfer into the buildings. Monitoring started at 8:00 AM and ended at 6:00 PM, during which data from all four buildings was recorded simultaneously at 30-minute intervals (Fig.2).

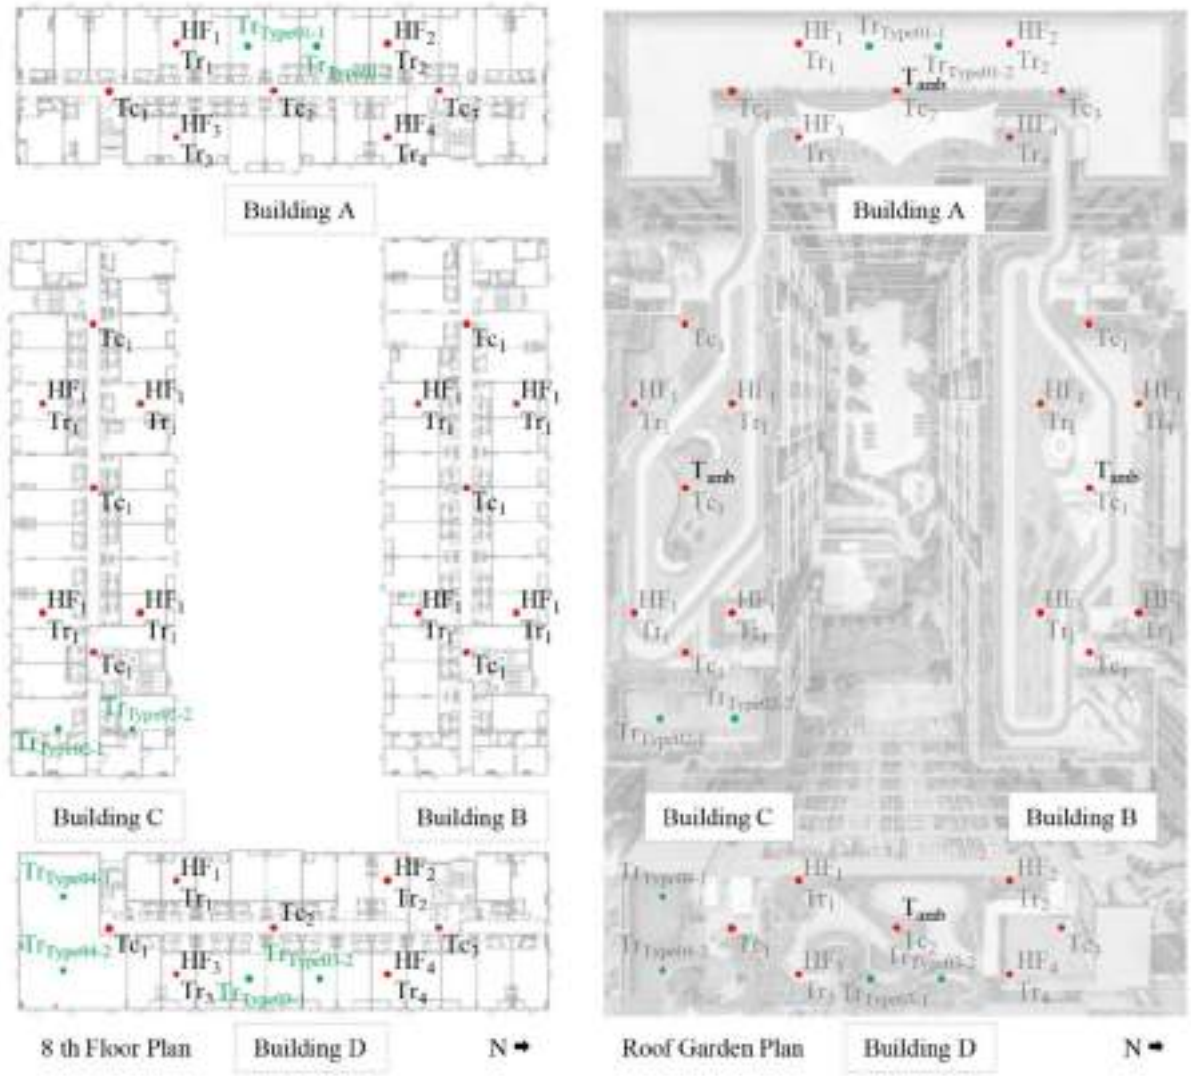

Fig. 2 Measured positions of four buildings

where:

T_r	Room temperature	K
T_c	Corridor Temperature	K
T_{amb}	Ambient temperature	K
HF	Heat flux	$W.\ m^{-2}$

RESULTS AND DISCUSSION

Location Specific Temperatures

The average indoor temperatures beneath the rooftop, which are specific positions corresponding to design types 01, 02, 03, and 04, were compared with the ambient temperature over the period from 08:00 AM to 06:00 PM. Between 08:00 and 09:30 AM, the average temperature at the Type 01 location did not differ significantly from the ambient temperature. However, from 10:00 AM to 06:00 PM, the average temperature at that location consistently exceeded the outdoor temperature by 0.36–2.44°C, with the maximum difference observed at 1:30 PM (Fig. 3). During the morning period (08:00–12:00 PM), the difference between the highest and lowest average temperatures among the specific rooftop garden locations was 1.36°C, whereas in the afternoon (12:00–04:00 PM), this temperature gap increased to 2.96°C (Table 2).

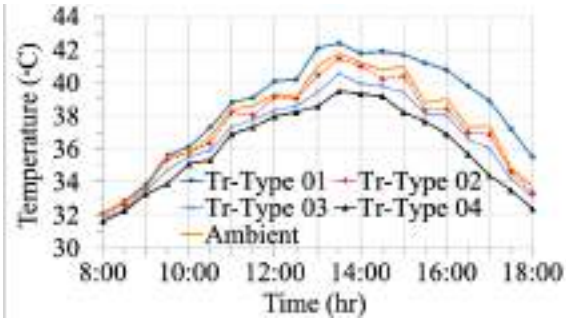

Fig.3 Hourly variations of temperature of location-specific (type 01, 02, 03, and 04)

Table 2 The average temperatures at specific positions for Type 01, 02, 03, and 04

Type /Ambient	Time	Average Temperature
type 01	08.00–12.00	36.19
	12.00–16.00	41.36
type 02	08.00–12.00	35.68
	12.00–16.00	39.83
type 03	08.00–12.00	35.23
	12.00–16.00	39.12
type 04	08.00–12.00	34.83
	12.00–16.00	38.40
Ambient	08.00–12.00	35.87
	12.00–16.00	40.22

In contrast, Types 02, 03, and 04 always recorded temperatures lower than the ambient temperature. At any given time, the temperature at Type 01 was higher than Type 02, Type 02 was higher than Type 03, and Type 03 was higher than Type 04. The average temperature differences throughout the day were 1.29°C, 0.55°C, and 0.65°C, respectively. Type 04 had an average temperature that was 1.52°C lower than the ambient temperature (Table 3).

Table 3 The differences in average temperatures at specific positions for Type 01, 02, 03, and 04

Type /Ambient	Average Temperature	Type comparerison	Temperature difference
Type 01	38.53	01 vs 02	1.29
Type 02	37.25	02 vs 03	0.55
Type 03	36.70	03 vs 04	0.65
Type 04	36.05	04 vs Ambient	-1.52
Ambient	37.56	–	–

Corridor Temperatures

The average corridor temperatures beneath the rooftop of Buildings A, B, C, and D, along with the ambient temperature, are compared over the time period from 8:00 AM to 6:00 PM. The corridor temperatures varied by 0.5–1.8°C throughout the day. At any given time, the temperature in Building A was always higher than in Building B, Building B was higher than in Building C, and Building C was higher than in Building D. The differences between the highest and lowest average corridor temperatures among the buildings were 0.51°C, 0.58°C, and 0.34°C, respectively. (Fig. 4). Notably, the indoor temperatures of Buildings C and D were lower than the average ambient temperature by 0.56°C and 0.89°C, respectively (Table 4).

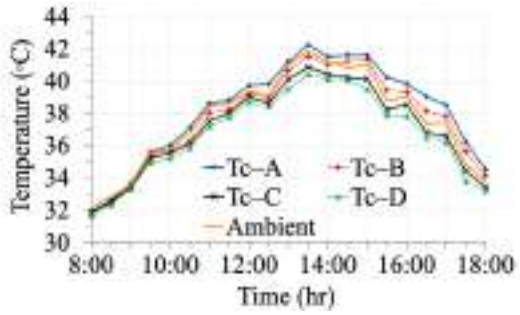

Fig.4 Hourly variations of temperature of corridor in buildings A, B, C, and D

Table 4 Comparison of average corridor temperature differences across each building

Building /Ambient	Average Temperature	Type comparerison	Temperature difference
Tc-A	38.10	A vs B	0.51
Tc-B	37.59	B vs C	0.58
Tc-C	37.01	C vs D	0.34
Tc-D	36.67	Ambient vs D	0.89
Ambient	37.56	Ambient vs C	0.56

Room Temperatures

The average indoor temperatures beneath the rooftop floor of Buildings A, B, C, and D were compared with the ambient temperature over the period from 08:00 AM to 06:00 PM. The average indoor temperatures varied by approximately 0.5–2°C throughout the day. It was found that Building A had the highest average indoor temperature, followed by Buildings B, C, and D, respectively, with Building D recording the lowest average indoor temperature. The temperature differences between the highest and lowest average indoor temperatures recorded across the buildings were 0.80°C, 0.72°C, and 0.49°C, respectively. (Fig.5). Interestingly, the indoor temperatures of Buildings C and D were lower than the outdoor temperature by an average of 0.25°C and 0.74°C, respectively (Table 5).

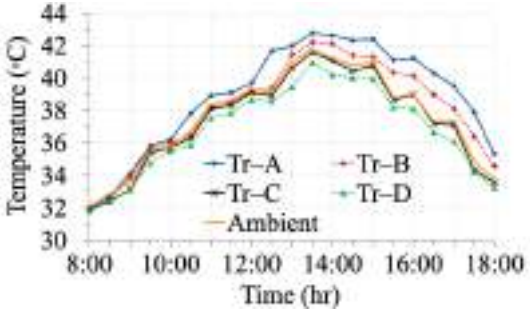

Fig.5 Hourly variations of temperature of room in buildings A, B, C, and D

Table 5 Comparison of average indoor temperature differences across each building

Building /Ambient	Average Temperature	Type comparerison	Temperature difference
Tr-A	38.83	A vs B	0.80
Tr-B	38.03	B vs C	0.72
Tr-C	37.31	C vs D	0.49
Tr-D	36.83	Ambient vs D	0.74
Ambient	37.56	Ambient vs C	0.25

Percentage heat flux reduction

Hourly variation in heat flux through the rooftop floor is presented over the course of the day. The heat flux is primarily influenced by thermal radiation, with solar radiation levels at approximately 799 W/m². The rooftop heat flux of Building A is about 32 W/m² higher than that of Building B, and similarly, Building C records 32 W/m² higher than Building D. As a result, Building D demonstrates the greatest reduction in heat gain through the rooftop floor and maintains indoor temperatures closer to the ambient temperature. (Fig. 6)

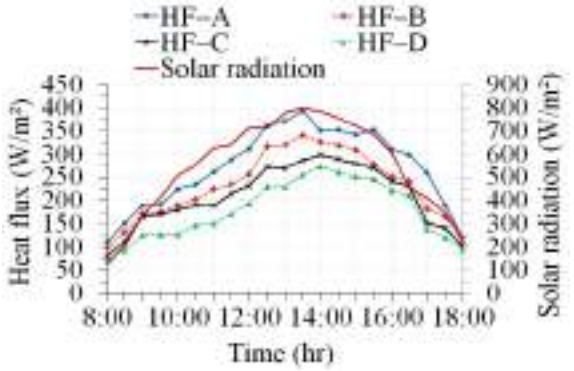

Fig.6 Hourly variations in heat flux and solar radiation of buildings A, B, C, and D

The measured percentage of heat flux reduction is used to calculate the heat flow rate through the rooftop floor as follows:

$$Reduction\ (\%) = \left(\frac{q_{before} - q_{after}}{q_{before}}\right) \times 100 \quad (1)$$

where:

q_{before} = heat flux before improvement (W/m²)
q_{after} = heat flux after improvement (W/m²)

The heat flux rate and the percentage reduction in heat flux for Building A compared to Building B, and for Building C compared to Building D, are illustrated (Figs. 7–8). The heat flux of Building B is lower than that of Building A by approximately 10–78 W/m², while Building D has a heat flux 8–53 W/m² lower than Building C. Between 08:00 AM and 12:00 PM, the percentage reduction in heat flux ranges from 9% to 19% for Building B compared to A and 11% to 29% for Building D compared to C. This indicates that in the morning hours, Buildings D and C outperform Buildings B and A due to the thicker substrate, different materials, and more extensive vegetation coverage in their rooftop garden designs. However, from 12:00 PM to 6:00 PM, Buildings D and C appear to perform similarly to Buildings B and A, with heat flux reductions of 7% to 21% and 8% to 16%, respectively.

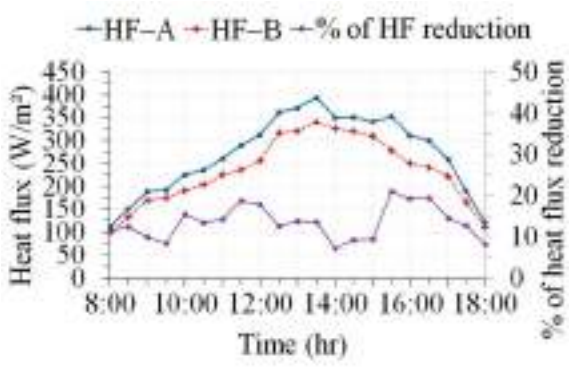

Fig.7 Hourly variations in heat flux and percentage heat flux reduction of the buildings A and B

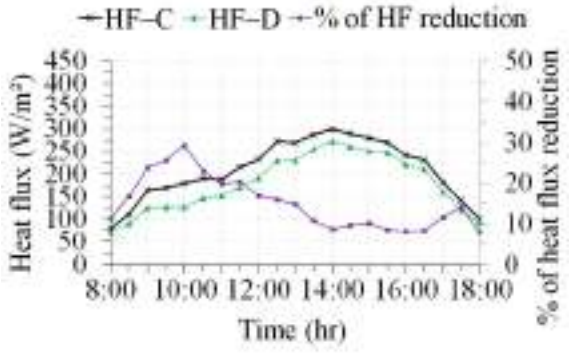

Fig.8 Hourly variations in heat flux and percentage heat flux reduction of the buildings C and D

CONCLUSIONS

The test results of heat reduction efficiency using rooftop garden designs tailored to the activities of residents in four condominium buildings show that the room temperature beneath the rooftop of Building D is consistently lower than that of Buildings C, B, and A, respectively. For Buildings D and C, field testing indicated that the indoor temperature below the rooftop does not reach excessively high levels, as it remains close to or lower than the ambient temperature, which is a particularly noteworthy finding. The heat flux rate and percentage reduction

in heat flux between Building A and B and Building D and C during the period from 8:00 AM to 6:00 PM show interesting trends, with reductions ranging from 7% to 21% and 8% to 29%, respectively. This demonstrates that the percentage of heat flux reduction throughout the day is influenced by the level of solar radiation and the design conditions of Types 01, 02, 03, and 04, comprising open walkways, lawn areas, vegetative coverage, and swimming pools, respectively. It is important for designers to promote rooftop activities that align with the needs of the building's users. However, further consideration is required regarding the structural load, supporting construction, and the budget implications for building owners.

THE ROLE OF ENVIRONMENTAL IMPACT ASSESSMENT AS AN EFFECTIVE TOOL FOR SUSTAINABLE DEVELOPMENT IN THAILAND

Chutarat Chompumth

Graduate School of Environmental Development Administration,
National Institute of Development Administration, Thailand

ABSTRACT

Environmental impact assessment (EIA) is viewed as an effective tool for achieving sustainable development because it includes vital components that can facilitate sustainable developments by assessing environmental impacts, use of resources and public acceptance on project development. In Thailand, EIA study was conducted to assess the environmental and social impacts of a planned development project. This research aims to study how EIA promote sustainable development in Thailand. EIA practices were analysed to see whether they included key components to meet sustainable development criteria. This research was a qualitative study. Data were collected through in-depth interviews with stakeholders. The result revealed that concepts of sustainable development were partly met by the Thai EIA. The obstacles that prevent the Thai EIA in achieving sustainability are top-down command, the lack of transparency in the projects' management, the limited and a low level of public participation. Public participation, one of the significant part of EIA was not effectively established. Many citizens who were directly impacted by development projects have less opportunities to participate in decision-making process. These problems lead to ineffective EIA and conflicts in the Thai society caused by unaccepted decisions. It could be concluded that EIA practice in Thailand may not serve as an effective tool to promote sustainable development. Therefore, Thai EIA practice should carefully analyses how development project might impact social and environment. It is necessary to ensure that the EIA practice are well planned with sustainability be balancing the needs for the environmental protection and the economic growth.

Keywords: Environmental Impact Assessment, Sustainable Development, Public Participation

INTRODUCTION

Environmental issues have become one of the major global concerns that affects all parties [1]. In Thailand, the mega development projects caused by economic and industrial development in the past period often leads to problems of unfair allocation of resources, causing local people in development area to be affected directly from the project without the proper care and suitable assistance. This process often be seen as lacks transparency since the approval of the project, where people do not receive information which increase the lack of public participation in decision-making and project implementation that does not comply with good governance. This problem has affected their ability to develop the country's infrastructure. Furthermore, the residents in the area face serious health problems The conflict from development projects is likely to increase and intensify. Therefore, this issue can be considered a big problem in Thai society [2].

In order to effectively solve the issue, any development projects cannot be implemented without involving with the surrounding communities, and considering the losses that occur to the environment that may deteriorate and affect social changes, including the health of the people who will receive pollution from the operation of that development project. Thus, the developing countries' trend nowadays are so focused on the importance of participation in the issue of effective environmental management.

SIGNIFICANCE OF THE STUDY

The concept of sustainable development has played a role in the current development of the global society since 1972. Since the United Nations has organized a summit on the human environment in Stockholm, Sweden, which calls for the world to take into account the effects of excessive use and the limitations of world resources. As a result of the meeting, the whole world began to increase their environmental attention and creates important international environmental law documents under the Stockholm Declaration on the Human Environment or the "Stockholm Declaration". The document supports the environmental rights for the first time, consisting of 26 important provisions as guidelines for sustainable development. Later in 1983, the United Nations established the World Commission on Environment and Development, commonly known as

the Brundtland Commission, to study the balance between the environment and development. This commission has published a document called Our Common Future that calls for the global society to transform our extravagant way of life and to change the guideline of development. In a manner that is safe for the environment and in accordance with the limits of nature, including the suggestion that humanity is able to achieve sustainable development [3].

Later in the year 1992, the Earth Summit was held in Rio de Janeiro, Brazil, which resulted in the establishment of an important document, Action plan 21 or "Agenda 21". This document's main role was to be a guideline for countries in the world to use and adapt accordingly, in order to achieve sustainable development. This will further ensure that both current and future generations will have sufficient natural resources to meet the needs of their livelihood. The concepts of Agenda 21 stated that the increase in population, consumption and technology are the main causes for changes in the environment. Therefore, humans must work together to reduce consumption that is extravagant, inefficient and also support sustainable development in all parts of the world. In addition, the Action Plan 21 proposes guidelines for solving all of the environmental problems; natural resource degradation, conservation of species diversity and species of living things, forest conservation, poverty, extravagant consumption problems, planning, management of education, health, solving problems in metropolitan areas and agricultural issues of farmers. These guidelines emphasize that it is the duty of every person, every group and every profession to achieve sustainable development, which is a way to overcome poverty and environmental destruction [4].

Environmental impact assessment (EIA) is defined as the systematic identification and evaluation of the potential impacts (effects) of planed projects, plans, programs, or legislative actions related to the physical, chemical, biological, cultural, and socioeconomic components of the environment [5]. EIA is aimed at integrating environmental aspects connected to the natural and human environment in making decisions related to the design, planning, implementation, and monitoring of interventions, in order to achieve sustainable development. It provides a framework for the integration of environment policies and development strategies that will lead toward sustainable development.

Therefore, the elements of an activity allow the burden of proving that this action will not cause significant harm. EIA could provide project alternatives and identify means of improving project selection, siting, planning, design, and implementation by preventing, minimizing, mitigating, and compensating for negative environmental impacts [4, 5].

Most importantly, one of the key elements of EIA is public participation which could provide data regarding the environmental issues of the purposed project area, project characteristics, and the identification and evaluation of latent impacts. Many results from EIA studies can make valued added to the development in terms of knowledge of environmental, social, and economic systems [6].

RESEARCH METHODOLOGY

In this research, qualitative research data were collected from two sources: 1) Primary data: In-depth interviews with stakeholders. The interview instrument was an open-ended questionnaire designed specifically for each key stakeholders. Including central government, local government agencies, academics from various agencies and nonprofit organizations, community leaders and public interviews. 2) Secondary data. The information obtained from the review of academic literature, academic papers and thesis article. The researcher will take the primary and secondary data to be validated, analyzed and synthesized to obtain information according to the objectives of the research. The researcher then used the descriptive analysis to summarize the content, comments and reviews. Then, present the issues set out in each interview topic to ensure the consistence of the study with the objectives of the study and then proposed the conceptual framework. This is to summarize the study on various issues and to obtain the most relevant and complete information. In-depth interviews were applied to collect data while purposive selection and snowball techniques were used to selected the research interviewees, including 30 key informants.

ENVIRONMENTAL IMPACT ASSESSMENT AND SUSTAINABLE DEVELOPMENT IN THAILAND

Environmental impact assessment is a commonly used tool for effective decision making. The scheme of EIA is that development can proceed in parallel with conserving the quality of the environment. This is started by considering the environmental impact from the initiation of the project and planning phase to the procession phase of the project. The abovementioned tool initiative will help reduce the impact and promote the use of limited natural

resources to gain maximum benefit [4]. The principle that the economic and technological development can proceed in parallel with the preservation of natural resources and the environment or the principles of "Sustainable development" [3]. It can be said that the environmental impact assessment process is part of a plan to contribute to sustainable development. This is to help prevent problems in advance which is consistent with the Precaution Principle. This principle is known for the recommendation to prevent problems in advance if there are signs or trends of that may cause serious consequences in the future.

The role of EIA in achieving sustainable development is crucial. Firstly, EIA supports integrate environmental considerations into development planning and decision-making processes. By evaluating possible impacts at an early stage, EIA enables the adoption of mitigation measures to minimize negative environmental impacts and boost project sustainability [7].

Secondly, EIA supports the preservation of ecosystems and biodiversity. Through the assessment of potential impacts on habitations and species, EIA identifies sensitive areas and promotes the adoption of measures to protect the environment, which aims to sustainably manage forestry, combat desertification, stop biodiversity loss, and protect ecosystems.

Thirdly, EIA promotes the sustainable consumption of natural resources. By assessing resource availability and evaluating resource use forms, EIA conducts an identification of sustainable resource management performs. Additionally, EIA also addresses climate change considerations. It assesses the greenhouse gas emissions, energy consumption, and climate change impacts associated with development activities. By identifying mitigation measures and promoting climate change adaptation strategies, which aims to combat climate change and its impacts [8].

In Thailand, The Natural Resources and Environmental Policy and Planning Office is the agency responsible for checking the accuracy of the preliminary environmental impact assessment report and proposing the report to the Board for consideration and approval before issuing the permit under the notification of the Ministry of Natural Resources and Environment. The process of evaluating the environmental impact is divided into 7 stages as follows: 1) critically evaluate what projects or activities require an EIA. In Thailand, The ONEP is responsible for defining the scope or project that requires an environmental impact assessment. 2) Defining the framework of the dimension of the group in the area, goals and key points that should be highlighted in the study to answer the question of the purpose of the study set. 3) Identifying the impacts in a detailed breakdown of each issues identified in Article 2, as well as the appropriate variables. This can be done by referencing EIA studies of other similar projects or by exploring both the impactors and the affected parties. 4) Environmental Impact Assessment which will describes the nature of the cause behind the effect, including the size and other dimensions of the impact in a concrete scientific way. This includes both short-term and long-term impact. 5) Evaluate the impact of Article 4 and the preceding priorities to simplify preventive measures, amendment or the reduction of Impacts 6) Establishment of Preventive measures. There are generally two types of preventive measures: structural measures and non-structured measures. And 7) Careful monitoring of environmental impacts to determine the efficiency and effectiveness of preventive measures, amendment or mitigation measures. Simultaneously, it also examines the accuracy of forecasts and impact assessments [9].

It could be said that in Thailand, the government has set up EIA practices in the constitution, which is the highest law in the administration of countries in many sections which cover both the principles of accessing information, principles of public participation and the principles of accessing the justice system. In the private sector, it was found that many establishments began to operate according to environmental governance principles. If Thailand is going to head to sustainability without conflict in society and environment, it needs to focus on the principles of effective EIA seriously and focus on effective implementation, including encouraging people to have access to environmental information. This is in order for the public or the citizens to be able to participate in decision making in the project which may cause environmental impacts effectively. Also, it is important to promote access to justice in cases and environmental disputes of all sectors, which Thailand should focus on the preparation of all sectors, especially the secondary level law that will make the operations of all sectors more efficient [10].

Importantly, EIA also fosters stakeholder engagement and participation. There should be a promotion of environmental awareness among all sectors. All sectors should be involved with the public sector to create guidelines to monitor the operations of both the public and private sectors continuously. This is to ensure the confidence and trust in the operation of the public. If all sectors are working

together, they will eventually be able to drive the country into sustainable development**.**

PUBLIC PARTICIPATION IN EIA PRACTICE IN THAILAND

Public participation is one of the most important principles of EIA, which is a universal principle that civilization places importance on and is the main issue that Thai society is interested in developing politics into a participatory democracy. Thus, the government must provide opportunities for the public and related parties in all sectors to share ideas, make decisions, create transparency and increase the quality of the decision making process that is mutually acceptable to all parties. It is generally accepted that public participation plays an important role in the national development process, society and environment. That is to say, participation is a social process that provides opportunities for those involved as stakeholders to participate in the awareness of information analyze problems, express opinions, coordinating and monitoring the impact of the operation, as well as participating in the implementation of any matter which is a solution to the problems of their community or locality. This method is carried out to meet the true needs of the public, which is in accordance with the government's policy to prevent, correct and manage correctly and efficiently as protection for the quality of the environment and the quality of the public's life [10].

As for the analysis of laws and regulations relating to the participation of people in making decisions in various development projects. It was founded that the Constitution of the Kingdom of Thailand 2007 and 2017 laid the framework of participation in the decision-making process at the project level in many sections, especially in Article 58 of the 2017 Constitution, which stated that any activity or project that may inflict a serious impact on the environment, natural resources and health of the people must initiate a process to listen to the opinions of the public and stakeholders from that activity or development project and must have an independent organization to give an outside viewer's opinions. In addition, the Constitution also gives rights to the public or communities in the management of natural resources and the environment in Article 59.

In addition, Thailand has set up a framework for the implementation of public participation in projects that affect public health and the quality of the environment through other secondary laws, including the National Environmental Quality Act 1992 and Notification of Ministry of Natural Resources and Environment on the type and size of the project or business, which must include preparation of an environmental impact analysis report and guidelines, procedures and guidelines for the preparation of the Environmental Impact Assessment Report 2010, which requires the state / private sector owners of development projects that are licensed by the government to allow the public to participate in the decision-making process of the project, activity or any project which has a wide scale impact on the quality, environment, health, way of life or interests with the local community. The project owner must provide the process of public participation through the process of public hearing.

It can be seen that Thailand has laid down a legal framework that is consistent with the principles of good governance and public participation. However, in order to result in concrete actions, there must be a mechanism in which enforcement of laws and practices are in accordance to meet the intent of the law [2, 10].

Presently, in Thai society, the key issue is that who has the authority to approve any activity or project, allow the public and stakeholders to participate in the decision-making process and the level of the public's satisfaction with the level of participation. Although, there are many laws in Thailand that show the intent and importance of public participation, there is still no law that gives the power to the role of the public to truly participate in the process of decision-making. The level of public participation in the decision-making processes in Thailand is considered to be low since the public has no real power on the decision [11]. If law enforcement cannot be conducted effectively, this may affect the effectiveness of public participation process in the EIA system [12].

OBSTACLES TO ENVIRONMENTAL IMPACT IN ACHIEVING THE SUSTAINABLE DEVELOPMENT GOALS

There are several difficulties that can hinder effective EIA in achieving the Sustainable Development. These problems arise from various sources and can impede progress towards sustainable development as follows.

Firstly, a lack of political will and commitment, without strong political will and commitment from governments and policymakers, it becomes

challenging to prioritize environmental concerns and allocate sufficient resources for sustainable development initiatives. Limited investment in environmental conservation, weak enforcement of regulations, and inadequate policy frameworks can hinder progress towards achieving sustainable development.

Secondly, a lack of awareness and understanding of environmental concerns among the local public and key stakeholders can hinder a headway towards achieving SD. Inadequate environmental education and awareness agendas limit the involvement and participation of individuals and communities in sustainable practices. Without a prevalent understanding of the significance of environmental conservation, it is a hard work to drive meaningful transformation.

Thirdly, inefficient institutional contexts, weak governance administration, and limited ability for environmental management can pose important obstacles to achieving sustainable development. Lack of coordination among government agencies, poor legislation and regulations, and corruption can hinder effective EIA. Strengthening institutional capacity, refining governance intuitions, and encouraging transparency and accountability are crucial for overcoming these challenges.

Fourthly, the lack of transparency within the project development management causes the public to lose confidence in the project.

Fifthly, lack of meaningful public participation is a key problem of effective EIA. From many case studies in Thailand, it was found that a large number of local people mentioned that the process of public participation does not cover all stakeholders and some have been prevented from participating in the process. If the public and organizations in the process are not involved in the public participation and cannot truly represent stakeholders and those affected by the decision, it can truly lead to problems and conflict later on in the process [7, 10].

These obstacles are immediate needed for environmental sustainability. Balancing social and economic development with environmental considerations is essential to overcome these challenges.

GUIDELINES FOR REDUCING ENVIONMENTAL CONFLICTS FROM DEVELOPMENT PROJECTS IN THAILAND

From many case studies in Thailand, it was found that the cause of the environmental conflict consists of 3 main issues: 1) The impact that people will receive from the operation of development projects, especially pollution which will severely affects the health of the residents in the area, including damage to crops and agricultural products of the community 2) Lack of public participation in the local development decisions. Government officials and project owners lack real public opinion in managing their natural resources and environment, especially during the beginning of the project 3) The public perceives that the benefits that the community will receive are quite low and not worth the loss of natural resources.

Therefore, the government sector and project owners must pay more attention to analyzing the causes of environmental conflicts, in order to properly solve the problem. This includes promoting public participation in EIA for environmental decisions to prevent such conflicts. Although, various development projects are prepared EIA reports, conflicts from the project still continue to occur. This indicates that the EIA report does not guarantee the public's confidence and acceptance of the specified measures in the report. Therefore; every sector must pay attention to analyzing the cause of the conflict in order to solve the problem efficiently [13].

Indeed, public participation that is considered to be successful includes enthusiastic participation from the public, bargaining power of stakeholders in the decision-making process within the project activities, participation in the determination of social goals and resource management to achieve the objective and it must be through voluntary participation. When the staff and personnel are involved in the management of participation, they can then fully understand the meaning of participation. Moreover, they will be able to create evaluation criteria based on relevant factors as the fundamental principle and able to evaluate the success of the level of participation, in order to develop a more efficient process [10, 12].

Public participation, which is one of the important principles of EIA and environmental governance, is an important concept that is expected to solve the problems of natural resource management and conflicts arising from various development projects, especially in the effectiveness of industrial operations that will lead to sustainable development in Thailand.

CONCLUSIONS

EIA is a systematic process that evaluates the potential environmental impacts of proposed projects, policies, and programs. It plays an important role in

achieving sustainable development by integrating environmental concerns into purposed development projects and activities. By identifying and assessing potential environmental risks and impacts, EIA ensures that development projects or activities are carried out in an environmentally responsible and sustainable manner.

The lack of effective EIA and proper public participation in decisions related to the operations of the government or private sector may cause conflicts between stakeholders and environmental damage. Development projects that have good objectives are beneficial to the public at certain times, which may not often provide the anticipated results. This outcome is due to the lack of transparency and public participation in decision-making and project implementation.

Therefore, to effectively and sustainably solve environmental problems, public participation in EIA system must be seriously considered and implemented. Also, it is crucial to create public awareness, discipline of people in the country and training for the public to have knowledge and understanding about the public's participation in the environmental management decision-making process, especially the duties and responsibilities of the people for the treatment of the environment. It can be concluded that the cooperation power of the people will be an important strategy that enables the industrial sector of Thailand to sustainably conduct business with the community further on in the future.

It could be summed that the EIA system identifies both the potential positive and negative impacts of the purposed project in advance. For the adverse impacts upon the natural and the socio-economic environment issues and mitigation measures were identified in advance. This enabled avoidance and/or minimization of impacts and make the project environmentally friendly and acceptable to the nearby community. Thus, EIA is a mechanism that facilitated identification of potential impacts and development of mitigation measures to reduce adverse significant impacts and foster sustainable development.

EFFECT EVALUATION OF TAILING SAND SOLIDIFICATION BY MICROBIALLY INDUCED CARBONATE PRECIPITATION

Lai Yongming[1, 2], Satoru Kawasaki[2] and Liu Qian[1]

[1]College of Resource Engineering, Longyan University, China; [2]Faculty of Engineering, Hokkaido University, Japan

ABSTRACT

Sporosarcina pasteurii (*SP*), the most commonly used urea-decomposing strain in microbially induced carbonate precipitation (MICP), faces challenges in treating complex tailing sand containing multiple heavy metal ions. This study screened and enriched indigenous urea-decomposing microorganisms to develop optimal bio-stimulation strategies for tailing sand treatment, combined with *SP* for tailing sand solidification. Comparative evaluations were conducted through surface strength test and heavy metal leaching toxicity test to examine the effectiveness of three treatment approaches: bio-stimulation alone, *SP* alone, and their combined application. Results demonstrated that the surface strength of sand samples after 7 cycles of combined solidification was 2.594 times that after 10 cycles of bio-stimulation, and 31% higher than *SP* solidification for 10 cycles. The combined solidification also achieved higher heavy metal immobilization rates compared to both bio-stimulation and *SP*. Calcite crystals generated by combined solidification were larger in size and more numerous, showed flaky arrangements, and tightly filled the pores between the tailing sand particles. This integrated approach successfully enhanced both mechanical properties and heavy metal immobilization efficiency in tailing sand.

Keywords: Microbially induced carbonate precipitation; Sporosarcina pasteurii; Indigenous urea-decomposing bacteria; Tailing sand

INTRODUCTION

Microbially induced carbonate precipitation (MICP) represents a new technology currently utilizing microbes to ameliorate soil conditions and immobilize heavy metals. Its core mechanism is` based on employing urease produced through microbial activity to transform Ca^{2+} and metal ions within the soil into carbonate precipitates, while simultaneously improving the physical attributes related to the soil and immobilizing heavy metal elements [1-2]. How the reaction proceeds can be seen in Eq. (1) and (2), with Me^{2+} representing heavy metal ions [3].

$$CO(NH_2)_2 + Ca^{2+} + 2H_2O \rightarrow CaCO_3 \downarrow + 2NH_4^+ \quad (1)$$

$$CO(NH_2)_2 + Me^{2+} + 2H_2O \rightarrow MeCO_3 \downarrow + 2NH_4^+ (2)$$

Sporosarcina pasteurii (*SP*) is the most effective microbes for MICP process through urea hydrolysis [4]. However, tailing usually contains heavy metals [5]. The growth of *SP* is inhibited, and its activity decreases [6] in environments with high heavy metal concentrations, consequently affecting the progress and efficiency of MICP. Considering that urea-decomposing bacteria are widely distributed in soil [7], and existing research has shown that tailing soil contains various genera of urea-decomposing bacteria with high heavy metal tolerance [8]. Therefore, how to effectively activate the activity of indigenous urea-decomposing bacteria and combine it with *SP* to simultaneously improve the mechanical properties of tailing sand and immobilize heavy metal ions is key to the implementation of MICP method within tailing management.

RESEARCH SIGNIFICANCE

This study first explores the effective formulation and concentration of a bio-stimulation solution that can activate the indigenous urea-decomposing bacteria, with the aim of obtaining the optimal bio-stimulation solution formulation suitable for tailing sand. Subsequently, solidification experiments were conducted by combining the screened and enriched indigenous urea-decomposing bacteria from the tailing sand with *SP*. The solidification strength and heavy metal immobilization effects of the three methods (bio-stimulation only, *SP* only, and combined solidification) were compared at different treatment cycles. This study aims to reveal the mechanism by which the combined solidification using indigenous urea-decomposing bacteria and *SP* betters the physical attributes within tailing sand, as well as immobilizing heavy metals.

MATERIALS AND METHODS

Tailing Sand

The tailing sand was taken from the tailing reservoir of Fujian Makeng Mining Co., Ltd. located in China. The basic characteristics of tailing sand was shown in Table 1. Referring to "Soil Environmental Quality - Risk Control Standard for Soil Contamination of Agricultural Land (Trial) [9]," using the risk screening values for soil contamination of agricultural land as the standard values, and based on "Technical Specification for Soil Environmental Monitoring [10]," employing the Nemerow pollution index method for evaluation, it is evident that both Cd and Zn in the tailing sand exceed the standard. Specifically, Cd exhibits moderate pollution, while Zn shows slight pollution.

Table 1 Basic characteristics of tailing sand

Parameters	Values	Parameters	Values
Dry density	1.9589 g/cm^3	Density	2 g/cm^3
minimum dry density	1.8283 g/cm^3	pH	9.5
maximum dry density	2.3746 g/cm^3	Fe	12.71%
Zn	375.61 mg/kg	Cd	1.327 mg/kg

Note: Determination methods for Fe, Zn and Cd: Samples are digested using a four-acid mixture, and the concentrations are determined by ICP-MS.

Formulating and Improving a Bio-stimulation Technique Applicable to Tailing Sand

Based on existing research findings[11], the starting formulation of the bio-stimulation solution is created in 1 L of distilled water: 3.5 g of sodium acetate, 5.35 g of ammonium chloride, 20 g of urea, 0.2 g of yeast extract, 0.01 mmol of nickel chloride.

The urease activity exhibited by the urea-decomposing bacteria stands as the key parameter influencing the success of MICP solidification. Consequently, the urease activity of the supernatant following bio-stimulation of tailing sand serves as both the assessment criterion and the outcome variable. The precise steps for improvement are as follows:

Screening of Optimal Carbon and Nitrogen Sources

Commencing with the initial bio-stimulation solution, one-variable experiments are to be performed by altering the carbon or the nitrogen source. A selection of equivalent mass quantities of glucose, fructose, maltose, starch, and molasses are to be used as the carbon sources. peptone, corn steep liquor, soybean meal, ammonium chloride, ammonium sulfate, and sodium nitrate are to be chosen as the nitrogen sources. Ten grams of air-dried tailing sand are to be introduced into a flask holding ninety milliliters of the bio-stimulation solution. The mixture is to be cultivated within an incubator. The urease activity within the conical flask is to be measured at consistent time intervals using the conductivity method, and this measurement is to serve as the evaluation criterion for identifying the most favorable carbon and nitrogen sources.

Identifying Crucial Factors Through PB Design

A Plackett-Burman (PB) design was utilized to examine the optimal carbon and nitrogen sources identified previously, along with other constituents in the bio-stimulation solution and the pH level of the solution. The objective of this design was to pinpoint the components exerting the greatest influence on urease activity, designating these as crucial factors. Following this, single-factor experiments were carried out by altering the concentration of each crucial variable in order to ascertain the most favorable concentration span for every one.

Determining the Optimal Bio-stimulation Solution Formulation

Urease activity was set as the outcome variable, with central composite design (CCD) being conducted employing Minitab16 program [12]. The best concentrations for every crucial variable were determined, thereby yielding the optimal formulation for the bio-stimulation solution intended for tailing sand.

Bacterial Suspension and Cementation Solution

The bacterium is *Sporosarcina pasteurii* (strain DSM33). The culture medium composition is as follows: 20 g/L yeast extract, 10 g/L ammonium sulfate, 15.8 g/L trisaminomethane. The experiments utilized the bacterial culture after 48 hours of cultivation.

The cementation solution is an equimolar blend of calcium chloride and urea. The concentration used in the experiments was 1 mol/L.

Molds and Methods

The experiments utilized aluminum boxes with a diameter of 10 cm and a height of 5 cm. there were some holes in the base of the box to allow waste liquid to drain. The tailing sand was placed inside the aluminum boxes.

The study was split into three sets: the *SP*, the bio-stimulation, and the combined solidification.

Concerning the *SP* set, the tailing sand underwent initial sterilization at 120 °C inside an oven over a 12-hour period. Based on the author's previous research findings [2], the one-phase low-pH MICP method was employed. Daily, 100 milliliters of the low-pH

bacterial suspension (pH = 3.5) was mixed with 100 milliliters of the cementation solution and then introduced to the sand samples. This constituted one treatment cycle.

Regarding the bio-stimulation set, the tailing sand remained unsterilized. Daily, 100 milliliters of the bio-stimulation solution was introduced as the initial step. Twelve hours later, 100 milliliters of the cementation solution was additionally applied. This constituted one treatment cycle.

For the combined solidification group, the tailing sand was also not sterilized. Daily, 100 milliliters of bio-stimulation solution was first added to the sand specimens, followed after 12 hours by the addition of a mixed solution of 50 milliliters low-pH bacterial suspension and 50 milliliters of the cementation solution. This constituted one treatment round.

Three different numbers of treatment cycles (4, 7, and 10) were investigated to study the effect of the number of treatment cycles on the solidification effect. Each treatment cycle was performed at 24-hour intervals. The control group sand samples were treated with 200 milliliters of deionized water.

After multiple treatment cycles, the following assessments were carried out: The penetration resistance of the solidified sand samples was tested using a mini penetrometer. Five points were uniformly tested on the top face of every sand specimen, then their average value was taken as the surface strength of the sand specimen. The leaching concentrations of Fe, Zn, and Cd within the sand specimens prior to and following solidification were determined using the Toxicity Characteristic Leaching Procedure (TCLP) method for hazardous waste [13].

RESULTS AND DISCUSSION

the Optimal Bio-stimulation Solution Formulation

the Best Carbon and Nitrogen Sources

The change in urease activity of the solution within the flasks over time using distinct carbon and nitrogen nutrient sources is illustrated in Figure 1. Upon employing starch and sodium acetate to provide carbon, the urease activity was relatively high, reaching the peak within a 48-hour period. Considering the range of sources of nitrogen, both inorganic and organic, ammonium sulfate, ammonium chloride, peptone, and soybean meal showed relatively high urease activity. Consequently, these six carbon and nitrogen sources, which showed relatively high urease activity and involved reduced bio-stimulation duration, were designated for the next stage of the PB experiment.

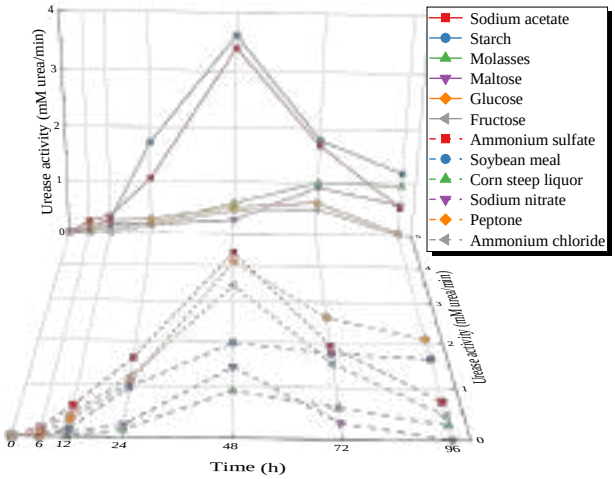

Fig.1 Change in urease activity over time under different carbon and nitrogen sources

Crucial Factors

6 carbon and nitrogen sources chosen based on the one-variable testing, accompanying the three additional ingredients present in the bio-stimulation preparation and the solution's pH, served as the 10 variables to be screened. With the urease activity in the suspension following 48 hours of bio-stimulation as the outcome measure, a PB experiment with N=12 trials was executed. The analytical outcomes can be viewed in Table 2. In this analysis, the P-value serves as a metric measuring the difference in the outcome value across varying factor levels. The P-values for sodium acetate, ammonium sulfate, urea, and pH value were all below 0.05, demonstrating that these items represent important influences on urease activity. The P-value for pH value was the smallest, indicating that pH value is the key determinant with the greatest impact on urease activity. These four variables were designated to be the crucial variables for the follow-up central composite design.

Table 2 Analysis of PB design

Factor	Level (g/L)		Effect	P-value
	-1	1		
starch	3.5	5.25	0.01	0.90
sodium acetate	3.5	5.25	-0.74	0.04
peptone	5.35	8	0.04	0.53
soybean meal	5.35	8	-0.37	0.07
ammonium chloride	5.35	8	0.10	0.26
ammonium sulfate	5.35	8	1.14	0.02
urea	20	30	0.71	0.04
yeast extract	0.2	0.3	-0.48	0.06
nickel chloride	0.01	0.015	-0.23	0.12
pH	7	9	2.33	0.01

the Optimal Formulation

The initial bio-stimulation solution composition was adjusted according to the beneficial and adverse influences of every factor shown in Table 2. Factors with negative effects were set at the –1 level, and factors with positive effects were set at the +1 level, resulting in the following composition: sodium acetate 3.5 g/L, $(NH_4)_2SO_4$ 8 g/L, urea 30 g/L, yeast extract 0.2 g/L, nickel chloride 0.01 mmol/L, and pH 9. Based on the formulation, one-variable tests were conducted by sequentially varying the level of each crucial factor while keeping other components constant. The urease activity at 48 hours at different levels of each crucial factor is shown in Figure 2. All four crucial factors possess optimal concentration ranges within which urease activity initially increases and subsequently decreases.

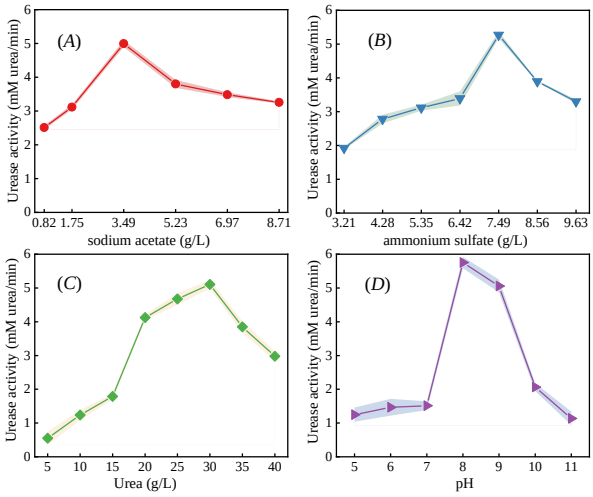

Fig.2 Effect of crucial factor concentration on urease activity

These four crucial factors served as independent variables, with the 48-hour urease activity as the response parameter. A CCD design was conducted. The model predicted a maximum urease activity of 6.54 mmol/L urea/min, and the corresponding optimal bio-stimulation solution composition was: sodium acetate 2.94 g/L, $(NH_4)_2SO_4$ 7.07 g/L, urea 28.86 g/L, yeast extract 0.2 g/L, nickel chloride 0.01 mmol/L, and pH 8.7. A bio-stimulation solution was prepared according to this formulation and used for cultivation with the tailing sand. Three replicates were prepared. The measured 48-hour urease activity was 6.6 mmol/L urea/min, which was close to the predicted value, verifying the accuracy of the model.

Surface Strength

Figure 3 shows the surface strength of sand specimens after undergoing treatment for 4, 7, and 10 cycles, respectively, using the three methods: *SP*, bio-stimulation, and the combined method. The surface strength of all after treatment was significantly improved in different amounts. When the number of treatment rounds was identical, the surface strength in sand specimens subjected to bio-stimulation was the lowest, while that subjected to combined solidification was the highest, showing considerable betterment in comparison with the *SP* treatment. For each method, the surface strength rose as the number of treatment rounds grew. Nonetheless, the bio-stimulation method resulted in relatively low urease activity, and even after 10 treatment rounds, the surface strength of the sand specimens was not high, which is insufficient to meet the strength requirements for tailing dams. While the surface strength of sand specimens after 4 cycles of combined solidification was comparable to that after 7 rounds of *SP* treatment. The surface strength of sand samples after 7 and 10 cycles of combined solidification was increased by 53% and 48% compared to the *SP* treatment at the same number of cycles, respectively, indicating that the combined solidification method indeed further enhanced the solidification strength. However, the rate of increase in surface strength after 7 cycles of combined solidification decreased rapidly, and the surface strength after 10 cycles showed no significant improvement compared to that after 7 cycles. This is because, with the increasing number of treatment rounds, more pores between the tailing sand particles were filled, which rendered it harder for the solution used for MICP to infiltrate.

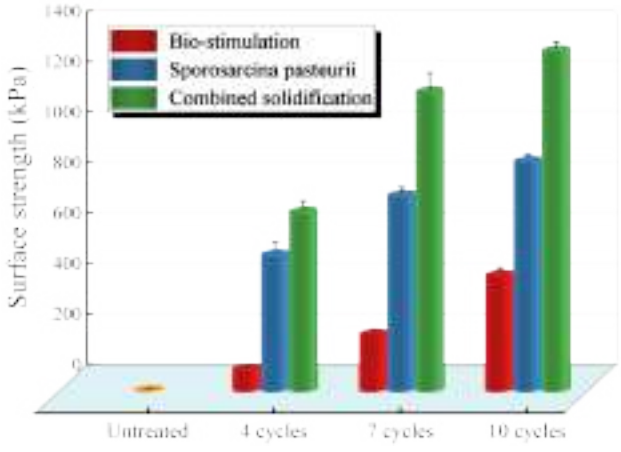

Fig.3 Surface strength of tailing sand

Heavy Metal Leaching Toxicity

Figure 4 presents the leaching concentrations of Fe, Zn, and Cd within untreated tailing sand and in samples that underwent 10 cycles using the three

methods. After solidification, the leaching concentrations of the three heavy metals were all notably lowered compared to the untreated sand samples. The order of heavy metal leaching concentration was: combined solidification < bio-stimulation < *SP*. The existing urea-decomposing bacteria in the tailing sand have high heavy metal tolerance and are uniformly distributed, providing more nucleation sites for carbonate precipitation. The carbonate ions generated during the MICP process can more easily combine with free heavy metal ions in the tailing sand. While during combined solidification, *SP*, which has higher urease activity, decomposed urea and produced more carbonate ions, further increasing the heavy metal immobilization rate. For the sand samples after combined solidification, the leaching concentrations of Fe, Zn, and Cd showed reductions of 89.2%, 72.5%, and 87.6%, respectively.

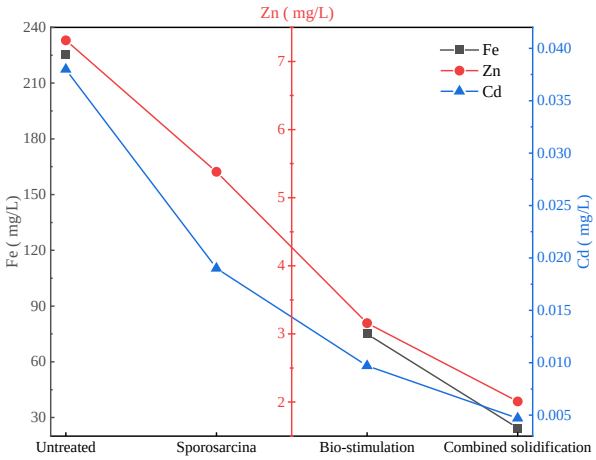

Fig.4 Heavy metal leaching toxicity of tailing sand

SEM Analysis

In the course of the MICP process, a competitive interaction exists between the nucleation and the growth of calcium carbonate crystals. [14]. Figure 5 shows SEM images of tailing sand before and after 10 cycles of solidification using the three methods. The indigenous urea-decomposing bacteria activated by bio-stimulation are spread out broadly and evenly throughout the tailing sand, which furnish additional nucleation sites. Furthermore, indigenous urea-decomposing bacteria have lower urease activity, inducing slower calcium carbonate formation, thereby facilitating the formation of new calcium carbonate crystals by nucleation. *SP* is an introduced exogenous bacterium with a limited migration and diffusion range. Moreover, *SP* has high urease activity, which can induce the formation of a large amount of calcium carbonate precipitate over a brief duration. It leads to calcium carbonate more readily precipitating on pre-existing crystals. As a result, the calcium carbonate crystal size in Figure 5(b) is smaller than in Figure 5(c). In addition, due to the lower urease activity of indigenous urea-decomposing bacteria compared to *SP*, less calcium carbonate is induced to form. Therefore, the number of calcium carbonate crystals in Figure 5(b) is also less than in Figure 5(c). During combined solidification, the indigenous urea-decomposing bacteria provided more nucleation sites, while the high urease activity *SP* induced the formation of more calcium carbonate. Therefore, both the number and size of calcite crystals in Figure 5(d) are greater than in Figure 5(b) and Figure 5(c). These crystals showed tight flaky arrangements, tightly wrapping around the sand particles, thereby achieving higher solidification strength.

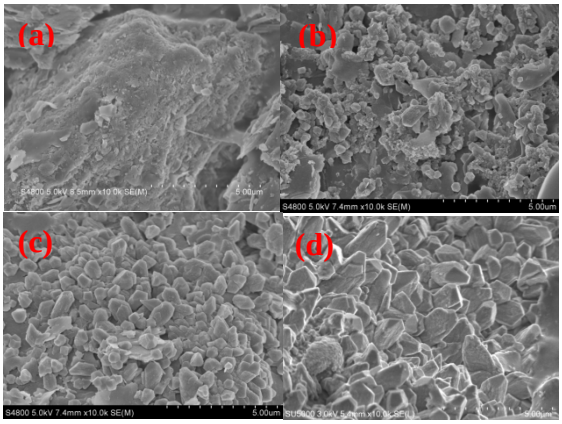

Fig.5 SEM images of tailing sand: (a) Untreated; (b) Bio-stimulation; (c) *SP*; (d) Combined solidification

CONCLUSIONS

This study proposed a method for solidifying tailing sand using indigenous urea-decomposing bacteria combined with *SP*, which improves the physical attributes related to the tailing sand while simultaneously immobilizing the heavy metals within it. The detailed findings are listed hereafter:

(1) The optimal bio-stimulation solution formulation for tailing sand is: sodium acetate 2.94 g/L, $(NH_4)_2SO_4$ 7.07 g/L, urea 28.86 g/L, yeast extract 0.2 g/L, nickel chloride 0.01 mmol/L, and pH 8.7.

(2) The combined solidification method further enhanced the solidification strength. The surface strength of sand specimens after 7 cycles of combined solidification was 2.594 times that after 10 cycles of

bio-stimulation, and 31% higher than *SP* solidification for 10 cycles.

(3) The combined solidification method further increased the heavy metal immobilization rate. At the same number of treatment cycles, the heavy metal immobilization rate for combined solidification was higher than that for both bio-stimulation and *SP* treated sand samples.

(4) The mechanism by which MICP improves mechanical properties is the ultimate filling of pores between tailing sand particles by calcium carbonate in the form of calcite crystals. Both the number and size of calcite crystals generated by combined solidification were greater than for *SP* and bio-stimulation.

The combined MICP approach demonstrated in this study offers significant practical advantages for sustainable mine tailing management, addressing critical environmental risks: (1) Mitigating structural failures of tailing dams through rapid strength gain; and (2) Preventing heavy metal migration into adjacent ecosystems. Moreover, utilizing bio-stimulation reduces reliance on exogenous microbial cultivation and lowers operational costs, while the optimized bio-stimulation solution ensures scalability for field applications. However, long-term stability under environmental stressors (e.g., acid rain, freeze-thaw cycles) warrants further investigation before large-scale implementation.

ABSTRACT

This research details the creation and enhancement of a compost powder rich in microbes intended for incorporation with clay pellets derived from agricultural waste, with the goal of producing a useful and eco-friendly growth medium. The compost was enhanced with microorganisms that dissolve phosphates, fix nitrogen, and provide antagonistic properties. By employing Response Surface Methodology (RSM), an ideal blend (0.7% phosphate solubilizers, 0.07% antagonists, and 2.0% nitrogen fixers) substantially boosted butterhead lettuce growth, resulting in 149.3 g per plant—surpassing both chemical fertilizer yields (128.5 g) and controls without fertilizer (67.4 g). The microbial mixture showed significant improvements in plant weight, leaf count, and height ($p < 0.05$). A feasibility study conducted under semi-pilot conditions revealed that all materials were sourced locally and economically, while the energy-efficient bio-coating process suited community-based production. The clay pellets made from rice husk ash and local clay effectively retained microbes and functioned as controlled-release agents. This adaptable production approach is consistent with the principles of a circular economy and the objectives of sustainable agriculture, encouraging wider implementation in both smallholder and organic farming settings. The findings confirm the technological, agricultural, and financial feasibility of the microbial compost powder and clay pellet combination, presenting a scalable biofertilizer solution that decreases dependence on synthetic inputs and enhances soil health alongside resource recovery.

Keywords: Microbial compost, Bio-coated clay, Response surface methodology, Azotobacter, Sustainable agriculture

INTRODUCTION

In the last few years, the shift towards eco-friendly farming practices has sped up because of growing worries about environmental damage, shifts in climate, and the decline of soil quality linked to heavy dependence on chemical fertilizers. Although artificial fertilizers enhance crop production significantly, their prolonged application has led to harmful effects on the environment, such as nutrient leaching, emissions of greenhouse gases, and the disturbance of natural soil microbial communities.[1], [2]. These drawbacks have led to the creation of different soil enhancers that promote both agricultural output and environmental sustainability.

Among these options, compost enriched with microbes stands out as a promising resource. This organically enhanced amendment integrates beneficial microorganisms into compost made from agricultural byproducts, resulting in improved nutrient cycling, support for plant growth, and the suppression of pathogens. [3]. Key microbial groups include phosphate-solubilizing bacteria (e.g., *Bacillus* spp.), nitrogen-fixing bacteria (e.g., *Azotobacter vinelandii*), and antagonistic microbes that inhibit soil-borne pathogens [4]. These microorganisms work together to enhance plant health and strength, aiding sustainable, organic, and regenerative agricultural practices with minimal inputs.

To improve the delivery and persistence of beneficial microbes in the rhizosphere, researchers have explored the use of fired clay granules derived from agri-waste as microbial carriers. These granules provide structural stability, moisture retention, and porosity, making them suitable for microbial encapsulation and slow-release delivery. A recent study by Saraphirom et al. demonstrated that fired clay granules could effectively preserve the viability of nitrogen-fixing bacterial cells during storage and facilitate their colonization in the soil environment [5]. This approach not only utilizes locally available ceramic and organic waste materials but also enhances the functionality of growing media in sustainable crop production.

Nonetheless, the effective execution of soil pellets made from microbial compost necessitates careful tuning of microbial mixtures to guarantee their suitability and performance. Response Surface Methodology (RSM), especially the Box-Behnken

Design (BBD), offers a robust statistical method to analyze and enhance complex multi-factor systems, allowing the determination of optimal microbial proportions for the best plant reaction. [6].

The primary goal of this research was to create and refine a compost powder formulation enriched with microbes, intended for application with clay pellets made from agricultural waste. This investigation sought to identify the most effective combination of three beneficial microbial groups—phosphate-solubilizers, nitrogen-fixers, and antagonistic species—and to test its biological effectiveness using butterhead lettuce (*Lactuca sativa*) as the subject of study. Additionally, the research examined the economic viability and environmental consequences of the product, bolstering its potential as a commercially viable, sustainable substitute for chemical fertilizers.

MATERIALS AND METHODS

Preparation of Microbial Compost Powder

Microbial compost powder was produced by integrating functional microorganisms into mature compost made from dried plant waste, cow manure, and rice husk ash, with a C:N ratio of ~25:1 to enhance microbial activity [1]. The mixture underwent aerobic composting for 60 days with periodic manual turning.

Post-maturation, the compost was shade-dried, pulverized, and sieved (2 mm) to yield a uniform, porous powder suitable for microbial adhesion and controlled release [7]. The formulation included phosphate-solubilizing Bacillus megaterium [3], antagonistic Azotobacter sp. [4], and nitrogen-fixing *A. vinelandii,* which has proven efficacy when immobilized on clay granules [5].

Each strain was cultured in nitrogen-free medium with potassium metabisulfite (KMS) to improve stress resistance, incubated at 28–30°C with shaking for five days, and adjusted to OD_{600} = 1.0. The microbial suspension was spray-coated onto the compost powder under sterile conditions and air-dried at ≤40°C to retain viability. Final moisture was kept below 12%, and the product was vacuum-sealed and stored at 4°C for stability.

Production of Clay Pellets

Clay pellets were produced using a mixture of local natural clay and rice husk ash (RHA), a by-product known to enhance thermal insulation, porosity, and water retention in ceramics [8]. The clay was sun-dried, ground, and sieved (1 mm), then mixed with 10–20% RHA by weight.

The blend, adjusted to 25–30% moisture for plasticity, was extruded into cylindrical pellets (5–7 mm diameter, 8–12 mm length), air-dried for 48 hours, and fired at 850–900°C for 5 hours. This firing range ensures both structural integrity and internal porosity suitable for microbial retention [9].

The fired pellets showed good durability, dimensional stability, and 12–18% water absorption, making them ideal microbial carriers. Use of RHA also supports waste valorization and lowers carbon emissions compared to conventional clay products [10]. The resulting porosity further enables effective microbial coating and slow-release fertilizer delivery.

Plant Growth Trials

The plant growth trials were conducted to evaluate the agronomic efficacy of microbial-enriched compost powder (MECP) in enhancing crop performance, improving soil quality, and increasing yield. The experimental design followed a structured protocol incorporating Response Surface Methodology (RSM) with Box-Behnken Design (BBD) to optimize the proportion of three functional microbial groups within the compost formulation. Butterhead Lettuce was selected for testing due to its rapid growth cycle and sensitivity to soil amendments. The range and levels of the independent variables for microbial supplementation in compost powder on the growth of Butterhead Lettuce was shown in Table 1. The plant was harvested after 60 days, and the dry weight was analyzed.

Table 1 Levels, actual and coded experimental independent variables for a microbial-enriched compost powder on the growth of Butterhead Lettuce

Variables	Coding	Unit	Levels		
			-1	0	+1
Phosphate-solubilizing bacteria concentration	X_1	%w/w	0.1	0.4	0.7
Antagonistic bacteria concentration	X_2	%w/w	0.07	0.235	0.4
Nitrogen-fixing bacteria concentration	X_3	%w/w	1.3	2	2.7

Statistical Analysis

Data collected from the growth trials were subjected to statistical evaluation using Design-Expert® version 13 (Stat-Ease Inc., USA). The analysis employed ANOVA for a quadratic model to assess the significance of treatment effects ($p < 0.05$). Model fitness was verified using lack-of-fit tests, adjusted R^2, and predicted R^2 values. Key factors considered in the Box-Behnken Design included: X_1: Phosphate-solubilizing bacteria concentration (%), X_2: Antagonistic bacteria concentration (%), and X_3: Nitrogen-fixing bacteria concentration (%)

The primary response variable was shoot dry

weight, with leaf number and plant height as secondary indicators. Response surface plots (2D contour and 3D surface) were generated to visualize factor interactions and determine the optimal MECP composition. Tukey's HSD post hoc test was conducted to identify statistically significant differences between treatments. The application of RSM enabled the prediction of optimal microbial ratios, which were subsequently validated through experimental results to confirm model accuracy and agronomic relevance [6].

Product Feasibility and Scalability

The production process of the microbial compost powder-coated clay pellet system was evaluated under semi-pilot conditions to assess its scalability and practical applicability. All materials used—including base compost, microbial inoculants, and clay mixtures—were selected based on local availability, low cost, and compatibility with existing composting and ceramic processing lines.

The microbial compost powder was formulated using materials and equipment replicable at community-level composting units. The bio-coating process employed low-energy drying (<40°C), and spraying equipment commonly used in agricultural cooperatives, demonstrating potential for low-tech adoption. The use of clay pellets fabricated from rice husk ash and local clay supports circular economy principles, valorizing agricultural residues into functional carriers [8], [9], [10].

The feasibility of product scaling was also reflected in the modular nature of the production steps, which can be adapted to fit various production capacities, from small-scale farmer groups to industrial settings. Moreover, the technology is aligned with global trends in biobased inputs and soil health enhancement, promoting sustainable agriculture [11], [12].

The entire system was designed with the intention to minimize capital investment while maximizing biological efficacy, shelf-life stability, and ease of use in field conditions. These characteristics suggest strong potential for commercialization or adoption in regenerative farming practices, especially in tropical and subtropical regions.

RESULT AND DISCUSSION

Optimization Outcome

The microbial compost powder formulation optimization was successfully conducted using Box-Behnken Design (BBD) under the Response Surface Methodology (RSM) framework. The independent variables included the proportion of phosphate-solubilizing microorganisms, antagonistic microorganisms, and nitrogen-fixing microorganisms, while the response variable was plant dry weight (g) of butterhead lettuce.

The ANOVA results for the quadratic model (Table 2) revealed that the model was statistically significant ($p < 0.0001$) with a very high coefficient of determination, indicating that the model could explain over 99% of the variability in the observed dry weight. The adjusted R^2 (0.9827) and predicted R^2 (0.9254) were also in close agreement, confirming the reliability and predictive accuracy of the model. Additionally, the Adeq Precision value of 33.96 indicated a strong signal-to-noise ratio, exceeding the minimum threshold of 4, confirming model adequacy for navigating the design space [13].

Among the factors, nitrogen-fixing microorganisms showed the highest *F*-value, suggesting that nitrogen availability was a dominant driver of biomass accumulation. Phosphate-solubilizing microorganisms and antagonistic microbes also contributed significantly to dry weight, supporting prior findings that multifunctional microbial consortia synergistically improve nutrient uptake and plant health [11], [14].

Pure Error	0.0017	2	0.0008			
Cor Total	0.9351	14				
R^2	0.9938					
Adjusted R^2	0.9827					

Interaction effects between factors were also significant, suggesting that optimal growth depends on individual microbial inputs and their functional coordination in the rhizosphere. The contour and 3D plot (Fig. 1) visualizes the combinatorial effects of the three factors. The maximum predicted dry weight (2.84 g) was achieved at 0.7% phosphate-solubilizers, 0.23% antagonists, and 2.70% nitrogen-fixers. This formulation was selected as the optimal microbial

blend. The experimental validation of this combination produced a dry weight of 2.83 g, closely matching the predicted value and confirming the model's robustness.

These results reinforce that microbial synergy is pivotal in enhancing plant productivity. The observed improvements align with previous studies reporting that co-inoculation of nitrogen-fixing and phosphate-solubilizing bacteria significantly increases biomass in leafy vegetables [15]. Moreover, antagonistic microbes likely contributed indirectly by suppressing soil pathogens and enhancing root health, consistent with biofilm-based consortia performance [12], [16].

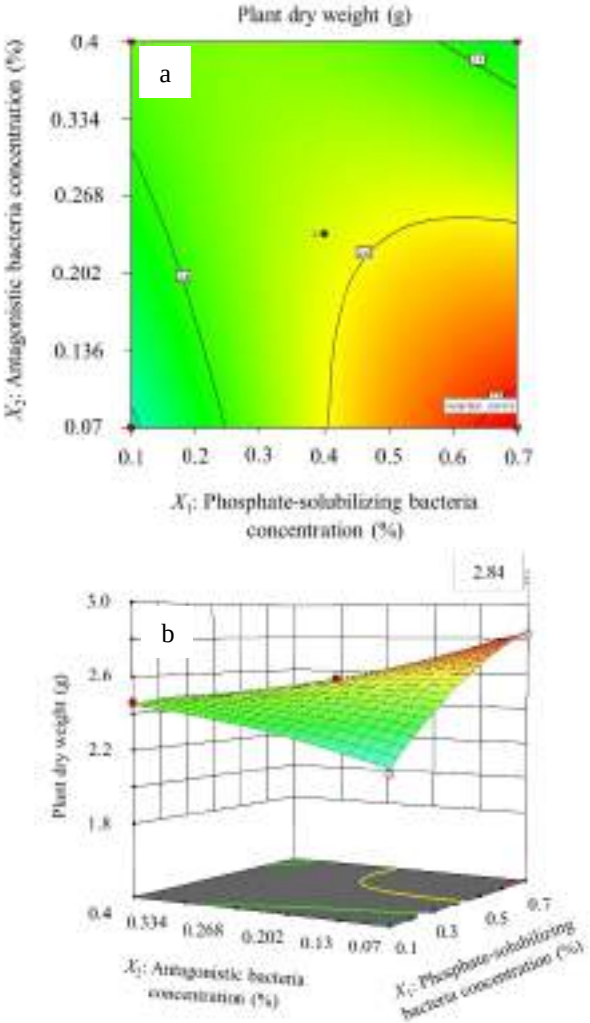

Figure 1 Response surface plots showing the effect of phosphate-solubilizing (X_1) and antagonistic bacteria (X_2) on plant dry weight. (a) Contour and (b) 3D surface plots. Maximum predicted weight (2.84 g) occurred at 0.7% X_1 and 0.235% X_2.

Application Potential Feasibility and Application Potential

The successful development of microorganism-enriched bio-coated clay granules (Fig. 2) marks a substantial advancement in designing scalable, sustainable, and low-cost biofertilizer delivery systems. These granules are engineered to function as a multifunctional carrier, offering mechanical support, prolonged microbial viability, and gradual nutrient release—thereby supporting improved plant growth and soil health.

The prototype was manufactured using readily available natural clay and agro-industrial residues, particularly rice husk ash (RHA), to produce a lightweight, porous matrix suitable for microbial adherence. The base material was extruded, sun-dried, and subsequently coated with the optimized microbial compost powder. The resulting granules displayed consistent shape, surface adhesion, and structural integrity, indicating their suitability for transportation, storage, and field application in tropical environments.

The development of bio-coated clay granules using microbial-enriched compost powder demonstrates high technical feasibility and market readiness. Its modular, low-energy production process—relying on locally available inputs such as rice husk ash and agricultural compost—supports cost-effective, community-level implementation.

From an economic perspective, the system minimizes production costs while enhancing crop yield, offering a favorable cost-benefit ratio compared to chemical fertilizers. This makes the product particularly attractive to smallholder farmers, eco-agriculture cooperatives, and organic growers seeking high-efficiency yet sustainable solutions [17], [18].

In terms of market potential, the product responds directly to global demand for bio-based, environmentally friendly soil amendments, aligning with circular economy and sustainable development frameworks [19]. Its multifunctional value—nutrient delivery, microbial support, and waste valorization—offers a competitive advantage in both local and export markets.

Moreover, alignment with policy trends such as SDG 12 and national biofertilizer promotion strategies enhances the prospect of regulatory integration and government support [20]. further enabling commercialization and scale-up.

The low-tech, modular production process demonstrates technical feasibility for community-based implementation without reliance on specialized equipment. The integration of locally sourced, biodegradable inputs and compost-derived

bioformulations also aligns with circular economy principles and sustainable agriculture goals. These features support potential adoption in both smallholder farming systems and eco-friendly commercial cultivation.

Fig. 2 presents the prototype of microorganism-enriched, bio-coated clay granules, produced from fired agri-waste clay blended with rice husk ash and coated with an optimized microbial compost powder. The background depicts shade-drying during mass production, while the inset highlights the granules uniform shape, coating integrity, and surface morphology, confirming their potential as a controlled microbial delivery system for sustainable agriculture.

Moreover, the system supports localized circular economy principles, as both the clay substrate and compost inputs are derived from agricultural by-products. This reduces waste while adding value to underutilized materials-contributing directly to SDG targets on sustainable consumption and production (SDG 12) [21].

Figure 2 Prototype of Bio-Coated Clay Granules with Microbial Compost Powder

Economically, the method of low-temperature drying and the use of gravity-based mixing and coating systems (rather than energy-intensive machinery) makes the technology accessible to smallholder farmer groups, rural entrepreneurship hubs, and eco-agricultural cooperatives. This is consistent with recent literature emphasizing the decentralization of biofertilizer production as a key strategy for ensuring accessibility in underserved regions [22]. From a biological perspective, the prototype effectively preserved the viability of microbial agents-including nitrogen-fixing, phosphate-solubilizing, and antagonistic strains-during coating and drying. When applied weekly over nine weeks in greenhouse trials, the granules demonstrated a sustained plant growth-promoting effect and improved soil properties. The use of a solid granular carrier ensures controlled release, improves root contact, and reduces microbial wash-off, which are commonly encountered challenges in liquid inoculant systems [23].

Given its promising agronomic response, low-cost production, and compatibility with small- and medium-scale farming systems, the bio-coated clay granule prototype presents strong potential for commercialization. Future studies should further explore shelf-life stability, mechanized pelletizing options, and field validation across multiple crop types. Technology also opens the possibility for product registration under national biofertilizer regulatory frameworks as highlighted in Yadav et al. [24], which could accelerate adoption and scaling.

CONCLUTION

This study successfully developed and optimized a microbial-enriched compost powder integrated with agri-waste-based fired clay granules to serve as a sustainable and scalable growing medium. The optimized formulation-comprising phosphate-solubilizing, nitrogen-fixing, and antagonistic microbes-significantly improved plant biomass and outperformed chemical fertilizer in controlled trials.

The production process is technically feasible, economically viable, and environmentally aligned, utilizing low-cost, locally available materials and low-energy techniques. Its modular design enables decentralized production and supports adoption by smallholder farmers and agricultural cooperatives.

Beyond agronomic benefits, the product offers strong market potential and policy relevance, aligning with global trends in sustainable agriculture, circular economy, and biofertilizer regulation. This innovation presents a promising platform for advancing regenerative farming and transforming agricultural residues into high-value inputs.

ABSTRACT

Japan is currently experiencing population decline due to a low birth rate and an aging society, raising concerns about the increasing extent of depopulated and uninhabited areas in the country. The aim of this study was to provide ecological insights into the management of infrastructure that has become infrequently used or abandoned due to this demographic decline and depopulation. As part of a broader investigation, we examined plant colonization and wildlife utilization of a paved road that had been left unused for approximately six years in Oita Prefecture, Kyushu Island, western Japan. The results showed that the absence of anthropogenic disturbance along the road resulted in 44.3% of the road surface being covered by vegetation. A total of 99 plant species (excluding 7 unidentified taxa) were recorded, including 39 woody species, with native species accounting for 93.9% of the species identified. Two-Way Indicator Species Analysis classified the vegetation into three distinct vegetation types. In addition, 10 mammalian species and four avian species were identified on the road, with native species accounting for 83.3%. Most animal activity occurred at night. No significant association was observed between vegetation type and wildlife use. However, the frequency of wildlife use was significantly higher on the abandoned road than on an adjacent road that remained in active use.

Keywords: Camera trap, Disused road, Infrastructures, Vegetation, Wild animal

INTRODUCTION

Japan's total population has been in decline since peaking in 2008, primarily due to persistently low birth rates and an aging population [1]. As a result, depopulated areas now comprise about 60% of the country's land area, and projections suggest that approximately 20% of currently inhabited areas will be uninhabited by 2050 [2,3,4]. This demographic shift is expected to accelerate the increase in infrequently used or abandoned forests, agricultural and residential land, and housing [3].

This underutilization of land has both social and ecological implications. Socially, negative outcomes include landscape deterioration [5,6], heightened risk of natural disasters [7], increased crime [8], and increased disruption of agricultural and daily activities associated with an increase in wildlife populations [8]. Ecologically, concerns have been raised about decreased biodiversity and ecosystem functions due to the expansion of bamboo forests [9], the conversion of grasslands into closed-canopy forests [10], dominance of certain species [11,12,13], reduction in understory vegetation by closed-canopy forests [14], and increased herbivory by deer [15]. However, the reduction of anthropogenic pressure on these areas may also have ecological benefits. For example, Inagaki et al. [16] and Ikegami et al. [17] have suggested that abandoned rice paddies and fallow fields function as diverse habitats and ecological compensation areas, including for threatened species. Similarly, Toivonen et al. [18] and Frenzel et al. [19] have reported that the cessation of grassland use has had the effect of increasing arthropod and avian diversity.

In addition to abandoned forests and farmland areas, the underutilization of infrastructure, such as railways and roads, has become increasingly common in depopulated and uninhabited regions of Japan [20-25]. How such infrastructure should be managed in the future is an extremely important challenge [20,21,22].

Therefore, the aim of this study is to provide ecological insights into the management of infrastructure that has become infrequently used or abandoned due to demographic decline and depopulation.

RESEARCH SIGNIFICANCE

Despite increasing recognition of land abandonment and infrastructure underutilization in depopulated regions, studies examining the ecological consequences of infrequently used or unused infrastructure remain limited. Existing research includes investigations on the relationship between abandoned railroads and pollinator communities [26], the effects of discontinued traffic on slope vegetation [27], and mammal use of forest roads (including unmanaged roads and roads that are

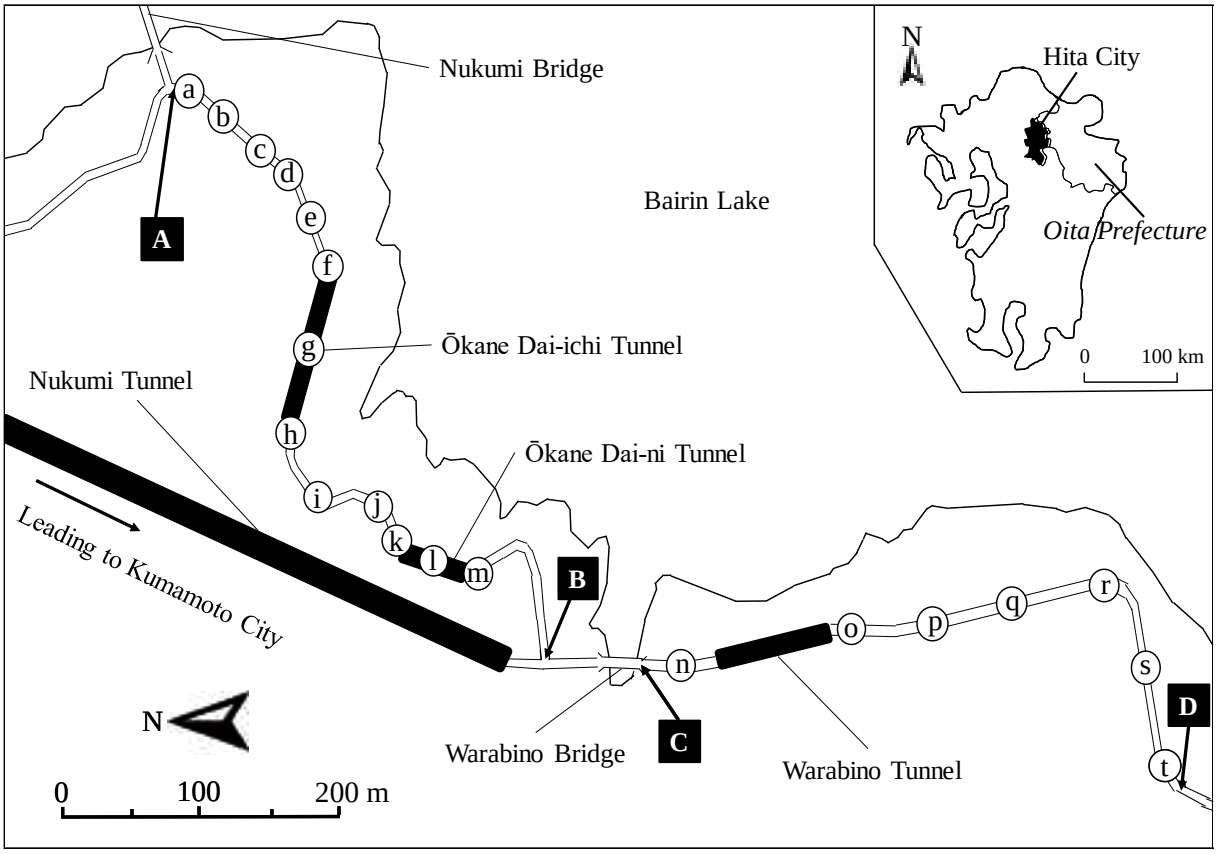

Fig.1 Schematic map of the study site

closed to traffic) [28]. The accumulation of empirical data on the interactions between unused infrastructure and natural ecosystems is considered to be extremely important for informing future management strategies. In this study, we investigated vegetation structure and wildlife utilization of an unmanaged paved road in Oita Prefecture, western Japan, approximately six years after it was closed.

SAMPLES AND METHODS

Study Site Overview

The study was conducted on Point A to Point D of Oita Prefectural Road 647 (Tochino-Nishi Oyama Route) running along Bairinko Lake in Hita City, Oita Prefecture (Fig.1). The section of road extending from Point A to Point B has a total length of about 600 m and has been closed to traffic since March 2014 due to the opening of the Nukumi Tunnel.

Survey Method

A total of 13 survey plots (a to m) were established at intervals of approximately 50 m between sections A and B (Fig.1). Surveys of vegetation and wild animal presence were conducted approximately 6 years after the cessation of road use.

Vegetation

In early October 2020, a quadrat measuring 15 m ×7 m (equal to the width of the road) was established at each survey plot. All vascular plant species present within each quadrat were recorded. Plant coverage, i.e., the percentage of road surface covered by the living plants, and total surface coverage, i.e., the percentage of the road surface covered by living plants, dead plants, fallen leaves and branches, and sediment, were estimated using the Braun-Blanquet cover-abundance scale [29]. Cover class values were converted to median percentages as follows: class r and + = 0.1%, 1 = 5.0%, 2 = 17.5%, 3 = 37.5%, 4 = 62.5%, and 5 = 87.5%. Each survey plot was classified into vegetation types by Two-Way Indicator Species Analysis (TWINSPAN) based on species presence/absence. For plots where no vegetation was observed, a fictitious species labeled “no vegetation” was assigned to enable inclusion into the analysis [29, 30]. Pearson’s $\chi 2$ tests were performed where appropriate. Statistical analyses were performed using PC-ORD ver. 4.25 (MjM Software Design) and SPSS Statistics ver. 27 (IBM).

Wildlife

Automatic cameras (TREL20J; GISupply) were installed at each of the 13 survey plots (a-m) to monitor wildlife activity. The monitoring was done

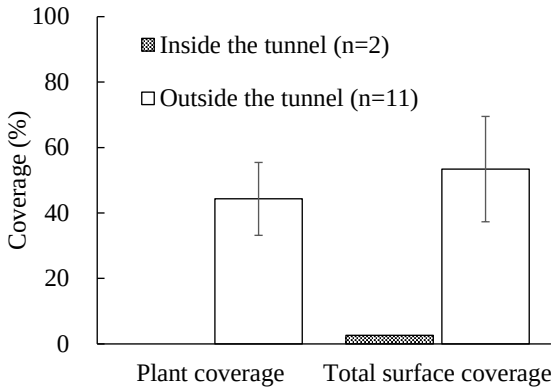

Fig.2 Plant coverage and total surface coverage (including dead plant material, litter, and sediment) in survey plots located inside and outside the tunnel

over two periods: from October 16 to October 28, 2020, and from November 13 to December 4, 2020 (Fig.1). Camera deployment, image acquisition, and data processing were performed as described by Tsukada et al. (2006) [31], Fujii et al. (2016) [32], and Kotani et al. (2016) [33].

Cameras were operated continuously throughout each survey period. The infrared sensor was set to trigger at 15-second intervals between activations. Sensor sensitivity was set to “low” for all plots except for plots located within tunnel sections (g and l), where sensitivity was set to high. For data analysis, multiple images of the same species captured within a 30-minute interval, or multiple individuals of the same species captured in the same frame, were treated as a single detection event. The total number of such detection events were treated as the number of effective images. The Relative Abundance Index (RAI) was then calculated using Eq. (1).

$$RAI = (Pn/(Cn \times Cd)) \times 100 \quad (1)$$

Where Pn is the number of effective shots, Cn is the number of cameras, and Cd is the number of camera operation days.

In addition to the 2020 surveys, a second survey was conducted in 2021 during the same periods, i.e., from October 16 to October 28 and from November 13 to December 4.

Automatic cameras were installed at seven locations (a, c, e, h, i, k, and m) between Points A and B along the closed road using the same method employed in the previous year (Fig.1). For comparison, an additional seven control plots (n to t) were established along an adjacent road section of approximately 600 m between Points C and D, where the road remains in regular use (Fig.1). To avoid excessive image capture triggered by vehicular traffic in the control plots, which would deplete the camera's

Photo 1 Road surface covered by such as vegetation, fallen leaves and sediment from experimental section A to B

battery and memory, the cameras were set to operate on a timer between 18:00 and 06:00.

Analyses were performed using a two-way analysis of variance (two-way ANOVA) without replication on square root-transformed values, and Tukey's HSD test, Mann-Whitney U test. Analyses were carried out using SPSS Statistics ver. 27 and R ver. 4.2.1.

RESULTS

Plant and Sediment Intrusion

Plant coverage and total surface coverage (including dead plant material, litter, and sediment) in the survey plots, both inside and outside the tunnel sections, are shown in Fig. 2. Within the tunnel, plant coverage and total coverage were 0.0% and 2.6%, respectively, indicating no vegetation establishment and minimal accumulation of organic debris or sediment. In contrast, plots located outside the tunnel sections exhibited a mean plant coverage of 44.3% and total coverage of 53.4%, suggesting that approximately half of the road was covered with vegetation and sediment (Fig.2, Photo 1).

Vegetation

A total of 99 plant species were identified across all of the survey plots, excluding seven unidentified taxa (Table 1). In addition to herbaceous species,

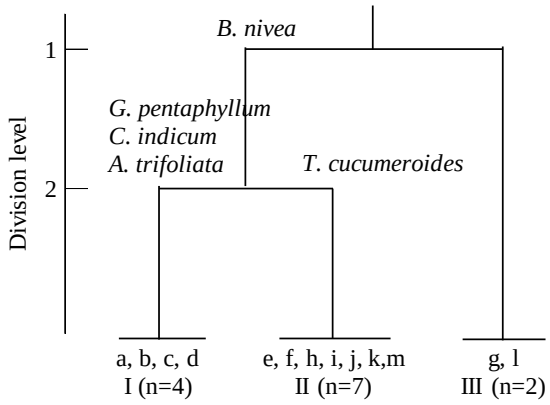

Fig.3 Classification of vegetation types based on Two-Way Indicator Species Analysis

including 42 perennials, 39 woody species were also recorded. Native species accounted for 93.9% of the total flora. No species listed as endangered by the Ministry of the Environment or regional authorities were observed.

TWINSPAN revealed that the survey plots were broadly classified into three vegetation types (Types I to III; Fig.3). Type III comprised two plots in the tunnel sections (g and l), where no vegetation was observed and only the notional “no vegetation” species was recorded. This classification is consistent with the absence of plant establishment shown Fig 1.

Type I included four plots (a, b, c, d) with a total of 61 species. The indicator species for this group was *Gynostemma pentaphyllum* (Thunb.) Makino. In addition, 22 species were unique to this type, including *Chrysanthemum indicum* L., *Akebia trifoliata* (Thunb.) Koidz., *Neolitsea sericea* (Blume) Koidz., *Pleioblastus argenteostriatus* (Regel) Nakai, and *Polystichum falcatum* (L.f.) Diels (Table 1). Type II consisted of seven plots (e, f, h, i, j, k, m), in which 84 species were recorded. The indicator species was *Trichosanthes cucumeroides* (Ser.) Maxim., and 45 species were unique to this type, including *Artemisia indica* Willd., *Rubia argyi* (H.Lév. et Vaniot) H.Hara, and *Trichosanthes kirilowii* Maxim. (Table 1). There were no significant differences between Type I and Type II in the proportion of native versus non-native species ($\chi 2 = 2.56$, df = 1, P = 0.11) or in the proportion of herbaceous versus woody species ($\chi 2 = 0.44$, df = 1, P = 0.84). A total of 39 species were shared between Types I and II. Of these, six species, i.e., *Boehmeria nivea* (L.) Gaudich., *Paederia foetida* L., *Miscanthus sinensis* Andersson, *Commelina communis* L., *Deutzia crenata* Siebold, and *Boehmeria spicata* (Thunb.) Thunb., exhibited high frequency of occurrence, with presence in more than 80% of plots in both types (Table 1).

Table 2 Relative Abundance Index (RAI) of wildlife species by vegetation type

Species	Vegetation type		
	I (n=4)	II (n=7)	III (n=2)
Nyctereutes procyonoides	64.4	43.3	12.1
Vulpes vulpes	17.4	16.5	3.0
Sus scrofa	13.6	18.2	-

*; Non-native species
See Fig. 3

Wildlife

Relationship between vegetation type and RAI

In the 2020 survey, a total of 10 mammalian species, including *Nyctereutes procyonoides* viverrinus, *Vulpes vulpes* japonica, *Sus scrofa* leucomystax, and 4 avian species, including *Streptopelia orientalis* and *Syrmaticus soemmerringii*, were recorded across all survey plots (Table 2, Photo 2-A, B and C). Although non-native species, such as *Procyon lotor* and Felis catus were also identified, native species accounted for 83.3% of all identified taxa. No species listed as endangered by the Ministry of the Environment or regional authorities were identified.

No significant differences in wildlife occurrence were observed between vegetation Types I and II. However, both Type I and II differed significantly from Type III (two-way ANOVA, P<0.01). In addition, the mean RAI was significantly lower in Type III than in Types I and Type II (Tukey's HSD test, P<0.01).

Relationship between time of day and RAI

The hourly RAI values are shown in Fig 4. Between 06:00 and 18:00, RAI values ranged from 0.7 to 2.8. However, a marked increase was observed during the nighttime period (18:00 and 06:00), with RAI values ranging from 9.3 to 24.2, indicating that most wildlife activity occurred during nocturnal hours.

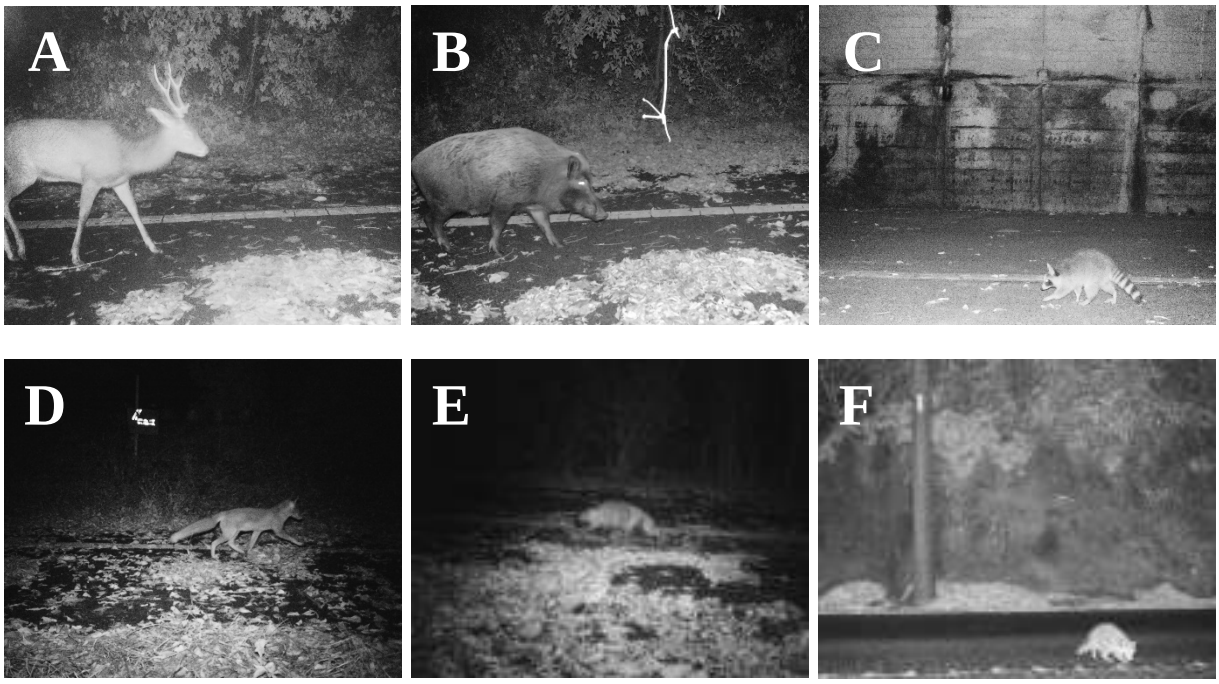

Photo 2 Examples of the wildlife recorded by automatic cameras in this survey

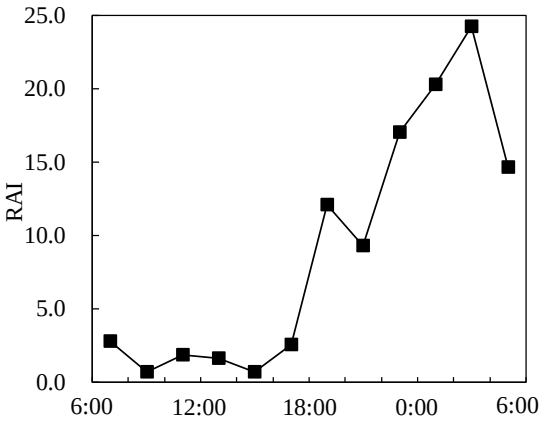

Fig. 4 Relative Abundance Index (RAI) of wild animals by time period

0.7 to 2.8. However, a marked increase was observed during the nighttime period (18:00 and 06:00), with RAI values ranging from 9.3 to 24.2, indicating that most wildlife activity occurred during nocturnal hours.

Relationship between presence/absence of traffic and RAI

In the 2021 survey, a total of nine mammalian species and four avian species were identified in the closed-road plots (a, c, e, h, i, k, and m; Sections A to B) (Fig.1, Table 3, Photo 2-D and E). In contrast, only two mammalian species were identified along the road that remained in use (n to t; Sections C to D) (Fig.1, Table 3, Photo 2-F).

A significant difference in wildlife occurrence was observed between closed-road and open-road sections (two-way ANOVA, $P<0.01$). The mean RAI was also significantly higher in the closed-road plots than in the open-road plots (Mann-Whitney U test, $P<0.01$).

The wildlife composition and its proportion of native species in both sections were generally comparable to those recorded in the 2020 survey (a to m; total of 14 plots). As in the previous year, no species listed as endangered by the Ministry of the Environment or by local authorities were identified.

DISCUSSION

Encroachment of Plants and Sediment into Paved Roads That Are No Longer in Use

The results showed that, after approximately six years of closure, a substantial portion of the road surface became covered by vegetation, fallen leaves, branches, and sediment (Fig.2). These findings suggest that periodic road maintenance, such as weeding (typically conducted once or twice a year in this area), as well as vehicular traffic, play important roles in preventing plant colonization and sediment deposition. In other words, in the absence of human disturbance, even paved road surfaces are colonized by vegetation and subject to sediment deposition over a relatively short timescale. Similar results were

Table 3 Relative Abundance Index (RAI) of wildlife species in closed road sections and open road sections

Species	Open road sections (n=7)	Closed road sections (n=7)
Nyctereutes procyonoides	82.4	-
Procyon lotor *	41.6	1.1
Vulpes vulpes	18.4	-
Cervus nippon	16.3	-
Meles anakuma	14.4	-
Felis catus *	11.9	-

Average RAI	16.3	0.2

*; Non-native species

reported by Uchida et al. [34] along disused railroad tracks. The findings of this study suggest that in the absence of weed control, plants rapidly invade roads and become established. Furthermore, that study reported that train operation exerted a suppressive effect on plant invasion and growth.

In contrast, vegetation establishment and sediment accumulation were not observed in the tunnel plots (Fig.2), indicating that tunnels are highly effective in preventing both external inflows of sediment and the establishment of vegetation through shading.

Established Vegetation

The cessation of vehicular traffic led to the colonization and establishment of a diverse variety of plants at the study site (Table 1). The included flora consisted of a higher proportion of perennial species compared to ephemeral taxa (i.e., annuals and biennials), and as well as many woody plants, suggesting that succession is somewhat advanced. Although no species of conservation value were observed, the majority of the species were native (Table 1). This may reflect the later stages of succession, since many non-native species commonly invading anthropogenic environments in Japan are light-demanding and generally less tolerant of shade [35].

Excluding the tunnel plots, the survey plots were broadly classified into two vegetation types, each characterized by distinct species assemblages (Fig.3, Table 1). The reason for this is not obvious, but the spatial continuity of survey plots within each vegetation type suggests that local site conditions, such as slope orientation, light availability, and soil moisture, may strongly influence vegetation structure. Of particular interest is the substantial overlap in species composition between the vegetation types. Several species, including *Boehmeria nivea* (L.) Gaudich., *Paederia foetida* L., *Miscanthus sinensis* Andersson, *Commelina communis* L., *Deutzia crenata* Siebold, and *Boehmeria spicata* (Thunb.) Thunb., were commonly recorded across both types and exhibited high frequencies. These species may be regarded as representative of vegetation developing on underutilized or abandoned roads in the region and could serve as indicator species for future road management.

Wildlife Utilization

Although the roads targeted in this study were not used by endemic or endangered species, many wild animal species were found to use these roads mainly at night (Table 2, Fig.4, Photo 2). Wildlife occurrence and abundance were significantly higher on unused roads compared to adjacent roads in active use (Table 3), suggesting that the elimination of anthropogenic disturbance, facilitates increased wildlife utilization. No significant relationship was observed between vegetation Types I and II (excluding tunnels) and the presence or abundance of wild animal species (Table 2), further suggesting that the absence of vehicular traffic was the primary factor affecting wildlife use.

One notable finding from this study is the detection of wild animals in the tunnels, despite the absence of vegetation and limited environmental complexity (Table 2, Photo 2-C). Although usage was lower than that in open sections, this represents one of the few documented cases of animal activity in disused road tunnels. Whether this reduced usage results from the absence of vegetation, limited light, or avoidance behavior related to the enclosed structure remains unclear (Table 2). Recently, ecosystems that have no historical precedent, such as ecosystems with artificial spaces, have been referred to as 'novel ecosystems' [36,37,38]. In light of the establishment of vegetation and the use of wildlife on paved roads (including tunnels) that are no longer used, such as the sites described above, the underutilized infrastructure described in this study could be considered a novel ecosystem.

In one of the few reports on the effects of infrequently used or unused infrastructure on local ecology, Suzuki et al. (2023) [28] reported that mammalian species composition along forest roads

varied according to road usage, and Arase et al. (2019) [27] demonstrated differences in slope vegetation associated with the presence or absence of road traffic. Dylewski et al. (2021) [26] reported that abandoned railway corridors supported greater abundance and diversity of pollinator communities than the adjacent grasslands. We believe that the results of this study corroborate these reports and offer new ecological insights for dealing with infrequently used or unused infrastructure.

Finally, it should be noted that in the 2021 control plots, camera operation was limited to nighttime hours (18:00 to 06:00) to avoid triggering by vehicular traffic (Table 3). However, given that the majority of wildlife activity occurred during this time period (Fig.4), this limitation is unlikely to have substantially affected comparisons with the continuously monitored plots.

CONCLUSION

The objective of this study was to provide ecological insights into the consequences of infrequently used or unused infrastructure. We investigated vegetation development and wildlife utilization of a paved road that had been unmanaged for approximately six years. The following findings were obtained. First, it was shown that even paved roads, when no longer subject to anthropogenic disturbance, can become covered with vegetation and sediment within a relatively short period of time. Second, the vegetation established on the paved road included not only ephemeral species but also perennial and woody species, indicating the progression of succession. Third, more wild animal species and individuals were observed on the road that was no longer in use compared to a road that remained in use. This difference was primarily attributed to the absence of vehicular traffic, rather than to differences in vegetation. Fourth, while tunnels are highly effective in preventing sedimentation and vegetation establishment on roads that are no longer used, they are also often used by some wild animals. Fifth, disused roads such as the one examined in this study could be considered as an example of a novel ecosystem.

A key future challenge is how to deal with infrequently used or unused infrastructure, which is increasing due to the accelerating aging of the population and declining birthrate. Despite the growing extent of such areas, ecological research on the effects of underused infrastructure remains limited. The findings reported here are therefore important in considering how such spaces should be managed in the future.

Of particular interest in this study was the finding that wild animals actively used disused roads and tunnels. Future research is needed to clarify the purpose of this use, such as for migration, foraging, or resting, and to examine the relationship between wildlife activity and the degree of vegetation succession on roads that have remained abandoned for longer periods of time.

ACKNOWLEDGMENTS

We thank the Hita Civil Engineering Office of Oita Prefecture for their cooperation in carrying out this study. We are also grateful to all individuals and organizations who contributed to the successful completion of the research.

[2]Department of Engineering, King Mongkut's Institute of Technology Ladkrabang Prince of Chumphon Campus, Chumphon, Thailand

ABSTRACT

This study focuses on groundwater recharge estimation and site identification for Managed Aquifer Recharge (MAR) in Suphanburi, Thailand, an agriculturally intensive region increasingly affected by floods and droughts. An integrated approach combining Geographic Information Systems (GIS), water balance analysis, and groundwater simulation using Visual MODFLOW was applied to assess recharge potential. Key factors, including land use, slope, and hydrogeology, were analyzed to delineate 5 suitable recharge zones. Field data from 13 observation wells collected between 2014 and 2024 were used to calibrate and validate the groundwater model. The model has high accuracy with R^2 values of 0.983 (calibration) and 0.992 (validation), and normalized RMSEs of 5.97% and 5.20%, respectively. The result showed that the highest recharge rates were 343.42 and 320.39 m^3/day, observed in urban and industrial zones near the Tha Chin River, with capacities sufficient to support over 1,600 people. This research provides a practical and replicable framework for MAR site selection and implementation, supporting data-driven water management strategies in flood and drought-prone regions.

Keywords: Groundwater Recharge Estimation, Water Resource Management, Flood and Drought, Site Identification, Managed Aquifer Recharge (MAR)

INTRODUCTION

Floods and droughts are recurrent and persistent challenges throughout Thailand, particularly in lowland areas adjacent to the mountainous regions of the central plains. These regions are characterized by steep topography, which exacerbates flash floods and recurring water-related disasters. Conventional solutions have proven insufficient in providing long-term resilience. In response, both governmental and private sectors have increasingly adopted water management approaches inspired by the late King Bhumibol Adulyadej's Sufficiency Economy Philosophy. This research directly addresses this critical gap by developing a scientifically robust and practically applicable Managed Aquifer Recharge (MAR) to support adaptive water resource management in vulnerable regions. These systems aim to capture and store excess rainwater during the wet season for use in the dry season, thereby simultaneously mitigating flood and drought risks with minimal financial investment and environmental disruption.

The concept of MAR has gained international recognition as a strategic response to water resource variability [1], [2]. In the United States, particularly in California, Arizona, and Texas, large-scale MAR such as the Kern Water Bank have been successfully implemented to stabilize water supplies for agriculture and urban use during multi-year droughts [3]. Israel and Australia have incorporated MAR into national water strategies, especially in arid and semi-arid zones, using techniques such as infiltration basins, injection wells, and riverbank filtration to enhance groundwater reserves [4], [5]. In India, particularly in the drought-prone state of Rajasthan, community-based MAR projects have demonstrated significant benefits in improving aquifer recharge, water quality, and agricultural productivity [6]. China also invested in artificial recharge programs as part of their national water sustainability frameworks [7], [8]. These global experiences underscore the scalability and adaptability of groundwater recharge to diverse climatic, geological, and socio-economic contexts.

In Thailand, MAR initiatives have been explored by agencies such as the Thai Department of Groundwater Resources (DGR) and the National Water Resources Officer (NWRO). Several pilot studies have been conducted to assess groundwater recharge feasibility in agriculturally intensive areas. Notable examples include MAR studies in Sukhothai, Lamphun, Phichit, and Kamphaeng Phet. However, these projects have often lacked continuity and have not yet been implemented systematically or on a scale. Moreover, previous studies primarily focused on engineering feasibility without fully integrating spatial analysis or mathematical modeling.

The study addresses this gap by developing a comprehensive groundwater recharge model tailored

to the Kra Seaw Reservoir area in Suphanburi Province, a region that frequently experiences extreme variations in water availability. The model utilizes hydrogeological data, GIS, and MODFLOW to simulate recharge potential and optimize aquifer storage strategies. The goal is to enhance water security, agricultural resilience, and long-term resource planning in flood and drought affected zones.

Ultimately, this study aims to provide a scientific basis for MAR implementation by integrating hydrological modeling, water balance assessments, and community-oriented resource planning. It aspires to serve as a decision-support tool for policymakers, water managers, and researchers working toward sustainable water resource management in Thailand and other similar geographic settings.

RESEARCH SIGNIFICANCE

This research aims to offer a practical solution to the water problems in Suphanburi, where floods and droughts often cause serious challenges. The recharge estimation and site identification for MAR was designed to store excess rainwater underground during the rainy season and make it available during dry periods. This helps reduce both water shortages and flooding in local communities.

WATER BALANCE APPLICATION

A water balance approach is essential to understand how much water enters, leaves, and is stored in a given area over time. This is especially important for designing and evaluating a groundwater recharge system, where the goal is to store excess water underground during wet periods and retrieve it during dry seasons [9], [10]. The water balance provides a systematic way to estimate available water resources and determine how much can be recharged into aquifers without causing negative effects.

The water balance in this study is divided into two key components: surface water balance and groundwater balance.

The surface water balance considers rainfall, runoff, evapotranspiration, and recharge to groundwater. The equation as shown in (1)

$$P = ET + S_R + R \pm \Delta V \quad (1)$$

Where P is total precipitation (rainfall) in unit mm., ET is evapotranspiration in unit mm., S_R is surface runoff in unit mm, R is groundwater recharge in unit mm. and ΔV is change in soil moisture or surface water storage in unit mm.

The groundwater system is analyzed separately to track how much water is added, used, and stored below ground. The groundwater balance equation as shown in (2)

$$R = G + D + W \pm \Delta S \quad (2)$$

Where R is groundwater recharges in unit mm., G is groundwater flow out of the system in unit mm., D is deep drainage to lower aquifer layers in unit mm., W is pumping or groundwater use in unit mm. and ΔS is change in groundwater storage in unit mm.

In the context of this study, the water balance is calculated on a monthly basis to reflect seasonal rainfall and groundwater fluctuations. However, the long-term trends are analyzed on an annual scale to evaluate sustainability. This approach ensures that the groundwater recharge will operate effectively, prevent land subsidence, and avoid environmental damage.

STUDY AREA

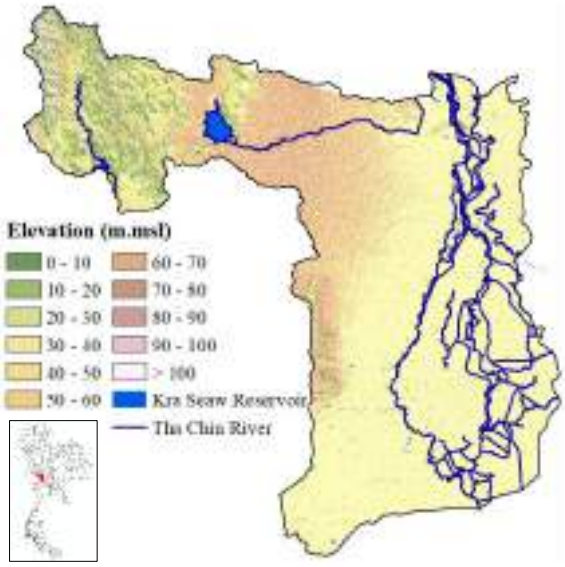

Fig.1 Location and slope in Suphanburi [11]

Suphanburi located in the central region of Thailand. The area was selected due to its high agricultural importance and frequent exposure to both drought and flood events. Suphanburi is also home to key water resources infrastructure, including the Kra Seaw Reservoir and the Tha Chin River, which play central roles in local water management. It far approx. 107 km. northwest of Bangkok. The province covers an area of about 5,358 km^2. It borders Chai Nat and Uthai Thani to the north, Nakhon Pathom to the south, Ang Thong and Ayutthaya to the east, and

Kanchanaburi to the west.

The terrain is mostly flat and consists of low-lying alluvial plains, which are well suited for rice farming and other agricultural activities. The western part of the province, especially Dan Chang, is characterized by rolling hills and forested areas. Elevation ranges from 10 to 400 meters above sea level, with higher terrain in the west and flatter plains to the east, Fig. 1.

Geology and Hydrogeology

The geology is predominantly composed of sedimentary rocks, including sandstone, limestone, shale, and chert, dating back to the Paleozoic–Mesozoic era. In the western regions, such as Dan Chang, igneous rocks like granite and basalt are also found. These geological conditions influence groundwater movement and aquifer characteristics [12].

The Hydrogeology is both unconfined and confined aquifers, particularly in the Tha Chin River basin, where groundwater yield exceeds 2 m^3/hr. in many locations. The aquifers are suitable for artificial recharge due to their permeability and storage capacity [13].

Climate

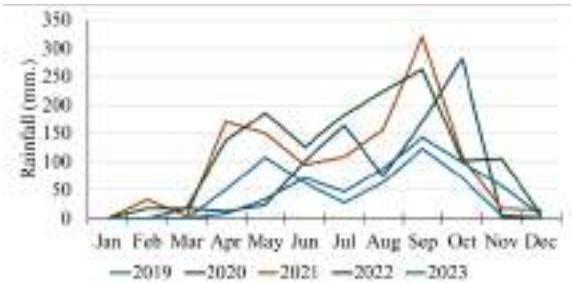

Fig.2 Annual rainfall in Suphanburi

According to Thai Meteorological Department, Suphanburi is in a tropical zone, with three seasons, summer season in February to May, rainy season in June to October and winter season in November to January [14]. Rainfall data from 2019 to 2023 shows high variability. Peak rainfall occurs from August to October, while the driest months are January to March. In recent years, irregular rainfall patterns—including prolonged dry spells and sudden heavy downpours—have been observed, indicating the growing influence of climate change on local hydrology.

Land Use and Groundwater Recharge

Land use plays a critical role in determining the feasibility and effectiveness of MAR. Different land types vary significantly in terms of their infiltration capacity, surface runoff generation, and soil permeability, all of which influence how much water can enter and be stored in underground aquifers.

According to Thai Land Development Department [11], Suphanburi, land use is predominantly agricultural, with other significant uses including forests, built-up urban areas, and water bodies. The major land use categories and their implications for groundwater recharge are described as followed [15].

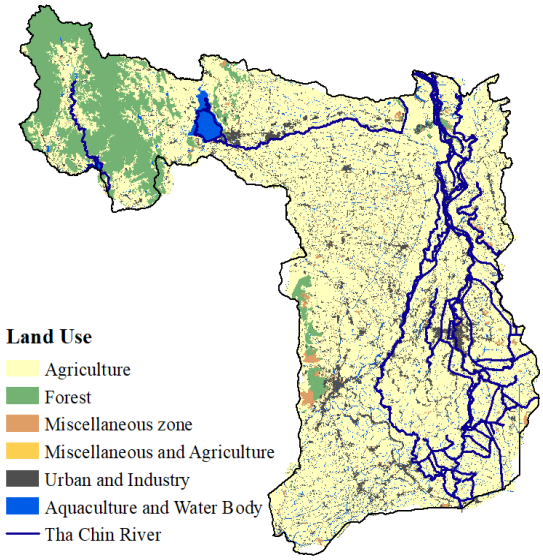

Fig.3 Land use in Suphanburi [11]

Agricultural areas (74.3%)—especially rice fields and field crops—cover the largest portion of the province. These lands typically have compacted soil due to plowing and machinery, which may limit natural infiltration. However, with appropriate soil management and recharge design (e.g., recharge ponds, infiltration basins), these areas can serve as viable recharge zones. Unused plots or fallow fields may offer better infiltration potential during off-seasons. Rice paddies may contribute to shallow recharge but are limited due to frequent waterlogging. Field crops (e.g., sugarcane, maize) have better potential for infiltration if combined with recharge structures.

Forest areas (12%), especially in the western highlands of Dan Chang District, offer high natural infiltration due to deep root systems and less surface sealing. These areas are ideal for natural recharge processes and can be preserved or enhanced as buffer

zones for groundwater replenishment. Forested land contributes to low surface runoff and helps stabilize the local hydrological cycle.

Urban and industrial zones (8.3%), including roads, buildings, and paved surfaces, have low infiltration capacity and generate high surface runoff. These areas are unsuitable for natural recharge but can still support artificial recharge through engineered solutions like injection wells, recharge shafts, or stormwater harvesting systems. In densely populated areas, care must be taken to avoid contamination risks.

Aquaculture and Water Bodies (3.5%), such as ponds, lakes, and irrigation canals can act as recharge reservoirs if they are hydraulically connected to the underlying aquifer. Some areas may allow recharge through percolation, especially if the base is unlined or partially permeable. However, these zones typically have limited recharge capacity without modification.

Miscellaneous zone (1.9%), found at the edges of agricultural zones or near forested hills. Depending on soil type and topography, they may provide good potential for recharge basin development, particularly if located above permeable aquifers.

In this study, land use data was used to classify recharge zones and assign recharge rates for simulation in the Visual MODFLOW model. Forested and agricultural areas were prioritized for MAR development due to their favorable infiltration characteristics. Urban and industrial zones, while limited in natural recharge capacity, were considered for technical interventions like injection wells or treated wastewater reuse.

METHODOLOGY

This study followed a structured approach combining field data, spatial analysis, and numerical modeling to design and evaluate a recharge estimation and site identification for MAR for Suphanburi. The main steps included data collection, conceptual model development, numerical simulation using Visual MODFLOW, model calibration, and scenario analysis.

Grid Design

Based on field conditions and geological structure, the study area was divided into two aquifer layers Upper layer: Unconfined aquifer (shallow groundwater) and Lower layer: Confined aquifer (deep groundwater).

The grid was divided into a uniform grid of 1×1 km^2 cells, resulting in 12,204 cells (108 columns × 113 rows). Each grid cell was assigned physical and hydraulic properties based on field data and soil classification.

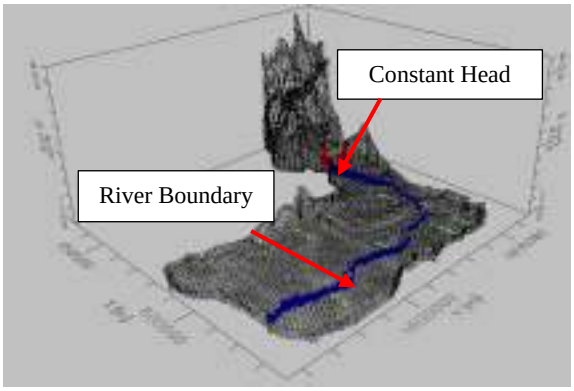

Fig.4 Numerical modeling for Suphanburi.

Assigning Aquifer Parameters

Key hydrogeological parameters were defined based on soil surveys and groundwater studies i.e. Hydraulic conductivity (K), Specific yield (Sy) for unconfined aquifers, Specific storage (Ss) for confined aquifers as show in Fig. 5 and Table 1.

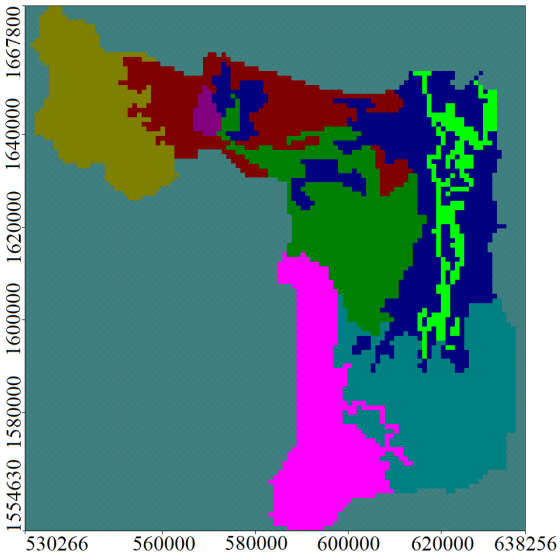

Fig.5 Input parameter zone

Table 1 Hydraulic Conductivity Values

No.	K_x and K_y (m/s)	K_z (m/s)	S_s
	1.0×10^{-6}	1.0×10^{-9}	1.6×10^{-4}
	1.0×10^{-7}	1.0×10^{-10}	1.0×10^{-5}
	5.0×10^{-6}	5.0×10^{-9}	2.0×10^{-4}
	1.1×10^{-6}	1.1×10^{-9}	5.0×10^{-5}
	7.5×10^{-6}	7.5×10^{-9}	1.6×10^{-4}
	1.0×10^{-2}	1.0×10^{-5}	2.0×10^{-4}
	1.0×10^{-5}	1.0×10^{-8}	2.0×10^{-4}
	1.0×10^{-3}	1.0×10^{-6}	5.0×10^{-5}

Recharge Estimation

Groundwater recharge rates were estimated using

a land-use-based recharge coefficient approach. Different recharge percentages were assigned based on land use types as shown in Fig.6 and Table 2.

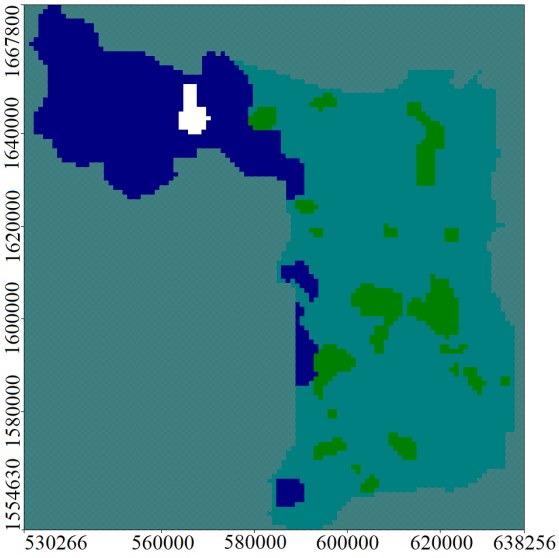

Fig.6 Location of recharge estimation

Table 2 Recharge Estimation Value

No.	Land Use Type	Percent of Rainfall (%)
	Forest	8
	Agriculture	4
	Urban and Industrial	1
	Water Body	0

Model Calibration and Verification

The model was calibrated by adjusting key parameters (hydraulic conductivity and recharge rate) to minimize the difference between simulated and observed groundwater levels. Groundwater data from 13 observation wells were used to calibrate the model. The calibration aimed to achieve: Normalized Root Mean Square Error (*RMSE*) below 10% of observed values and high correlation (R^2 > 0.9) between simulated and observed heads

Sensitivity Analysis

To assess the model's reliability, a sensitivity analysis was performed by adjusting key parameters (±25%, ±50%, ±75%) and observing the impact on groundwater levels [16], [17]. This helped identify which variables had the greatest influence on model output and supported more accurate prediction under future scenarios.

Site Identification

Finally, the model was used to simulate the impact of artificial recharge in five selected zones over a 5-year period (2025–2030). Changes in storage, inflow, and outflow were monitored using the Zone Budget tool in Visual MODFLOW. These simulations helped determine the effectiveness of groundwater recharge in suitable location followed by Tanachaichoksirikun [18].

RESULTS AND DISCUSSION

Calibration and Verification Results

The model was calibrated using data from 13 observation wells across the province in 2014-2019. The comparison between observed and simulated groundwater levels showed strong agreement i.e., Root Mean Square Error (*RMSE*) was 1.28 m, Standard Error (*SE*) was 0.32 m, Normalized *RMSE* was 5.97% and correlation coefficient (R^2) was 0.983. The verification results using data from 13 observation wells across the province in 2020-2024 was *RMSE* was 1.18 m, *SE* was 0.34 m, Normalized *RMSE* was 5.20% and correlation coefficient (R^2) was 0.992. These values confirm that the model reliably represents groundwater behavior and can be used for scenario simulations [19], [20].

Sensitivity Analysis Test

Sensitivity tests showed that hydraulic conductivity had the greatest influence on groundwater levels, followed by recharge rates. Changes of ±25%, ±50%, and ±75% in hydraulic conductivity caused noticeable shifts in water levels, indicating the importance of accurate field measurement of aquifer parameters.

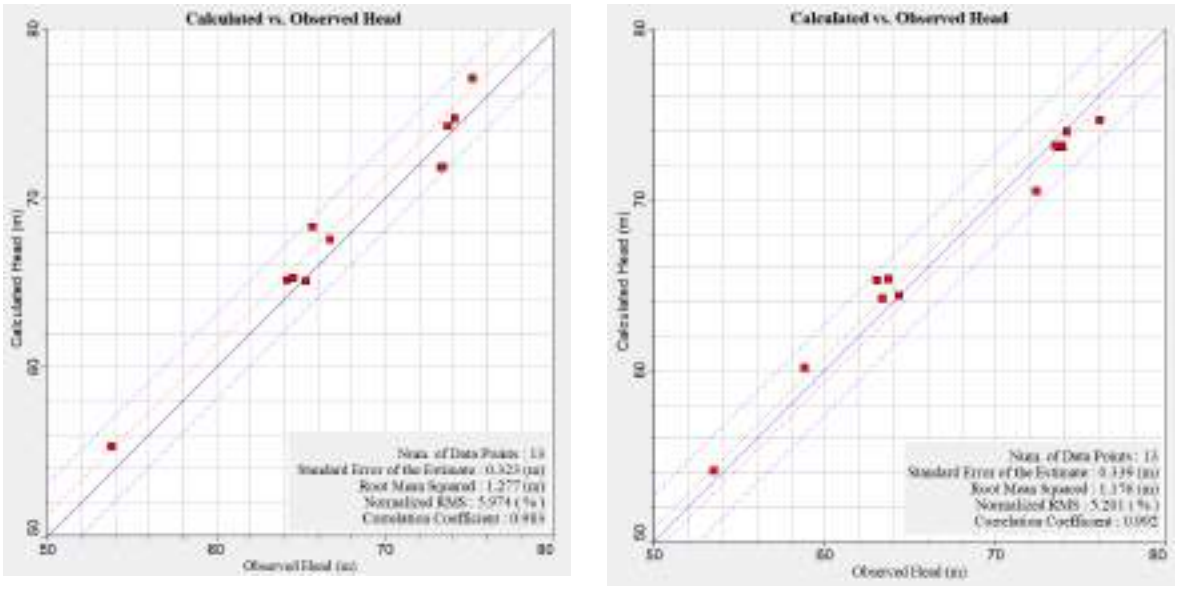
Scenario Simulations

Locations were selected to test the groundwater budget under artificial recharge conditions over a 5-year simulation period (2025–2030).

The result revealed that Tha Chin River Basin and Urban and Industry experienced positive water storage gains, indicating effective recharge into aquifers. Dan Chang, U Thong, and Pho Phraya zones showed little or no net recharge, due to either low permeability, high extraction rates, or unsuitable geology. This confirms that not all areas are equally suitable for groundwater recharge, and site selection must consider hydrogeological compatibility.

Recharge Volumes and Beneficiaries

In 2025-2030, the groundwater recharge simulation estimated the following recharge volumes, including, Tha Chin River area was 320.39 m^3/day



(a) Calibration (b) Verification

Fig.7 Calibration and verification results

Table 3 Groundwater Recharge Volume and Beneficiaries

Location	Recharge Volume (m^3/day)	Recharge Volume (liters/day)	Water Use per Person (liters/day)	Estimated Number of Beneficiaries(people/day)
Tha Chin River	320.39	320,39	200	1,601.95
Urban and Industry	343.42	343,42	200	1,717.10

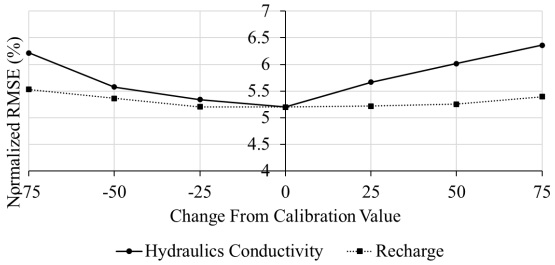


Fig.8 Sensitivity analysis

and urban and industrial zone was 343.42 m^3/day as shown in Table 3. The average per capita water use of 200 liters/day, the number of people who could benefit from the stored water is 1,602 people in Tha Chin River area and 1,717 people in urban and industrial zones. This demonstrates the potential of groundwater recharge to support water needs during dry seasons, especially in urban and semi-urban.

CONCLUSIONS

This study successfully developed and tested a groundwater recharge estimation and site identification approach for Managed Aquifer Recharge (MAR) in Suphanburi, Thailand, using GIS-based spatial analysis and Visual MODFLOW simulations. By integrating hydrological, geological, and land use data, the model identified zones with high recharge potential and evaluated the impacts of artificial recharge under various scenarios.

Simulation results showed that only two out of five selected areas—Urban and Industry and Tha Chin River Basin—had favorable conditions for groundwater budget, based on recharge volume, aquifer response, and safety from contamination. These zones were capable of storing groundwater at rates exceeding 300 m^3/day, benefiting more than 1,600 people per site during dry periods.

The findings highlight the importance of site-specific planning, emphasizing that groundwater recharge is not suitable for every area but can be highly effective when applied under the right hydrogeological and land use conditions. Moreover, the study demonstrates how combining local knowledge with scientific tools can support cost-effective and sustainable water management.

ABSTRACT

Drainage capacity is determined by the use of space and characteristics of sub-watershed. However, changes in the use of space that are not integrated can cause flood and inundation, particularly in areas where spatial planning considers only administrative boundaries and neglects the characteristics of sub-watershed. This challenge is evident in Palembang City, one of the oldest cities that has developed starting from the Musi River Delta, the longest river on the island of Sumatra. 66% dominated by swamp land, which is influenced by the ebb and flow of the Musi River. Due to limited land, swamps are filled in, thereby affecting the urban drainage system. A notable example is Lambidaro sub-watershed, which is among the 21 watershed areas. Changes in land use are significant after the opening of the arterial road connecting the East Sumatra Crossroad, which passes through Palembang City. Approximately more than 70% of the swamp areas have been filled for the development of the East Sumatra Cross-Island Road, followed by residential areas under permit, offices, and businesses. However, the development process is not accompanied by the arrangement of an integrated drainage system, high intensity rain, causing excessive flood during high-intensity rain. Therefore, this study aimed to analyze spatial planning of Lambidaro sub-watershed in designing urban drainage system. The results showed that additional retention ponds were needed to temporarily accommodate excess rainwater due to an increase in runoff. This was caused by the high tide of the Lambidaro River and slow infiltration into the soil.

Keywords: Drainage Capacity, Flood and inundation, Drainage system, Spatial planning, Retention ponds

INTRODUCTION

The rapid changes in land use across several urban areas in Indonesia are due to urbanization and industrial development. Most of these changes are carried out by reclaiming swamps, using riverbanks, and converting forest and agricultural land. The impact has changed water flow patterns in sub-watershed areas, thereby affecting flow patterns that cause flood and inundation due to excessive run-off [1]. Human activities, including urbanization through land reclamation, have a very significant impact on water quantity, quality, and aquatic ecology. This poses the danger of flood, household, and industrial waste, where water accumulating for a long time is impossible to return and requires very large costs for recovery [2].

The problem of surface water run-off with the characteristics of peak flood and inundation is influenced by several factors. These include urbanization, inappropriate land filling of swamps, tidal influences caused by sedimentation, and pollutants from river upstream as well as sub-watershed[3]. The ability to manage flow, run-off mitigation, infiltration, and water quality is related to land use conditions. The relationship between the water flow system and spatial planning is an important key to establish a policy in reducing flood hazards. However, both spatial planning and water management are not carried out in reality. This shows the need for analysis to explore the relationship between hydrotopographic conditions, types of land cover, duration and time of rain, and tidal height, which are modeled using spatial analysis, to support decision making for spatial planning and water management [4].

RESEARCH SIGNIFICANCE

This research is important to determine the characteristics of drainage channels, hydrology, and flow hydraulics in the Lambidaro river subsystem, in order to design flood control through various discharge analysis scenarios with a 10-year return period. Analysis is conducted to determine the effectiveness of drainage channel plans to reduce peak flood discharge and the timing of their occurrence. Flood modeling using advanced software and remote sensing data has significantly improved flood risk management by reducing uncertainty and

producing accurate flood maps that consider the impacts of climate change. Flood maps play a crucial role in risk assessment, enabling flood risk analysis, damage assessment, and effective planning for timely response and community protection.

LITERATURE REVIEW

Urban Development and Flood Problems in Palembang City

Similar to the development of several urban areas in Indonesia, Palembang City has a very significant development. This can be observed from the population growth, which average 1.03% with a population of 1,780,000 people in 2024 (BPS Palembang City, 2024) [1]. When the average population growth remains at 1.03%, the population will reach 1,963,340 people in 2035, with 42.6% in the City Center. Based on this significant growth, there is a projection for the concentration of population in urban activity centers, causing an expansion of land use for various activities. This expansion changes the various functions of "water parking" land, turning into built-up land, without considering watershed ecosystem.

Based on BMKG data (2024), the highest rainfall in Palembang City is 18 - <34.87 mm/day in November, and the lowest is <18 mm/day in May-August. Surface water is difficult to predict in the distribution in space and time. Meanwhile, the discharge observation system through AWLR in several areas along the river is not functioning properly. This has caused various problems in predicting the peak of flood and potential areas. In October 2024, the Bendung, Buah, Sekanak, and other sub-watershed areas in Palembang City experienced flood due to high-intensity rain [5]. To address these challenges, various efforts to control flood have been made. In Buah, a retention pond was added, while the Sekanak sub-watershed in the City Center was carried out by dredging the river to widen the overflow capacity. Bendung sub-watershed was constructed by freeing up land along the riverbank to accommodate the overflow of the river, or by adding water pumps for evacuating floodwaters. However, all these mitigating strategies have not shown that the annual flood problem can be overcome. All flood control system must start from the existing ecosystem conditions of the DAS. From these conditions, simulation analysis is conducted to determine flood discharge for each return period, which can be used to determine the appropriate drainage system [6]. Therefore, a specific method through a more useful and accurate analysis needs to be carried out. This includes data transformation into a Geographic Information System (GIS) using Multicriteria Analysis in decision making[7-10]. The method can be used as a combination of policy and technical solutions, but also as a model in presenting watershed environmental conditions to obtain better data quality and analysis.

METHOD

Data

In accordance with the morphological conditions of watershed, Palembang City divided into 21 sub-watershed areas. In terms of quality (see Fig.1), Lambidaro sub-watershed covering 5.42 km^2 has gained significant attention due to water condition, which ranges from critical (51.6%), slightly critical (27.65%), to non-critical (4.98%). The largest section in critical condition is downstream (56.64%), followed by upstream Lambidaro (43.36%).

Land use is dominated by shrubs, trees, fields, and forests, comprising approximately 72%, and settlements 4.74% which potential to experience changes. Settlement development mainly occurs in the left section close to the main/outer ring road of Palembang City (Musi two bridge). In comparison, the right section is still dominated by bushes and swamps, but currently the development of residential areas is increasing downstream.

As presented in Fig.1, the run-off coefficient value is 0.66, showing that 34% of the total rainfall in sub-watershed can still be infiltrated.

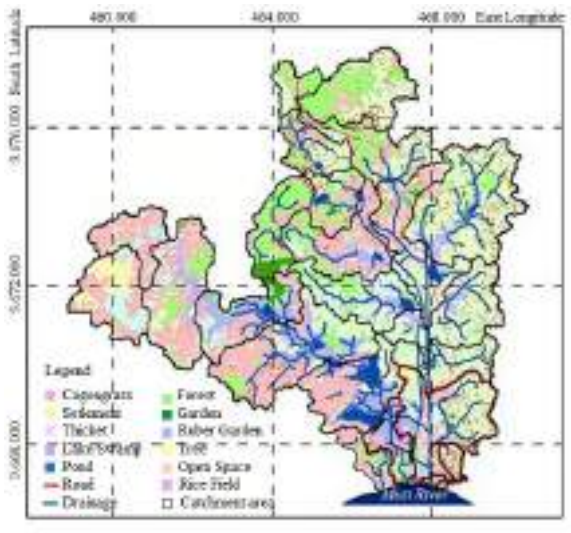

Fig. 1 Upstream and downstream Lambidaro sub-watershed

Comprehensive flood management is an effective method to reduce adverse consequences and as part of mitigation [11]. Flood modeling is an important method that can accurately predict and reduce the impact of flood [12]. Hydrologic Engineering Center - River Analysis System (HEC-RAS), developed by

the US Army Corps of Engineers, is one of the software programs capable of performing flood mapping on a large scale [13]. HEC-HMS (Hydrologic Modeling System) is able to produce output in the form of time series outflow of rainfall intensity along with land use as flow input in HEC-RAS modeling [14]. Digital Elevation Model (DEM) is also used to obtain topographic information to identify basin and lowland areas [15] to determine the depth of flood in simulations with HEC-RAS [16]. In this experiment, Lambidaro sub-watershed in Palembang City was used as the study area to conduct flood simulations using HEC-RAS and HEC-HMS.

The data used were river hydrometry data, longitudinal and transverse river cross-sections, river slope and area and watershed density. Spot height and land use data were needed to analyze the infiltration coefficient and time concentration. Rainfall data (R) were used to calculate rainfall intensity (I) in each sub-watershed, with a maximum value of 83.07 mm recorded in 2024. Meanwhile, the primary data were land use obtained from small-format aerial photography through unmanned aerial vehicle (UAV) aircraft and multispectral cameras. Other data include longitudinal and transverse river cross-section measurements, retention pond cross-section, Lambidaro river tidal, hydrology, and river hydraulics, which were measured and observed directly in the field.

Methods

The method used in this study was hydrological model and Geographic Information System (GIS). The hydrological model used was HEC-RAS, while the hydrodynamic model was applied to calculate the amount of runoff and trace flood flow in the river. Hydrodynamic analysis was carried out on the downstream Lambidaro river subsystem, obtained from the results of cluster analysis [17]. This analysis used a 1-dimensional unsteady flow model (Duflow) with the maximum rainfall intensity boundary conditions of a 25-year return period obtained from hydrological model and tidal observation forecasts at the mouth of the downstream Lambidaro sub-watershed. The first stage in the hydrodynamic analysis was to form a schematic of water system network in sub-watershed [18], which is adjusted to the results through terrain morphology and terrain processing analysis. The second stage was to enter the dimensions of the water structure, channel cross-section, boundary conditions (tides, rain from hydrological analysis results), and flow discharge. After the calculation of each segment/cross-section, several hydraulic parameters were obtained, such as flood level, flow velocity, channel discharge, and water level in the river and channel [19].

The distribution of inundation occurring in the river subsystem was obtained by combining the results of hydrodynamic and spatial analyses. The water level in the river and channel was interpolated to obtain the distribution of water level in the selected sub-watershed [20]. Subsequently, the distribution of water level was overlaid with the topographic conditions of this sub-watershed in the form of a DEM with a pixel size of 1m x 1m to obtain inundation height with a 25-year return period.

With several land use change scenarios, variation in inundation height in sub-watershed areas can be analyzed. These scenarios are used to assess the condition of this sub-watershed, which influences the pattern of river environmental control. The first scenario is by changing the type of spatial planning pattern through changes in land use for the C value (infiltration coefficient) to decrease, serving as an indicator of the amount of infiltration [21]. The second scenario is by changing the type of land use for C value to increase, suggesting reduced infiltration and suggesting that the river subsystem is beginning to experience hydrological stress [22]. . The research flow diagram is shown in Fig. 2.

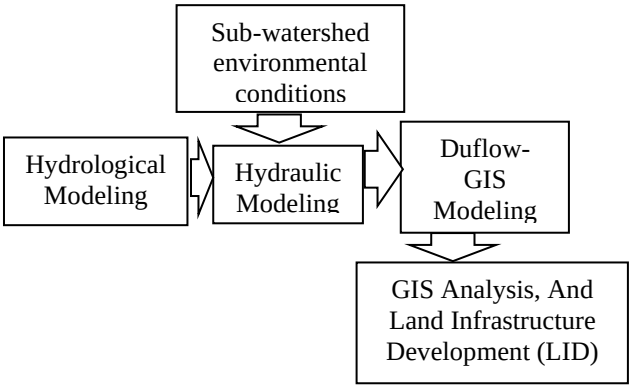

Fig. 2 Study method flowchart

RESULT AND DISCUSSION

Correlation Between Surface Runoff and Watershed Morphometric Characteristic Variables

Correlation analysis was conducted to answer the problem regarding spatial relationship between land use and sub-watershed morphometry, as well as the associated influence on the amount of surface run-off. The strength of the relationship between the independent variables (sub-watershed morphometric characteristics) and the dependent variable, runoff (Q), was observed through the Pearson correlation value. The correlation value ranged from -1,000 to 1,000. A value of -1,000 showed a very strong correlation but was negative, while a value of 1,000 showed a very strong/very close correlation with a positive direction.

The results of cluster analysis between T (Texture ratio), Bh (Basin relief), and C (Coefficient

infiltration) variables in the Lambidaro sub-watershed show that T values are based on relief conditions. The increase in peak discharge is the result of increased efficiency between relief conditions and flow density. The highest Rn value indicates greater vulnerability to increased peak discharge. The correlation between Dd (drainage density), Bh (Basin relief), Rn (Rugedness number), C (Coefficient infiltration), and Q (Debit) in the Lambidaro sub-watershed is obtained from the multiplication of Bh and Dd values, which have a very strong correlation between variables with correlation values of 0.836 and 0.905, respectively. The highest Concentration Time (Tc) is in the Lambidaro sub-system at 28.5 minutes. This describes the longest time for water to flow from the furthest distance to its outlet. All morphometric parameters are correlated with the drainage network.

Characteristics of Lambidaro Sub-Watershed

Inundation often occurs in Lambidaro Sub-watershed, particularly in the downstream areas and around flood plains, during the rainy season and high tides. Lambidaro Sub-watershed, covering 65.25 km^2 has different morphometric characteristics from others in Palembang City. Based on the drainage pattern, this sub-watershed is divided into two, namely left and right, which flow into the Musi River, with morphometric characteristics shown in Fig. 3.

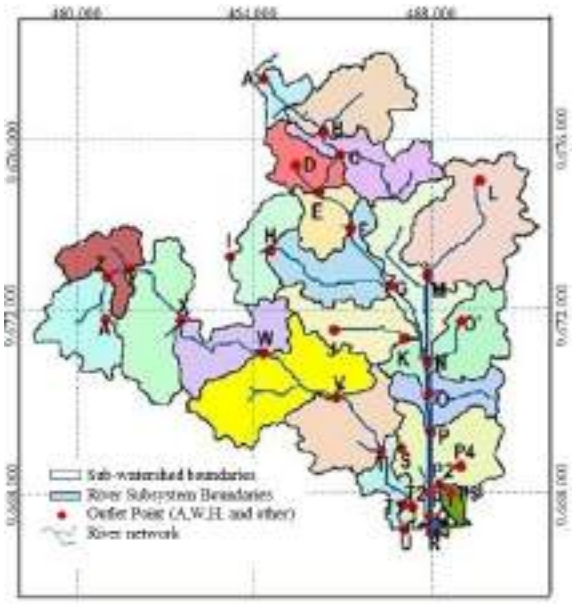

Fig. 3 Morphometric characteristics of Lambidaro sub-watershed

This sub-watershed has a varying height of less than 10 m msl in the left section, and 36 m msl upstream. The slope gradient is dominated by 0-3%, with steeper areas exceeding 8%, particularly.

The river conditions are still natural, specifically upstream, while the left has been normalized by strengthening the banks.

Hydrodynamic Model of Lambidaro Sub-Watershed

HEC-RAS-Arc-GIS model simulation was conducted on Lambidaro sub-watershed. Schematic of water management network based on DEM extraction with flow pattern producing sub-watershed boundary and morphometry to describe run-off in flood plain was built first, as shown in Fig. 4. This structure was built by inputting transverse and longitudinal profile data of the channel per segment based on field measurement results, with channel width ranging from 11-18 m. Boundary conditions for HEC-RAS model consisted of run-off from upstream, while downstream boundary conditions included water level at river mouth. Hydrological parameters of rainfall were taken from the analysis result of maximum daily rainfall distribution using Gumbell method for 25-year period of 163 mm/day. The weighted C value of each system was calculated from the results of spatial analysis of land use, slope gradient, soil type, and flow density, as shown in Fig. 1.

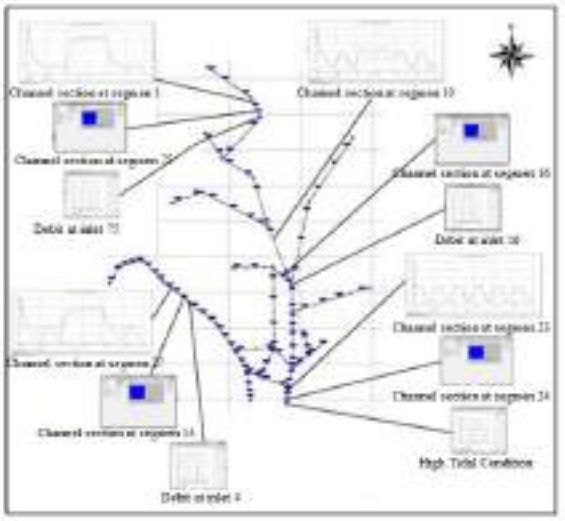

Fig. 4 Schematic of the Lambidaro river flow profile

The results of hydrodynamic modeling and the existing conditions were analyzed with a 25-year return period scenario. Subsequently, water level in each segment was transformed into Lambidaro sub-watershed DEM, interpolated with the Hydro-processing procedure to obtain the distribution of inundation using a 25-year return period scenario.

The results obtained were classified into six categories, namely (1) non-inundated areas, (2) inundated with a height of less than 0.25 m,

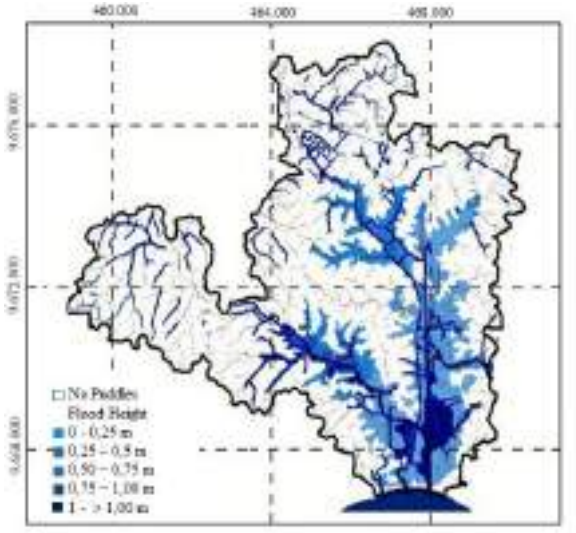

Fig. 5 Distribution of inundation due to changes in land use in Lambidaro sub-watershed

(3) a height of 0.25 - 0.5 m, (4) a height of 0.5-0.75 m, (5) a height of 0.75-1 m, and (6) a height of more than 1 m. Fig. 5 shows the results of hydrodynamic modeling using the HEC-GeoRas model, followed by an analysis of the distribution of inundation that will occur with a 25-year return period scenario.

The inundated areas are characterized by flow accumulation with a slope of 0-3%, dominated by swamps. The calibration of this model is shown by the suitability of the inundation height that occurs in the field with $R^2 = 0.869$.

For the right Lambidaro sub-watershed, the influence of tides on upstream covers area of 756.81 ha, with 2821.6 ha in the middle 2821.6 ha and 513.23 ha downstream. Meanwhile, for the left section, the upstream section covers 1854.5 ha, the middle 380.5 ha, and the downstream 131.1 ha. The distribution of inundation superimposed is shown in Fig. 6.

Land Use Change Scenario

Resolving the reduction of inundation distribution by regulating land use as part of Land Infrastructure Development (LID) in spatial planning, Land Utilization Change Scenarios are made of 5 Scenarios, namely:

(1) The first scenario is by changing the type of land use to a green park (city forest) to reduce the C value.
(2) The second scenario is by changing the type of land use of the upstream into settlements based on the current development of the city, to increase the C value.
(3) The third scenario is the same as the first, which is only carried out downstream.
(4) The fourth scenario is the same as the second, which is only carried out downstream.
(5) The fifth scenario is by changing land use with different C values ranging from 0.2 to 0.9

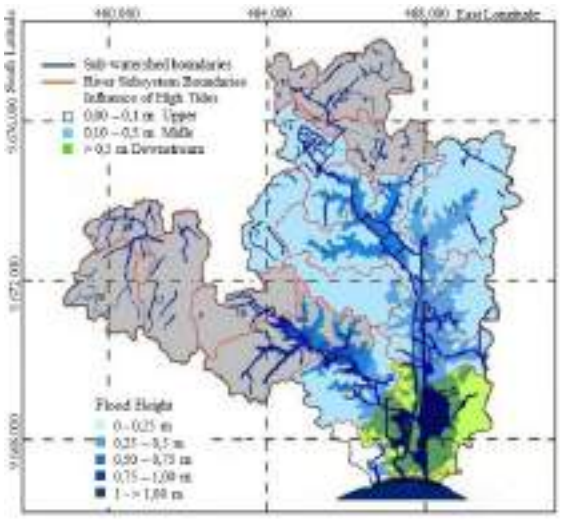

Fig. 6 Distribution of inundation is superimposed on the upstream, middle, and downstream

Several effects of land use change scenarios in the upstream, middle, and downstream sub-watershed by reducing and increasing the run-off coefficient value C per sub-watershed are carried out to reduce and increase the inundation that occurs, as shown in Fig. 7.

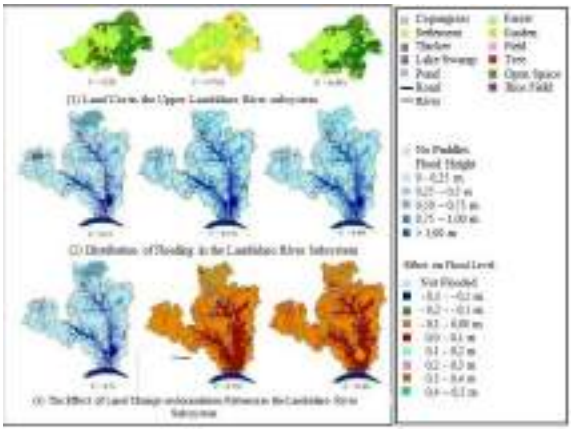

Fig. 7 Effects of changes in land use in the upstream Lambidaro sub-watershed

.

CONCLUSION

In conclusion, this study analyzes spatial planning of Lambidaro sub-watershed in designing urban drainage system. The results obtained are as follows,

1) The average drainage capacity is 14.25 m3/sec, which is unable to drain the 25-year return period water discharge of 52.43 m^3/sec.
2) The planned flood discharge for the 25-year return period produces inundation of 609.01 ha or

approximately 1.1% of Lambidaro sub-watershed. The inundation period varies between 3 hours to 59 hours, with a flood height of 0.01 m from the left river bank elevation +2.5 m to 1.80 m from the right river bank elevation +1.5 m

3) The effect of changes in land use in several scenarios proves that areas of inundation will expand from downstream, middle to upstream when there is no proper control.

ABSTRACT

This study aims to reproduce regional water quality characteristics of the Seto Inland Sea from the 1990s to the 2010s using a food chain model based on the Monte Carlo method. The study area was divided into 13 regions, each treated as an independent box. A total of 28 ecosystem parameters were statistically estimated for each box through repeated simulations. The model successfully reproduced the observed ranges of dissolved inorganic nitrogen (DIN) concentrations and phytoplankton biomass for both decades using parameter sets derived through the Monte Carlo method. The estimated parameters showed regional variations and were consistent with observed differences in phytoplankton community composition and ecological traits such as growth and sinking rates. These findings indicate that the proposed method is effective for reducing parameter uncertainty while reflecting regional ecosystem characteristics. Furthermore, the results suggest that region-specific parameter settings are essential for simulating the entire Seto Inland Sea.

Keywords: Food Chain Model, Ecosystem Parameter, Monte Carlo Method, Seto Inland Sea

INTRODUCTION

Fisheries in coastal seas have developed through nutrient inputs, such as nitrogen and phosphorus, from rivers and industrial discharges. However, yields have been declining in many coastal regions worldwide due to ecosystem changes caused by climate change, overfishing, and water pollution [1].

Numerical models are widely used for marine ecosystem management. However, uncertainties in biological processes have been reported to reduce model accuracy [2, 3]. These uncertainties are mainly attributed to errors in parameter settings [4]. Therefore, complex models with many parameters are not always practical, and simplified models may be more useful for supporting policy decisions [5].

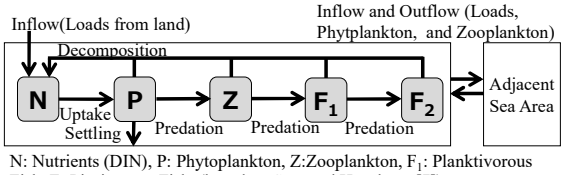
To address this uncertainty, our previous study developed a food chain model based on the Monte Carlo method consisting of two boxes representing coastal and offshore areas, and applied it to the eastern Seto Inland Sea (Harima Nada) [6]. In that study, ecosystem parameters were assigned for each box based on the dominant phytoplankton types, with the range of parameter values adjusted individually for each box. This approach successfully reproduced the water quality characteristics of the 1990s and 2010s, during which nutrient concentrations changed significantly. In the present study, we estimate ecosystem parameters using the Monte Carlo method, applying a common range of values across all boxes, to reproduce water quality characteristics in diverse regions, and evaluate their validity based on regional differences in observed phytoplankton species.

RESEARCH SIGNIFICANCE

Ecosystem parameters vary across water areas, and modelers have traditionally tuned them within general ranges. However, it is difficult to accurately set all parameters, often leading to subjectivity. This study proposes an approach for parameter estimation using the Monte Carlo method to reduce subjectivities through a statistical framework. The derived parameters reflect the specific characteristics of each water area. The approach offers useful guidance for parameter selection in high-resolution numerical models to improve the reproducibility of water quality conditions in various regions.

MODEL AND METHODS

The NPZFF food chain model, originally developed for Lake Biwa [7] and modified for Harima Nada [6], was further improved in this study by replacing total nitrogen (TN) with dissolved inorganic nitrogen (DIN), which is directly available to organisms. The model equations and schematic structure are presented in Table 1 and Fig. 1.



N: Nutrients (DIN), P: Phytoplankton, Z:Zooplankton, F_1: Planktivorous Fish, F_2 Piscivorous Fish (based on Sato and Hayakawa[7]).

Fig.1 Structure of the food chain model.

Table 1 Food chain model description (based on Sato and Hayakawa [7]).

Phytoplankton Biomass:

$$\frac{dM_p}{dt} = G_p - P_p - E_p - R_p - D_p - O_p + IN_p$$

$$G_p = g_p \cdot \left(1 - \frac{\gamma_{min,p}}{\gamma_p}\right) \cdot \exp(-\beta_p \cdot M_p) \cdot \frac{H_p}{H} \cdot M_p \quad P_p = g_z \cdot \frac{M_p}{k_z + M_p} \cdot M_z \quad E_p = e_p \cdot M_p \quad R_p = (r_p + \varepsilon_p) \cdot M_p \quad D_p = \frac{d_p}{H} M_p$$

$$O_p = \frac{\sum_{j=1}^{n} V_{out,j}}{V} \cdot M_p \quad IN_p = \frac{\sum_{j=1}^{n} V_{in,j} \cdot M_{p,j}}{V}$$

Phytoplankton Nutrients:

$$\frac{dC_p}{dt} = \rho_p \cdot \frac{C_N}{k_p + C_N} \cdot \left(1 - \frac{\gamma_p}{k_{max,p}}\right) \cdot M_p - (P_p + E_p + R_p + D_p + O_p) \cdot \gamma_p + IN_p \cdot \gamma_{p,j} \qquad \gamma_p = \frac{C_p}{M_p}$$

Zooplankton Biomass:

$$\frac{dM_z}{dt} = G_z - P_z - E_z - R_z - O_z + IN_z$$

$$G_z = P_p \cdot \delta_z \quad P_z = g_{f_1} \cdot \frac{M_z}{k_{f_1} + M_z} \cdot M_{f_1} \quad E_z = \begin{cases} G_z \cdot (1 - \gamma_p/\gamma_z) & if \quad \gamma_z \geq \gamma_p \\ 0 & if \quad \gamma_z < \gamma_p \end{cases} \quad R_z = (r_z + \varepsilon_z) \cdot M_z \qquad O_z = \frac{\sum_{j=1}^{n} V_{out,j}}{V} \cdot M_z$$

$$IN_z = \frac{\sum_{j=1}^{n} V_{in,j} \cdot M_{z,j}}{V}$$

Zooplankton Nutrients:

$$\frac{dC_z}{dt} = \begin{cases} G_z \cdot \gamma_p - (P_z + R_z + O_z - IN_z) \cdot \gamma_z & if \quad \gamma_z \geq \gamma_p \\ G_z \cdot \gamma_p - G_z(\gamma_p - \gamma_z) - (P_z + R_z + O_z) \cdot \gamma_z + IN_z \cdot \gamma_{z,j} & if \quad \gamma_z < \gamma_p \end{cases} \qquad \gamma_z = \frac{C_z}{M_z}$$

Planktivorous Fish Biomass:

$$\frac{dM_{f_1}}{dt} = G_{f_1} - P_{f_1} - E_{f_1} - R_{f_1}$$

$$G_{f_1} = P_z \cdot \delta_{f_1} \quad P_{f_1} = g_{f_2} \cdot \frac{M_{f_1}}{k_{f_2} + M_{f_1}} \cdot M_{f_2} \quad E_{f_1} = \begin{cases} G_{f_1} \cdot (1 - \gamma_z/\gamma_{f_1}) & if \quad \gamma_{f_1} \geq \gamma_z \\ 0 & if \quad \gamma_{f_1} < \gamma_z \end{cases} \quad R_{f_1} = (r_{f_1} + \varepsilon_{f_1}) \cdot M_{f_1}$$

Planktivorous Fish Nutrients:

$$\frac{dC_{f_1}}{dt} = \begin{cases} G_{f_1} \cdot \gamma_z - (P_{f_1} + R_{f_1}) \cdot \gamma_{f_1} & if \quad \gamma_{f_1} \geq \gamma_z \\ G_{f_1} \cdot \gamma_z - G_{f_1}(\gamma_z - \gamma_{f_1}) - (P_{f_1} + R_{f_1}) \cdot \gamma_{f_1} & if \quad \gamma_{f_1} < \gamma_z \end{cases} \qquad \gamma_{f_1} = \frac{C_{f_1}}{M_{f_1}}$$

Piscivorous Fish Biomass:

$$\frac{dM_{f_2}}{dt} = G_{f_2} - E_{f_2} - R_{f_2}$$

$$G_{f_2} = P_{f_1} \cdot \delta_{f_2} \quad E_{f_2} = \begin{cases} G_{f_2} \cdot (1 - \gamma_{f_1}/\gamma_{f_2}) & if \quad \gamma_{f_2} \geq \gamma_{f_1} \\ 0 & if \quad \gamma_{f_2} < \gamma_{f_1} \end{cases} \quad R_{f_2} = (r_{f_2} + \varepsilon_{f_2}) \cdot M_{f_2}$$

Piscivorous Fish Nutrients:

$$\frac{dC_{f_2}}{dt} = \begin{cases} G_{f_2} \cdot \gamma_{f_1} - R_{f_2} \cdot \gamma_{f_2} & if \quad \gamma_{f_2} \geq \gamma_{f_1} \\ G_{f_2} \cdot \gamma_{f_1} - G_{f_2}(\gamma_{f_1} - \gamma_{f_2}) - R_{f_2} \cdot \gamma_{f_2} & if \quad \gamma_{f_2} < \gamma_{f_1} \end{cases} \qquad \gamma_{f_2} = \frac{C_{f_2}}{M_{f_2}}$$

Nutrients:

$$\frac{dC_N}{dt} = L_N - O_N + DP_N + DZ_N + DF1_N + DF2_N - I_N$$

$$L_N = \frac{L_{in}}{V} + \frac{\sum_{j=1}^{n} V_{in,j} \cdot C_{N,j}}{V} \quad O_N = \frac{\sum_{j=1}^{n} V_{out,j}}{V} \cdot C_N$$

$$DP_N = \{E_P + (P_p - G_z) + R_p\} \cdot \gamma_p \qquad DZ_N = \begin{cases} \{(P_z - G_{f_1}) + R_z\} \cdot \gamma_z & if \quad \gamma_z \geq \gamma_p \\ G_z \cdot (\gamma_p - \gamma_z) + \{(P_z - G_{f_1}) + R_z\} \cdot \gamma_z & if \quad \gamma_z < \gamma_p \end{cases}$$

$$DF1_N = \begin{cases} \{(P_{f_1} - G_{f_2}) + R_{f_1}\} \cdot \gamma_{f_1} & if \quad \gamma_{f_1} \geq \gamma_z \\ G_{f_1} \cdot (\gamma_z - \gamma_{f_1}) + \{(P_{f_1} - G_{f_2}) + R_{f_1}\} \cdot \gamma_{f_1} & if \quad \gamma_{f_1} < \gamma_z \end{cases}$$

$$DF2_N = \begin{cases} R_{f_2} \cdot \gamma_{f_2} & if \quad \gamma_{f_2} \geq \gamma_{f_1} \\ G_{f_2} \cdot (\gamma_{f_1} - \gamma_{f_2}) + R_{f_2} \cdot \gamma_{f_2} & if \quad \gamma_{f_2} < \gamma_{f_1} \end{cases} \qquad I_N = \rho_p \cdot \frac{C_N}{k_p + C_N} \cdot \left(1 - \frac{\gamma_p}{\gamma_{max,p}}\right) \cdot M_p$$

Study Area and Input Data

The study area covers the entire Seto Inland Sea. Based on differences in water quality characteristics—such as nutrient concentrations and phytoplankton biomass—the area was divided into 13 boxes, each representing a distinct water region (Fig. 2).Exchange volumes of seawater were obtained from JCOPE2M [8,9]. Boundary conditions and in-domain data for DIN concentrations and phytoplankton biomass (as chlorophyll-a) were interpolated from observations provided by the Ministry of the Environment of Japan. These data were weighted using 500-m mesh bathymetry data from the Japan Oceanographic Data Center. Parameters for zooplankton, planktivorous fish, and piscivorous fish were set based on values reported in previous studies.

The land-derived DIN load was estimated by applying a DIN/TN ratio of 0.8 to TN loading data [10], based on observational study [11] and previous report [12]. The carbon-to-chlorophyll a ratio (C/Chl-a) was set to 56.4 based on observational data from the Seto Inland Sea [13].

Fig.2 Study area consisting of 13 model boxes .

Calculation Procedure

To estimate ecosystem parameters for each water area, we first defined variation ranges for all 28 ecosystem parameters in the food chain model based on values reported in the literature (Table 2). The following procedure was then used. Each simulation continued until the system reached a periodic steady state. Steps 1 and 2 were repeated until 1,000 valid parameter sets were obtained.

Step 1:

Parameter values were randomly sampled from these ranges, and two separate simulations were conducted using boundary conditions representing the 1990s and the 2010s, respectively.

Step 2:

Each simulation result was accepted only if it satisfied the following two criteria, evaluated under periodic steady-state conditions.

(i) The average values of DIN concentration and biomasses at steady state fall within the observed ranges for the 1990s and 2010s.

(ii) The coefficient of variation (standard deviation divided by the mean) for DIN concentration and each biomass at steady state in the 2010s simulation is 0.2 or less.

In our previous study [6], the variation ranges of ecosystem parameters were adjusted for each box based on the dominant phytoplankton types to reproduce water quality in each box. In contrast, this study employed uniform variation ranges across all boxes, as widely as possible based on literature values, to minimize subjectivity in the parameter estimation process.

For simplicity, water quality within each box was simulated independently without coupling with adjacent boxes.Model reproducibility was evaluated by comparing the simulated DIN concentrations and phytoplankton biomasses with observed values.

The validity of the parameters that achieved acceptable reproducibility was studied based on phytoplankton species composition and related ecological characteristics.

Table 2 Variation ranges for 28 ecosystem parameters

Category	Name	Min.	Max.
Phyto-plankton	Maximum growth rate	0.3	2.5
	Exocytosis rate	0.01	0.3
	Maximum nutrients uptake rate	0.1	1
	Half saturation constant	0.01	1
	Congestion effect constant	0.1	2
	Respiration rate	0.01	0.3
	Mortality rate	0.01	0.3
	Deposition rate	0.01	3
	Maximum N:C ratio	0.17	0.2
	Minimum N:C ratio	0.02	0.06
Zoo-plankton	Maximum growth rate	0.1	0.8
	Assimilation rate	0.6	0.8
	Half saturation constant	0.09	0.18
	Respiration rate	0.01	0.03
	Mortality rate	0.02	0.07
	N:C ratio	0.06	0.12
Plankti-vorous Fish	Maximum growth rate	0.11	0.16
	Assimilation rate	0.7	0.9
	Half saturation constant	0.02	0.05

	Mortality rate	0.003	0.008
	N:C ratio	0.04	0.1

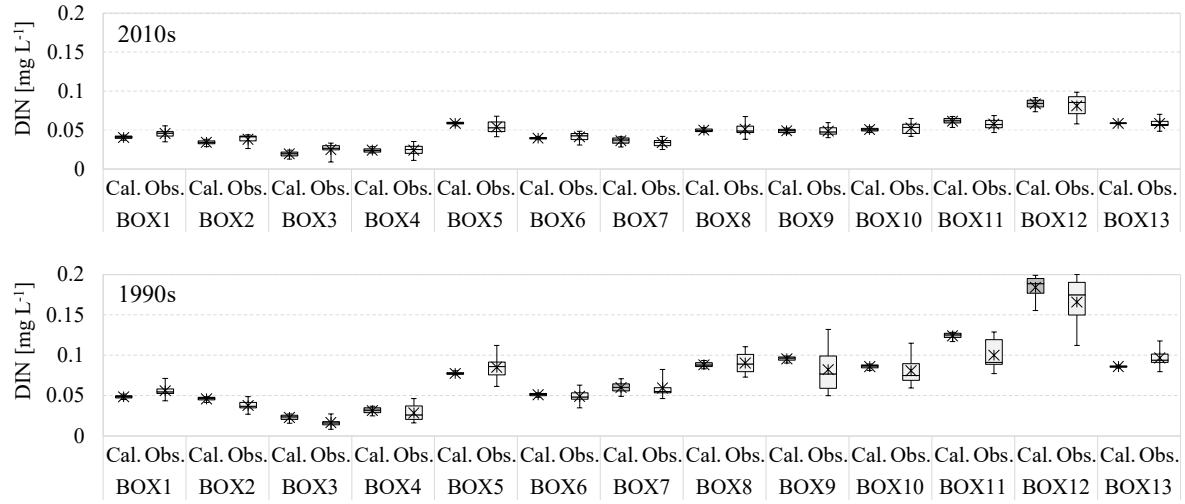
RESULTS AND DISCUSSION

Model Reproducibility and Regional Water Quality Characteristics

Comparisons between simulated and observed values are shown in Fig. 3 for DIN concentrations and in Fig. 4 for phytoplankton biomass, both between the 1990s and the 2010s. Both figures present boxplots of 1,000 simulation results and 10 years of observational data, along with their respective averages. Since only simulations within the observational range were accepted as valid, all results naturally reflect the water quality characteristics of each box.

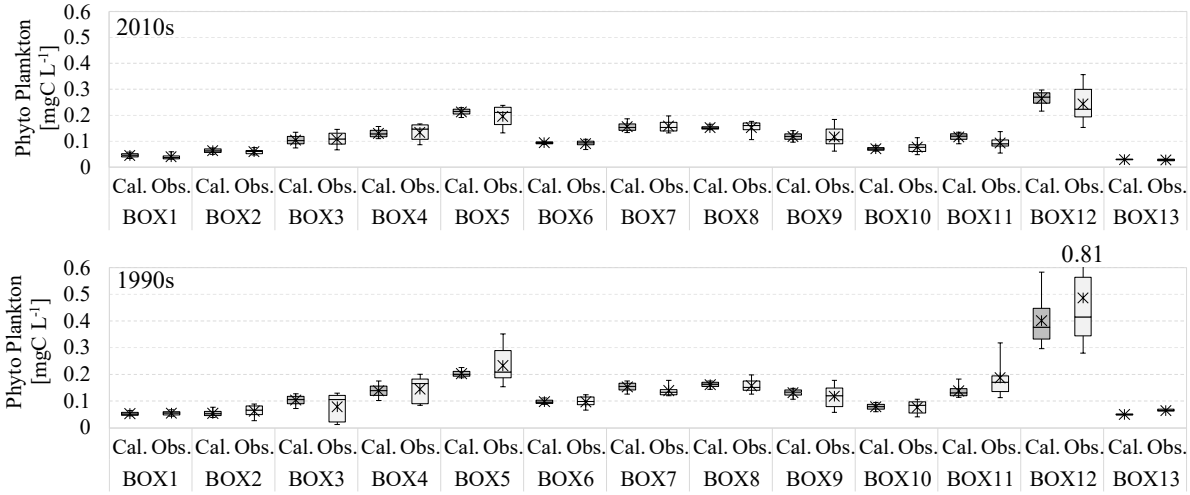
Phytoplankton biomass generally ranged from 0.1 to 0.2 mgC L^{-1}, but was below 0.05 mgC L^{-1} in BOX1 and 13, and reached 0.24 mgC L^{-1} in BOX12.

In the 1990s, compared to the 2010s, DIN concentrations showed small changes in the western boxes (BOX1–5), while higher values were observed in the eastern side of the Seto Inland Sea (BOX6–13). Phytoplankton biomass, on the other hand, increased significantly only in BOX12 and 13 compared to the 2010s.



The top and bottom of the box represent 75th and 25th percentiles respectively. The top and bottom of the vertical line represent 95th and 5th percentiles. The inner line is the median and the asterisk represents the average.

Fig.3 Comparison of calculated and observed DIN concentrations between the 1990s and the 2010s.



The top and bottom of the box represent 75th and 25th percentiles respectively. The top and bottom of the vertical line represent 95th and 5th percentiles. The inner line is the median and the asterisk represents the average.

Fig.4 Comparison of calculated and observed phytoplankton biomass between the 1990s and the 2010s.

Evaluation of Ecosystem Parameters

Fig. 5 shows key ecosystem parameters that exhibited notable differences among the boxes, and Fig. 6 presents the phytoplankton species composition in the 2010s provided by the Ministry of the Environment of Japan, spatially interpolated and adjusted for each box.

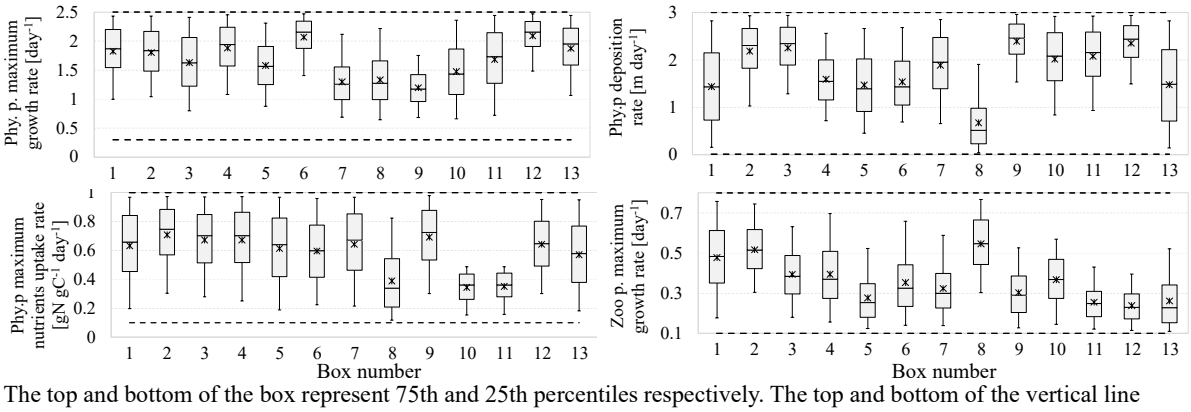
Relatively low maximum growth rates of phytoplankton were estimated in BOX7, 8, and 9, which is consistent with previous report that diatoms generally grow faster than dinoflagellates [14]. In contrast, BOX1 and 2 showed relatively high growth rates despite a higher proportion of dinoflagellates. It is possible that these "others" types included fast-growing species, which may have contributed to higher estimated maximum growth rates.

The maximum nutrient uptake rates were relatively low in BOX8, 10, and 11.In BOX8 and 10, this aligns with finding that dinoflagellates typically have lower uptake rates than diatoms [15]. In contrast, BOX11 exhibited a lower maximum nitrogen uptake rate despite the dominance of diatoms. It is generally understood that phytoplankton tend to exhibit higher nitrogen uptake rates when ammonium nitrogen is abundant. According to data from the Ministry of the Environment of Japan, the ratio of ammonium nitrogen—readily available to phytoplankton—to total DIN in BOX11 was lower than in the surrounding areas.This may have contributed to the reduced maximum nitrogen uptake rate of phytoplankton in this region.

The deposition rate of phytoplankton was lowest in BOX8, which may be attributed to the lower abundance of diatoms with heavy silica shells.

Zooplankton maximum growth rates were relatively high in BOX1, 2, and 8. The value for BOX8 aligns with finding that cryptophytes, which were dominant in this area, are high-quality food sources that promote zooplankton growth [16]. In BOX1 and 2, the influence of "other" phytoplankton types may again be a factor.

These findings suggest that the estimated parameters were consistent with the phytoplankton species composition in each region. To reproduce regional water quality differences using the box model, different ecosystem parameters should be applied for each area. This may also apply to high-resolution models, suggesting that appropriate parameter settings should be carefully considered for each region.



The top and bottom of the box represent 75th and 25th percentiles respectively. The top and bottom of the vertical line represent 95th and 5th percentiles. The inner line is the median and the asterisk represents the average. The dashed lines indicate the maximum and minimum values of the predefined parameter range.

Fig.5 Estimated ecosystem parameters showing regional variations among 13 boxes.

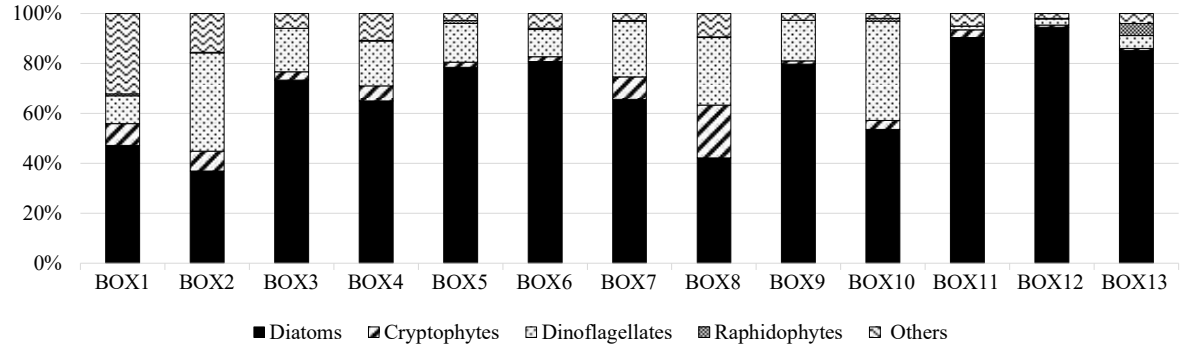


Fig.6 Observed phytoplankton species composition in 2010s.

CONCLUSIONS

This study estimated ecosystem parameters in multiple regions of the Seto Inland Sea using a Monte Carlo based food chain model. The model successfully reproduced the water quality characteristics for both the 1990s and 2010s, including DIN concentrations and phytoplankton biomass. The estimated parameters reflected regional differences in phytoplankton communities and were consistent with known ecological traits, such as growth rates and sinking velocities.

These results suggest that using region-specific parameter settings is essential for accurately simulating ecosystem dynamics in coastal waters. The proposed approach provides a practical framework for reducing parameter uncertainty and may be useful for improving the reliability of high-resolution numerical models applied to eutrophic coastal seas.

[1]School of Engineering, King Mongkut's Institute of Technology Ladkrabang, Thailand

ABSTRACT

The lack of freshwater resources on small tourism islands causes a critical issue with direct effects for the quality of life within local communities and the long-term sustainability of tourism activities. This problem is particularly worsened in regions lacking centralized community water supply systems, where groundwater serves as a crucial source of water for domestic consumption. This study aims to assess the feasibility of developing groundwater resources for establishing a community water supply system on small tourism islands. The research employed a mathematical groundwater model using the MODFLOW program to simulate groundwater flow and analyze the zone budget, based on head contour data and land use patterns in the study area. The results revealed that the most suitable location for groundwater development is the lowland community area, which functions as a discharge zone with high potential for groundwater accumulation and circulation. The MODFLOW simulation accurately demonstrated the quantity and flow direction of groundwater, providing valuable insights for planning a sustainable water supply system to enhance long-term water security for small tourism islands.

Keywords: Groundwater Development, Community Water Supply, Zone Budget, MODFLOW, Small Tourism Island

INTRODUCTION

The world is currently facing a freshwater scarcity crisis, affecting both the quality and quantity of available water [1]. This issue severely impacts people's quality of life, particularly on small islands. These islands have geographical and natural resource limitations, making access to freshwater for consumption difficult. They primarily rely on rainwater and groundwater, which have become insufficient due to increasing human activities, especially the continuously expanding tourism sector [2, 3]. As a result, the demand for water has risen, placing further pressure on already limited water resources.

Si Chang Island is an area clearly facing significant challenges related to freshwater scarcity and contamination [4]. At present, the island lacks a community water supply system, as previous attempts to produce municipal water from seawater have failed, and existing reservoirs are unable to retain water due to leakage issues [5]. Consequently, residents must rely on collecting rainwater in storage tanks and importing freshwater from external sources. This results in high costs not only for the water itself but also for transportation, making freshwater unnecessarily expensive—despite being a necessity that should be affordably accessible.

Given these challenges, this research highlights the importance of establishing a community water supply system on Si Chang Island to promote sustainable self-reliance in freshwater resources. The primary objective of the study is to identify and evaluate suitable groundwater sources for developing a raw water supply system. To achieve this, the study utilizes geological data, Geographic Information Systems (GIS), and MODFLOW software to construct spatial models that systematically and accurately analyze groundwater behavior and flow direction in the area [6].

The integration of MODFLOW modeling with zone budget analysis is internationally recognized as a critical tool for assessing groundwater potential and supporting sustainable water resource management. For example, in India, semi-arid Palar sub-basin, MODFLOW was employed to simulate groundwater flow, enabling an accurate assessment of the groundwater balance and effectively supporting local water management strategies [7]. In Egypt, Visual MODFLOW was combined with Multi-Criteria Decision Analysis (MCDA) to inform future pumping plans, while zone budget was applied to assess the suitability of different zones for groundwater source development [8]. Similarly, in Ethiopia's Tana Basin, MODFLOW-NWT was used to examine the effects of climate change on groundwater levels, with zone budget helping to evaluate changes in groundwater systems under various scenarios [9].

In Thailand, GIS techniques are integrated with MODFLOW to simulate groundwater flow with high accuracy. Zone budget was applied to assess water balance within designated zones, serving as a foundation for long-term sustainable water resource management strategies [10–12]. These examples demonstrate that the combined use of MODFLOW and zone budget not only enables detailed simulations of groundwater dynamics but also supports

sustainability assessments for water resource utilization. This approach is adaptable to conditions specific to Thailand, particularly in small island areas like Si Chang Island where freshwater resources are limited. Applying these tools is expected to significantly enhance the scientific planning and implementation of a sustainable community water supply system.

RESEARCH SIGNIFICANCE

This research addresses the urgent need for a reliable freshwater supply on small tourist islands by focusing on the identification and evaluation of suitable groundwater sources in areas with limited hydrogeological data. By applying MODFLOW modeling, the study offers critical insights into the development of a sustainable community water supply system. Its findings contribute to closing existing data gaps and supporting informed decision-making for long-term water resource management. Moreover, this approach is transferable to other island regions facing similar challenges, providing a valuable framework for improving water security and accommodating the continued growth of the tourism sector.

GROUNDWATER BUDGET

A groundwater budget is an evaluation of the continuous flow of water into and out of a groundwater system, which must remain in balance over time. The water balance equation is used to quantify the total volume of water entering and leaving the system or a defined groundwater storage area. The difference between inflows and outflows indicates the change in groundwater storage, either as an increase or a decrease, as expressed in Eq. (1)

$$I - O = \Delta S \quad (1)$$

Where: I = Inflow, O = Outflow, ΔS = Change in Storage. When considering a groundwater storage area at the sub-basin level, as illustrated in Eq. (1), and focusing specifically on the groundwater budget, the equation can be written as follows:

$$I + G_{in} + Q_g - G_{out} - E_g - T_g = \Delta S_g \quad (2)$$

Where: I = Recharge from the surface to the aquifer, G_{in} = Groundwater flow into the system, Q_g = Flow into and out of the system via streams, G_{out} = Groundwater flow out of the system, E_g = Evaporation from groundwater, T_g = Transpiration from groundwater by plants, ΔS_g = Change in groundwater storage

In this study, the groundwater balance will be analyzed separately for each zone to illustrate spatial variations in groundwater inflow and outflow. This analysis will support the identification of areas that are both suitable and potentially sustainable for future development.

STUDY AREA

Fig. 1 Location and slope in Si Chang Island [13]

Si Chang Island, a small island in the Gulf of Thailand, is located approximately 12 kilometers off the coast of Si Racha District and about 36 kilometers from Chonburi City. The island covers a land area of approximately 7.65 square kilometers and is surrounded by an additional 9.65 square kilometers of marine territory.

The island's terrain is predominantly composed of rocky hills and mountainous areas, with around 80% of the total land area consisting of elevated peaks. The highest point, situated in the northern part of the island, reaches approximately 192 meters above sea level [13]. The topography is characterized by uneven elevation distribution: about 67% of the area lies between 0–50 meters above sea level, 26% between 50–100 meters, 6% between 100–150 meters, and only 1% exceeds 150 meters, as shown in Fig. 1

These geographical features, particularly the limited flatland and rugged terrain, present significant challenges for freshwater resource management, especially in terms of groundwater recharge and resilience to climate change impacts.

GENERAL AND TOPOGRAPHY

Based on the geological map of Chonburi Province [14], Si Chang Island is primarily composed of sedimentary rocks from the Chonburi Group, which were deposited during the Carboniferous–Permian (CP) period. These formations include sandstone, argillaceous limestone, shale, and chert. Such rock types can store groundwater within limestone caverns and fracture systems (jointing systems) [15].

The island's terrain is mostly limestone mountains, especially in the north, while the east and southwest consist of granite. The western coast features rocky outcrops, cliffs, and some sandy beaches. Groundwater is found at depths of approximately 50 meters, primarily within limestone layers where it's stored in caverns or fractures within the limestone. The expected groundwater yield is less than 2 cubic meters per hour, with a low total dissolved solids (TDS) content of less than 500 mg/L [16].

RAINFALL AND TEMPERATURE

Si Chang Island's climate is influenced by both the northeast and southwest monsoons, resulting in three distinct seasons: the hot season (mid-February to May), the rainy season (June to October), and the dry season (November to mid-February).

Average temperatures range between 25°C and 35°C, with April and May typically being the hottest months of the year. According to data from the Si Chang Island rainfall station [17], the island receives an average annual rainfall of approximately 1,000 to 1,200 millimeters, the majority of which occurs during the monsoon season. However, a declining trend in precipitation has been observed, particularly during the dry season, when rainfall is minimal. Even during the rainy season, precipitation tends to be intense yet unevenly distributed, leading to temporal and spatial variability in water availability.

LAND USE

Fig. 2 shows the land use classification of Si Chang Island. Based on land use data from the Department of Land Development (2020), approximately 70% of Si Chang Island remains as green space, primarily composed of deciduous forests—either mature or under active restoration. Urbanized areas, including residential zones and built structures, occupy around 16% of the island, reflecting a moderate level of human development.

The remaining land uses are distributed as follows: industrial areas (3.37%), government facilities (2.58%), harbors (0.42%), laterite pits (1.40%), and beaches (3.67%). Surface water bodies are minimal, collectively accounting for less than 2% of the island's total area. A more detailed land use classification includes deciduous forest under restoration—36.46% (2.36 km²), mature deciduous forest—35.09% (2.27 km²), urban areas and structures—16.01% (1.00 km²), and other functional zones such as government offices, industrial zones, gravel pits, and ports—collectively covering less than 1 km². Water sources, including reservoirs and natural water bodies, comprise only 0.52% and 0.48% of the area, respectively [18].

These land use characteristics have a direct influence on the island's groundwater recharge potential. While forested and natural soil areas promote effective infiltration and aquifer recharge, the expansion of impervious surfaces—such as buildings and roads—can significantly reduce permeability. Consequently, integrated water resource management must carefully balance the retention of permeable land cover with the demands of built infrastructure.

Fig. 2 Land use in Si Chang Island [18]

WATER QUALITY

According to the drinking water quality standards established by the Department of Health in 2020 [4], the overall water quality on Si Chang Island is classified as "acceptable." This classification indicates that the water may be used for consumption in the absence of alternative sources. However, water treatment is required prior to use due to the presence of coliform bacteria and Escherichia coli (E. coli), which are commonly associated with gastrointestinal illnesses such as diarrhea.

In contrast, the southern part of the island—an uninhabited area designated for waste disposal—shows contamination from several hazardous substances, including arsenic and fluoride, at concentrations exceeding permissible limits. As a result, the water quality in this area is deemed unsafe for any purpose, including human consumption.

METHODOLOGY

This study employed a systematic approach that integrated field investigations, spatial analysis, and numerical modeling to simulate groundwater flow and assess the feasibility of groundwater resource development on Si Chang Island. The methodology involved collecting and analyzing geological and hydrogeological data from the area, developing a conceptual model of the groundwater system, simulating groundwater flow using Visual MODFLOW software, calibrating the model against observed field data, and analyzing multiple scenarios to evaluate the potential and formulate strategies for sustainable groundwater management on the island.

CONCEPTUAL MODEL AND BOUNDARY CONDITION

The conceptual model of Si Chang Island was developed using topographic, geological, hydrogeological, soil, and land use data. The model's upper boundary was defined as a recharge boundary representing rainfall infiltration, while its outer boundaries were assigned as constant head boundaries due to the island being surrounded by seawater. The model comprises six layers: the top layer is an unconfined aquifer; the second layer consists of colluvial deposits; the third through fifth layers represent confined limestone aquifers; and the bottom layer is modeled as a no-flow boundary, corresponding to impermeable bedrock. The thickness of each layer was defined based on local hydrogeological characteristics. Groundwater abstraction from existing wells was incorporated as pumping boundaries. Reservoir boundaries were excluded from the model due to the limited water storage capacity of local reservoirs.

HYDRAULIC CONDUCTIVITY

In this study, hydraulic conductivity (K) values were assigned based on the assumption that the subsurface is heterogeneous and isotropic. The top layer, representing an unconfined aquifer, was assigned spatially variable hydraulic conductivity values, as illustrated in Fig. 3 For layers 2 through 5, which correspond to confined limestone aquifers, hydraulic conductivity values are summarized in Table 1.

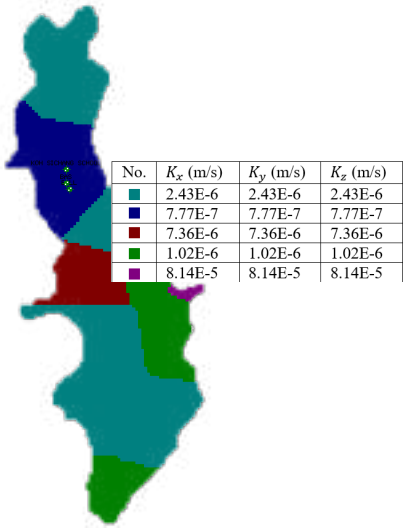

Fig. 3 Hydraulic conductivity of the topsoil layer

Table 1 Parameters for groundwater model layers

No.	K_x (m/s)	K_y (m/s)	K_z (m/s)
Layer 2	3.50E-5	3.50E-5	3.50E-5
Layer 3	4.75E-6	4.75E-6	4.75E-6
Layer 4	1.50E-6	1.50E-6	1.50E-6
Layer 5	6.50E-7	6.50E-7	6.50E-7
Layer 6	7.75E-7	7.75E-7	7.75E-7

RECHARGE

Groundwater recharge in the study area was estimated by delineating recharge zones based on land use and soil characteristics, in combination with local rainfall data. Varying recharge percentages were assigned to each land use category to reflect differences in infiltration potential.

Table 2 Initial groundwater recharge rate

Recharge Zones	Recharge Rate (% Rainfall)
1. Urban Area	1
2. Dene Deciduous Forest	20
3. Disturbed Deciduous Forest	15
4. Industry	1
5. Harbor	1
6. Government Office	1
7. Laterite Pit	30
8. Reservoir	20
9. River and Ocean	0

ZONE BUDGET

The study area was divided into six budgeting zones, as illustrated in Fig. 4, based on predominant land use types, including agricultural, urban, forested, and industrial areas. Each land use type exhibits

distinct patterns of water consumption and groundwater flow, which are essential for evaluating groundwater inflow and outflow within each zone. The assessment integrates multiple factors, such as rainfall, infiltration capacity, local water demand, and geological conditions. This integrated approach facilitates the effective identification of zones with high potential for groundwater resource development.

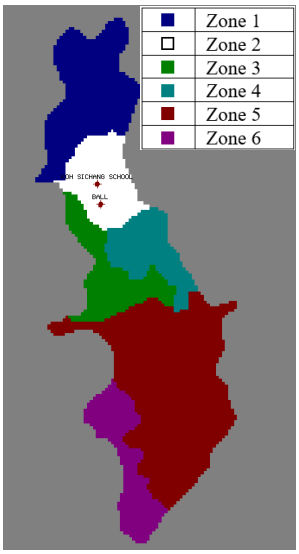

Fig. 4 Zone budget

SCENARIOS

A numerical groundwater flow model was employed to simulate the impacts of recharge variations across six designated zones under three climate change scenarios: RCP2.6, RCP4.5, and RCP8.5. The simulation was conducted over a 10-year period, from 2025 to 2035.

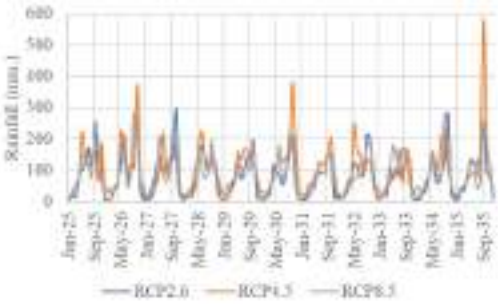

Fig. 5 Rainfall based on climate models, 2025-2035

Future rainfall projections for the period 2025 to 2035, based on the HADGEM2-AO climate model, indicate that the RCP4.5 scenario produces the highest rainfall, reaching nearly 600 mm in October 2035. In contrast, the RCP2.6 and RCP8.5 scenarios exhibit similar trends, with comparatively lower rainfall levels, as illustrated in Fig. 5. The inclusion of all three Representative Concentration Pathways (RCPs) provides a comprehensive perspective on future climate variability, enabling a more robust assessment of potential risks and uncertainties in the projections.

RESULTS AND DISCUSSION

CALIBRATION AND VERIFICATION RESULTS

This model was further developed based on the work of Srisuk et al. [19]. Model calibration and validation were performed by comparing the simulated groundwater levels with observed data from three monitoring wells on Si Chang Island, namely the Football Field Well, the Basketball Court Well, and the Koh Si Chang School Well, all of which are located within the community area. However, due to data limitations [19], this study divided the datasets used for calibration and validation into two periods: groundwater level data from May 2023 for model calibration, and groundwater level data from August 2023 for model validation.

Calibration results (Fig. 6a) yielded a Root Mean Square Error (RMSE) of 0.128 meters, a Standard Error (SE) of 0.031 meters, a Normalized RMSE of 9.158%, and a coefficient of determination (R^2) of 0.997.

Model validation (Fig. 6b) produced an RMSE of 0.117 meters, an SE of 0.066 meters, a Normalized RMSE of 9.591%, and an R^2 of 0.998.

Both calibration and validation results fall within acceptable thresholds, with Normalized RMSE values below 10%, which is considered satisfactory for groundwater modeling applications [20]. Therefore, the model is deemed reliable for use in this study and suitable for further analysis of groundwater potential in the area.

SENSITIVITY ANALYSIS

A sensitivity analysis was conducted to evaluate the influence of key parameters on the model's performance [21]. This study focused on assessing the sensitivity of three primary parameters: hydraulic conductivity (K), recharge rate, and constant head (CH) within the Si Chang Island area.

The results revealed that the constant head had the most significant impact on simulated groundwater levels, followed by hydraulic conductivity and recharge rate, respectively, as shown in Fig. 7. Variations in the constant head by ±25%, ±50%, and ±75% resulted in substantial changes in groundwater levels, emphasizing the importance of accurately defining boundary conditions that reflect real-world hydrogeological settings. These findings also underscore the necessity for precise field measurements to ensure the reliability of input parameters used in groundwater modeling.

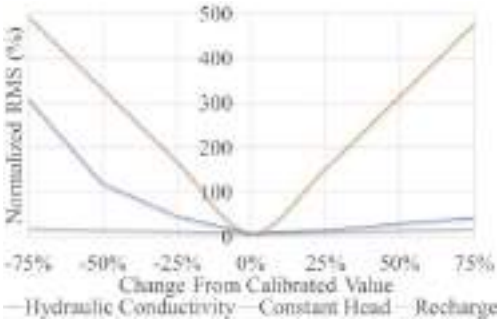

Fig. 7 Model sensitivity analysis

GROUNDWATER EXPLORING SCENARIOS

In this study, groundwater behavior on Si Chang Island was simulated using a Zone Budget approach, which divided the area into six zones. The model evaluated the impacts of climate change over a 10-year period (2025–2035) under three scenarios: RCP2.6, RCP4.5, and RCP8.5.

As shown in Fig. 8, among the six zones, Zone 5—characterized by forested land with favorable infiltration conditions—exhibited the highest average groundwater recharge rate, approximately 1,040 m³/day. However, it also experienced the highest loss to the sea, averaging 860 m³/day, with an additional outflow of 185 m³/day to Zones 3, 4, and 6.

Zone 1, a steep mountainous recharge area, had the second-highest recharge rate at around 670 m³/day but also contributed significantly to seawater loss and lateral flow, transferring about 125 m³/day to Zone 2. Zone 2, a community area and lowland discharge zone, had a low recharge rate (40 m³/day) but received substantial inflow from Zones 1, 3, and 4, totaling about 200 m³/day, with minimal loss to the sea (50 m³/day).

Zone 3 showed an average recharge rate of 345 m³/day, but due to its steep terrain, nearly all recharge was lost to the sea. It received water from Zone 5 and transferred water to Zone 4. Zone 4, also a lowland community zone, had limited recharge and seawater loss but functioned primarily as a transit zone, receiving water from Zones 3 and 5 and discharging to Zone 2.

Zone 6 demonstrated relatively high recharge but experienced even greater losses to the sea. It received some water from Zone 5, averaging around 90 m³/day.

Across all three climate scenarios, the RCP4.5 scenario resulted in the highest recharge values, particularly in October 2035, which aligns with the projected rainfall trends. However, differences among the scenarios were relatively minor in magnitude.

These findings highlight the effectiveness of spatial groundwater budgeting in identifying recharge and discharge dynamics, even in data-scarce environments. This approach supports informed decision-making for the development of sustainable community water supply systems in vulnerable island settings.

CONCLUSION AND RECOMMENDATIONS

Currently, Si Chang Island lacks a community water supply system, forcing residents to rely on rainwater harvesting and the importation of freshwater—both of which involve high costs for water and transportation. Consequently, water becomes an unnecessarily expensive resource despite being a necessity. This research aimed to identify and evaluate suitable groundwater sources to support the development of a cost-effective and sustainable community water supply system.

A spatial groundwater model was developed using

Geographic Information System (GIS) tools in conjunction with the MODFLOW program, under conditions of limited available data. The study analyzed six hydrological zones across three climate change scenarios—RCP2.6, RCP4.5, and RCP8.5—projected for the period 2025–2035 using the HADGEM2-AO climate model.

The findings indicate that Zone 2 is the most suitable area for developing groundwater resources for community water supply under all three climate scenarios. This suitability is supported by both water quality and quantity. Located in a low-lying, populated area that functions as a discharge zone, Zone 2 receives substantial inflows from Zones 1, 3, and 4 while experiencing minimal losses to the sea. In terms of water quality, Zone 2 is also favorable, as it is not directly connected to Zones 5 and 6 in the island's southern region, where groundwater contamination from hazardous substances such as arsenic has been identified. As a result, water from Zones 5 and 6 should be excluded from future water supply planning.

However, concerning water quantity in Zone 5, while there's a high rate of groundwater recharge, there's also a significant amount of water lost to the sea and outflowing from the zone. The findings highlight the importance of accurate data and a thorough understanding of the study area for planning the selection of suitable zones for establishing a community water supply. Both water quality and quantity must be considered to ensure an effective and sustainable solution for the future.

ABSTRACT

The agricultural productivity of tidal swamp land in the Air Saleh Swamp Irrigation Area (DIR), Banyuasin Regency, South Sumatra Province, Indonesia is still sub-optimal. One of the causes is the lack of irrigation water supply in the 2nd and 3rd planting season. A significant effort to overcome this problem includes the construction of canal blocking that functions to maintain water level during high tide in channel and soil moisture on land used for rice growth. The construction of canal blocking is designed to maintain water level in channel and groundwater on agricultural land covering an area of 144 ha. Therefore, this research aimed to fulfill the availability of irrigation water using a combination of rainfall systems and canal blocking to improve agricultural land productivity. Canal blocking construction was made of coconut tree trunks, which were packed with sacks full of local soil to enhance structural solidity and reduce decomposition. On the outside, sacks were installed containing a mixture of sand and cement which functioned to withstand erosion by water flow. The construction of canal bulkhead was installed with 10-inch PVC pipes draining water into channel to regulate flow level during excessive rainfall. These trunks were used as the main construction material because of local availability, resistance to submersion in water, durability against shear and overturning forces. Furthermore, simulation and optimization of water management system were carried out by modeling using the HEC-RAS program. This allowed for analysis of water level during irrigation with sediment transport and accumulation when flushing and functioning as drainage.

INTRODUCTION

The Air Saleh Swamp Irrigation Area (DIR) in Banyuasin Regency, South Sumatra Province, Indonesia, is categorized as suboptimal land, facing limitations or constraints in terms of productivity. This land is classified as type C hydrotopography, which has not been flooded by high tide. The groundwater level is less than 50 cm and is dependent on rainwater as a source of irrigation water [1]. Generally, the rainy season occurs from October to April, while the dry season spans from May to September. In this context, the planting pattern that has been implemented at DIR is Rice-Rice rotation, with planting seasons carried out 2 times. Planting Season I (one) is carried out from October to January with agricultural productivity of 5 to 6 tons/ha. Meanwhile, Planting Season II (two) spans from March to June, and agricultural productivity of 2 to 3 tonnes/ha (Survey results, 2025), which is still sub-optimal. To address this limitation, the use of canal blocking has been proven effective. Hapsoh [2] conducted an experiment for chili cultivation in Siak Regency, Riau Province, and produced 14-15 tonnes/ha, compared to when there was no construction. High production from water supply method through canal blocking has increased chili cultivation by expanding cultivated land through the conversion of oil palm land into food crops or horticultural cultivation land, which is more productive [3].

The strategy to increase rice production on sub-optimal land should be a government priority in providing and socializing the appropriate technology during cultivation. The government also needs to maintain the availability of New Superior Variety (VUB) seeds, fertilizers, and agricultural machinery (in Indonesia the same as Alsintan, Beginning, 2023). As a new strategy, construction of canal blocking has a good effect on maintaining groundwater level and keeping the land in wet or humid conditions. When water level is raised to 0.6 m, the wet effect can extend to 200 m perpendicular to canal [4].

Several canal blocking structure technologies have been built in various areas that have sub-optimal land conditions. However, many experienced construction failures due to the use of less suitable materials. Stability of canal bulkhead structure with a span of 5 meters and construction materials that are resistant to safe shear and overturning forces are required. This is because seepage in the downstream part of canal bulkhead will still occur, causing an increase in water level at upstream part and flow time [5]. A previous research had shown that a greater speed of water flow in channel with increasing time correlated with a higher value of erosion depth [6].

Therefore, the use of local fill soil with a permeability value of <0.125 cm/hour was recommended as an embankment body [7].

In an experiment conducted by Ade et al [8]. using a hydraulic simulation process with the HEC-RAS model showed that the average water level was able to exceed the land elevation [8]. However, it was not optimal, as the average height of the inundation was only 0.001 m or 1 mm [9]. From previous research, the results of hydraulic simulations showed that operational losses contributed a significant volume compared to seepage losses in physical infrastructure and management using operator-based and non-automatic control structures [10]. In most of the operating scenarios, the maximum seepage losses was 10%, and the remaining 90% was related to operations. This showed that fluctuation in inflow to canal caused an increase or decrease in operational losses, serving as a determining factor in affecting the total losses.

Controlling water level at the tertiary stage by farmers is essential for successful irrigation systems. To achieve this, a flap gate type is developed, operating predominantly as drainage during rice growth. The model also supplies water when plant enters the generative phase, achieving an average rice production of 7.5 t/ha. This condition shows that with proper water management, balanced fertilizer application, and adaptive rice varieties, cultivation in tidal lowland areas is successful and prevents land shifts [11]. To perform flushing, installing a pump in the middle intake can increase water circulation in canal with a one-way outflow during low tide. Although the inflow depends on the closing gate when in the same position, the volume of rainwater can be discharged for each rainy day [12].

Under existing conditions and network expansion with narrow intake channel, the duration of rainwater deficit tends to be shorter. Therefore, the leaching and drainage aspects require more water storage and wide intake channel. In comparison, flushing criteria require the use of pumps and gates [13]. To maintain the condition of water in each plot of land and tertiary channel, maximum operation of automatic water gate is required. Furthermore, to prevent oxidation of pyrite layer, water level must be above the base elevation [14].

RESEARCH SIGNIFICANCE

Therefore, a flow management method should be adopted to improve system performance and operational losses, by enhancing the operation of water level regulation and canal bulkhead structures [15,16]. There is a need to provide adequate water storage facilities, which can store excess supply during low water demand and shortage. The developed model is expected to help in estimating excess/shortage of water supply in relation to demand, thereby storing excess water for use during periods of high demand [17].

Water storage can help farmers meet their needs, particularly in dry and shortage conditions. Moreover, farmers need to consider the appropriate fertilizer dosage and the use of additional organic materials derived from cultivation residues, which are expected to increase the availability of nutrients in the soil. The use of short-lived and drought-resistant varieties can help overcome the problem of crop failure in the middle stage caused by water scarcity. According to previous research, rainfed rice fields generally have limiting factors for water and nutrients, showing the need for technology to achieve sustainable yields [18].

METHODOLOGY

Research Location

The research location was situated at coordinates Longitude 104° 54’ 39” – 105° 00’ 45” East longitude and between Latitude 2° 41’ 42” – 2° 43’ 11” South latitude (Fig.1). Specifically, the research was performed in Air Saleh Village, Telang District, Banyuasin Regency, South Sumatra Province, Indonesia. To reach the location, the river route is used through a speedboat from Kuto Besak Pier, Palembang City for approximately 2 hours.

Fig.1 3-4-2 Band combination Landsat image, DIR Air Saleh research location

Data

Water Level Data (AWLR)

Water level observations were carried out using an AWLR (Automatic Water Level Recorder) device at 8 points. Measurement data were taken from 2 types of water level measured at the same time. These include groundwater (TMAT), representing the height of water in the ground, and channel water level (TMAS) which is the height of water in channel.

Soil Investigation (Hand Drill and Sondir)

Soil investigation aims to evaluate the condition of soil layer at the research location and determine the depth of hard type. The analysis is carried out to obtain soil parameter data for calculations in planning of canal blocking structure. Sondir testing refers to SNI 2827: 2008 (Indonesian National Standard) to obtain parameters of soil layer penetration resistance in the field using a quasi-static penetration sondir tool. These parameters are cone resistance Cw (qc), shear resistance Tw (fs), shear ratio (Rf), and total soil shear (Tf), which are used for the interpretation of soil layers as part of the design of canal blocking structure foundation. Meanwhile, hand boring testing refers to SNI 4148-1: 2017 (standard for sampling fine-grained soil with thin-walled tubes for geotechnical purposes). The purpose of hand boring testing is to determine soil layer and take samples of disturbed and undisturbed soil for testing physical and engineering properties in the laboratory.

Rain Data

Rain data were taken from the website: POWER DAV: https://power.larc.nasa.gov/data-access-viewer/ National Aeronautics and Space Administration (NASA), with a time interval of 20 years, namely between January 1, 2005, to December 31, 2024. These data included estimates of long-term climatological averages, meteorological quantities, and surface solar energy fluctuations

Canal Blocking

Canal blocking functions to maintain water level when the tide is high in channel and soil moisture in the land needed for rice plant growth. The location of canal blocking structure as shown in Fig. 2 and Fig.3 is on the Main Drainage Channel (SDU-3U) which is +/- 20 m from the Tertiary-1U channel.

Canal blocking construction was made of coconut tree trunks, which were selected as the main material due to availability, resistance to water immersion, strength against shear and overturning forces, and easy workability. The inner filling material of canal blocking was in the form of sacks filled with local soil to achieve solid structure and reduce decomposition. For the outer side, sacks containing a mixture of sand and cement (1: 4) were installed to withstand erosion by water flow (see Fig.4a)

Fig.2 Location of Canal Blocking Placement

As shown in Fig. 4a, the width of canal blocking was 12 m with a height of 2.80 m from the bottom of channel. At the beginning to end of the width, 15-10 inch PVC pipes were installed to allow water to enter channel (Fig. 4c). The pipes also serve as a water retention boundary in the rice plant root zone and drainage when there is excess water during high rainfall.

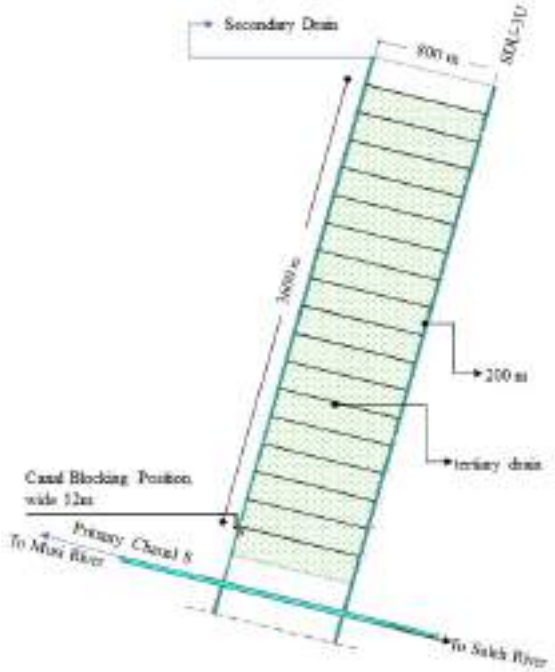

Fig. 3 Installation site for Canal Bulkhead building

The installation of pipes was arranged into 2 rows with different heights (Fig. 4c), namely :

a. The outer part of canal blocking (the beginning of the incoming tide)

(1) The first row of PVC pipes height is set based on the lowest tide level. This allows for high tide to enter, which is + 60 cm from the bottom of channel.

(2) The second row is installed at a height of 153 cm from the bottom of channel which is useful for dividing water pressure load when the tide is high on canal blocking structure.

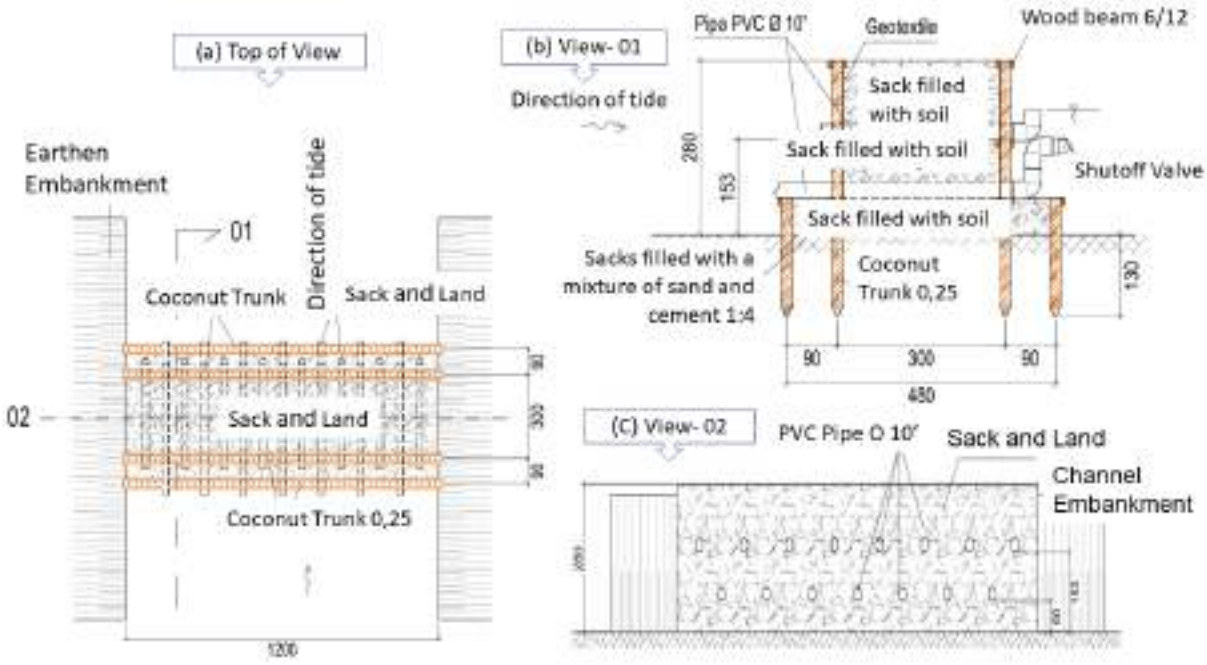

Fig. 4 Canal blocking plan: (a) Top view of canal blocking position;(b) Front view, construction of blocking canal;(c) Front view, PVC pipe placement

b. The inner part of canal blocking (the high tide enters the secondary channel)

(1) On the first row, 2, 10-inch L-Bows (Fig. 4b) are connected and 10-inch PVC pipes are installed, equipped with valves useful for closing when the tide is low.

(2) On the second row (Fig 4b), 10-inch L-Bows (swan model) are connected with a height measured based on the root zone of the rice plant. These L-Bows function to retain water on the land needed for the growth of the rice plant, which is -50 cm from the land elevation.

Implementation Method

Modeling with the HEC-RAS Program is carried out through 2 stages with 3 trial scenarios or implementations, namely:

Stage 1 (existing condition/baseline):
Scenario 1:
(1) Unsteady Flow Type
(2) Boundary Condition:
  a. flow hydrograph (El Nino/dry season)
  b. stage hydrograph (observation of tidal height)
(3) Analysis results:
  a. Water level elevation in channel
  b. Water level elevation on land
  c. Groundwater level elevation

Scenario 2:
(1) Unsteady Flow Type
(2) Boundary Condition:
  a. flow hydrograph (La Nina/rainy season)
  b. stage hydrograph (observation of tidal height)
(3) Analysis results:
  a. Water level elevation in channel
  b. Water level elevation on land
  c. Groundwater level elevation

Scenario 3 :
(1) Unsteady Flow Type
(2) Boundary Condition :
  a. flow hydrograph (Normal Condition
  b. stage hydrograph (observation of tidal height)
(4) Analysis results :
  a. Water level elevation in channel
  b. Water level elevation on land
  c. Groundwater level elevation

Stage 2 (installation of canal blocking)
Scenario 1:
(1) Unsteady Flow Type
(2) Simulation with the installation of canal blocking structure
(3) Boundary Condition:
  a. flow hydrograph (El Nino/dry season)
  b. stage hydrograph (observation of tidal height)
(4) Analysis results:
  a. Water level elevation in channel
  b. Water level elevation on land
  c. Groundwater level elevation

Scenario 2:
(1) Unsteady Flow Type
(2) Simulation of Canal Blocking Structure
(3) Boundary Condition:

a. flow hydrograph (La lina/rainy season)
b. stage hydrograph (observation of tidal height)

(4) Analysis results:
a. Water level elevation in channel
b. Water level elevation on land
c. Groundwater level elevation

Scenario 3:

(1) Unsteady Flow Type

(2) Canal Blocking Building Simulation

(3) Boundary Condition:
a. flow hydrograph (Normal Condition
b. stage hydrograph (observation of tidal height)

(4) Analysis results:
a. Water level elevation in channel
b. Water level elevation on land
c. Groundwater level elevation

RESULT AND DISCUSSION

Rainfall Frequency Analysis

Rainfall frequency analysis was carried out using four methods namely Log Normal Distribution, Log Pearson III Distribution and Gumbel Distribution to predict the probability of rain with a certain intensity in a period of time. The results of the Chi-Square test showed that the best distribution was using Log Pearson III (Table 1), with a Chi-Critical value = 3.841 and a Chi-Square value of 1,500.

Table 1 Chi-Square test CH maximum

Class	P(x >= Xm)		Ef	R (mm)	Of	Ef - Of	$(Ef-Of)^2$ / Ef
5	0,200	0 < P <= 0,2	4,000	83,616	3,000	1,000	0,250
	0,400	0,2 < P <= 0,4	4,000	69,232	6,000	2,000	1,000

Hourly Rainfall Calculation

The calculation of rainfall intensity uses the Mononobe method [19], with return periods of 2 years, 5 years, 10 years, 25 years, 50 years, and 100 years as well as duration ranging from 5 minutes to 360 minutes, as shown in Table 3.

Table 3 Hourly rainfall count

T	(hour)	1	2	3	4	5	6
Distribusi	(%)	0,550	0,143	0,100	0,080	0,067	0,059
R2	42,936	23,615	6,142	4,308	3,430	2,896	2,532
R5	52,051	28,628	7,445	5,223	4,158	3,511	3,069

Nakayasu Method Unit Hydrograph

This research uses the Nakayatsu unit hydrograph with the dimensions of SCS (Soil Conservation Service) [20].

As a synthetic unit hydrograph, the discharge is expressed as discharge (q) against peak discharge (Qp) and time (t) against the rise time of the unit hydrograph (Tp). When the peak discharge (Qp) and the delay time for an effective rainfall duration are known, the unit hydrograph can be estimated (Fig. 5).

The parameters used to calculate the Nakayasu designed hydrograph are:
Watershed Area : 3.04 Km2
Channel Length (L) : 3.8 Km
Concentration Time (tc) : 0,729
Nakayasu Coefficient (α) : 1,362
Flow coefficient : 0,45

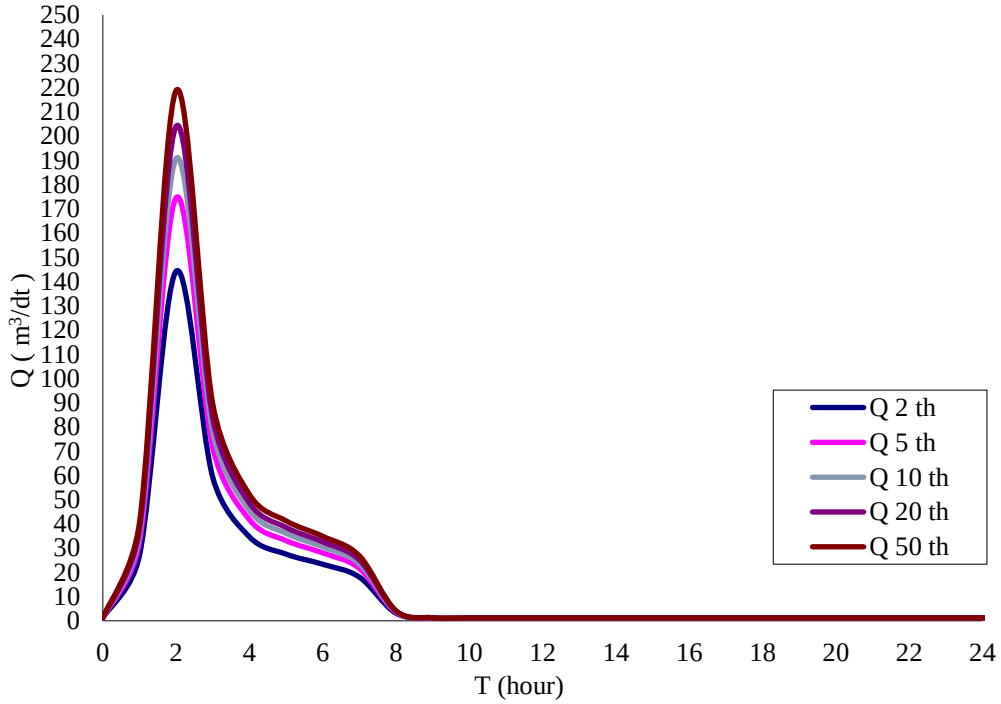

Fig. 5 Flood discharge hydrograph using the Nakayasu method

Analysis of Canal Blocking Modeling

Coconut (Cocos Nucifera) is the only member of the Cocos genus from palm family or Arecaceae. This tree grows in coastal areas and lowlands, with heights ranging from 15 m to 30 m, and trunk diameter of 0.25 m to 0.40 m. The part of the coconut tree trunk that can be used for construction wood (strength class I to IV) is the tip from the base to ¾ of the length and the top from the base to half the length. In this research, the type of coconut tree trunk used for canal blocking structure is arranged with the following provisions:

(1) Channel functions as a navigation path with low to medium usage level.
(2) Canal acts as a barrier downstream of channel where the upstream uses a backfilling compacted peat dam in adaptive and protected areas.
(3) Canal blocking is constructed on channel with a width of > 10 m and a length of 8 m to 50 m.
(4) One end of the coconut pole that will be stuck vertically (hereinafter referred to as the coconut pole tie) is sharpened using an axe. The number and size of the coconut pole ties are made wide at 8 m and the depth of the mineral soil.
(5) The pile driving process takes place until the coconut pole reaches the required depth 2-4 m (mineral soil or the wood can no longer be moved).
(6) The coconut poles that have been installed are connected to the transverse coconut poles (horizontal) using bolts, nuts, and large washers measuring 0.25" x 35-45 cm.
(7) After the wooden construction is ready or finished, the installation of a layer of non-waterproof fabric or geotextile is continued.

The evaluation of canal bulkhead design is carried out to assess whether each part is functioning appropriately, and provide suggestions for improvements. The methods used to evaluate the design of each part are as follows:

Bulkhead subsidence

The method used to evaluate the design of the coconut tree trunk bulkhead is to measure the subsidence and deformation using waterpass as well as visual observations of installed trunk. Measurement of structural subsidence is carried out by comparing the elevation of the structure after completion and during construction. A major impact of structural subsidence is deformation, which refers

to change in shape due to internal or external forces. Based on the results of observations after the installation of the canal divider (January-June, 2025) based on re-measurement of the height of the coconut trunk, using a waterpass, there was a difference in elevation of -2.13 cm.

Maintaining Groundwater/Pool Water Level

Installation of PVC pipes on canal blocking with a 2-row system is effective in reducing water flow during low tide. This maintains fresh water from rain in rice fields and increases water level in the upstream part of canal divider. The change in water level during January–July, 2025, near the canal divider was 0.36–0.48 m. Compared to a distance of approximately 1000 m from the canal divider, it was 0.10–0.12 m.

Reducing flood height or seepage

A strong and precise canal blocking installation system can prevent flooding during high tides and rainfall. Additionally, it is capable of maintaining humidity or water availability for irrigation during the dry season, enabling the achievement of 3 seasons, with a rice-rice-rice planting pattern. The groundwater level in April–July was approximately 0.32–0.14 m only in the area near the canal, which constitutes approximately ¼ of the observation area.

Reducing sedimentation in channel

Installation of canal blocking on secondary channel with long inundation times can cause anaerobic conditions in channel and potentially lead to shallowing or sedimentation, thereby reducing long-term inundation.

CONCLUSIONS

In conclusion, this research explored the potential of irrigation water using a combination of rainfall systems and canal blocking to improve agricultural land productivity. The results obtained were as follows:

(1) Installation of canal blocking on secondary channel in tidal swamp irrigation areas had a positive impact on increasing agricultural land productivity. Planting and harvesting seasons can be done 3 times a year with rice-rice-rice crops.
(2) Proper installation of canal blocking affected the height of water level in channel, land, and groundwater. Effectively, during the second and third planting seasons, groundwater levels can be reached at an average of 0.3–0.12 m. Others are assisted by pumps to raise the water.
(3) Long inundation due to the construction caused excessive shallowing/sediment in channel. On average, shallowing will occur as high as 0.12 – 0.22 m.
(4) Construction of canal blocking on channel with coconut tree trunks had a stronger bearing capacity with a geotextile blanket on the outside to reduce seepage. Average decline, about 0.022 m for a period of about 6 months.

ABSTRACT

The Community Multiscale Air Quality (CMAQ) model is widely used for simulating $PM_{2.5}$ concentrations but often suffers from biases due to inaccurate emission inventories and model parameterizations. This study develops a source-decoupled Light Gradient Boosting Machine (LightGBM) that leverages individual emission source contributions as predictors to correct biases in CMAQ-simulated $PM_{2.5}$ over Thailand, with a primary focus on interpretability using SHAP (Shapley Additive exPlanations). The proposed model is trained on three predictors derived from decoupling CMAQ-simulated $PM_{2.5}$ by emission sources, including biomass burning (BB), anthropogenic (AT), and other sources. Hyperparameters are tuned via spatial 5-fold cross-validation on the training set, and final performance is evaluated on a hold-out test set. The proposed model achieves strong performance (R^2 = 0.71 and RMSE = 9.95 μg/m^3), outperforming the CMAQ model (R^2 = 0.07 and RMSE =17.70 μg/m^3). SHAP values analysis shows that the BB-decoupled predictor dominated the bias correction, increasing the predicted values by 4.68 ± 13.45 μg/m^3 in the dry season and reducing by 7.44 ± 1.48 μg/m^3 in the wet season, relative to the model's expected output (~24.56 μg/m^3). SHAP interaction effects suggest a possible overestimation of BB and AT contributions during high $PM_{2.5}$ episodes. Our finding provides insights into how each source contributes to correcting the CMAQ biases and could guide future efforts to refine CMAQ emission inputs.

Keywords: Bias correction, Chemical transport model, Fine particulate matter, LightGBM, Thailand

INTRODUCTION

Fine particulate matter ($PM_{2.5}$) has remained a major air quality concern in Thailand for decades, with the annual average consistently surpassing the World Health Organization guideline of 5 μg/m³ [1]. Major $PM_{2.5}$ sources in Thailand include biomass burning (BB) and anthropogenic (AT) emissions [2]. Studies show that prolonged $PM_{2.5}$ exposure is linked to increased risks of respiratory diseases [3] and mortality risk from cardiovascular diseases [4]. However, these studies often rely on data from sparse air quality monitoring (AQM) stations, which do not fully cover the entire spatial study area, especially in Thailand [5]. This highlights the need for accurate and high-resolution $PM_{2.5}$ data.

Chemical transport models (CTMs), such as the Community Multiscale Air Quality (CMAQ), are widely used to estimate atmospheric pollutants, including $PM_{2.5}$. However, they are prone to biases due to factors, such as poor quality of emission inventories, inaccurate meteorological input, and incomplete chemical mechanisms. For example, the Fire INventory from NCAR (FINN) version 1.5 has been reported to cause underestimation of CTM-simulated $PM_{2.5}$, due to limitations in fire detection [6] and outdated emission factors [2]. It underscores the need for post-processing bias correction.

Several methods have been applied to address bias in CTM outputs, ranging from traditional statistical methods such as linear regression (LR) [7], to more advanced techniques such as the Kalman filter [8] and analog methods [9]. In recent decades, machine learning (ML) models have gained popularity for bias correction. These models adjust CTM outputs based on observed data, similar to LR, but they can learn nonlinearities in the data and usually yield better results [10]. Common ML models are tree-based models (TBMs) [10,11] and deep learning (DL) [12]. TBMs, such as Light Gradient Boosting Machine (LightGBM), are particularly favored for their ease of use, and strong predictive capabilities [13].

However, most ML-based studies treat simulated $PM_{2.5}$ as a single aggregated predictor [10,12], neglecting individual emission sources contributions. This hinders the model's ability to learn source-specific patterns, potentially limiting its performance. In Thailand, BB, in particular, exhibits strong seasonal patterns, peaking during the dry period (mid-October to mid-May) [14]. Our previous work shows that decoupling BB contributions using the CMAQ and incorporating them into a LightGBM model significantly improves its performance [11]. However, the study mainly focuses on performance gains without exploring how source-decoupled predictors influenced the model predictions.

Building upon the prior study, we apply SHapley Additive exPlanations (SHAP), an additive feature

attribution method where the model output is expressed as a linear combination of feature contributions [15], to explain a LightGBM model's behavior. Recognizing that AT emissions are also a major contributor to $PM_{2.5}$, we expand the model input to include decoupled predictors for BB, AT, and other sources. To isolate the role of emission sources, we rely solely on CMAQ-simulated $PM_{2.5}$ as predictors, omitting auxiliary variables such as meteorological and land-use data used in the previous work. This approach allows us to uncover how different emission sources influence bias correction.

RESEARCH SIGNIFICANCE

This study addresses a gap in current ML-based bias correction methods for CTM by incorporating source-specific $PM_{2.5}$ contributions simulated from the CMAQ model into the LightGBM framework. We also demonstrate which source contributions have the greatest impact on the bias correction of the LightGBM model through SHAP analysis. Findings of this study can offer valuable insights for improving ML-based bias correction for CTM and guiding the refinement of emission input for CMAQ simulations.

METHODOLOGY

Study area and observed data

The study area, covering Thailand, was divided into five regions (Fig. 1) based on the Thai Meteorological Department's criteria. Hourly observed $PM_{2.5}$ data were retrieved from the Pollution Control Department and Bangkok Metropolitan Administration. The study period covers three years, from 2019 to 2021. Hourly $PM_{2.5}$ values exceeding 450 μg/m³ (0.00047% of the dataset) were treated as anomalies and excluded. Hourly data were then averaged daily when over 75% of data were available. AQM stations with less than 70% daily $PM_{2.5}$ data each year were further excluded to maintain yearly representativeness.

WRF-CMAQ simulation

Meteorological variables simulated by WRF v.4.3 provided input for CMAQ v.5.3.3 to simulate $PM_{2.5}$ concentrations. WRF-CMAQ was set up with two nested domains that cover Asia with a 45-km grid and Thailand with a 15-km grid resolution, the latter of which serves as the study area. CMAQ outputs at 15-km resolution were resampled to 1-km using bilinear interpolation. The WRF-CMAQ model configurations of this study (i.e., WRF physics schemes, CMAQ chemical mechanisms, and emission inputs) matched those described in [14], except for the BB emissions, which used FINN v.2.5.

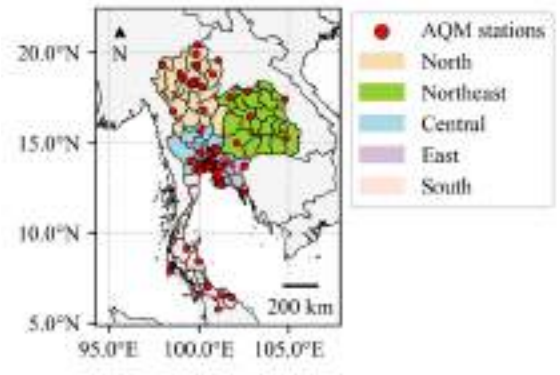

Fig. 1 The study area

To prepare the CMAQ predictors, the CMAQ model was run in three cases: C1) all emissions included, C2) AT emission excluded, and C3) BB emission excluded. The outputs and the calculation of decoupling the emission contribution are outlined in Table 1. CMAQ_PM25 is the baseline predictor, while CMAQ_PM25_AT, CMAQ_PM25_BB, and CMAQ_PM25_Othr represent source-decoupled predictors. Fig. 2 illustrates the daily average of observed $PM_{2.5}$ levels, along with baseline and source-decoupled predictors across all AQM stations.

Table 1 Summary of CMAQ simulation cases and emission decoupling calculations

CMAQ running cases	
C1	All emissions include (CMAQ_PM25)
C2	AT emissions excluded (CMAQ_PM25_No_AT)
C3	BB emissions excluded (CMAQ_PM25_No_BB)
Decoupling individual emission contribution	
C1 – C2	AT contribution (CMAQ_PM25_AT)
C1 – C3	BB contribution (CMAQ_PM25_BB)
C3 – (C1 – C2)	Other contribution (CMAQ_PM25_Othr)

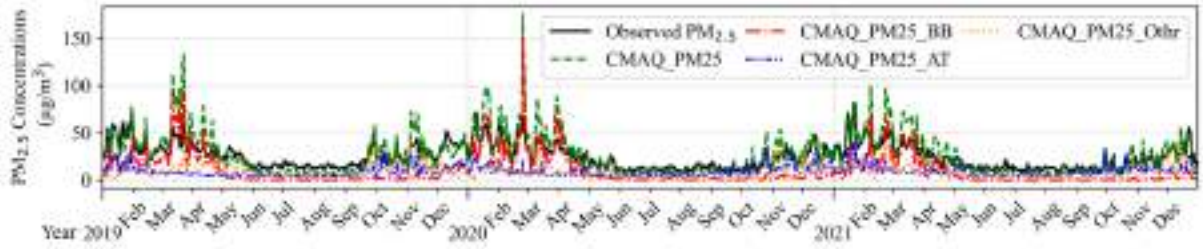

Fig. 2 Daily average of observed and CMAQ-simulated $PM_{2.5}$ across all AQM stations from 2019 to 2021

LightGBM modeling framework

From 103,639 samples across 125 AQM stations, we randomly split the data into training (80%) and test (20%) sets by AQM stations, ensuring regional representation via stratified random sampling. We repeated this process with five different random seeds and developed five independent sub-frameworks for robust results. For each sub-framework, we built two LightGBM models (baseline and source-decoupled models) and tuned hyperparameters independently.

Hyperparameter tuning was performed using a Bayesian optimization algorithm on the baseline predictor, with spatial 5-fold cross-validation (CV), where the data was split based on stations. The optimal hyperparameters were then applied to evaluate both models using spatial CV, as well as overall CV (sample-based splitting). Evaluation metrics included R^2, the root mean square error (RMSE), and the mean absolute error (MAE). The evaluation was conducted over the full period, covering all samples, and across the wet season (mid-May to mid-October) and the dry season (mid-October to mid-May).

Both CV aspects were repeated 50 times with different random seeds, yielding 50 sets of validation scores per model. These scores were compared using a one-tailed paired t-test at a 95% confidence interval to assess differences. Final validation scores were averaged across 50 CV repetitions and five sub-frameworks. The models were finally trained on the full training set and tested on the holdout set, with test scores averaged across the five sub-frameworks.

We applied SHAP to the source-decoupled model using the TreeExplainer [16], with a tree-path dependent approach. It was fitted separately on the training set of each sub-framework, and SHAP values were computed on the corresponding test set. The resulting five SHAP value sets were averaged for overlapping samples to produce final SHAP values.

RESULTS AND DISCUSSION

The LightGBM model performance

As shown in Table 2, the sourced-decoupled model significantly outperforms the baseline model for both overall and spatial CV (p-value < 0.05). This improvement likely stems from the decoupling process, which reveals source-specific patterns and helps the model to better identify and correct CMAQ biases. For example, CMAQ_PM25_BB exhibits a consistent seasonal pattern over three years (Fig. 2), with higher $PM_{2.5}$ levels in the dry season and lower levels in the wet season due to reduced forest fires and agricultural burning, and more frequent rainfall. This seasonal pattern, particularly from BB, enhances the effectiveness of the decoupling process in the dry season. This is reflected in a more pronounced improvement in model performance during this season compared to the wet season.

Interestingly, when using only CMAQ-simulated $PM_{2.5}$ as a predictor, the spatial and overall CV scores are nearly identical. This contrasts with usual trends, where spatial CV scores are usually lower due to the location generalization challenge [11]. By removing other features, such as meteorological and land-use data, the model becomes simpler. This can reduce the risk of overfitting, particularly to spatial patterns learned from those features.

Table 2 Validation scores of the LightGBM models

Period	Model	Overall CV			Spatial CV		
		R^2	RMSE (μg/m^3)	MAE (μg/m^3)	R^2	RMSE (μg/m^3)	MAE (μg/m^3)
Full period	Baseline	0.67	10.82	6.99	0.66	10.94	7.04
	Source-decoupled	0.72	9.92	6.45	0.71	10.18	6.55
Wet season	Baseline	0.44	5.46	4.14	0.43	5.53	4.25
	Source-decoupled	0.47	5.33	4.03	0.45	5.40	4.11
Dry season	Baseline	0.58	13.43	9.06	0.57	13.58	9.07
	Source-decoupled	0.65	12.21	8.20	0.64	12.55	8.32

Table 3 Test scores of the LightGBM and CMAQ models

Period	Model	R^2	RMSE (μg/m^3)	MAE (μg/m^3)
Full period	CMAQ	0.07	17.70	9.98
	Baseline	0.66	10.75	6.90
	Source-decoupled	0.71	9.94	6.44
Wet season	CMAQ	-0.08	7.40	5.77
	Baseline	0.38	5.44	4.17
	Source-decoupled	0.42	5.29	4.05
Dry season	CMAQ model	-0.22	22.38	13.03
	Baseline model	0.58	13.32	8.88
	Source-decoupled	0.64	12.25	8.13

The test scores of both LightGBM models closely align with the validation scores, indicating the models generalize well to unseen data (Table 3). For comparison, the performance of the CMAQ model was evaluated on the same test set and was found to perform worse. Despite this, the LightGBM models show limited performance at high $PM_{2.5}$ ranges in both seasons, tending to underestimate the concentrations of $PM_{2.5}$. This limitation is illustrated by elevated relative MAE (RMAE) computed on test sets in Fig. 3.

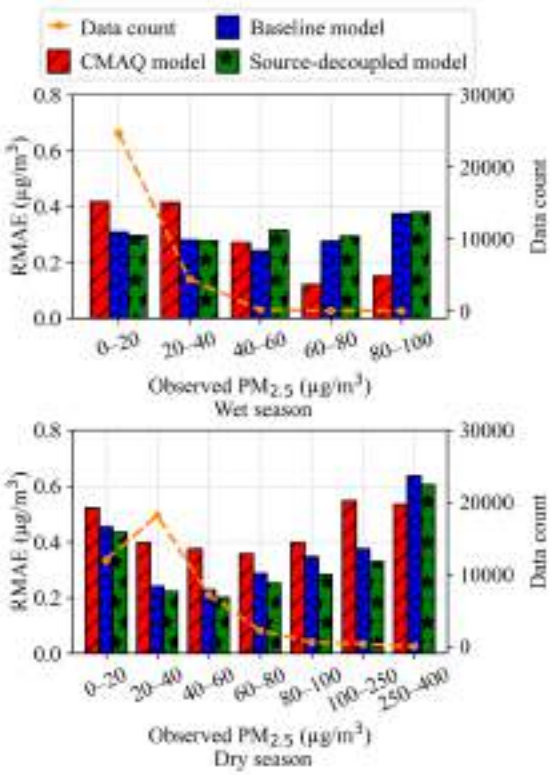

Fig. 3 RMAE values of the CMAQ, baseline and source-decoupled models in the wet and dry seasons

Because high $PM_{2.5}$ concentration events are rare in both seasons and the models were intentionally designed to be simple with few predictors to prevent overfitting, the LightGBM models may have limited performance over such rare events.

SHAP analysis

Mean SHAP and mean |SHAP| values

All decoupled predictors display similar trends, where higher predictor values are associated with higher SHAP values (Fig. 4). Notably, SHAP values for CMAQ_PM25_BB plateau beyond 200 μg/m³. This provides further evidence of the model's limited ability to generalize at extreme $PM_{2.5}$ levels.

Among decoupled predictors, CMAQ_PM25_BB exhibits the highest mean absolute SHAP (mean |SHAP|) value for the full period, indicating that it is the most important predictor, followed by CMAQ_PM25_AT and CMAQ_PM25_Othr as illustrated in the upper plot of Fig. 5. The wet and dry seasons also show the same important order.

To assess the direction of predictor contributions, seasonal analysis was preferred as it helps group SHAP values into more homogeneous ranges and mitigate cancellation when averaged, as shown in the lower plot of Fig. 5. During the wet season, all predictors negatively contribute to $PM_{2.5}$ predictions, reducing them relative to the model's expected output (~24.56 μg/m³). CMAQ_PM25_BB shows the strongest contribution, followed by CMAQ_PM25_AT and CMAQ_PM25_Othr. Conversely, during the dry season, they exhibit positive contributions, with CMAQ_PM25_BB again leading, followed by CMAQ_PM25_Othr and CMAQ_PM25_AT. Overall, CMAQ_PM25_BB emerges as the most influential predictor, consistent with its strong seasonal variability.

CMAQ_PM25_AT and CMAQ_PM25_Othr show similar mean SHAP values, and they have lower contributions than CMAQ_PM25_BB in both seasons. This could be due to their relatively lower concentrations and the lack of a distinctive temporal pattern, unlike CMAQ_PM25_BB. Despite their similar mean SHAP values, CMAQ_PM25_AT yields greater standard deviation compared to CMAQ_PM25_Othr (Fig. 5). One potential reason could be its spatial variability, with higher concentrations in densely populated areas, such as Central Thailand. This spatial pattern may make CMAQ_PM25_AT more useful in predicting $PM_{2.5}$ in these regions.

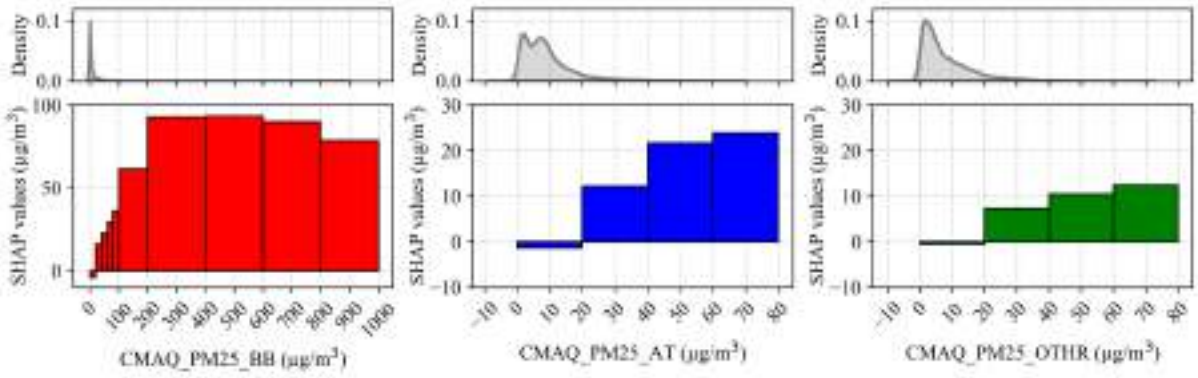

Fig. 4 Bar plot between mean SHAP values and corresponding CMAQ predictor intervals. The upper subplots show the distribution of CMAQ predictor values fitted using Kernel Density Estimation

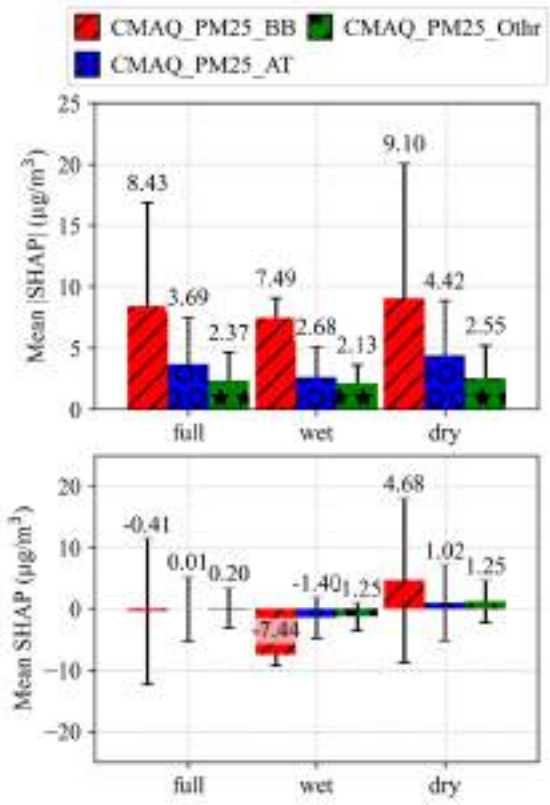

Fig. 5 Mean |SHAP| values (upper) and mean SHAP values (lower) of source-decoupled predictors

SHAP interaction effects

Feature interaction could be another reason for the higher variability of CMAQ_PM25_AT compared to CMAQ_PM25_Othr. We computed pairwise interaction values and found that the interaction between CMAQ_PM25_BB and CMAQ_PM25_AT is the strongest. Fig. 6 visualizes the interaction between them. When CMAQ_PM25_BB values are lower than 75 μg/m³, higher values of CMAQ_PM25_AT are observed with increased SHAP values of CMAQ_PM25_BB, suggesting a synergistic relationship where both predictors together push $PM_{2.5}$ predictions higher. However, when CMAQ_PM25_BB values exceed 75 μg/m³, this relationship reverses. Higher values of CMAQ_PM25_AT are associated with lower SHAP values of CMAQ_PM25_BB.

SHAP values vs. CMAQ's biases

Although SHAP values do not provide direct quantification of biases in the CMAQ model, they provide insights into how LightGBM adjusts its outputs, which can be interpreted to form hypotheses about potential biases in the CMAQ-simulated $PM_{2.5}$ by emission source. The observed interaction between CMAQ_PM25_BB and CMAQ_PM25_AT suggests that the LightGBM model learn to use these predictors to cooperatively correct biases in the CMAQ outputs. Specifically, during high pollution episodes, characterized by elevated values of both predictors, the model assigns relatively lower SHAP values. This pattern suggests the model's attempt to suppress a possible overestimation in the CMAQ model for these sources. Based on the hypothesis, refining the emission inputs or adjusting the CMAQ model parameters, particularly for the BB contribution, which is identified as the most influential predictor, could enhance the performance of the CMAQ model. Moreover, this interaction effect also implies that if future ML modeling frameworks adopt decoupling strategies, it would be worthwhile to consider decoupling both BB and AT emissions because it could enhance the ML model's bias correction efficiency.

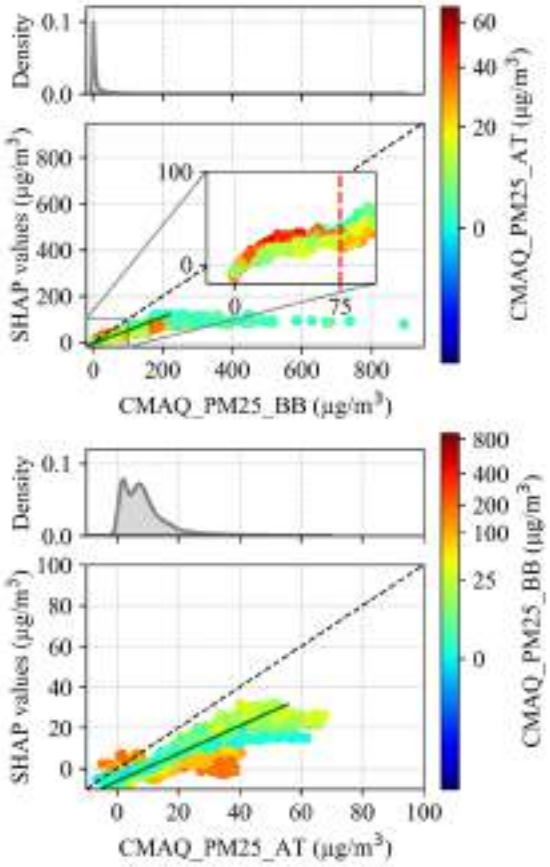

Fig. 6 SHAP Dependence plot for CMAQ_PM25_BB and CMAQ_PM25_AT

CONCLUSIONS

This study developed an interpretable LightGBM model to correct CMAQ-simulated $PM_{2.5}$ in Thailand by using three source-decoupled predictors, including CMAQ_PM25_BB, CMAQ_PM25_AT and CMAQ_PM25_Othr. The model demonstrated strong predictive performance and effectively reduced CMAQ biases, particularly in the dry season. SHAP analysis revealed the dominant influence of

CMAQ_PM25_BB and suggested possible overestimations in the CMAQ model for BB and AT contributions during high pollution episodes. These findings highlight the effectiveness of the decoupling approach for improving CMAQ simulations and offer a practical guide for refining emission inventories and CMAQ model configurations.

Future work could apply DL, such as Neural Networks, to assess whether decoupled emission source predictors remain effective in more complex architectures. Moreover, incorporating additional features (e.g., meteorological and land-use data) may further enhance model performance.

ABSTRACT

Harima Nada, located in the eastern Seto Inland Sea, Japan, has experienced progressive oligotrophication over the past three decades. To support effective nutrient management, it is essential to understand the hydrodynamic variations controlling nutrient transport and distribution. As a semi-enclosed sea with limited exchange with the open ocean, Harima Nada's hydrodynamics are strongly influenced by riverine inflows and sensitive to wind and atmospheric conditions. In this study, we investigated the impacts of river discharge on physical fields of Harima Nada by season using an ocean-atmosphere coupled model combining the Regional Ocean Modeling System (ROMS) and the Weather Research and Forecasting (WRF) model. The impacts were calculated by comparing simulations with and without river inflow in summer and winter. The results showed that river inflow increased sea surface temperature in summer and while it slightly lowered sea surface temperature in winter. Salinity decreased in both seasons, with a stronger surface decline in summer. The model better reproduced temperature and salinity with river inflow than without river inflow condition. In summer, temperature RMSE decreased by 0.26 ℃ and IA increased by 0.03; salinity RMSE decreased by 2.03 PSU and IA increased by 0.59. In winter, temperature RMSE decreased by 0.14 ℃ and IA increased by 0.01; salinity RMSE decreased by 1.02 PSU and IA increased by 0.41. In conclusion, summer's increased river inflow enhances density stratification through sea surface warming and salinity reduction, suppressing vertical mixing, whereas winter's weaker stratification and lower discharge limit these fluvial effects.

Keywords: Harima Nada, River inflow, Ocean model, Physical fields

INTRODUCTION

Although the Seto Inland Sea and Harima Nada experienced eutrophication during rapid economic growth in the 1960s, they have gradually shifted towards low nutrition in recent decades. This ongoing decline in nutrient levels has negatively impacted the fisheries industry and brought increasing attention to nutrient management policies [1-2]. As part of the measures, artificial nutrient supply using treated sewage water is being promoted in Harima Nada. However, the optimal approach for increasing nutrient levels to prevent both eutrophication and oligotrophication has yet to be determined. To address this issue, it is essential to develop an ocean model capable of accurately predicting future nutrient dynamics and their impacts on water quality and marine ecosystems.

Harima Nada, as a semi-enclosed coastal sea surrounded by land, with limited exchange with other open ocean, making it highly sensitive to both terrestrial and atmospheric influences. In such shallow coastal areas, oceanic circulation is strongly affected by atmospheric conditions such as wind speed and air temperature [3], which govern surface mixing and the vertical transport of nutrients-necessitating consideration of short-term ocean-atmospheric interactions [4]. Moreover, the region's geographical setting amplifies its vulnerability to terrestrial inputs, particularly freshwater discharge from rivers. The vertical distribution of these river inflows plays a critical role in shaping density stratification, mixing dynamics, and nutrient transport processes within this semi-enclosed system.

To access the impacts of river discharge on the coastal environment of Harima Nada, this study compares the vertical profiles of temperature, salinity, and density between summer and winter under conditions without and with river input. Seasonal variations in water column structure are examined in light of observational data obtained at a coastal monitoring site.

RESEARCH SIGNIFICANCE

This study highlights the critical role of river inflow in shaping the physical fields of Harima Nada, a semi-enclosed and shallow coastal sea that is particularly sensitive to freshwater inputs. By comparing ocean conditions with and without river inflow, the study demonstrates how riverine input influences stratification and physical structure across different seasons. The inclusion of river inflow improves model performance, leading to more

accurate representations of stratification and circulation patterns. These findings provide a basis for future biogeochemical modeling in Harima Nada, and contribute to ongoing efforts to develop seasonally adaptive management strategies.

METHODOLOGY

Evaluation Method and Model Structure

A coupled ocean-atmospheric model was employed to investigate the physical environment of the Harima Nada region. Model results were compared with observational data from 15 observation points in the Harima Nada area, as shown in Figure 1. Observations were conducted monthly at three depths: surface, middle, and bottom. For model-observation comparison, values were extracted from corresponding depths: 0.5 m (surface), 10 m (middle), and 1 m above the seafloor at each observation site (bottom). Among these sites, one analysis point located in the area most influenced by river inflow was selected for further investigation. At this point, time series over all vertical layers and seasonal mean vertical profiles in summer and winter were analyzed to more clearly demonstrate the impact of river discharge.

Fig.1 Observation Station in Harima Nada and Selected Analysis Point

The structure of the coupled system is illustrated in Figure 2. In this coupled framework, the Weather Research and Forecasting (WRF) model supplies meteorological forcing variables to Regional Ocean Modeling System (ROMS). Utilizing these inputs along with the Coupled Ocean-Atmospheric Response Experiment bulk flux algorithm [5], ROMS computes surface momentum and heat fluxes, which serve as upper boundary conditions for the ocean model, then ROMS sends the updated Sea Surface Temperature (SST) to WRF, closing the air–sea feedback loop. Through this two-way exchange, the coupled model simulates realistic ocean-atmospheric interactions over the Harima Nada region.

Fig.2 Structure of the ROMS-WRF Coupled Model

Model Conditions

Model configurations are summarized in Table 1. The simulation was conducted from December 2009 to November 2010, with a spin-up period starting from June 2009 to allow model stabilization. Since Harima Nada is a very shallow sea, equal vertical layer thicknesses were applied in the ocean model to ensure numerical stability and facilitate consistent interpretation of the model outputs.

Table 1 Model configurations applied to the ROMS - WRF coupled model for Harima Nada

ROMS model		
Horizontal domain		the Seto Inland Sea
Horizontal grid number		200 × 100
Horizontal resolution		3.0 km
Vertical layer number		32
Vertical distribution		Equal Layer Thickness
Boundary and initial conditions	Ocean boundary and initial	HYCOM-NCODA (1hour, 1/12°)
	Tidal	TPXO9 Atlas v.5
	River	1. without river input 2. with river input
WRF model		
Horizontal domain		the entire western Japan
Horizontal resolution		6.0 km
Vertical layer number		30
Boundary and initial conditions		ERA5
Physics option	microphysics	Morrison 2-moment sheme
	cumulus	no cumulus
	planetary boundary layer	MYNN3
	land-surface	Noah LSM
	radiation	RRTMG

River Boundary Conditions

The river boundary conditions are summarized in Table 2. The model accounts not only for major rivers flowing directly into Harima Nada but also incorporates key rivers from adjacent coastal areas to better capture the regional freshwater influence.

To account for the buoyancy-driven spread of freshwater, a top-biased vertical distribution was applied, with values decreasing from surface to bottom.

To better understand the seasonal influence of

river discharge, this study also incorporated time-varying river temperatures. Figure 3 shows time series of river discharge, river temperature, and sea surface temperature for all rivers, including those outside Harima Nada.

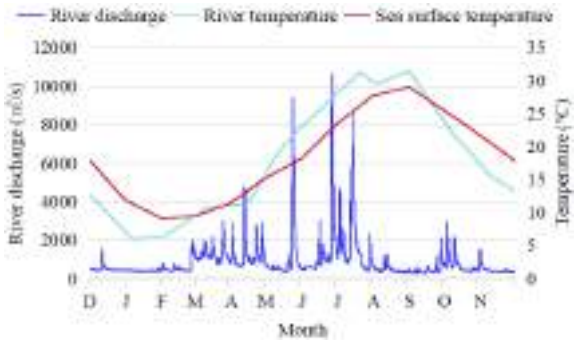

Fig.3 Time series of river discharge [6-7], river temperature [7] and sea surface temperature [8] of study area

Based on these settings, the with river simulation was conducted and compared to the without river inflow conditions for two representative seasons: winter, when river temperature and discharge was low (December, 2009 - January, 2010), and summer, when both were high (June, 2010 - July, 2010). The comparison focused on the vertical distributions of temperature, salinity, and density.

Table 2 The river boundary conditions

River boundary conditions	
Number of rivers	18 rivers, including 11 that flows directly into Harima Nada and 7 from neighboring coastal regions
River discharge	Results from Modified Hydro–BEAM and Water Information system
River temperature	Monthly water temperature values of the Kako River
PSU	0
River input algorithm	Volume vertical influx
River vertical distribution	Discharge decreases gradually from the surface to the bottom

RESULTS AND DISCUSSION

The model's overall reproducibility for temperature and salinity improved when river inflow was included, as indicated by the statistical indicators in Table 3 and Table 4, which present seasonal statistical indicators for temperature and salinity, respectively. The statistical indicators were calculated based on comparisons between model outputs and observational data at 15 sites, with monthly observations at three depths (surface, middle and bottom). For each season-summer (June-July) and winter (December-January) a total of 90 samples per variable were used (15 sites × 3 depths × 2 months). For the entire year (12 months), the sample size increased to 540 per variable. One sample corresponds to a model-observation pair at a specific site, depth, and month.

The results indicate that the inclusion of river inflow significantly improved the model's reproducibility across both summer and winter seasons, with particularly notable enhancements in salinity.

In summer, the temperature reproducibility improved with Root Mean Square Error (RMSE) reduction of 0.26 ℃ and an increase in Index of Agreement (IA) by 0.03, while salinity showed RMSE reduced 2.03 PSU and IA increase of 0.59. In winter, the improvements were slightly smaller: temperature RMSE decreased by 0.14 ℃ and IA increased by 0.01; salinity RMSE decreased by 1.02 PSU with an IA increase by 0.41.

These results suggest that increased river discharge during summer enhances density stratification by warming the sea surface and reducing salinity, thereby suppressing vertical mixing. In contrast, winter conditions with lower discharge and weaker stratification limit the extent of these fluvial effects.

To further clarify the seasonal impact of river inflow, the following sections present detailed comparisons for each physical variable, focusing on water temperature, salinity and density.

Table 3 Reproducibility metrics for simulated water temperature

	River Conditions	R	RMSE	MAE	IA
Summer	Without river inflow	0.92	1.58	1.28	0.91
	With river inflow	0.92	1.32	1.05	0.94
Winter	Without river inflow	0.99	0.55	0.46	0.99
	With river inflow	1.00	0.41	0.34	1.00

Water Temperature

River inflow affects seawater temperature through the input of freshwater with different thermal properties. Figure 4 compares the vertical distribution of summer-averaged water temperature over winter and summer, at the analysis point shown in Figure 1, under with and without river conditions. The results demonstrate that river inflow elevates surface temperatures through the input of relatively warmer freshwater, while deeper layers show minimal thermal response. This differential heating pattern confirms that the thermal influence of river discharge is predominantly confined to the upper water column, thereby strengthening vertical stratification during summer months.

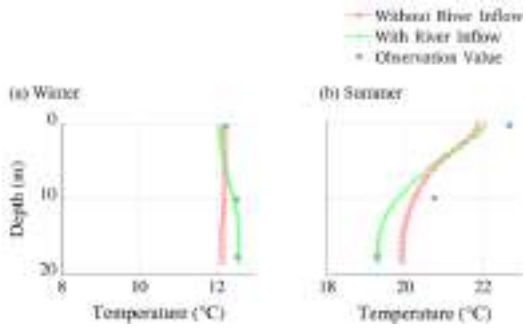

Fig.4 Comparison of average vertical temperature profiles

The summer-averaged vertical profile highlights the vertical structure of temperature differences caused by river inflow. Figure 5 show time series of the vertical temperature distribution at the analysis point for winter and summer, under both with and without river conditions. The results reveal a clear seasonal contrast in river-induced thermal effects. During winter, although river water is colder than seawater, its limited discharge volume and low density prevent significant vertical mixing, causing the colder freshwater to remain confined to the surface layer. In contrast, summer conditions exhibit pronounced surface warming due to both increased river discharge and higher freshwater temperatures. The combination of greater flow volumes and enhanced buoyancy results in stable stratification, with warm surface waters overriding cooler subsurface layers. This seasonal pattern demonstrates how variations in both temperature and discharge magnitude jointly control the vertical thermal structure of coastal waters.

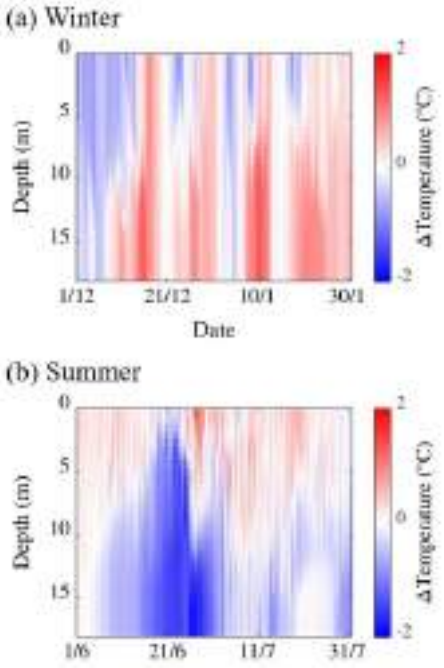

Fig.5 Time series of full-depth temperature differences (with river inflow – without river inflow)

Water Salinity

Riverine inputs not only affect seawater temperature, but also significantly alter the salinity structure of nearshore waters through the supply of freshwater. Figure 6 compares the vertical distribution of salinity averaged over winter and summer, under with and without river conditions, at the analysis point shown in Figure 1. The results show that river inflow clearly decreases surface salinity, with the effect being stronger in summer due to enhanced stratification. In contrast, salinity differences are more moderate in winter, likely due to increased vertical mixing and lower river discharge.

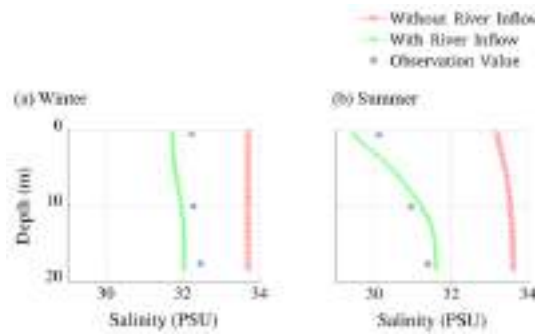

Fig.6 Comparison of average vertical salinity profiles

To obtain a more complete understanding of salinity variation, time series data were also examined. Figure 7 present the time series of vertical salinity profiles at the analysis point during winter and summer, under both river conditions. Showing that with riverine conditions, surface salinity significantly decreases in summer, forming a distinct freshwater layer, while in winter, although less diluted, a decrease in surface salinity and an enhancement of salinity leapfrogging can still be observed. This suggests that river inflow not only affects surface salinity, but also strengthens the stratification structure of the water column.

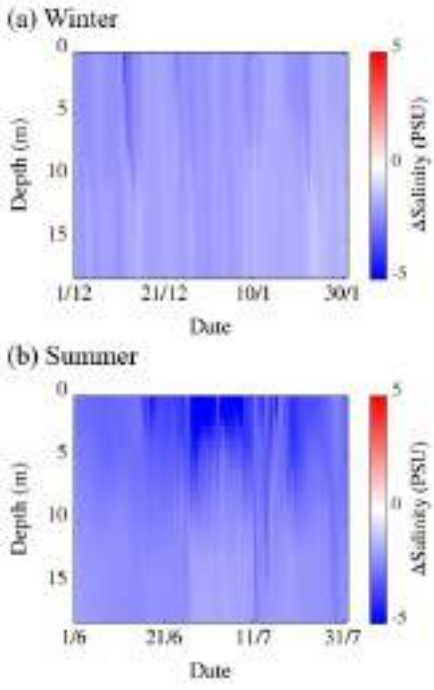

Fig.7 Time series of full-depth salinity differences (with river inflow – without river inflow)

Water Density

The density of seawater is affected by a combination of temperature and salinity. In general, the lower the temperature, the higher the density; the higher the salinity, the higher the density. Thus, river inflow, by bringing freshwater with low salinity and high temperature, creates a lighter water column in the nearshore region, which in turn alters the vertical density structure of the water column and affects the mixing state of the upper and lower water column.

Figure 8 compares the vertical distribution of mean density in summer and winter under with and without river conditions. The results show that in the summer with a river, the density of the surface layer is significantly lower than that of the bottom layer, and the location of the density jumps is clear, with obvious stratification structure; while in the winter, the overall density distribution is much smoother, especially in the without river inflow condition, and there is almost no visible jump structure. This suggests that river inflow enhances seasonal stratification, especially in summer, and has a particularly strong effect on the vertical stability of seawater.

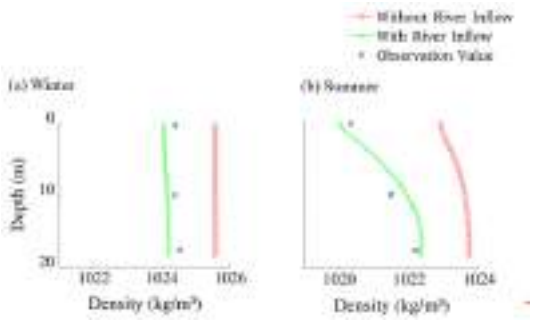

Fig.8 Comparison of average vertical density profiles

Furthermore, to quantify the strength of density lamination, the Brunt-Väisälä oscillation frequency (N^2) is often used as a measure of the vertical stability of the water column. It is defined as follows [9]:

$$N^2 = -\frac{g}{\rho_0} \cdot \frac{d\rho}{dz} \qquad (1)$$

where g is gravitational acceleration (m/s²), ρ_0 is reference density (kg/m³), and $d\rho/dz$ is the vertical gradient of density (kg/m⁴), S_o is the sea water density. The larger the N^2, the more stable the stratification of the water column is and the more difficult it is to mix the upper and lower layers. This indicator can effectively reflect the combined effects of temperature and salinity changes on the density structure.

Figure 9 shows the time-series variation of N^2 in summer and winter (with and without river inflow

conditions). It can be seen that the stability of stratification is generally higher in summer than in winter, with or without rivers, which mainly stems from the fact that the seawater becomes lighter by heat in summer, while the warm water and large amount of freshwater imported by rivers enhances the buoyancy of the upper water body, resulting in a clear stratification structure with a clear inhibition of upward and downward mixing due to the increase in the difference in density between the surface layer and the bottom layer. Comparatively, in winter, water bodies under no river conditions produced homogeneous, well-mixed water columns, while river inputs maintained weak stratification through surface freshening despite colder temperatures.

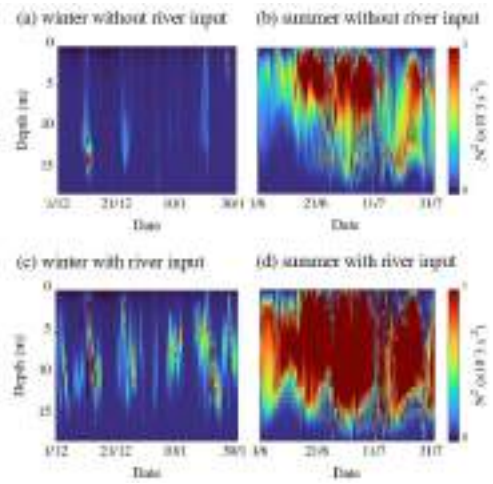

Fig.9 Time-series variation of Brunt - Väisälä frequency squared (N^2) under different river discharge and seasonal conditions

CONCLUSIONS

This study quantifies river inflow's control on coastal stratification using a coupled ocean-atmospheric model. Results reveal pronounced seasonal effects: summer's warm, high-discharge conditions create strong stratification through surface warming and freshening, while winter's reduced inflow maintains weak but persistent freshening. River inputs thus critically modulate nearshore physical structure year-round. According to the simulation results, river inflow strengthens vertical stratification in summer and contributes to moderate desalination in winter, shaping nearshore physical structure throughout the year. The model successfully reproduced these seasonal patterns, demonstrating good agreement with observations.

ABSTRACT

Cities that continue to rely on fossil fuel-powered cars, contributing to greenhouse gas emissions and climate change, face significant challenges regarding green transportation. In addition to the growing dependence on fossil fuels, the fluctuating prices of these fuels and air pollution from traditional transportation severely impact public health. These issues can be addressed by adopting electric vehicle (EV) technology to replace fossil fuel-powered cars. Adequate service center facilities are essential for promoting EV adoption and fostering a sustainable transportation ecosystem. The characteristics of a site are vital for constructing EVSCs. This study aims to identify suitable locations and environments for EVSCs in Jakarta Province. Various data sources, including the Detailed Spatial Plan (RDSP) of the Special Region of Jakarta Province, existing condition maps, and population density, are utilized to optimize the development of EVSCs using overlapping map techniques (Geographic Information Systems). Furthermore, this study compares the characteristics of current EVSC locations in Jakarta with those in Hefei, China. Hefei City is well-established in achieving high EV adoption, indicating it has sufficient EVSC facilities to meet users' charging needs. The findings suggest that the placement of EVSC facilities must consider major highways, commercial buildings, retail businesses, and development and conservation areas. Adequate EVSC facilities in appropriate locations within the Jakarta area are crucial for meeting users' demands for green mobility.

Keywords: Electric Vehicle, Service Centre, Green Transportation, Facilities, Geography Information System (GIS)

INTRODUCTION

Climate change and rising greenhouse gas emissions are becoming pressing worldwide issues, particularly in urban regions that continue to rely on fossil fuel vehicles [1]. To address environmental concerns, air pollution, and reliance on fossil fuels, several major cities, including Jakarta, have begun to shift to sustainable transportation systems through the use of electric vehicles (EVs).

However, the availability of vehicle units is not the only factor determining the effective implementation of electric vehicles; the supporting infrastructure must also be ready. The Electric Vehicle Service Center (EVSC) is a critical component of such infrastructure, as it ensures the convenience, safety, and dependability of electric vehicle operations [2]. EVSCs offer vehicle testing, repair, and maintenance services, and act as a starting point for the recycling of end-of-life power batteries [3]. As a result, a fixed and strategic site for the EVSC is critical to ensuring the efficiency of the after-sales service chain.

The availability and equitable distribution of EVSCs is a key factor in driving widespread adoption of electric vehicles [3]. In Jakarta, the challenge is that the number of EVSCs is still limited and unevenly distributed. In addition, the absence of a comprehensive spatial database of ideal locations for the development of these facilities further complicates efforts to expand the EVSC network.

As a result, a data-driven and spatial strategy is required to establish the ideal location for EVSC development in Jakarta. This study aims to identify and optimize the placement of EVSC facilities using a Geographic Information System (GIS)-based spatial overlay method. For contrast, this study also looks at Hefei City, China, which is noted for having one of the highest rates of electric vehicle adoption and a robust supporting infrastructure system.

This method should create a more strategic, adaptive, and long-term EVSC deployment planning model. This study's findings are projected to make a substantial contribution to the formulation of environmentally friendly transportation policy and increase city infrastructure readiness for an era of inclusive and efficient car electrification.

RESEARCH SIGNIFICANCE

Jakarta, the country's capital and commercial hub, presents a significant challenge in developing an environmentally friendly transportation infrastructure. With a land area of 661.52 km² and 159,083 electric vehicle (EV) users as of April 2024, the city has significant potential to shift to a sustainable mobility system. However, supporting infrastructure in the form of Electric Vehicle Service Centers (EVSC) is

still limited, with only five service locations accessible, all from the Wuling brand. On average, one EVSC in Jakarta serves around 31,800 people and covers a 132.3 km² area, making it unsuitable for providing convenient and efficient electric car services.

Fig.1 Map of Jakarta's Administrative Boundaries

For instance, Hefei City in China, with an area of 11,434 km², has erected at least eight EVSCs for the Wuling brand, each having an average service range of 1.43 km. Hefei is not only geographically larger, but it is also actively developing a national EV ecosystem through progressive laws and full backing from the municipal administration. The goal of producing 1 million electric vehicles by 2025 solidifies Hefei's status as a role model for the creation of a green metropolis based on transportation electrification [4].

Fig.2 Map of Hefei's Administrative Boundaries

Table 1. Comparison of Jakarta and Hefei areas

City	Area	Total EVSC Wuling	Average
Jakarta	661,52km2	5	132,3km
Hefei	11,434km2	8	1,43km

This number reflects a relatively low EVSC density of only one EVSC serving over 31,800 EV customers and covers a huge area that is disproportionate to everyday mobility needs and supporting infrastructure. Hefei, on the other hand, is not only physically larger, but it has also established a progressive EV ecosystem with higher EVSC density and aggressive national production targets.

This study employed a GIS-based spatial overlay analysis to identify optimal locations for the development of EVSCs in DKI Jakarta. The analysis integrated multiple spatial layers, including the distribution of existing EVSCs, population density, the detailed land use plan, and the road network. Data were validated to comply with Jakarta Satu geospatial standards, followed by data cleaning, clipping, simplification, and conversion to spatial formats. The spatial analysis followed a three-stage GIS approach:

1. Intersection: Identified overlapping areas between existing EVSC locations and urban infrastructure layers.
2. Buffer (5 km): Created service radii around existing EVSCs based on urban mobility standards, representing optimal user accessibility.
3. Clip & Merge: Integrated multiple geospatial datasets to generate a composite priority map, highlighting underserved regions for future development.

This approach ensures a data-driven foundation for identifying EVSC development zones that are both technically feasible and socially impactful. A composite suitability score was generated for each spatial unit to evaluate the level of demand and accessibility for EVSC deployment. The results were then validated against secondary data sources and mobility patterns, and the outcomes were presented as thematic maps and analytical tables to inform strategic, data-driven EVSC planning across Jakarta.

Spatial Distribution and Coverage Analysis of Existing EVSC Facilities in Jakarta

To support the spatial analysis and service coverage mapping, a comprehensive inventory of existing Electric Vehicle Service Centers (EVSCs) in DKI Jakarta was compiled. The dataset includes 15 service centers operating under various operators, with Wuling identified as the dominant brand currently providing dedicated EV servicing infrastructure. Each entry in the table presents the name of the location, full address, and corresponding geospatial coordinates (latitude and longitude) for spatial integration within GIS-based analysis.

Table 2. Existing Wuling EVSC Facilities in Jakarta

5	Prima Harmoni	Jl. Balikpapan No.11, RT 08/RW 06, Petojo Selatan, Gambir, Jakarta Pusat, DKI Jakarta 10160	-6.1604	106.8196
6	Maju Motor Senayan	Jl. Asia Afrika No. 17 RT.001 RW.003 Kel. Gelora, Kec. Tanah Abang, Jakarta Pusat 10270	-6.2166	106.8007
7	Prima Fatmawati	Jl. RS. Fatmawati No. 45 A E RT.002/RW.005, Cipete Selatan, Cilandak, Kota Jakarta Selatan 12411	-6.285	106.792
8	Pegasus Lenteng Agung	Jl. Raya Lenteng Agung No. 8 RT 3/RW 1, Lenteng Agung, Jagakarsa, Jakarta Selatan, DKI Jakarta 12610	-6.3099	106.8206
9	BZHC Pondok Indah	Jl. Sultan Iskandar Muda No.Kavling 9, RT.9/RW.1, Kby. Lama Sel., Kec. Kby. Lama, Kota Jakarta Selatan, Daerah Khusus Ibukota Jakarta 12310	-6.2543	106.7793
10	Arista Kalimalang	Jl. Raya Kalimalang No. 20A, Duren Sawit, Jakarta Timur 13440	-6.2455	106.9093

These facilities are dispersed across multiple municipalities, including West Jakarta, Central Jakarta, East Jakarta, South Jakarta, and North Jakarta, though the distribution remains relatively uneven.

The spatial analysis assessed the service coverage and unmet demand for Electric Vehicle Service Centers (EVSC) in Jakarta. The study was performed using a three-step Geographic Information System (GIS)- based approach: Intersection, Buffer, and Clip and merge. The first stage, Intersection, maps the current distribution of EVSCs across Jakarta's subdistricts, represented by red squares. This initial visualization highlights the existing service network's spatial concentration and potential gaps.

Fig.3 Intersection Process of EVSC in Jakarta

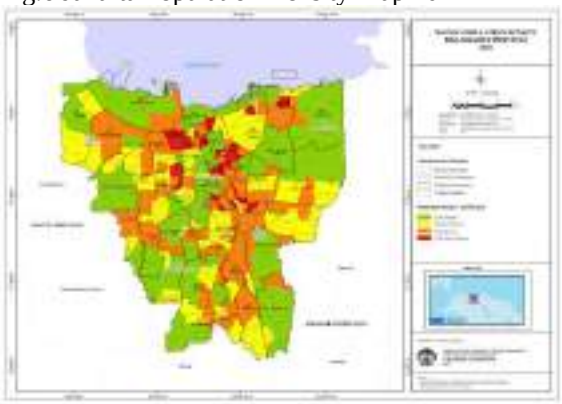
The second stage involves applying a 5-kilometer buffer around each service center to estimate its effective service range. Based on commonly accepted standards in urban transport studies [11, 12], a 5 km service radius is considered optimal to ensure convenient access to EV service centers. The spatial analysis followed established GIS-based methodologies [13, 14] that utilize intersection, buffering, and clip-and-merge techniques to map current service coverage and identify underserved areas. The resulting buffer zones, shown in light green, represent areas within optimal proximity to EVSC facilities, based on general accessibility standards for urban transportation services [11]. This step helps to visualize the spatial reach of the current infrastructure.

Fig.4 Buffer Process of EVSC in Jakarta

In the final stage, Clip & Merge, a spatial overlay analysis is performed to delineate areas that fall outside the 5-kilometer buffer zones. These regions, highlighted in purple hatching, indicate underserved zones where current EVSC facilities do not provide adequate coverage. Identifying these gaps is crucial for planning future EVSC development to ensure equitable access and support electric vehicle adoption.

Fig.5 Clip and Merge Process of EVSC in Jakarta

Fig.6 Jakarta Population Density Map 2021



The analysis reveals that several districts in North Jakarta, East Jakarta, parts of West Jakarta, and Southern Jakarta remain outside the optimal service radius. This finding suggests a clear need for targeted infrastructure investments in these areas to address geographic disparities and promote a more inclusive and resilient EV ecosystem in Jakarta.

There are some notable contrasts when compared to the EVSC distribution model in Hefei, which is known for its cluster and corridor strategy. In Hefei, EVSCs are concentrated in the city center and commercial districts, with significant EVSC corridors along important transit routes (for example, metro lines or arterial highways). The service radius in Hefei is often smaller (about 1-3 km in the city center) to encourage high adoption of electric vehicles in urban mobility. However, suburban areas have a greater radius. In comparison, the layout in Jakarta, as seen on this map, uses a more spread node method with a 5km radius coverage. This technique is consistent with the more dispersed character of Jakarta's road network and the necessity to serve a diverse range of residential areas.

Fig.7 Land Use of Jakarta Cultural Map

Fig.8 Jakarta Protected Area Map

Spatial Overlay Analysis for Identification of Potential EVSC Locations

The priority locations for EVSC development were identified through a comprehensive spatial overlay analysis integrating multiple geospatial datasets, including Jakarta’s 2021 population density map (Figure 6), land use and cultural activity zones (Figure 7), and protected area boundaries (Figure 8). The analysis aimed to optimize service coverage while balancing environmental and urban planning considerations. Each map layer was assigned a score reflecting its relative influence on EVSC demand, with higher population density and urban cultural zones contributing positively, and protected areas constraining development options.

Fig.9 The Spatial Overlay Analysis

To facilitate interpretation and strategic planning, the composite scores were classified into five priority levels using a constant of 0.8, calculated as follows:

6−25=0.8\frac{6 - 2}{5} = 0.856−2=0.8

The final classification ranges were defined as:

- **Priority I**: 5.6 – 6.4 (Very High Need)
- **Priority II**: 4.7 – 5.5 (High Need)
- **Priority III**: 3.8 – 4.6 (Moderate Need)
- **Priority IV**: 2.9 – 3.7 (Low Need)
- **Priority V**: 2.0 – 2.8 (Very Low Need)

The spatial overlay analysis produced a comprehensive priority map illustrating potential sites for future Electric Vehicle Service Center (EVSC) development throughout DKI Jakarta. This map synthesizes layers of population density, existing EVSC distribution, detailed land use plans (RDTR), and transportation networks, resulting in a visual classification of urban areas according to service demand and spatial suitability. The analysis revealed significant spatial disparities, with central and highly urbanized districts exhibiting higher priority levels, while peripheral and protected zones were identified as lower priority or excluded from development consideration. Key urban subdistricts in South Jakarta, East Jakarta, and West Jakarta emerged as critical areas for EVSC expansion, reflecting both unmet service needs and strategic connectivity potential. This map provides a data-driven foundation for guiding equitable and sustainable EVSC network expansion in Jakarta, ensuring alignment with broader urban planning and green mobility objectives.

The spatial priority map for potential Electric Vehicle Service Center (EVSC) development in Jakarta (Figure 5) provides an integrated visualization of service needs across the metropolitan area. The analysis combines spatial layers, including existing EVSC locations, service coverage buffers (5 km radius), population density, and urban land use patterns derived from the city's detailed spatial plan. The overlay results highlight significant geographic disparities in EVSC accessibility, particularly in southern, eastern, and parts of western Jakarta, where high-priority zones (Priority I and II) are concentrated but lack sufficient service coverage. Several underserved districts with dense residential areas and strategic transport corridors, such as Jagakarsa, Pasar Minggu, Duren Sawit, and Kalideres, emerge as key candidates for future EVSC deployment to enhance spatial equity and support growing EV adoption. Conversely, the northern and central districts exhibit relatively better service coverage but still present localized gaps, especially in industrial and port-adjacent zones. The integration of environmental protection areas further informs sustainable site selection by identifying zones where EVSC development should be avoided. Overall, the spatial analysis offers a data-driven basis for prioritizing EVSC infrastructure expansion, ensuring alignment with both mobility demand and green urban development objectives.

Discussion

The spatial overlay analysis conducted in this study highlights significant geographic disparities in the current Electric Vehicle Service Center (EVSC) network in Jakarta. Compared to the more advanced and strategically clustered EVSC system in Hefei, Jakarta's EVSC deployment remains sparse and uneven, especially in high-density and fast-growing residential areas. GIS-based methods enabled the identification of underserved districts in the southern, eastern, and southwestern parts of the city. This underscores the need for a more targeted, data-driven infrastructure development strategy to support Jakarta's transition toward sustainable transportation [15, 16]. Optimizing EVSC locations based on spatial demand factors—such as population density, land use patterns, and transportation network connectivity—can significantly improve service equity and support broader electric vehicle (EV) adoption [17].

In the context of green cities, EVSCs serve as critical infrastructure for energy transition and sustainable mobility. Well-distributed and strategically planned EVSCs uphold the green city principle, where electric vehicles produce zero exhaust emissions, contributing to cleaner air [18, 19]. Clean technology becomes especially appealing and viable in densely populated areas that strive for better air quality. Site selection should consider proximity to users, EV distribution in the area, and the service capacity of each station [6, 20]. The reliability of charging infrastructure and battery swapping systems is also crucial for sustaining EV operations [21]. Placement decisions must coincide not only with technical and geographical issues but also with broader urban sustainability goals, such as integrating public transportation with green mobility, decreasing congestion, and supporting equitable service distribution [16].

When deciding on the optimum site, consider the distance from the user's location [7], the distribution of electric vehicles in the area [8], and the service capacity that the service center can offer [9]. The dependability of charging infrastructure and battery swapping systems is crucial to facilitate the sustained functioning of electric vehicles [10]. This placement considers not only technical and spatial aspects but also urban sustainability goals such as integrating public transportation with green mobility, reducing congestion, and ensuring fair and equitable service distribution. EVSC's closeness to toll lanes, terminals, commercial districts, and industrial areas enables it to be part of a comprehensive low-emission mobility ecosystem.

Jakarta could benefit from adopting a hybrid EVSC layout strategy—blending cluster, corridor, and nodal approaches—similar to successful practices in Hefei. This would ensure better service

coverage across dense urban cores and peripheral commuter zones, supporting a more inclusive and resilient low-emission mobility ecosystem [17]. As the number of EV users grows, Jakarta must proactively expedite the development of EVSCs to minimize service bottlenecks and maintain user satisfaction. Incentive policies, public-private partnerships, and the integration of technology and service information systems should support investment in EVSCs. Furthermore, incorporating user behavior research through surveys and service quality assessments will ensure that future EVSC infrastructure meets the evolving needs of urban EV users and fosters a more inclusive, accessible, and sustainable mobility system.

CONCLUSIONS

This study highlights the essential role of Electric Vehicle Service Centers (EVSCs) as crucial infrastructure for the sustainable transition to electric mobility in urban areas. The spatial analysis conducted using GIS-based overlay techniques reveals that the current distribution of EVSCs in Jakarta is uneven and inadequate, leaving significant regions—particularly in South, East, and parts of West and North Jakarta—beyond the optimal 5-kilometer service radius. This gap poses a substantial obstacle to broader EV adoption and user satisfaction. In contrast, the EVSC deployment model in Hefei illustrates a more advanced and strategic approach, characterized by dense clusters in urban centers and corridor-based coverage along key transport routes. Hefei's smaller service radii and integrated infrastructure offer valuable insights for Jakarta's future planning.

The results reveal critical service gaps and prioritize zones for future EVSC development, providing actionable insights for policymakers and Urban planners should focus on the recommended priority locations to address current geographic disparities and align with urban mobility patterns, promoting equitable access to EV services. Comparisons with the successful EVSC model in Hefei further highlight the importance of adopting a strategic, spatially adaptive infrastructure planning approach. Moving forward, integrating dynamic mobility data, real-time EV adoption trends, and stakeholder input can enhance the robustness of this planning framework. Ultimately, the study supports Jakarta's goal of building a resilient, sustainable, and inclusive electric mobility ecosystem, contributing to broader climate and urban livability objectives.

THE IMPACT OF URBAN VILLAGE DEVELOPMENT ON FEMINIZATION OF INDONESIAN MIGRANT WORKERS (PMI) IN WEST JAVA: A SPATIO-TEMPORAL ANALYSIS FROM 2018, 2021, AND 2024 VILLAGE POTENTIAL (PODES) MICRO DATA

Chotib [1], Mohamad Axel Putra Hadiningrat [2], Beti Nurbaiti [3], Adzkia Nabila Zahrani[4]

[1,2] School of Strategic and Global Studies Universitas Indonesia; [3] Universitas Bhayangkara Jakarta Raya, Jakarta, Indonesia, [2] ;[4] Faculty of Economics and Business Universitas Indonesia

ABSTRACT

Based on a report from BP2MI (Indonesian Migrant Worker Protection Agency) in 2023, West Java Province has the third rank after East Java and Central Java in sending Indonesian Migrant Workers (PMI) abroad (BP2MI, 2023). The temporary processed results of the 2024 PODES (Village Potential) data show that the largest number of female PMIs came from West Java Province, namely 100,675 people. This is much greater than the male PMI which amounted to 41,667 people from the same province. The ratio of female PMI which is greater than male PMI illustrates the feminization of PMI in West Java. This research will describe the spatial patterns of villages experiencing PMI feminization in West Java, and their changes over time: before, during, and after Covid-19 pandemic. More specifically, this research aims to: (1) Analyze the changes in spatial patterns of villages experiencing feminization of Indonesian Migrant Workers (PMI) in West Java ; (2) Conduct a panel analysis of the impact of urban/rural status of village. geographical, socio-economic, and level of development factors on the feminization of PMI from West Java; (3) Analyze the spatial dependencies of feminization of PMI from West Java; (4) Compare the spatial patterns and spatial dependencies of feminization of PMI between before, during, and after the Covid-19 pandemic. The method of analysis in this research are descriptive and inferential analysis. Descriptive analysis creates cross tabulations between each independent variable (rural/urban status, geographical characteristics, socio-economic factors, and level of development) against the dependent variable (Feminization of PMI, which is indicated by Sex Ratio of PMI). Inferential analysis creates panel regression modeling, and spatial regressions. The results of the two analyzes were then compared before the pandemic (PODES 2018), during the Covid-19 pandemic (PODES 2021), and after the Covid-19 pandemic (PODES 2024). It is hoped that the results of this research can be used as input in implementing policies regarding the facilitation of sending PMI to improve the welfare of the community, both migrant workers and village residents of origin.

Keywords: Indonesian Migrant Workers (PMI); Feminization; Panel Regression Modeling; Spatial Regressions; West Java

INTRODUCTION

The BP2MI (The Indonesian Migrant Workers Protection Board Of The Republic Of Indonesia) report as of June 2023 shows that West Java Province is the third sender of PMI (Indonesian Migrant Workers) in Indonesia after East Java and Central Java (www.bp2mi.go.id). Meanwhile, West Java Province ranks first in sending female PMI based on PODES 2024 data. This province is experiencing feminization of PMI which illustrates the number of female PMI being more dominant than male PMI, and this is one of the global issues in discussing migrant workers.

The feminization of PMI in West Java is likely to be various between regions within it, as is the diversity of sending PMI itself. This variation is certainly inseparable from the urban/rural status of a village factor, whether as an urban or a rural village. This variation can also be caused by the variation of other characteristics of village, such as geographical, socio-economic aspects, and characteristics of the level of development of the region.

The objectives of this research are as follows:

1) To analyze the spatial patterns of villages experiencing feminization of intertemporal PMI shipments in West Java;
2) To analyze the influence of village-urban/rural status factors, geographic factors, socio-economic factors, and level of development on the feminization of intertemporal and inter-village PMI shipments in West Java;
3) To analyze the spatial dependency of feminization of intertemporal and inter-village PMI shipments in West Java;
4) To compare the spatial patterns of feminization of PMI shipments before (PODES 2018), during (PODES 2021) and after the Covid-19 Pandemic (PODES 2024).

RESEARCH SIGNIFICANCE

So far, research on sending migrant workers has been conducted more qualitatively and focuses more

on individual factors as motivation for migrant workers to leave the country, and also highlights many problems with the sending process of migrant workers which tends to be non-procedural. The results of those researches are depicted in various national and international journals.

Research conducted by [1] has explored how mining projects shape gendered experiences and subjectivities through a feminist ethnographic approach in Tanzania and Tajikistan. Using participant observation, interviews, and visual methods, the research focuses on conservation areas in Tanzania and remote mountains in Tajikistan.

An ILO publication by [2] presents the latest estimates of the number of international migrant workers to 2022, disaggregated by age, sex, country income group and region. The report uses data from 189 countries and territories based on national labour force surveys, censuses and other administrative sources. It finds that between 2019 and 2022, growth in the number of international migrant workers slowed to less than 1% per year, compared to an average of 2.8% per year before the pandemic.

Our research conducts spatial modeling that focuses on sending migrant workers dominated by female workers (feminization of migrant workers) using quantitative methods on sending migrant workers villages in one of the provinces known as a sending area for migrant workers, and also has the largest number of female migrant workers in Indonesia (based PODES 2024 micro data analysis).

We explore some variables determining the sending of female migrant workers from villages in West Java Province. The variables are selected from three micro datasets of PODES 2018, 2021, and 2024. The variables are as follow: rural/urban status, number of disasters, village topography, source of income of residents, and one variable from the district/city government that handles district/city minimum wage policies.

The use of those variables in the analysis of factors influencing the sending of migrant workers, especially female migrant workers, has been widely used by many researchers. For example, Postar found that topography plays a major role in driving female labor migration both directly and indirectly. In Tanzania, limited access to land and employment opportunities marginalize local female by male migrants, prompting female workers to migrate out. Meanwhile, in Tajikistan, difficult terrain forces women to work hidden in informal mines, which then gives rise to social stigma and gender pressure. Thus, topography is not only a physical barrier, but also forms a social structure that drives migration, hidden labor, and marginalization of women in areas of resource exploitation.

The study conducted by [3] aimed to analyze the impact of the major earthquake that occurred in Nepal in 2015 on labor migration patterns, specifically to understand whether and how the disaster affected the level of female worker migration. This study uses a quantitative approach with the difference-in-differences (DiD) method that utilizes two main data sources: the Nepal Labor Force Survey of 2007/08 and 2017/18 to measure internal and international (to India) migration; and administrative work permit data from 2008 to 2018 for international migration (except to India). The results show that in general, the earthquake disaster did not have a significant impact on the level of female worker migration, both internally and internationally. However, there are specific exceptions: when using the damage classification, a significant increase in the likelihood of female migration to the Gulf countries was found, as well as an increase in the number of international work permits for women by 13% after the earthquake.

The status of a rural or urban village determines the population's consideration to migrate or not. Urban villages are considered more developed than rural villages, so it can be hypothesized that urban villages will restrain their residents from migrating abroad, while rural villages encourage internationally migration.

The study by [4] aims to analyze the causes of gender inequality in migration, especially why young women from rural areas are more likely to migrate to cities than men, especially during the period of economic growth and urbanization in China. The study finds that the process of urbanization, especially through the establishment of Special Economic Zones (SEZs), significantly increases the migration of young women from rural areas to cities, almost twice as much as the migration of men. Urbanization creates economic opportunities and enlarges the marriage market (especially for men with high economic status), which encourages young women to move to cities for better employment and marriage prospects. Young women are more responsive to urbanization because they seek opportunities to “marry up” (hypergamy). Cities are seen as providing access to more educated and higher-income single men.

Theoretically, villages that rely on the agricultural sector tend to encourage their residents to migrate because their real wages are lower than if they went to cities that rely on the manufacturing and services sectors [5]. Meanwhile, according to research results from [6], it was stated that income difference and non-agricultural sectors influence female workers to migrate. In more detail, the wage gap between the sending country and the receiving country is the main attraction. Although jobs such as domestic workers abroad have low wages in the destination country, they are still higher than the standard salary in Indonesia. This research also stated that non-agricultural households with irregular incomes are more motivated to migrate because their jobs tend to

be unstable. Therefore, migration is considered as a way to get a more stable income.

The study conducted by [7] aims to analyze the effect of poverty, Provincial Minimum Wage, and investment on the level of international migration of female workers in Indonesia. The method used is explanatory which explains the relationship between independent variables and dependent variables. The unit of analysis used was 9 provinces in Indonesia from 2012-2019 which were processed using panel data regression using the Fixed Effect Model (FEM). The results of the study indicate that the minimum wage has a positive and significant effect on the level of international migration of female workers. This means that when the minimum wage increases, the level of female labor migration also increases.

Meanwhile, our research will analyze the effect of kabupaten/kota minimum wages on sending female migrant workers to a village in West Java by using panel regression model.

HYPOTHESIS

As stated in the previous section regarding the research objectives, the hypotheses that can be put forward in this research are as follows:

1. There was a certain spatial clustering of the sending of female migrant workers between villages in West Java in the three years of observation.
2. There is some effects of the urban status of village, geographical factors, socio-economic factors, and level of development factors on the sending of female migrant workers.
3. There are spatial dependencies in the sending of female migrant workers to villages in West Java in the three years of observation.
4. There is a decline in the context of the magnitude of female migrant worker deployments between before (2018) and after the Covid-19 pandemic (2021 and 2024).

RESEARCH METHODS

The main data source for this research uses three micro datasets of Village Potential (PODES) in 2018, 2021, and 2024 provided by the Central Statistics Agency (2024). These datasets contain information on physical, geographical, social, economic, cultural conditions, availability of road infrastructure, educational facilities, health facilities, village security conditions, and others.

Village potential data collection is carried out every 3 years. The last data collection was carried out in 2024, so the series of datasets in the last three data collection periods used in this research are PODES 2018, PODES 2021, and PODES 2024.

Specifically, the independent variable data for the Regency/City Minimum Wage (UMK) was obtained from the Decree of the Governor of West Java concerning the Regency/City Minimum Wage of West Java Province in 2018, 2021, and 2024.

With data sources from PODES, the unit of analysis in this research is the village/kelurahan (for village in Kota) with a total number of 5957 villages/kelurahan. With data sources from PODES, the unit of analysis in this research is the village/sub-district (for village in Kota) with a total of 5,957 villages/sub-districts. Because there are three years of observation, there will be 17,871 observations/cases in a panel data analysis.

The analysis method used in this research are descriptive statistics which describes the development of PMI feminization between kabupatens in West Java Province during three years of observation; and inferential analysis through panel regression modeling of three years. The regression model developed is as follows:

$$RJK_PMI_{it} = \beta_0 + \beta_1 * URBAN_{it} + \beta_2 * BENCANA_{it} + \beta_3 * TOPOGRAFI_{it} + \beta_4 * D_{INC1\,it} + \beta_5 * D_{INC2\,it} + \beta_6 * UMK_{it} \quad \text{.....4.1.}$$

Where:

RJK_PMI	=	Sex Ratio of PMI sent by a village
URBAN	=	Urban/Rural Status of village
BENCANA	=	Number of disaster occurrence per year in a village
TOPOGRAFI	=	Topography of village (Plain=1; Others=0)
D_INC1	=	dummy for manufacturing sector as the main source of income for villagers (agriculture sector as ref. category)
D_INC2	=	dummy for the services sector as the main source of income for villagers (agricultural sector as ref. category)
UMK	=	Kabupaten/Kota Min. Wage (in Rupiahs per month)
$\beta_0, \beta_1, \ldots, \beta_5$	=	Regression coefficient for each independent variable
i, t	=	i is for observation i (village i); t is for time t

Descriptive analysis is processed by SPSS 27, and inferential analysis (panel regression) is processed by Stata 16. The operational definition of each variable is shown by Table 1.

Table 1. Operation Definition of Variables

Notation	Operational Definiton	Question Number
Depeendent Variable		
RJK_PMI	(Number of Female migrants/Number of Male migrants)*100%	(R402B2/ R402B1)*100
Independent Variables		
TOPOGRAPHY	Topography of most of the village/sub-district areas. (1=Plain; 0=Others).	Podes 2018: R305B Podes 2021 and Podes 2024: R305A
DISASTER	Number of village/sub-district residents affected by disasters in the year before PODES data was published	Podes 2018: Addition of R601AK8 to R601JK8 Podes 2021: R602 Podes 2024: R602
URBAN	Urban/rural area status (1=urban village; 0=rural village)	R105
D_INC1	dummy for manufacturing sector as the main source of income for villagers (agriculture sector as ref. category)	R403
D_INC2	dummy for the services sector as the main source of income for villagers (agricultural sector as ref. category)	R403
UMK	Minimum wage for district/city (in rupiah per month) where the village/sub-district is located	Data from other sources (West Java Provincial Government).

This research also uses GeoDa to conduct spatial analysis through LISA (Local Indicator of Spatial Association), to describe whether there is a clustering of feminization in certain areas; and to test whether there is a spatial dependency on PMI feminization in West Java.

RESULT AND DISCUSSION

Descriptive Anaysis

The result of descriptive analysis with cross-tabulation analysis of the distribution of feminization, namely when the sex ratio is above 100%, by kabupaten/kota is presented in Table 2. In general, the PMI sex ratio in West Java reached 200% and above, although it decreased during the observation period, namely from 267.52% in 2018 to 267.12% in 2021, and decreased to 241.62% in 2024. This shows that when the pandemic occurred, the sending of female migrant workers decreased compared to before the pandemic period.

Almost all kabupaten/kota in West Java have sex ratio of migrant workers above 100%, which shows that the number female migrant workers are larger than number of male migrant workers. Cimahi City had the highest sex ratio in 2018, which was 640%, meaning that out of 100 male migrant workers, there were 640 female migrant workers. This figure then dropped to 366.67% in 2021, and 300% in 2024. The lowest sex ratio is in Bogor City, which is 97%. But this figure then rose to 150% in 2021, and 140% in 2024. More detailed variations in sex ratios between districts/cities and over time are presented in Table 2.

Table 2. Feminization of PMI by Kabupaten/City: West Java, 2018, 2021, and 2024

Kab/City	Sex Ratio ((Female/Male)*100%)			# of Villages
	2018	2021	2024

Source: Analyzed by authors (2025)

Panel Regression Analysis

Almost all variables have a significant impact on the departure of female PMI from a village. The variable that is not significant is the number of residents affected by the disaster. Meanwhile, the classification variable of rural/urban areas is significant at $\alpha = 10\%$.

In the analysis with FEM (Fixed Effect Model), the results are different. The Topography variable remains significant, but the direction is reversed. This means that female PMI departures tend to come from villages with non-plain topography. The Disaster and Urban variables remain insignificant. The main source of income for residents is significant in the tertiary sector (services) with a negative direction. This means that there is a real difference in female PMI departures that tend to come from agricultural villages rather than villages whose main source is the tertiary sector. The UMK variable remains

significant, namely that PMI departures tend to come from areas with low UMK.

In the REM (Random Effect Model) analysis, similar to the CEM (Common Effect Model) analysis, almost all variables are significant, except for the Disaster and Urban variables.

Chow Test :

H_0 : CEM

H_1 : FEM

The results of this test lead to the decision to reject H0 , meaning that the FEM analysis is better than CEM .

Hausman test

H_0 : REM

H_1 : FEM

From the results of the Hausman test above, it can be concluded that H0 is rejected, meaning that analysis with FEM is better than REM.

Lagrange Multiplier (LM) Test:

H_0 : CEM

H_1 : REM

The results of this analysis provide a decision to reject H0, which means that the REM model is better than CEM.

Overall, from the three tests above, it can be stated that the FEM model is the best choice in panel analysis. This means that the intercept varies between times, but the slope of each variable is relatively unchanged (fixed) between times.

As presented in the FEM analysis results (Table 3), these findings show that the model generally describes the role of the variables proposed in the model play a role in the variation in the number of female dominant migrant workers sent by villages in West Java. The variables have significant role are: Topography (TOPOGRAFI) and Regional Minimum Wage (UMK).

The TOPOGRAPHY variable has a negative coefficient which shows that PMI shipments dominated by female tend to come from villages with non-sloping/flat topography, such as peaks/cliffs, slopes, and valleys. The second variable that has a significant influence is UMK (Reginal Minimum Wage) with a positive direction, but with a small magnitude.

Table 3. Parameter Estimates with Fixed Effect Model (FEM)

5.3. LISA Analysis

Local Indicator of Spatial Association (LISA) describes the spatial clustering of feminization in West Java Province. Clustering occurs in certain areas that describe spatial associations as measured by Moran's I parameter. The number of villages included in the high-high cluster has decreased relatively slightly. This can also be seen in the Morans's I parameter which tends to decrease slightly from 0.5 in 2018 to 0.428 in 2021, and increases slightly to 0.456 in 2024. The same pattern also happened to the number of villages included in the Low-Low cluster.

Table 4. LISA Analysis between 3-Years of Observation

Parameter	2018	2021	2024
Moran's I	0.501	0.428	0.456
High-High (#N)	308	319	300
Low-Low (#N)	1199	1264	1158
Low-High (#N)	163	180	150
High-Low (#N)	82	109	123
Sign. P = 0.05 (#N)	1271	1437	1182
Sign. P = 0.01 (#N)	417	360	480

Not Sign.	4205	4085	4226

Source: Analyzed by authors (2025)

Spatially, the pattern of feminization clustering tends not to experience much change over time. High feminization clustering tends to occur in the northern and southern regions of West Java. In the northern region, it mainly occurs in the cities of Cirebon, Karawang, and Indramayu. While in the south it tends to occur in the cities of Cimahi, Sukabumi, and Cianjur

5.4. Spatial Dependencies

The results of classical regression from three different years show results that are not much different. Almost all variables have significant impact on the feminization of PMI deployment from villages in West Java. Only the disaster variable shows inconsistent results, both in terms of the magnitude

and direction of the coefficient, as well as its significance. While all variables have a consistent impact, both in magnitude, direction and significance.

In general, it can be explained that feminization occurs in villages with plain topography, originating from rural villages, villages where the main occupation of the population is agriculture, and where the district/city minimum wage is low.

In the spatial dependency test, there is also a spatial lag. Table 5 shows the spatial lag coefficient (ρ) of 0.38; 0.33; and 032. This shows the spatial effects of villages in the surrounding areas in terms of feminization. A village will experience an increase of between 0.32 - 0.38 percentage points in terms of the sex ratio of migrant workers (feminization) from it's neighbour villages.

CONCLUSION

From the description of the results of the analysis and discussion above, several points can be concluded, in accordance with the objectives of the research in answering the research questions, namely:

1. In general, there is a relatively slight decrease in the phenomenon of feminization of sending PMI from villages in West Java.
2. The results of the panel analysis show the influence of fixed independent variables in influencing the pattern of feminization of villages in West Java.
3. Almost all variables have a significant influence, except for the Disaster variable. It can be said that feminization occurs in villages with plain topography, from rural villages, villages with the main occupation of the population is in the agricultural sector, and those with low district/city minimum wages.
4. There is spatial dependency in the phenomenon of feminization in sending PMI from villages in West Java.

ABSTRACT

Aircraft noise is a significant environmental impact associated with airport operations, affecting both the quality of life in surrounding communities and influencing land use. This paper presents a modeling framework for evaluating the impacts of airport noise around Thailand's major airports. The proposed framework consists of 2 components: 1) Noise impact analysis, to evaluate the exposure patterns of aircraft noise using the Aviation Environmental Design Tool (AEDT) mathematical model, which is a GIS-based analytical approach enriched with historical noise measurement data and aircraft operational characteristics, to forecast Noise Exposure Forecast (NEF) contours, and 2) Temporal comparative analysis using statistical correlation and GIS optimization to evaluate changes in noise-affected zones. The model was validated at 5 major airports, including Suvarnabhumi, Don Mueang, Chiang Mai, Chiang Rai, and Phuket airports. The results of noise impact assessments, which consider accessibility and land use compatibility of communities around airports, risk exposure patterns and population distribution can be reliably determined. At the national level, 363,800 residents are affected by aircraft noise, with 57,330 people living in high-impact zones. Validation results show high correlation (R^2 = 0.89-0.94) between measured and predicted values. The findings support integrating noise assessment into airport planning, especially for future projects like Chiang Mai Airport No.2, and recommend adopting ICAO-based land use controls to protect communities.

Keywords: Aircraft Noise, Aviation Environmental Design Tool (AEDT), Noise Exposure Forecast (NEF), Land Use Planning

INTRODUCTION

Thailand's aviation sector has experienced unprecedented growth over the past decade, emerging as a critical component of Southeast Asia's transportation hub strategy [1]. Following the post-COVID-19 recovery, the sector has demonstrated remarkable resilience with flight volumes increasing 15-20% annually during 2022-2023, significantly exceeding pre-pandemic levels [2]. This rapid expansion has positioned Thailand as a regional aviation leader, with five major airports currently handling over 140 million passengers annually and projections indicating potential doubling of flight operations by 2035 [3].

However, this aviation boom has intensified environmental challenges, particularly aircraft noise pollution, which has emerged as a critical constraint to sustainable airport development [4]. Current estimates indicate that approximately 363,800 residents across Thailand's major airports are exposed to significant aircraft noise, with 57,330 people living in high-impact zones (NEF > 40) where noise levels severely affect quality of life [5]. The problem is particularly acute around densely populated airports such as Suvarnabhumi International Airport, Don Mueang, Chiang Mai, and Phuket, where expanding noise footprints increasingly conflict with urban development and residential areas [6,7].

Aircraft noise creates multidimensional impacts including sleep disturbance, elevated stress, reduced cognitive performance, and property value depreciation [8,9]. WHO and ICAO have established clear links between prolonged noise exposure and cardiovascular disease, hypertension, and mental health disorders [4,10].

Thailand's reactive approach to noise management has significant gaps compared to international best practices, resulting in community conflicts, costly retrofitting, and airport expansion limitations [11,12,13]. The lack of standardized assessment protocols and coordinated land use planning threatens sustainable aviation growth [14].

This challenge is critical as Thailand advances major airport expansion projects including Chiang Mai Airport No. 2, Andaman International Airport, and facilities in eastern provinces [15]. Without proactive noise management frameworks, these projects risk replicating existing problems [16].

The Aviation Environmental Design Tool (AEDT), developed by the Federal Aviation Administration (FAA), represents the international gold standard for aircraft noise modeling and impact assessment [13]. However, its application in Thailand's unique contexts

requires validation for national planning purposes [17].

Therefore, this research is critical in applying the AEDT tool to evaluate and analyze aircraft noise pollution levels in airport areas, particularly in regions with planned new airport development projects and to examine temporal changes in noise-affected areas using statistical and spatial analysis.

METHODOLOGY

This study aims to evaluate aircraft noise impacts around airports using the Aviation Environmental Design Tool (AEDT) through quantitative analysis processes comprising 5 main steps. Thus, the methodological framework guide to achieve the objectives of this research was presented in Fig 1.

Data Assessment and Verification

Relevant data associated with flight operations and aircraft noise levels were systematically collected and validated. This included aircraft noise level data expressed in decibels, flight path information such as Standard Instrument Departures (SID), Standard Terminal Arrival Routes (STAR), and Instrument Approach Charts, as well as air traffic statistics comprising aircraft types, time of operations, and prevailing wind directions. All datasets were rigorously verified and organized to serve as input parameters for the subsequent aircraft noise simulation process.

Model Development

The assessment of forecasted aircraft noise levels in the form of Noise Exposure Forecast (NEF) contours was conducted using the mathematical simulation model known as the Aviation Environmental Design Tool (AEDT). AEDT is a modeling tool developed by the Federal Aviation Administration (FAA) for predicting aircraft noise and emissions. The tool is capable of generating various types of forecasted noise contours, including NEF, Day-Night Average Sound Level (DNL), and Effective Perceived Noise Level (EPNL), as well as estimating aircraft-related air pollutant emissions such as VOCs, SO_2, and NO_x. AEDT was developed as an integration of the earlier INM (Integrated Noise Model) and EDMS (Emissions and Dispersion Modeling System), with enhancements including the incorporation of a Geographic Information System (GIS) database for improved usability.

The AEDT system consists of 3 primary data:

1) Study Database: This database contains the project-specific input data in the AEDT Standard Input File (ASIF) format. These files are organized as XML files (<ASIFXML>) and include essential information such as the geographical location of the airport, flight paths, case study parameters, community locations, study boundaries, and flight schedule data throughout the year.
2) Airport Database: This database comprises infrastructure information of the airport, including the official airport names according to ICAO and ATA codes, meteorological data, geospatial coordinates of runways and surrounding airport facilities.
3) Fleet Database: This includes technical and operational information about aircraft types and engine performance, compiled from international standard sources such as the ICAO Engine Emissions Databank (EDB), the ICAO Aircraft Noise and Performance (ANP) Database, and the Eurocontrol Base of Aircraft Data (BADA).

The Aviation Environmental Design Tool employs the Noise Exposure Forecast (NEF) metric, which integrates both noise level and frequency of exposure over annual operations following FAA technical specifications [13], as shown in Eq. (1)

$$NEF = EPNL + 10log_{10}(N_d) + 10log_{10}(N_n) - 88 \quad (1)$$

Where, EPNL = Effective Perceived Noise Level (dB)
N_d = Daytime operations (07:00-22:00)
N_n = Nighttime operations (22:00-07:00)
88 = Normalization constant

Model Validation & Calibration

Statistical validation employs multiple metrics ensuring reliability against field measurements [18], as shown in Eq. (2)

$$R^2 = 1 - (SS_{res} / SS_{tot}) \quad (2)$$

Where, $SS_{res} = \Sigma(NEF_{measured} - NEF_{predicted})^2$
$SS_{tot} = \Sigma(NEF_{measured} - NEF_{mean})^2$

Acceptable criteria: $R^2 \geq 0.85$, RMSE $\leq$ 3.0 dB, $|MBE| \leq 1.5$ dB following international aviation noise modeling standards [19].

Comparative Analysis & Impact Assessment

A spatial comparison was performed by overlaying the NEF contours from two different years onto aerial imagery to analyze changes in the noise contour boundaries. These changes reflect variations in the number of daily flight operations as well as the overall spatial extent of the noise-affected areas.

The analysis considered forecasted noise exposure contours based on the standards recommended by the International Civil Aviation Organization (ICAO), which provide land use guidelines for different NEF levels as follows:

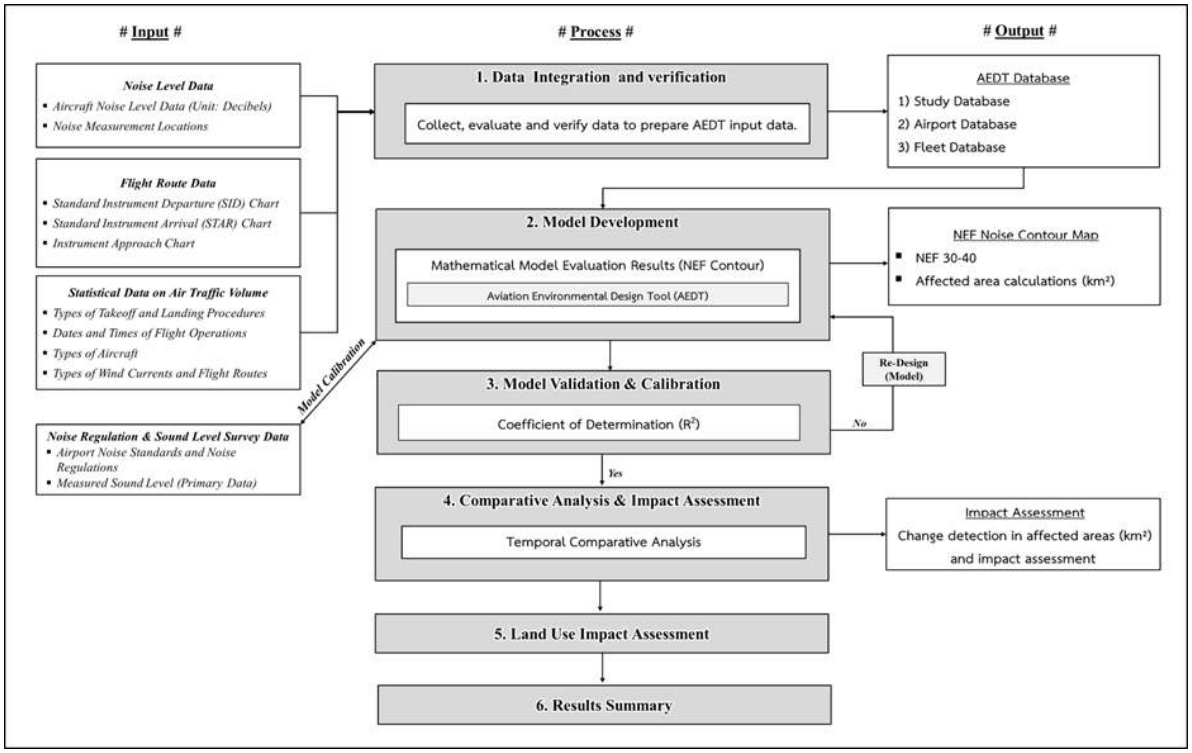

Fig 1. Methodological framework of developing airport noise assessment using AEDT

- NEF less than 30: This area is considered unaffected by aircraft noise and is generally suitable for all types of land use.
- NEF 30–35: Aircraft noise in this area causes a low level of disturbance. Mitigation measures are recommended, such as installing sound insulation materials or air-conditioning systems in residential buildings.
- NEF 35–40: This area experiences a moderate level of noise disturbance. Appropriate noise mitigation strategies should be implemented.
- NEF greater than 40: This area is subject to severe aircraft noise impact. Land acquisition or compensation measures may be necessary to address the adverse effects on residents and land use.

Quantitative assessment of noise contour evolution using GIS analysis techniques based on established spatial analysis methodologies [20], as shown in Eq. (3)

$$Relative\ Chang\ (\%) = \frac{Value_{after} - Value_{before}}{Value_{before}} \times 100 \quad (3)$$

Where, $Value_{after}$ = the value in the later year
$Value_{before}$ = the value in the earlier year

Statistical significance testing employs two-sample t-test with $\alpha = 0.05$ significance level according to environmental monitoring protocols [21].

Land Use Impact Assessment

ICAO Annex 16 compatibility assessment with population impact calculation following established environmental assessment guidelines [22], as shown in Eq. (4)

$$PI = \Sigma(\rho_i \times A_i \times PIF_i) \quad (4)$$

Where, PI = Population Impact index
ρ = population density (persons/km²)
A = affected area (km²)
PIF = Population Impact Factor

Results Summary

The summary of simulation results and impact analysis in both spatial and quantitative aspects was developed using the AEDT database and noise contour maps, which delineate affected areas in square kilometers. These outputs serve as tools to support evidence-based policy decision-making.

CASE STUDY

This study selected 5 major airports in Thailand, each with distinct physical contexts, operational characteristics, and surrounding land-use patterns, as case studies for evaluating aircraft noise impacts using the Aviation Environmental Design Tool (AEDT). The simulation results were compared with

actual noise measurement data, and spatial trends in noise impacts were analyzed. The selected airports are:

- Suvarnabhumi Airport (BKK): Located in Bang Phli District, Samut Prakan Province.
- Don Mueang Airport (DMK): Located in Don Mueang District, Bangkok.
- Chiang Mai International Airport (CNX): Located in Mueang Chiang Mai District, Chiang Mai Province.
- Mae Fah Luang – Chiang Rai International Airport (CEI): Located in Mueang Chiang Rai District, Chiang Rai Province.
- Phuket International Airport (HKT): Located in Thalang District, Phuket Province.

RESULTS

The results of the development and application of models with the case study were as follows:

Aircraft Noise Impact Assessment Results Using AEDT Model

Based on the generation of aircraft noise contours using actual flight operation data during the noise monitoring period, the mathematical model Aviation Environmental Design Tool (AEDT) was employed. The air traffic data from each airport was processed in the model to forecast daily aircraft noise levels. This process produced NEF (Noise Exposure Forecast) contour maps, as well as correlation values between the measured NEF levels and the NEF values simulated by the AEDT for each airport, as summarized below.

Noise Contour Simulation Results

Mathematical model assessment results in the form of Noise Exposure Forecast (NEF) contours, evaluated from flight situation data from January 1, 2023, to December 31, 2023, A summary of the affected areas within NEF 30-40 and NEF > 40 zones was shown in Table 1 and Fig 2.

Table 1 The affected areas according to 2023 flight situations within NEF contours

Airport	Daily Flight Operations	Affected Area (km²)		
		NEF >40	NEF 30-40	Total
Suvarnabhumi Airport	602	3.89	15.55	19.04
Don Mueang Airport	493	3.05	14.31	17.36
Chiang Mai International Airport	198	1.14	5.09	6.20
Mae Fah Luang - Chiang Rai Airport	34	0.15	0.66	0.81
Phuket Airport	285	1.40	4.91	6.31

Model Validation Results

To evaluate of the Aviation Environmental Design Tool (AEDT) in predicting aircraft noise levels, a comparative analysis was conducted between the Noise Exposure Forecast (NEF) values obtained from actual sound level measurements and those simulated by the AEDT model, using synchronized dates and times at each airport.

The analysis revealed that the correlation coefficients (R^2) between the measured NEF values and those generated by the model ranged from 0.89 to 0.94, indicating a high level of accuracy in AEDT's noise simulation performance within the context of Thai airports. Detailed results were shown in Table 2.

Table 2 Model Validation of AEDT and actual sound level measurements

Airport	Population in NEF >40 (persons)	Population in NEF 30-40 (persons)	Total Affected Population	Land Use Index
Suvarnabhumi Airport	23,340	124,400	147,740	0.67
Don Mueang Airport	18,300	115,000	133,300	0.62
Chiang Mai International Airport	6,840	35,630	42,470	0.71
Mae Fah Luang - Chiang Rai Airport	450	1,980	2,430	0.81
Phuket Airport	8,400	29,460	37,860	0.74

Note: All correlation coefficients exceed acceptable threshold of $R^2 \geq 0.85$; RMSE values meet criterion of ≤ 3.0 dB

Fig 2. Noise Exposure Forecast (NEF) Contour Map Based on Flight Operations in 2023

Spatial Comparison of Noise Exposure Forecast (NEF) Contour Maps

To better understand the temporal dynamics of aircraft noise impact, a comparative assessment was conducted using NEF contour data from 2018 and 2023. The analysis focused on two key exposure thresholds NEF > 40 and NEF 30–40 to evaluate the spatial extent of noise-affected areas in square kilometers across five major airports in Thailand. Table 3 presents the quantitative results of this comparison, highlighting both the absolute and percentage changes in noise exposure zones over the five-year period. These changes reflect evolving patterns in flight operations, airport expansions, and surrounding land use, which collectively influence noise propagation and its associated impacts on communities.

DISCUSSION

The study demonstrates AEDT's effectiveness in Thai airport contexts, with correlation coefficients (R^2 = 0.89-0.94) meeting international standards [26,30]. Spatial analysis reveals heterogeneous noise impact patterns across different airport types and operational contexts. Chiang Mai International Airport's 45.2% expansion reflects rapid tourism recovery, while Phuket Airport's 28.6% reduction suggests effective operational optimization [23,24].

Population impact analysis indicates 363,800 residents affected by airport noise nationally, with 57,330 in high-impact zones requiring immediate attention. This substantial exposure underscores the surgency for comprehensive noise management strategies following ICAO guidelines [22,25].

Table 3 Spatial comparison of NEF affected areas between 2018 and 2023

Airport	Affected Area (km²)						Change (km²) (%)		
	2018			2023			2018-2023		
	NEF >40	NEF 30-40	Total	NEF>40	NEF 30-40	Total	NEF>40	NEF 30-40	Total
Suvarnabhumi Airport	3.63	14.87	18.50	3.89	15.55	19.04	0.26 (7.2%)	0.68 (4.6%)	0.54 (2.9%)
Don Mueang Airport	3.56	13.29	16.85	3.05	14.31	17.36	-0.51 (-14.3%)	1.02 (7.7%)	0.51 (3.0%)
Chiang Mai International Airport	0.91	3.36	4.27	1.14	5.09	6.20	0.23 (25.3%)	1.73 (51.5%)	1.93 (45.2%)
Mae Fah Luang – Chiang Rai Airport	0.12	0.53	0.65	0.15	0.66	0.81	0.03 (25.0%)	0.13 (24.5%)	0.16 (24.6%)
Phuket Airport	2.04	6.80	8.84	1.40	4.91	6.31	-0.64 (-31.4%)	-1.89 (-27.8%)	-2.53 (-28.6%)

Land Use Impact Assessment

Analysis results indicate several critical findings regarding airport noise impacts and their implications for land use planning based on ICAO Annex 16 guidelines and international best practices for sustainable airport development [22,25], as shown in Table 4.

Table 4 Population impact assessment based on ICAO land use compatibility

Airport	Average NEF (Measured)	Average NEF (AEDT)	Correlation Coefficients (R^2)	RMSE (dB)
Suvarnabhumi Airport	32.4	33.1	0.92	2.1
Don Mueang Airport	31.8	32.3	0.89	2.8
Chiang Mai International Airport	28.7	29.2	0.94	1.9
Mae Fah Luang - Chiang Rai Airport	25.3	25.8	0.91	2.3
Phuket Airport	29.6	30.1	0.90	2.5

CONCLUSIONS

This research validates AEDT as an accurate tool for airport noise assessment in Thailand, with a prediction accuracy of R^2 = 0.89–0.94. The study found that four out of 5 major Thai airports experienced increased noise-affected areas (ranging from 3.0% to 45.9%) between 2018 and 2023, totaling 52.1 km² nationwide. Currently, approximately 363,800 people are affected by airport noise, with 57,330 residents living in high-impact zones that require immediate attention.

The research reveals distinct regional patterns: metropolitan airports show steady growth, northern airports demonstrate rapid expansion due to tourism recovery, while southern airports show potential for operational optimization. For Thailand's planned airport expansion projects, including Chiang Mai Airport No. 2 and Andaman International Airport, noise impact assessment must be integrated from the initial planning stages. The study recommends establishing mandatory noise impact zones in airport master plans and developing integrated transportation and land use planning protocols to address the expanding noise footprint and protect affected communities.

STUDY OF DRIFTWOOD ACCUMULATION CONDITIONS IN MOUNTAIN RIVERS THROUGH FIELD SURVEYS AND HYDRAULIC EXPERIMENTS

Yuriko Matsubayashi[1], Sae Nagahata[2] and Motoki Makino[3]

[1]Faculty of Science and Engineering, Iwate University, Japan; [2,3] Graduate of Faculty of Science and Engineering, Iwate University Japan

ABSTRACT

Clarifying the topographical conditions necessary for driftwood accumulation in mountain rivers is thought to be useful in predicting the amount of driftwood generated during heavy rain disasters. Although much research has been conducted on the macro-topographical conditions for driftwood accumulation, there have been no detailed surveys or research results on how many contact points are necessary for each piece of driftwood to accumulate, or what their spacing is. In this study, we conducted field surveys and hydraulic experiments to record and analyze the number of contact points between driftwood and obstacles necessary for driftwood to accumulate, as a topographical condition necessary for driftwood floating down the river to accumulate.

Both the field surveys and hydraulic experiments confirmed that driftwood floating down the river can accumulate even at a single point of contact with an obstacle. Furthermore, the largest amount of driftwood accumulated at two points of contact. The field surveys and hydraulic experiments obtained results that are useful for estimating the amount of driftwood that accumulates, based on the distribution of protrusions in the river topography and the length of the driftwood.

Keywords: Driftwood, Heavy rain disaster, Mountain rivers, Accumulation

INTRODUCTION

In recent years, heavy rainfall disasters have been increasing in Japan due to climate change. In addition, changes in the mountain environment and an increase in the number of short duration heavy rainfall events have resulted in increased damage due to the accumulation of driftwood in narrow areas and on bridges. It is important to understand and manage the amount of driftwood generated during heavy rainfall disasters to prevent the spread of damage caused by driftwood. Many studies on the generation and movement of driftwood have been conducted in Japan and overseas. Komori et al. have modeled the export of large wood at watershed scale [1]. Many studies have also been conducted on driftwood drifting and deposition on bridges [2]. Okamoto et.al. have conducted experimental study about accumulation and failure of driftwood on bridge pier [3]. Numerical simulations to estimate the behavior of individual driftwood are used as an effective method to understand the behavior of driftwood [4]

In this study, experiments and field investigations were conducted to clarify the conditions for driftwood deposition due to contact with independent obstacles in complex terrain, such as mountain rivers, in order to help improve prediction accuracy regarding driftwood movement, deposition, and runoff.

RESEARCH SIGNIFICANCE

In mountain rivers, driftwood accumulates in riparian forests, topographic changes, and uneven terrain, and moves with the rising water level. Knowledge of these conditions will improve the accuracy of estimating the potential volume of driftwood in mountain rivers and the volume of runoff during floods. In this study, we compared the number and distance of contact points between the deposited driftwood and obstacles, which are important for knowing the thresholds of deposition and migration, by means of field surveys and experiments.

METHOD

To understand the characteristics of the contact points between driftwood and obstacles when it is deposited in mountain rivers, we conducted tank experiments and field surveys and compared the results of each to clarify the characteristics of the number and distance of contact points between deposited driftwood and obstacles.

Experiments

The scale of the experiment was set to 1/20 with reference to the Koge River where the field survey was conducted, and the experiment was conducted in an experimental flume 30 cm wide and 178 cm long as shown on Fig.1. The average slope of the Koge River was used as a reference, and the slope was set to 1/44. A pump was used to circulate the water, and a rectifier was installed upstream of the tank. Sandpaper was placed on the bottom and walls of the tank to reproduce the roughness of a mountain riverbed.

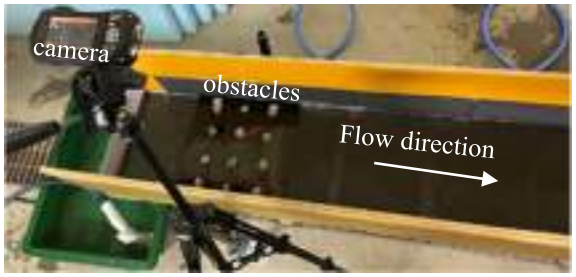

Fig.1 Experimental flume

A model of driftwood was put in the upper part of flume, and its accumulation on the obstacles placed on the riverbed was recorded by a camera placed over the flume for analysis. The size of the driftwood models were 4 mm and 6 mm in diameter and 8 cm in length to conduct experiments with 1.6 m driftwood. The obstacles on the riverbed were gravels of 15 to 20 mm in height and 15 to 35 mm in diameter attached to boards and placed in the flume, as shown in Fig.1. The central spacing was 4 cm, 6 cm, and 8 cm, and they were arranged in staggered and square grids (Fig2, Fig3 and Fig4). The water depth around the obstacles in the experiment was about 15 mm, and the flow velocity was fastest near the center of the flume due to friction on the wall, with an average velocity of 0.33 m/s and a Froude number of 0.86.

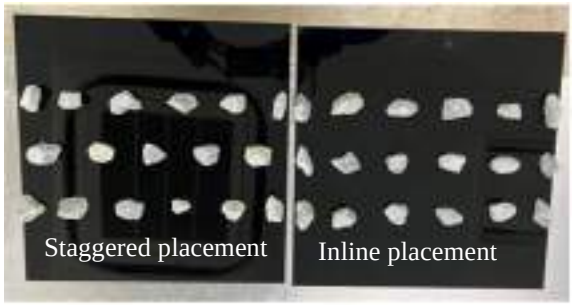

Fig.3 Gravels with 6 cm spacing

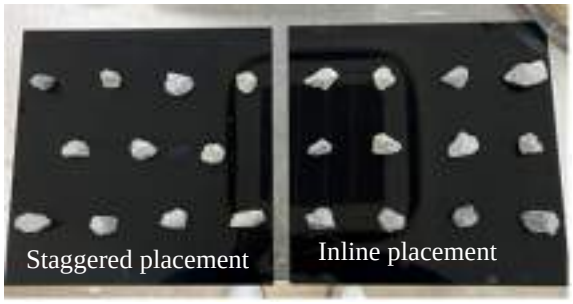

Fig.4 Gravels with 8 cm spacing

For each type of obstacle in the riverbed, experiments were conducted 75 times, with the upstream and downstream sides of the gravel-lined board reversed.

Field Survey

Field surveys were conducted on mountain rivers in Iwate Prefecture, and the size of accumulated driftwood, the location and height of contact points with obstacles such as riparian forests and stones, and the surrounding topography were recorded and analyzed. Fig.5 shows photo of measuring.

A total of 100 driftwoods, 79 in the Koge River and 21 in the Kitayama River were surveyed. All driftwood with a circumference of at least 1.5 cm and a length of at least 0.3 m were measured as we moved through the surveyed area.

Fig.5 Measuring driftwood (Koge River)

RESULTS

Experiments

To examine the effect of gravel spacing and the number of contact points on driftwood capture rate, we compared the number of driftwood pieces captured in each arrangement pattern. The location and number of contact points at which driftwood accumulates varied depending on small changes in the flow in each experimental case. Fig.6 and Fig. 7 shows driftwood accumulated at one and two contact points. Fig. 8 and Fig. 9 show the percentage of captured driftwood pieces in each of the gravels for different spacings. A similar trend was observed for the 4 mm and 6 mm diameter grids. The capture rate decreased with increasing grid spacing, and there was no clear difference in capture rate between the different arrangements of the grids. Regardless of the spacing, deposition by the two contact points was the most frequent. Under all conditions, a single contact point was sufficient for deposition.

Fig.6 Deposition with 1-point contact

Fig.7 Deposition with 2-points contact

The narrower the distance between the gravels, the more driftwoods were deposited with two-point contact, and at the narrowest distance of 4 cm, the more driftwoods were deposited with three points of contact.

The driftwood model started parallel to the flow but turned and changed direction depending on the flow or by hitting gravels. Some driftwood was deposited at single point and then stopped moving, while others continued oscillating. In the present analysis, we did not separate the sedimentation state

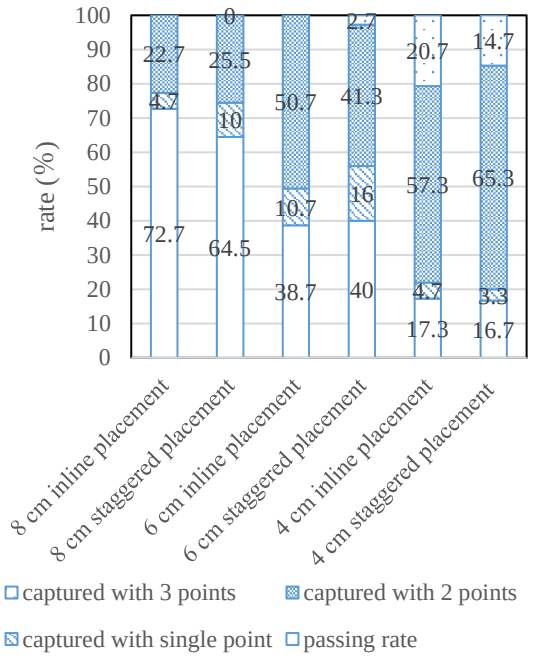

Fig.8 Capture rate of driftwood (4 mm in diameter)

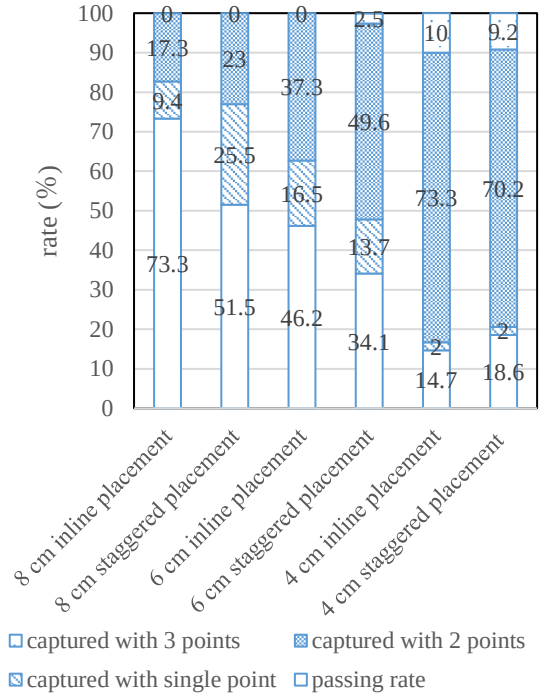

Fig.9 Capture rate of driftwood (6 mm in diameter)

Field Survey

The number of contact points that allow driftwood capture is important information for examining the driftwood accumulation conditions in rivers. Table 1 shows the number of contact points of driftwood and obstacles observed, with driftwood deposited at two points of contact and driftwood deposited on stones being the most common. Some driftwood was deposited at a single contact point.

The position of the contact point is shown in Fig.10 as a percentage of the length of the driftwood. The contact points are distributed close to the right and left edges of the driftwood. The contact points are distributed near the right and left edges of the driftwood, suggesting that the accumulation of the driftwood near the edges of the driftwood was caused by contact with an obstacle.

By comparing the height of the driftwood pile and its diameter, it is possible to estimate whether the driftwood was rolling along the riverbed or floating near the surface when it was deposited. Fig. 11 shows the relationship between the height of the contact points above the bed and the radius of the driftwood.

Many of the driftwoods were deposited by contact with obstacles higher than the driftwood radius, indicating that most of the deposited driftwoods drifted near the water surface during flooding and were deposited by contact with obstacles.

Table 1 Number of measured driftwoods

Number of contact points	Obstacle			
	Riparian wood	Stone	Driftwood	Combination
1	4	6	1	
2	7	32		6
3	4	20		2
4	1	10	1	
5		3		1
6		1		
7		1		

Note: Combination: combinations of contact points with stones, riparian wood, driftwood or grasses

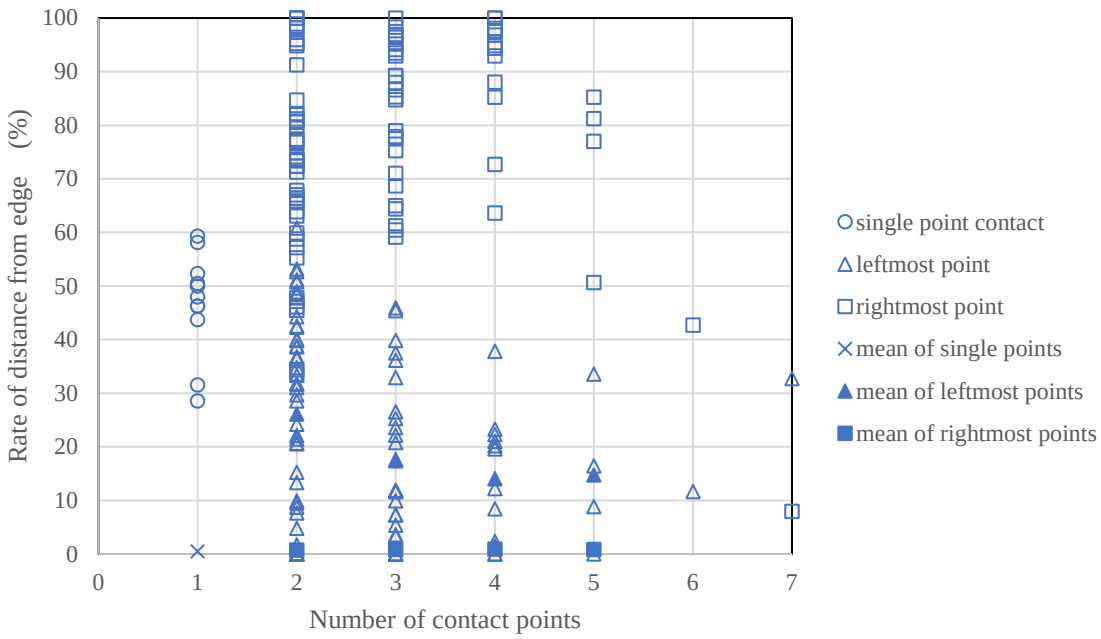

Fig.10 Contact position of driftwood

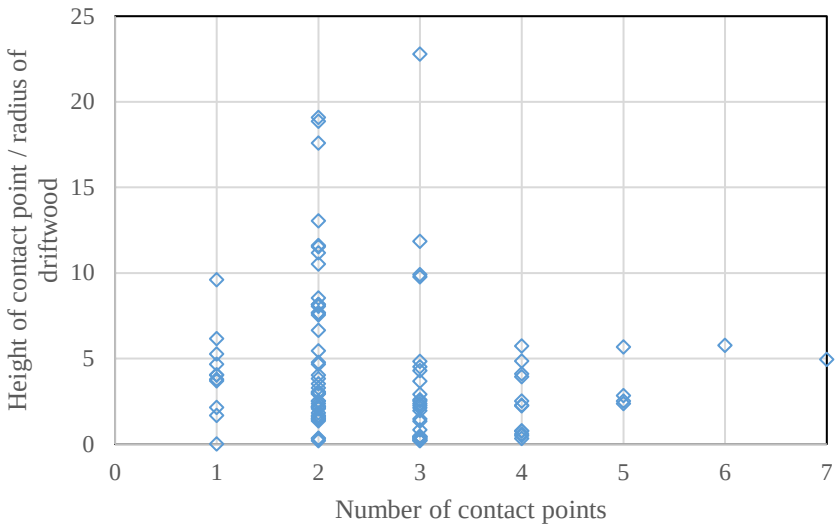

Fig.11 Height of contact point

CONCLUSIONS

The experiment and field survey of contact points of driftwood showed similar results in terms of the distribution of the number of contact points between the accumulated driftwood and the obstacle, with the largest number of driftwoods deposited at two contact points, although driftwood was deposited at one contact point. In both the experiment and the field survey, the number of driftwood pieces deposited at three or more points of contact decreased.

The results indicate that driftwood is more likely to be captured in a river when the length of driftwood drifting during a flood is longer than the distance between two or more points of obstruction in the river.

DEEP LEARNING-AUGMENTED LAKE ECOSYSTEM MODELING FOR IMPROVED FORECASTING OF ALGAL BLOOMS AND HYPOXIA IN ENCLOSED AREA

Jinichi Koue[1], Sota Yoshikawa[1], Katsutoshi Hirayama[1]

[1]Graduate School of Maritime Sciences, Kobe University, Japan

ABSTRACT

Accurate forecasting of phytoplankton dynamics and hypoxia in freshwater ecosystems is vital for effective water quality management amid accelerating climate and anthropogenic pressures. This study develops a hybrid deep learning framework combining physical–chemical mass-balance equations with recurrent neural networks (RNN, LSTM) to enhance predictions of chlorophyll-a, -b, -c and dissolved oxygen (DO) in Lake Biwa, Japan. Two approaches were compared: Case 1 using conventional inputs, and Case 2 incorporating mechanistic biogeochemical constraints. Short-term forecasts at 0.5 m depth showed marked improvements in peak chlorophyll prediction under Case 2, especially with LSTM (e.g., Chl-b RMSE halved from 0.63 to 0.33 µg/L), reflecting better capture of rapid physiological and transport dynamics. For DO at 90 m, Case 2 reduced RMSE by ~50% for LSTM and by an order of magnitude for RNN, successfully reproducing hypoxic events below 2 mg/L during 2020 stratification. This highlights enhanced sensitivity to ecological thresholds through physics-informed modeling. However, long-term forecasting revealed limitations; Case 2 underperformed for chlorophyll due to fixed hyperparameters failing to represent seasonal nonlinearities and ecosystem feedbacks (e.g., Chl-b LSTM RMSE rose from 0.21 to 1.37 µg/L), though DO predictions remained improved. These results demonstrate the potential and challenges of integrating mechanistic constraints into neural forecasting for adaptive lake management and water quality optimization under changing environments.

Keywords: Deep Learning, Algal Blooms, Hypoxia, Lake Biwa, Ecosystem Modeling

INTRODUCTION

Climate change and anthropogenic pressures are increasingly disrupting the physical and biogeochemical stability of freshwater ecosystems worldwide. Among the most pressing consequences are the intensification of hypoxia and harmful algal blooms (HABs), which threaten aquatic biodiversity and compromise water resource sustainability. Despite long-term nutrient reduction efforts, large-scale cyanobacterial blooms persist in major lakes such as Lake Taihu in China [1] and Lake Erie in North America [2], underscoring the resilience of these phenomena to conventional mitigation.

Lake Biwa, Japan's largest freshwater lake, now exhibits similar signs of ecological degradation. Supporting over 14 million people in the Keihanshin region, the lake is hydrologically divided into a deep North Basin and a shallow South Basin, with inflows from 117 rivers and limited outflow through the Seta River and Biwako Canal. Since the first major bloom in 1983, Microcystis-dominated surface accumulations have caused filtration disruptions and the release of odor compounds such as 2-methylisoborneol and geosmin, reaching levels as high as 180 ng/L and 390 ng/L in 2020, respectively—necessitating emergency treatment [3].

Meanwhile, deep-water hypoxia in the North Basin has intensified during summer stratification, driven by suppressed vertical mixing, sediment oxygen demand, and internal phosphorus release. Dissolved oxygen concentrations below 2 mg/L are frequently observed, especially in the Imazu Basin, endangering benthic habitats and accelerating eutrophication. Although factors such as nutrient inflow, aquaculture discharge, and climate-induced shifts in wind and runoff patterns have been identified [3], the mechanistic links between bloom formation and hypoxia remain insufficiently understood.

Recent advances in coupled physical-biogeochemical models have improved system understanding [3], while machine learning techniques—particularly Long Short-Term Memory (LSTM) networks—have shown promise in forecasting bloom dynamics [4]. However, integration of these approaches remains limited. Here, we develop a hybrid modeling framework that combines long-term water quality data from the Lake Biwa Environmental Research Center with meteorological inputs from the Japan Meteorological Agency. By merging process-based models with neural network architectures including Feedforward Neural Networks, Recurrent Neural Networks (RNN), and LSTM [5–8], we aim to improve prediction of

key ecological indicators such as phytoplankton biomass, nutrient concentrations, and dissolved oxygen. This integrative approach enhances forecasting capabilities for lake ecosystem management under accelerating environmental change.

RESEARCH SIGNIFICANCE

This study demonstrates the potential of integrating physico-chemical process-based balance equations into deep learning models for improving the prediction accuracy of key water quality parameters in Lake Biwa. The hybrid approach enhanced short-term forecasts of chlorophyll and dissolved oxygen, supporting more effective algal bloom management and water treatment operations. By capturing complex ecosystem dynamics, this framework offers a promising tool for early warning systems and long-term risk assessment in freshwater environments, thereby advancing the application of AI-augmented modeling in ecological forecasting.

METHODOLOGY

This study developed and compared two deep learning-based frameworks for forecasting water quality in Lake Biwa, utilizing both observational and process-informed input structures. Water quality data were obtained from the Lake Biwa Environmental Research Institute of Shiga Prefecture, and meteorological data were provided by the Japan Meteorological Agency. Two input configurations were considered: Case 1: Direct assimilation of observed physicochemical parameters. Case 2: Use of process-derived variables computed from a mass-balance ecosystem model originally developed by Koue [3], which represents key biogeochemical dynamics within the lake. These variables were designed to encode mechanistic insights into the data.

For both input cases, two types of deep learning architectures were employed: a Recurrent Neural Network (RNN), and a Long Short-Term Memory (LSTM) network. This comparative modeling approach enabled assessment of the predictive performance and interpretability associated with purely empirical versus process-based input features.

Machine Learning Predictive Technology

Feedforward Neural Network (NN)

A feedforward neural network (NN) is the simplest form of neural network, where data flows in a single direction—from input to output—without looping back. It consists of three main types of layers: input, hidden, and output. Each input node receives a value, multiplies it by a weight, adds a bias, and sends the result to the hidden layer. The hidden layer then processes these values using an activation function, such as ReLU or sigmoid, and passes the outputs forward. The output layer receives these final values and produces the network's prediction or classification. In this structure, information always moves forward; it does not return to previous layers.

Recurrent Neural Networks (RNN)

Recurrent Neural Networks (RNN) are designed to handle sequential data by retaining past information through recursive connections. Unlike feedforward networks, which treat each input independently, RNN use hidden states to propagate temporal information, making them effective for modeling time-dependent processes such as speech recognition, language modeling, and environmental forecasting.

The input at time t is denoted as x_t and the hidden layer state is denoted as h_t. The hidden state h_t is computed from the input x_t and the hidden state h_{t-1} of the previous step. This recursive computation allows modeling of long-term dependence in time series data.

In this study, the Simple Recurrent Neural Network (Simple RNN) is employed due to its fundamental architecture, which facilitates both theoretical analysis and practical implementation. Despite its simplicity, it effectively captures basic temporal dependencies in time series data.

The following variables are defined. The input x_t at time t is a feature vector representing the observed data. The hidden state h_t is a vector representing the internal state of the network, which holds past information in a compressed form. The update law of this hidden state is expressed by the following equation.

$$h_t = act(Wx_t + Uh_{t-1} + b) \quad (1)$$

where W is the weight matrix from the input layer to the hidden layer, U is the weight matrix representing the recursive coupling of the hidden layer, b is the bias term, and act is the nonlinear activation function. Commonly used activation functions include the tanh function and the ReLU function.

Long Short-Term Memory (LSTM)

The Long Short-Term Memory (LSTM) network is a variant of RNN that addresses the vanishing gradient problem and captures long-term dependencies more effectively. LSTM introduces a memory cell (ct) and three gating mechanisms: the forget gate (f), input gate (i), and output gate (o), which control the flow of information as follows:

$$\mathbf{f = \sigma(Wfxt + Ufht - 1 + bf)} \quad (\mathbf{2})$$

$$\mathbf{i} = \boldsymbol{\sigma}(\mathbf{Wixt} + \mathbf{Uiht-1} + \mathbf{bi}) \quad (3)$$

$$\mathbf{o} = \boldsymbol{\sigma}(\mathbf{Woxt} + \mathbf{Uoht-1} + \mathbf{bo}) \quad (4)$$

$$\mathbf{g} = \mathbf{tanh}(\mathbf{Wcxt} + \mathbf{Ucht-1} + \mathbf{bc}) \quad (5)$$

$$\mathbf{ct} = \mathbf{ft} \odot \mathbf{ct-1} + \mathbf{it} \odot \tilde{\mathbf{c}}\mathbf{t} \quad (6)$$

$$\mathrm{ht} = \mathrm{ot} \odot \tanh(\mathrm{ct}) \quad (7)$$

The conceptual diagram of the LSTM is shown in Fig. 1. Here, m represents the dimension of the input to the LSTM, and n represents the dimension of the output. The input at time t is denoted as $x_t \in \mathbb{R}_m$, the hidden state and output at time t are denoted as $h_t \in \mathbb{R}_n$ and c_t represents the cell state. $W \in \mathbb{R}_{n\times m}$ and $U \in \mathbb{R}_{n\times n}$ are the weight matrices, and $b \in \mathbb{R}_n$ is the bias term. g represents the input to the internal cell, f is the forget gate, i is the input gate, and o is the output gate. In these equations, $\boldsymbol{\sigma}$ and tanh are activation functions, and $\odot$ denotes element-wise multiplication. The cell state (ct) functions as long-term memory, updated selectively by the gates to retain relevant information.

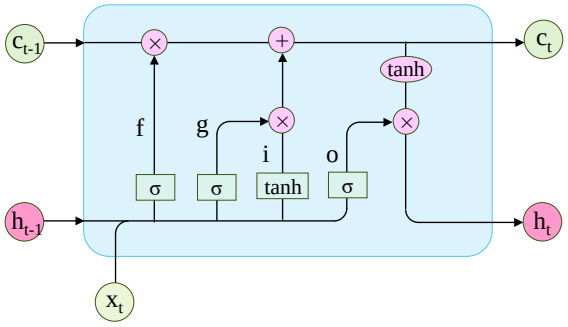

Fig.1 Conceptual diagram of the LSTM

Deep Learning-Based Frameworks

The two frameworks developed in this study are used to predict water quality at depths of 0.5 m and 20 m, and 60 m at Imazu-oki in the northern part of Lake Biwa. The water quality data used as input data are twice-monthly observations by the Lake Biwa Environmental Research Institute of Shiga Prefecture, and the meteorological data are from the Hikone District Meteorological Observatory of the Japan Meteorological Agency.

The framework generates the concentration of chlorophyll a, b, and c (Chl-a, b, c), and dissolved oxygen (DO) as prediction output. In Case 1, observed environmental variables were used directly as model inputs. Table 1 shows the observation data used. Biweekly observational data were used, with missing values interpolated linearly and observation times standardized across variables prior to model input. In Case 2, model inputs were derived from a mass-balance formulation representing key biogeochemical processes. These values were calculated using a mechanistic water quality model previously developed by Koue [3], which simulates nutrient and phytoplankton dynamics in Lake Biwa.

Table 1 Observation data used as input values in Case 1

Predicted value	Input Parameters
Chl-a, b, c	Ammonium nitrogen, Nitrite nitrogen, Nitrate nitrogen, Phosphate phosphorus, pH, Water temperature, Transparency, DO
DO	Chlorophyll-a-c, Ammonium nitrogen, Nitrite nitrogen, Nitrate nitrogen, Phosphate phosphorus, pH, Water temperature, Transparency, DO, Dissolved organic

Learning and Forecasting Periods

To evaluate predictive performance across different ecological time scales, both short-term and long-term forecasting models were developed. The training periods were defined separately for each target variable based on data availability. For phytoplankton biomass, the model was trained using data from April 1998 to March 2019. For dissolved oxygen, the training period spanned from April 2004 to March 2019.

Two forecasting horizons were considered: Short-term models were designed to predict water quality variables up to two weeks in advance, with forecasts validated over a three-year period from April 2020 to March 2023. Long-term models were developed for one-year-ahead predictions, with validation performed using data from April 2019 to March 2020.

The same network architecture and hyperparameters were used for both the short-term and long-term forecasting models to enable a consistent comparison of model performance across different temporal scales.

Evaluation Metrics

Root Mean Square Error (RMSE)

RMSE is a metric used to assess the prediction error between observed and forecasted values. It is defined by the following equation:

$$\mathrm{RMSE} = \sqrt{\left(\frac{\Sigma(y_i - \hat{y}_i)^2}{n}\right)} \quad (8)$$

where y_i represents the observed values, $\hat{y}_i$ represents the predicted values, and n is the number of data

points.

Mean Bias (MB)

MB is used to assess systematic errors (bias) between predicted and observed values. It is defined by the following equation:

$$MB = \frac{1}{n}\sum(\hat{y}_i - y_i) \quad (9)$$

where y_i represents the observed values, $\hat{y}_i$ represents the predicted values, and n is the number of data points. MB indicates whether the predictions are consistently overestimated or underestimated, with positive values suggesting an overestimation and negative values indicating an underestimation.

RESULTS

Short-Term Forecasting Results

Chlorophyll-a-c

Figure 2 shows the prediction results for chlorophyll a, b, and c in Case 1 and 2 at 0.5 m depth. Table 2 also shows the evaluation indices for each model. The results of the analysis show that in Case 2, the agreement between the measured and predicted values at the peak improved for all chlorophylls compared to Case 1. This may be due to the fact that the balance equation expresses the physicochemical processes involved in the variation of chlorophyll concentration as mathematical equations, enabling learning from input data with essential characteristics, which contributed to more accurately capturing rapid changes in chlorophyll concentration. Furthermore, the overall improvement of the evaluation index was confirmed, suggesting the effectiveness of the method proposed in this study.

Table 2 Chlorophyll-a, b, and c evaluation index in the surface layer (0.5 m depth)

Predicted value	Model	RMSE (μg/l)		MB (μg/l)	
		Case1	Case2	Case1	Case2
Chl-a	NN	1.67	1.67	-0.42	-0.05
	RNN	1.53	1.79	-0.37	-0.30
	LSTM	2.50	1.78	-1.10	-0.22
Chl-b	NN	0.36	0.36	-0.11	-0.02
	RNN	0.37	0.39	-0.02	-0.06
	LSTM	0.63	0.33	-0.16	-0.03
Chl-c	NN	0.25	0.21	-0.10	-0.01
	RNN	0.27	0.24	-0.12	-0.06
	LSTM	0.25	0.24	-0.14	-0.04

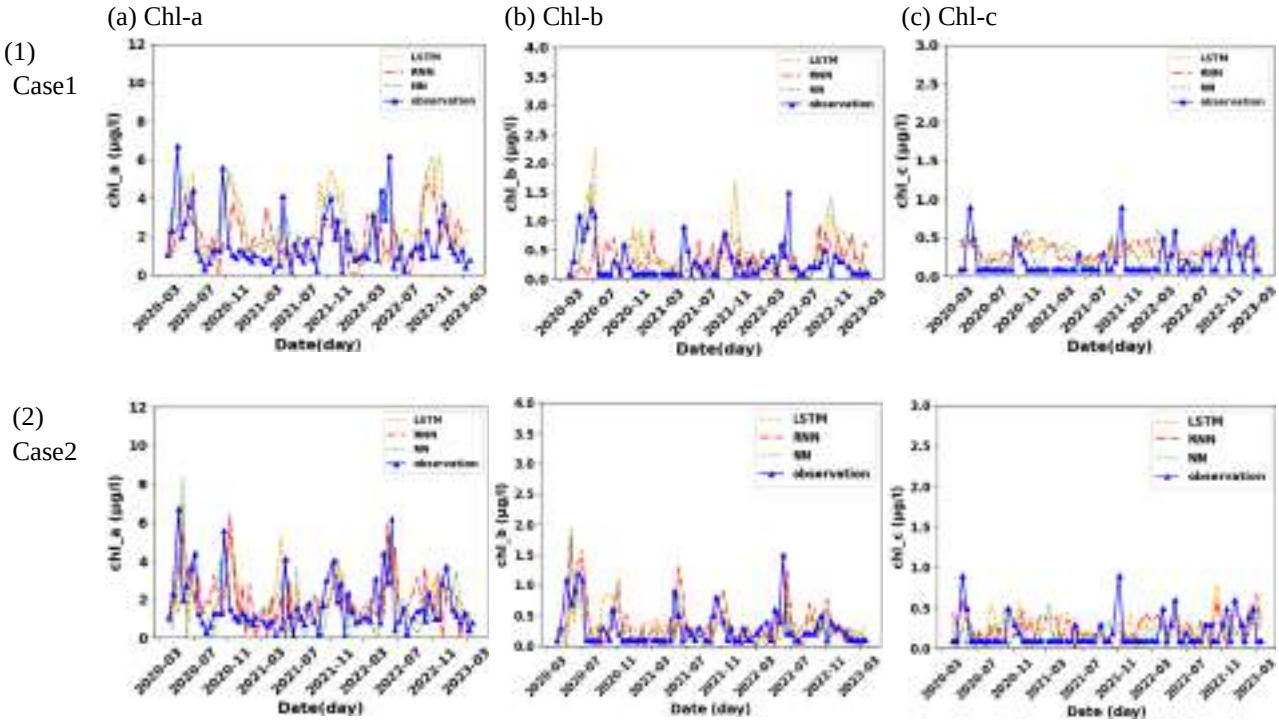

Fig. 3 Comparison of chlorophyll-(a) a, (b) b, (c) c, in (1) Case 1 and (2) Case 2 in the surface layer (0.5 m depth)

Dissolved oxygen

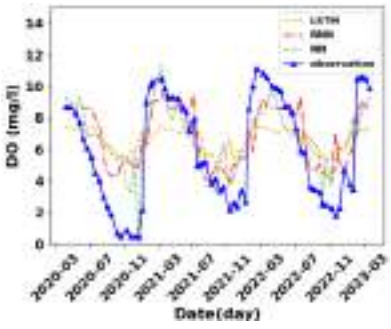
To evaluate the model's predictive performance under different input conditions, forecasts of dissolved oxygen (DO) at 90 m depth were compared between Case 1 (conventional inputs) and Case 2 (with a balance equation). This depth, located within the stratified hypolimnion of Lake Biwa's North Basin, is highly susceptible to oxygen depletion and nutrient accumulation, making it a critical zone for assessing internal water quality degradation. Figure 4 shows the predicted results of DO for Case 1 and Case 2 at the lake bottom (90 m depth). Table 3 also shows the evaluation indices for each model.

Substantial gains were observed in DO predictions under Case 2. At both 90 m and near-bottom depths, RMSE values were reduced by approximately 50% for LSTM and nearly an order of magnitude for RNN compared to Case 1. Crucially, the model accurately predicted the 2 mg/L hypoxic threshold during the 2020 low-oxygen event, demonstrating improved sensitivity to biogeochemical transitions. These enhancements are attributed to the inclusion of a physicochemically-informed balance equation that accounted for oxygen production and consumption processes, including photosynthesis, organic matter degradation, and respiration. By embedding these dynamics into the model, temporal variations in DO were more faithfully reproduced, particularly under stratified conditions. This result highlights the potential of hybrid frameworks to enhance predictive accuracy for ecologically critical variables in complex freshwater systems.

Table 3 DO evaluation index in the bottom of the lake (90 m depth)

Predicted value	Model	RMSE (mg/l)		MB (mg/l)	
		Case1	Case2	Case1	Case2
DO	NN	2.33	1.60	-0.80	-0.79
	RNN	2.30	1.37	-0.92	-0.32
	LSTM	2.89	1.57	-0.67	-0.18

(1) Case1



(2) Case2

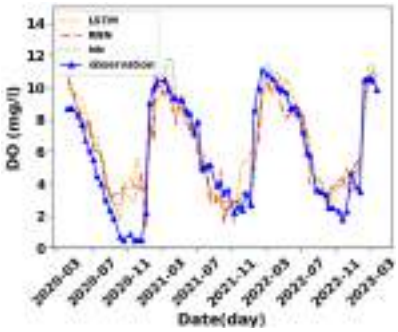


Fig. 4 Comparison of DO, in (1) Case 1 and (2) Case 2 in the bottom of the lake (90 m depth)

Long-Term Forecasting Results

Chlorophyll-a-c

Figure 5 shows the predicted chlorophyll (a) a, (b) b, and (c) c for Case 1 and 2 in the surface layer (0.5 m depth). Table 4 also shows the evaluation indices for each model. Table 4 shows that for all chlorophyll types, a decrease in prediction accuracy was observed in Case 2 compared to Case 1. Figure 5 shows that the main issue is the prediction during the peak period, and this is especially true for chlorophyll b. Given the improved accuracy in short-term forecasting, it can be inferred that the hyperparameters of the model do not adequately capture long-term time-series fluctuations, which is the main cause of the lower forecasting accuracy. Specifically, in the deep learning models of RNN and LSTM, hyperparameters such as the number of neural network units, number of neurons, and batch size do not adequately reflect the complex nonlinear factors (seasonal variation of environmental conditions, interactions among organisms, changes in nutrient concentration, weather conditions) are not adequately reflected, which may be a reason for the lower accuracy.

Dissolved oxygen

Figure 6 shows the predicted results of DO for Case 1 and 2 at the lake bottom (90 m depth). Table 5 shows the evaluation indices for each model.

The results of the analysis using the DO prediction model generally showed good agreement with the observed data (Figure 6(c)), with Case 1 failing to adequately reproduce the temporal variation pattern (timing of increase or decrease) of dissolved oxygen concentration, whereas Case 2 succeeded in capturing the observed variation with high accuracy. This improvement in prediction accuracy is also supported by quantitative evaluation indices (Table 5), which show a marked improvement in Case 2 compared to Case 1.

Table 4 Chlorophyll-a, b, and c evaluation index in the surface layer (0.5 m depth)

Predicted value	Model	RMSE (µg/l)		MB (µg/l)	
		Case1	Case2	Case1	Case2
Chl-a	RNN	3.08	2.16	-2.30	1.65
	LSTM	1.73	2.18	-0.49	1.67
Chl-b	RNN	0.23	1.19	-0.08	-0.78
	LSTM	0.21	1.37	-0.08	-0.85
Chl-c	RNN	0.22	0.26	-0.05	-0.03
	LSTM	0.37	0.26	-0.23	-0.03

CONCLUSION

In this study, we compared the short-term and long-term predictions of water quality parameters in Lake Biwa between Case 1, which uses only conventional input values, and Case 2, which incorporates a balance equation that takes physico-chemical processes into account. The results showed that Case 2 improved the prediction accuracy of chlorophyll (a, b, c) at the peak in the short-term prediction, confirming that the expression of physicochemical processes by the balance equation is effective. On the other hand, for dissolved oxygen, improvement was confirmed in Case 2 for all evaluation indices. This may be due to the fact that the introduction of the balance equation explicitly incorporated complex interactions such as oxygen consumption and production processes in the ecosystem into the model.

In the long-term prediction, a decrease in prediction accuracy was confirmed in Case 2 compared to Case 1 for all chlorophyll (a, b, c) species. This result may be due to the fact that the hyperparameters of the deep learning models, such as RNN and LSTM, do not properly capture long-term time-series variations. For dissolved oxygen, Case 2 was able to capture the variability of observed values with high accuracy at the bottom of the lake (90 m depth).

These results confirm that the introduction of a balance equation that takes into account physico-chemical processes has a markedly improved effect, especially in the short-term prediction of chlorophyll (a,b) and dissolved oxygen. The model developed in this study enables more accurate prediction of the timing of blue-green algae blooms, and is expected to contribute to optimizing the timing of activated carbon application at water treatment plants. Furthermore, we hope that the results of this study will contribute to the long-term, highly accurate prediction of anoxia in Lake Biwa in the future and help to take into account the contribution rate of the dominant factors in anoxia.

ABSTRACT

Offshore facilities such as, artificial islands, floating houses, cities, and airports are constructions for infrastructure, habitation, entertainment, industrial or commercial purposes, and infrastructure built on the ocean. They can either be grounded as artificial islands or floating on airfilled or light materials. Recent developments show a trend of airport construction offshore. If these are floating airports can be situated above deeper waters or further offshore. These can even be used for the development of airports reclaimed lands close to the coast. An offshore airport provides certain advantages for the planning of sustainable infrastructure: (a) reduced air pollution and noise effects for adjacent neigh borhoods; (b) safe operation during difficult weather conditions, at day and at night and land at night; (c) an airstrip away from other urban structures to prevent accidents during take-off and landing; (d) the extension of city centers that are built near the coast; (e) the possibility of green planning at areclaimed plot. If the airport is floating, this allows to position it even further away from the city center, to prevent noise and air pollution and to provide safety to city inhabitants in the event of accidents on the airport and during take-off and landing. We present here a detailed analysis on the feasibility for the construction of an offshore airport at above site from a planning and engineering perspective. This study synthesizes literature (1930–2025) to evaluate the planning paradigms, engineering feasibility, and environmental impacts of floating offshore airports. Utilizing a systematic review methodology, we analyze projects (e.g., Japan's Mega-Float, Dalian Jinzhou Bay) and case studies (e.g., Taiwan's South Star Project). Key findings indicate: (1) Pneumatic Stabilized Platforms (PSP) offer deep-water adaptability but face cost-accessibility trade-offs; (2) Reclamation-based airports reduce wave instability yet accelerate coastal erosion; (3) Taiwan's experience highlights stakeholder conflicts in coastal development. We conclude that floating airports require multi-criteria feasibility frameworks balancing technical innovation with ecological safeguards.

Keywords: Offshore airport, Floating house, Harbor construction, Environmental impact, Sustainable development.

INTRODUCTION

A floating airport is an airport built and situated on a very large floating structure (VLFS) located many miles out at sea utilizing a flotation type of device or devices such as pneumatic stabilized platform (PSP) technology. As the population increases and land becomes more expensive and scarce, VLFS such as floating airports could help solve land use, pollution and aircraft noise issues.

This review adopted a three-phase literature synthesis approach:(1) Identification: Scopus/Web of Science databases queried (keywords: "floating airport," "VLFS," "offshore reclamation," 1930–2025). (2) Analysis: Thematic applied to: Planning drivers, Structural technologies, Environmental trade-offs, Policy conflicts (e.g., Taiwan's SSP)

The first discussion of a floating airport was for trans-Atlantic flights. At that time a passenger aircraft capable of making the trip could be built, but because of the massive need for fuel for the flight, it had a limited payload. An article appeared in the January 1930 issue of Popular Mechanics in which a model of a floating airport located in the Atlantic was proposed. To make safe flight possible with the aviation technology of that time, it called for eight such airports in the Atlantic. But unlike future floating airport ideas which were free floating, this 1930 concept had a floating airport platform, but with stabilizer legs which prevent the flight deck from pitching and rolling, similar in concept to some of today's off shore oil rigs. The idea of floating airports was forgotten until in 1935 the famous French aviation pilot and builder Bleriot gave one of his last

interviews in which he made the case for floating airports in mid-Atlantic; he called them Seadromes as a solution to economical trans-Atlantic passenger flights [1] .

In theory, issues and problems of land-based airports could be minimized by locating airports several miles off the coast. Takeoffs and landings would be over water, not over populated areas, thereby eliminating noise pollution and reducing risks of aircraft crashes to the land-locked population.
Since little of the ocean's surface is currently being used for human activity, growth and alterations in configuration would be relatively easy to achieve with minimal impact to the environment or to local residents who would utilize the airport. Water taxis or other high speed surface vessels would be a part of an offshore mass transit system that could connect the floating airport to coastal communities and minimize traffic issues.

Fig. 1 Offshore floating airport with land connection.

Fig. 2 Floating airport close to the city-center.

A floating structure, such as a floating airport, is theorised to have less impact on the environment than the land-based alternative. It would not require much, if any, dredging or moving of mountains or clearing of green space and the floating structure provides a reef-like environment conducive to marine life. In theory, wave energy could be harnessed, using the structure to convert waves into energy to help sustain the energy needs of the airport.

MODERN FLOATING AIRPORT PROJECTS

In 2000, the Japanese Ministry of Land, Infrastructure, and Transport sponsored the construction of Mega-Float, a 1000-metre floating runway in Tokyo Bay. After conducting several real aircraft landings, the Ministry concluded that floating runways' hydro-elastic response would not affect aircraft operations, including precision instrument approaches in a protected waterway such as a large bay. The structure has been dismantled and is no longer in use.

Fig.3 Partim view of aircraft moving on airport-ponton.

The pneumatic stabilized platform (PSP) was proposed as a means for constructing a new floating airport for San Diego in the Pacific Ocean, at least three miles off the tip of Point Loma. However, this proposed design was rejected in October, 2003 due to very high cost, the difficulty in accessing such an airport, the difficulty in transporting jet fuel, electricity, water, and gas to the structure, failure to address security concerns such as a bomb blast, inadequate room for high-speed exits and taxiways, and environmental concerns.

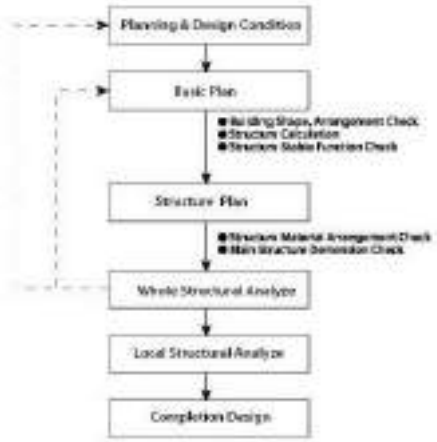

Fig.4 Planing and design flow chart of offshore airport.

Achmad Yani International Airport, the first floating airport in the world started construction on 17 June 2014, and had to be completed in 2016. However, only the passenger terminal and apron is floating.

Dalian Jinzhou Bay International Airport is mainland China’s first offshore floating airport. The project was officially approved in October 2022 and is currently under construction.

Table 1: Comparative Analysis of Floating Airport Technologies

Technology	Cost (USD/km²)	Stability	Environmental Impact
PSP (San Diego)	$12B	High (deep water)	Low seabed disruption
Reclamation (Kansai)	$20B	Moderate	High habitat loss
Hybrid (Dalian)	$8.5B	High	Moderate (turbidity)

COASTAL LANDS – TAIWAN CASE STUDY

Due to the fragility and sensitivity of coastal resources, once destroyed, they are extremely difficult to recover, in addition to reducing the value of water and product quality Ying want open outside, and environmental hazard, harm homeland security, the threat of people's lives and property, causing social problems. Therefore, the use and management of coastal zones require special care, under the principle of conservation of resources and development of both resources, according to the ecological characteristics and economic development needs resources, coastal resources for the overall planning and evaluation, are sequentially partitioned, so can the coastal zone be sustainably developed.

Coastal and soil erosion has always been a problem for many island countries like Taiwan [16]. In addition, many countries engage in massive reclamation (coastal modification) as a result of the rising awareness of population growth, trade development, and national defense. For example, Dubai engages in massive reclamations for trade and tourism, Japan built Kansai International Airport for transportation, China spent billions of RMB on land reclamation for military purposes and the constructions of airports (REF DALIAN), and the South Star Project (SSP) of Kaohsiung in Taiwan is fbeing evaluated.

Due to the rise of environmental awareness in recent years, the objection of environmental groups and nearby residents, and fund shortages, SSP is still under construction after 30 years. We are facing several questions [17]. Should the SSP be continued? What should be done to cope with the incessant coastal and soil erosion of island countries (Taiwan)? Is land reclamation the only solution? How to manage coastal modifications on the long run? What are the funding sources for such a huge project? Should we consider and listen to the opinions of environmental groups and nearby residents? If so - how to gather their opinions? How many stakeholders should be considered? What should be done after listening to their opinions? All of these questions gradually emerge.

Taiwan's southwestern coast exemplifies tensions between infrastructure planning and environmental resilience. The South Star Project (SSP) delay underscores engineering-feasibility challenges in sediment management (Fig. 6–9) and environmental-impact conflicts with coastal communities [17]. Unlike Japan's Mega-Float, SSP's 30-year stagnation reflects inadequate stakeholder integration—a critical planning gap for floating infrastructure.

After understanding the geographical location and surroundings of Taiwan and the problems Taiwan is facing, we should start with the following:

(I)Finding examples of reclamation and labor-consuming and money-consuming projects that benefit future generations at abroad and learn from them.

(II)Understanding possible pollution and waste sources that come along with reclamation.

(III)Investigating the sources and flows of funds for reclamation and how the government invests in and solicit investments in such projects.

(IV)Investigating future trends of land reclamation in Taiwan or using coastal water surfaces in different ways.

Overview of coastal Taiwan Land Use

The marine environment is an invaluable property of mankind. Land reclamation is one way of making use of coastal shallows which can be developed to different types of economic use, such as for accommodation, cultural, conservation, but also for industrial and purposes of infrastructure. The reclamation of land by building an artificial island is achieved by the construction/repair of bank revetments around the perimeters before combining those with existing islets with sand or landfill. An artificial island is primarily used as a site for shallow water petroleum exploration or the reception of large tank ships or transportation of minerals. Floating cities (seasteadings) are basically large steel constructions that are partially submerged in the ocean[9]. They are usually modified from naval vessels that were formally used for marine development activities (i.e. floating cities above large deep-sea mines that serve as multifunctional complexes to provide accommodation, shopping and event entertainment for miners) [8,12].

The development of offshore airports has been an ongoing trend worldwide. Examples of offshore airports on reclaimed land include the Honolulu International Airport of Hawaii [29], and Japan's Nagasaki Kansai Airport [11]. In fact, the government actually planned the construction of an offshore airport before the Taoyuan International Airport was

built. However, due to rigorous protests by local elected representatives, concrete development of the project has yet to take place.

Fig.5 Japan's Nagasaki Kansai Airport

Offshore land reclamation

In 2009, the typhoon, Morakot brought a lot of mud which sedimented in the river estuary of Kao-Ping River, Taiwan government and local Kaohsiung government planned to use the sediment for the Nanhsing project area. Therefore, Taiwan government hopes to re-promote Nanhsing project in order to develop the urban area of Kaohsiung. Because of the heavy sediment brought by Morakot, the downstream of Kao-Ping river was sedimented, these sands could be used for land reclamation to develop harbor, offshore airport and bigger industries. It could also increase the financial development and be used as the base of Kaohsiung airplane.

The SSP project is proposed to be built near the existing Kaohsiung airport and the second harbor, which is 3 km by 1 km. It was expected to be built at 3 square kilometer and was planned to be replacing the existing Kaohsiung airport and become the international airport of the South. However, since no funding was received from the government, the plan was postponed.

Fig.6 South Star Project (SSP) of Kaohsiung in Taiwan

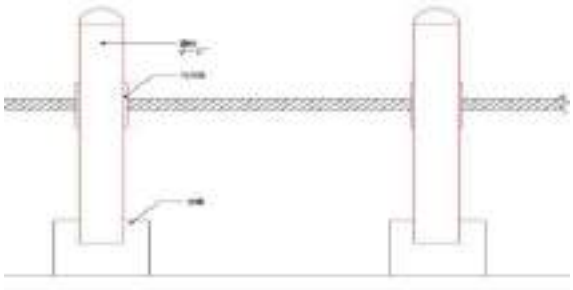

Fig.8 Elevation-South Star Project (SSP) of Kaohsiung in Taiwan

Fig.9 South Star Project (SSP) of Kaohsiung in Taiwan

Advantages of an Offshore Airport

Developing Offshore airports is a trend in the world, and we concluded three merits as follows: Firstly, the plane could take off or land at night, because the offshore airport is far away from the city and could fly or land at anytime without disturbance by the night. Second of all, because of the long distance between offshore airport and the city, the noise and air pollution could be reduced[8,12]. In addition, it could make the flyway clear which could reduce the judgment error about the plan landing (Take the event happened in Da-yuan & Singapore as examples.) PLUS land space use! More and more construction space is needed and becomes a major problem all over the world. Namely, how to use the spaces more properly has become the major point in the transportation design. The bigger space the more quantities, efficiency and more importance. the floating airport was under precise calculation and integrated with several techniques.

GLOBAL WARMING, CLIMATE CHANGE, AND SEA LEVEL RISE.

In light of global warming and climate change, NOAA (National Oceanic and Atmospheric Administration) is predicting that, by 2050, most coastal cities in the U.S. likely will be threatened by at least 30 days of fooding each year.3 That is for coastal cities on the Mainland. Islands in the Pacifc (including Hawaii) will likely have it much worse. Moreover, reputable scientists are saying that, by 2100, the oceans will rise between 2.5 and 6.5 feet

feet (0.8 and 2 meters), which is more than enough to food many U.S. coastal cities. That is enough for a lot of concern and worry.

This research will review existing knowledge on global warming and climate change, particularly in terms of sea level rise. It will examine how much of a threat global warming really is, and suggest that it is, in fact, serious enough that major preparations should begin now. It will look at the causes of global warming and consider the reasons for the controversy that has surrounded it. The research will report on what might happen in the future and take a look at what has already started happening around the world, and here in Hawai‘i, as a result of global warming and climate change. It will present what the international community has recommended be done to slow down the process of climate change, and look at comments made by the president of the U.S. as he speculates on what might be coming up in the future.

Unfortunately, short of eliminating all greenhouse gasses from the atmosphere, the literature tells us that there are no permanent solutions to the problem of climate change and sea level rise. There are, however, various recommended strategies to manage or mitigate global warming, and they will be examined here, culminating in a focus on foating development, not as a solution to the problem, but as one strategy among a number of strategies to mitigate the problem.

This research document briefly reviews existing knowledge of global warming and climate change, along with the consequences. It examines sea level rise, and briefly discusses the controversy that still lingers, allegedly because of what oil companies have done. It goes through strategies for mitigating sea level rise, with a final focus on floating development, not as a solution, but as one of a number of suggested ways to mitigate the problem of sea level rise.

CONCLUSION

(1) Planning: Floating airports mitigate urban noise but require integrated transport links (water taxis/undersea tunnels). (2) Engineering: PSP technology suits deep-water sites; reclamation remains cost-effective for <30m depths. (3) Environment: Artificial reefs enhance marine biomass, but dredging elevates turbidity (Taiwan’s SSP case). (4) Policy: Taiwan’s experience urges early engagement with NGOs/residents in Environmental Impact Assessments.

THE ECONOMIC RESILIENCE MODELING OF STREET VENDORS HOUSEHOLDS WITH SOCIAL CAPITAL AS AN INTERVENING VARIABLE: A CASE STUDY OF STREET VENDORS IN EAST JAKARTA

Beti Nurbaiti [1], Mohamad Axel Putra Hadiningrat [2], and Chotib Hasan [3]

[1] Universitas Bhayangkara Jakarta Raya, Jakarta, Indonesia, [2, 3] Universitas Indonesia, Depok, Indonesia,

ABSTRACT

Problem statement from this research dissertation is to examine how East Jakarta street vendors achieve household economic resilience. The research approach used quantitative method were used to assess the economic resilience of the households of street vendors: (1) sociodemographic traits; (2) transitory locations (Loksem); (3) base/fixed sites (Lapak); (4) hawkers (Asongan); (5) local government-assisted locations (Lokbin); (6) social capital. Data from 420 respondents was gathered using a quantitative approach. In Lokbin, social capital influences the economic resilience of street vendors' households by acting as an intervening factor on factors including income, education, migrant status, and sales. The results of this research according to the Sobel Test, two variables street vendors with migratory status and those with a diploma or higher show significance and a positive impact only when mediated by the intervening variable of social capital. Economic resilience is positively impacted by the social capital variable. There is a statistically significant influence on the kind of street vendors evaluated at LokBin. Conclusion: the economic resilience is directly impacted by sociodemographic traits. The economic resilience of street vendors has been demonstrated to be mediated by social capital, sociodemographic traits, and trading location.

Keywords: Economic Resilience; Social Capital ; Street Vendors; Sobel Test; East Jakarta

INTRODUCTION

The presence of street vendors (known locally as PKL) in major urban centers like Jakarta represents a critical component of the informal sector, especially in terms of providing employment opportunities for low-skilled migrant populations. While this sector plays a vital role in absorbing labor and reducing unemployment, it also poses significant urban challenges, including spatial disorder, traffic congestion, and urban slum development.

Street vending is not unique to Jakarta or developing countries such as Indonesia. Similar phenomena are observed globally in Syria [1], Uganda [2], Australia [3], and India [4]. Street vendors operate within the informal economy, often turning to vending as a livelihood strategy due to limited access to education, technical skills, and financial capital. Despite these constraints, the sector remains attractive due to its low entry barriers and flexibility. However, unregulated vending practices, often facilitated by informal agreements with local authorities (referred to as "hidden actors"), result in widespread misuse of public spaces such as sidewalks, overpasses, green belts, city parks, and urban forests.

A large portion of street vendors in Jakarta are long-settled migrants. The continuous rural-to-urban migration flow driven by improvements in transportation, technology, and public services reflects a common belief that urban areas offer better life prospects compared to rural regions [5]. Female migrants, in particular, constitute a substantial part of this workforce and actively contribute to both local and global informal labor markets [6]. Their journey is often marked by limited resources, lacking in skills, capital, and formal education [7]. The informal sector, however, offers a degree of resilience due to its adaptability, even during times of economic instability. Its capacity to generate employment plays a crucial role in alleviating poverty and reducing unemployment [8][9].

Social capital encompasses elements such as group affiliation and networking, mutual trust and solidarity, social cohesion and inclusion, collective action, information sharing, and empowerment. Within the street vending community, these components form the foundation of mutual support systems, enabling access to markets, trading techniques, and informal financing channels outside conventional financial institutions [10]. This form of capital is often complemented by spiritual capital and the strategic use of micro-spatial environments for living, production, and vending, all contributing to the household's economic resilience.

Based on the aforementioned discussion, this study is designed to address the following research questions:

1) Is there a direct influence of social capital, vending location, and sociodemographic characteristics on the economic resilience of street

vendor households?
2) Is there an indirect influence of vending location and sociodemographic characteristics on the economic resilience of street vendor households through the intervening variable of social capital?

This research fills the research gap related to economic resilience in the informal sector, specifically the economic resilience of street vendors.

RESEARCH SIGNIFICANCE

This study is grounded in a strong theoretical foundation, particularly drawing from theories of social capital and household economic resilience within the context of the informal sector. Social capital serves as the primary framework, based on the approach developed by [11], as well as key concepts introduced by [12] and [13].

Social Capital

Social capital as a set of norms, networks, and trust that facilitates cooperation and collective action among members of a community. The concept of social capital was also developed. They classify social capital into six key dimensions: (1) Group and network; (2) Trust and solidarity; (3) Collective action and cooperation; (4) Information and communication; (5) Social cohesion and inclusion; and (6) Empowerment and political action.

The six dimensions illustrate how communities are interconnected, how trust is built, and how systems of information exchange and mutual support are developed—particularly vital in enhancing economic resilience among vulnerable groups such as street vendors.

Economic Resilience

In addition to the social capital framework, the theory of household economic resilience also serves as a critical reference in this study. According [14], economic resilience refers to a household's sustained ability to meet its basic needs—such as food, education, healthcare, and shelter—while also possessing the capacity to recover from economic shocks. This resilience is not solely measured by income levels but also by adaptability, income diversification, and the strength of their social networks.

This research aligns with findings who examined the impact of social capital on the well-being of informal sector actors in Jakarta. Their study demonstrated that social capital, particularly in the form of trust and networks, plays a significant role in enabling micro-entrepreneurs to access economic opportunities and endure socio-economic pressures. These findings reinforce the notion that in informal economies, social relationships are not merely supplementary; they are a foundational element of household economic sustainability.

In this research, street vendors' economic resilience is assessed based on a framework, using survey indicators such as: housing conditions, household income, children's education, and financial security. However, due to the pandemic's economic impact, most vendors saw a sharp decline in their savings—some reported having no savings at all.

HYPOTHESIS

After conducting a literature review and selecting theoretical references aligned with the chosen research variables, the following research hypotheses were formulated for analysis:

1. **Hypothesis 1 (H1)**: There is a direct influence of social capital on the economic resilience of street vendor households.
2. **Hypothesis 2 (H2)**: There is a direct influence of street vendor type, based on vending location, on the economic resilience of street vendor households.
3. **Hypothesis 3 (H3)**: There is a direct influence of sociodemographic characteristics on the economic resilience of street vendor households.
4. **Hypothesis 4 (H4**): There is an indirect influence of vending location and sociodemographic characteristics on the economic resilience of street vendor households through the intervening variable of social capital.

RESEARCH METHODS

The researcher conducted a field survey over a period of six months, from November 30, 2021, to May 27, 2022. The study focused on street vendors (PKL) located in East Jakarta, covering ten districts: (1) Cakung, (2) Cipayung, (3) Ciracas, (4) Duren Sawit, (5) Jatinegara, (6) Kramat Jati, (7) Makasar, (8) Matraman, (9) Pasar Rebo, and (10) Pulogadung.

The research adopted a quantitative approach, beginning with the collection and analysis of numerical data. This approach aimed to enhance the depth and contextual understanding of deductive findings by providing complementary insights. As suggested by [16], such a strategy is expected to enrich data interpretation and offer more comprehensive and applicable solutions to real-world problems.

Quantitative Data Processing

The sampling method for the quantitative phase employs multi-stage random sampling, taking into account quotas for each municipality, with selected sub-districts and urban villages in East Jakarta. Primary data collected from street vendors will be processed using SPSS to examine research variables including trading locations, sociodemographic characteristics, and their impact on household

economic resilience.

RESULTS AND DISCUSSION

Descriptive Statistics Processing Results

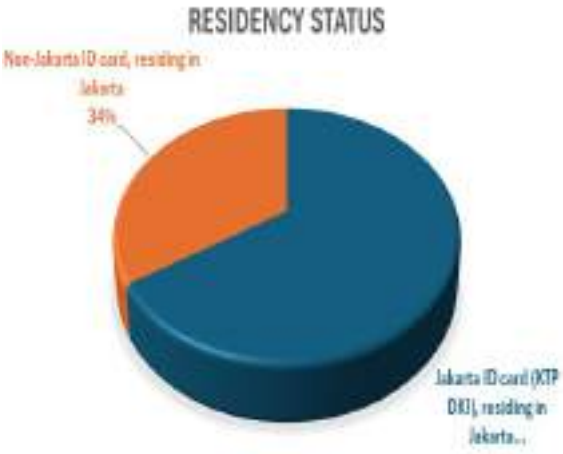

Figure 1. Residency Status
(Source: Processed by Author, 2023)

Referring to the field survey results in Figure 1 it is evident that the majority of street vendors have become Jakarta residents and enjoy the facilities provided by the DKI Jakarta Provincial Government. Street vendors with non-Jakarta ID cards still choose to live in Jakarta because the facilities and trading advantages they obtain are greater than those in their places of origin.

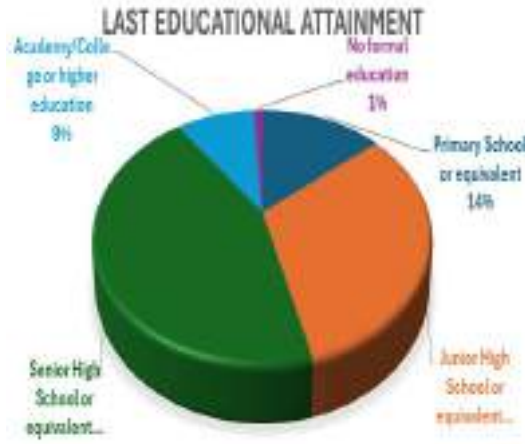

Figure 2. Educational Background
(Source: Processed by Author, 2023)

Based on Figure 2, the educational background of street vendors is dominated by high school graduates and equivalent (44%), followed by junior high school and equivalent (32%), elementary school and equivalent (14%), academy/higher education (9%), and no schooling (illiterate) (1%). From an educational perspective, the majority of street vendors have low education levels with only a few having higher education.

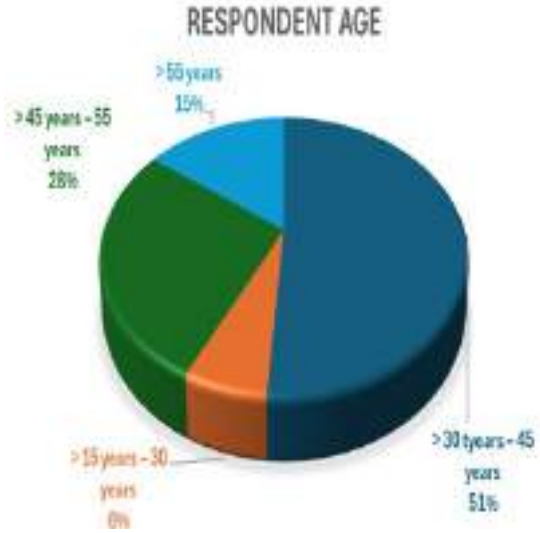

Figure 3. Respondent Age
(Source: Processed by Author, 2023)

The primary data analysis results in Figure 3 show that the age of street vendors who trade is mostly within the productive age range of >30 years – 45 years (41%), followed by >15 years – 30 years (25%), >45 years – 55 years (22%), and the least represented are those >55 years old at (12%). The majority of street vendors are in their productive years with only a few being elderly.

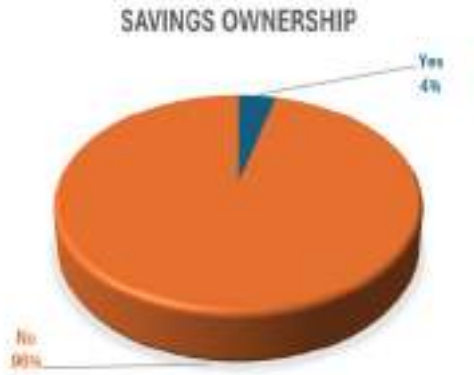

Figure 4. Savings Ownership
(Source: Processed by Author, 2023)

Furthermore, from the primary data results in Figure 4, it was found that 96% of street vendors do not have savings and only 4% of street vendor respondents have savings. Based on field interviews, street vendors who have savings mostly already use digital marketing/marketplaces, including WhatsApp, Instagram, GoFood, and GrabFood. Therefore, it can be concluded that digitalization is important for improving the economic resilience of street vendors.

Hypothesis and Sobel Test Results

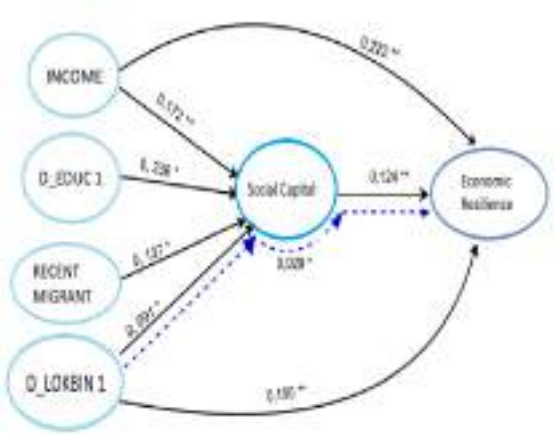

Figure 5. Conceptual Model of Social Capital as an Intervening Variable (Research Novelty)
(Source: Processed by Author, 2023), where *) Significant at α=10%; **) Significant at α=5%)

1. **Hypothesis-1 (H1)** is accepted/proven, confirming that there is a direct influence between social capital and the economic resilience of street vendor households at a 5% significance level. The regression coefficient of social capital on street vendor household economic resilience has a positive direction of 0.124. In the scope of social sciences, referring to statistical test results is more focused on analyzing the direction/pattern of relationships between variables. Therefore, it can be concluded that if social capital is good/quality, then the economic resilience of street vendor households will also increase.
2. **Hypothesis-2 (H2)** is accepted/proven, confirming that there is a direct influence between the types of street vendors based on their trading locations in Designated Areas (LokBin) and street vendor household economic resilience at a 5% significance level. For the other three trading locations: Temporary Locations, Permanent/Stall Locations, and Mobile/Peddling Locations, these are not significant/do not affect street vendor economic resilience. The regression coefficient of LokBin on street vendor household economic resilience has a positive direction of 0.190. This can be concluded that LokBin has a positive impact on street vendor household economic resilience. In other words, street vendors in LokBin have better economic resilience compared to street vendors in other trading locations.
3. **Hypothesis-3 (H3)** is accepted/proven, confirming that there is a direct influence between sociodemographic characteristics in the income aspect of street vendors and street vendor household economic resilience at a 5% significance level. For other sociodemographic characteristics such as age, gender, education level, and migration status (recent and lifetime) are not significant/do not directly affect street vendor economic resilience. The regression coefficient of income on street vendor household economic resilience has a positive direction of 0.222. This can be concluded that street vendors with high income will have good household economic resilience. This means that the better the income level of street vendors, the more economically resilient they become.
4. **Hypothesis-4 (H4)** is accepted/proven, confirming that there is an indirect influence between trading locations and sociodemographic characteristics on street vendor household economic resilience through the intervening variable of social capital at a 10% level. This is proven by the Sobel test, where the regression coefficient of the intervening variable has a positive direction of 0.127. The results of this calculation show that social capital has an intervening influence on other variables, namely income, diploma-level education and above, street vendors with recent migrant status, and those selling in LokBin, on street vendor household economic resilience.

Analysis of Direct Effect of Trading Location on Street Vendor Household Economic Resilience

The results of the second hypothesis test show that only Street Vendors (PKL) who trade in Designated Areas (Lokbin) have a significant effect on their household economic resilience. Three other types of locations—Temporary Locations (Loksem), Permanent/Stall Locations, and Mobile/Peddling Locations—do not show meaningful effects.

Lokbin is an area officially provided by the DKI Jakarta Provincial Government as regulated in Governor Regulation No. 10 of 2015 concerning Street Vendor Management and Empowerment. The purpose is to avoid sporadic buying and selling activities in public spaces, maintain city order, and improve public comfort and safety.

Figure 6. Street Vendors as Hawkers (Source: by Author, 2023)

Street vendors in Lokbin receive various facilities such as tents, tables, and chairs, as well as affordable cleaning and security fees (Rp 150,000/month). This is much cheaper compared to unofficial 'tribute' costs when trading illegally (Rp 500,000–600,000/month). This allows street vendors in Lokbin to allocate more funds for business development.

Nevertheless, many street vendors are reluctant to move to Lokbin because the location is considered less strategic—far from crowds, stations, bus stops, or public activity centers. They prefer public spaces such as sidewalks and parks that are frequently passed by the public.

Figure 7. Street Vendors with Lapak for Selling (Source: by Author, 2023)

This phenomenon aligns in The Production of Space, which explains that social activities require space. Street vendors create their own "social space" in public spaces as a form of survival struggle in the city. Similar problems occur in various large cities, but countries like Japan have provided special places for street vendors that are neat, clean, and comply with regulations, including limited operating hours and food hygiene permits.

In Jakarta, the challenge is how to encourage street vendors to be more interested in trading in Lokbin. One solution is to make Lokbin more attractive, for example by adding public facilities such as free wifi, entertainment stages, and budget-friendly culinary zones for young people and students, so that the location becomes a comfortable and strategic gathering place.

Analysis of Direct Effect of Sociodemographic Characteristics on Street Vendor Household Economic Resilience

Based on data processing results, it is proven that the sociodemographic characteristic that has a significant direct effect on household economic resilience is street vendor income. Other sociodemographic characteristics have indirect effects on street vendor household economic resilience.

The educational level of street vendors is dominated by high school graduates and equivalent (44%), followed by junior high school and equivalent (32%), elementary school and equivalent (14%), academy/higher education (9%), and no schooling (illiterate) (1%). From an educational perspective, the majority of street vendors have low-to-medium education, with only a few having higher education. Illiterate street vendors are still found, though not many. During field surveys, most street vendors still consider formal education not a priority because they allocate their time, energy, and thoughts to focus on trading. Therefore, education level does not have a significant direct effect on street vendor household economic resilience, and they feel satisfied with low-to-medium education levels as long as they can have sufficient income for their families.

Analysis of Social Capital as an Intervening Variable on Street Vendor Household Economic Resilience

There is an influence of social capital as an intervening variable on street vendor household economic resilience. Generally, street vendors have low-to-medium education levels, forcing them to pursue this profession in the urban informal sector according to the data. A street vendor can achieve higher education if they utilize the social capital they possess. One sub-dimension of social capital is networks/kinship groups (Group and Network).

The sub-dimension of social capital utilized by street vendors is Trust and Solidarity, where there is mutual trust and solidarity between both parties, resulting in the practice of social capital sub-dimensions in the form of Empowerment and Political Action. The existence of the Information and Communication sub-dimension plays a role when street vendors who initially worked as employees seek places to study while selling online through social media and colleagues, enabling them to complete their studies successfully..

Figure 8. Selling Facility at Lokbin (Source: by Author, 2023)

There are several important aspects that make recent migrants more economically resilient compared to lifetime migrants: (1) **social factors**; (2) **cultural factors**; and (3) **communication factors.**

Information and communication aspects as impacts of urban modernization become driving factors for recent migrants' economic resilience, especially those who utilize online marketing. Marketing through marketplace utilization on social media helps street vendors increase income and profits, enabling them to achieve household economic resilience.

1. CONCLUSION

The study found that social capital within the street vendor (PKL) community in East Jakarta's Designated Locations (Lokbin), when supported by adequate income levels, positively influences household economic resilience. However, individual factors such as age, gender, education level, and migration status both recent and lifetime do not have a significant or direct impact on economic resilience. Street vendors can improve their income by using digital marketing and marketplace platforms like WhatsApp, Instagram, GoFood, and GrabFood. Increased income enables them to meet daily needs, save, and strengthen their economic resilience. While recent migrant status does not directly affect economic resilience, it does have a direct influence on social capital. The study suggests further research into how street vendors utilize social capital as an intangible asset and what factors influence their willingness to relocate to Lokbin for improved economic conditions.

SOLIDIFICATION CHARACTERISTICS OF SOIL CONTAINNING COAL WASTE (PART II)

Shoji Kamao[1], Rin Itagaki[1] Satoshi Shigemura[1] and Yuta Murakami[2]

[1]Civil Engineering, Nihon University, Japan; [2] JR East Consultants Co. Ltd, Japan

ABSTRACT

Coal was used as fuel for steam locomotives, and coal cinders (coal waste), which contained ash and small pieces of unburned coals, were buried underground for disposal. Recently, redevelopment projects have been planned in Japan for former rail depot sites where coal cinders were once disposed of. In such redevelopment projects, buried coal cinders have frequently been excavated, making it challenging for developers to dispose of and process the excavated coal waste. Excavated coal cinders must be treated and disposed of as industrial waste, not soil. Although the soil with coal cinders has been excavated from the ground, it cannot be used as backfill material under Japanese environmental law[1], even if put back in place. Instead, it is disposed of as industrial waste needs high disposal costs. The high disposal cost and the shortage of final disposal sites have increased the cost of redevelopment projects. The authors have published some papers showing that adding cement and clay to coal cinders can produce improved soil with high unconfined compressive strength.

This paper investigates the properties of improved coal cinders mixed with cement and clay for use as backfill materials, not for industrial waste. In addition to the unconfined compression test, compaction tests and cone index tests were also conducted to clarify the characteristics of the improved material. The results of all the tests were good for subgrade materials. However, when the compacted improved soil was removed from the mold and re-compacted, a decrease in strength was observed compared to the first time. Further consideration is also necessary when re-excavating improved soil.

Keywords: Coal cinders, Construction waste soil, Cement solidified soil, Strength Characteristics

INTRODUCTION

In Japan, the Shinagawa–Yokohama railroad began service in 1872, and a nationwide railroad network was subsequently developed [2, 3]. For approximately 100 years, until around 1975, steam locomotives using coal as fuel were in operation. The coal cinders used by these steam locomotives were buried in the ground as construction material for railroad sites. However, there are no detailed records regarding the buried coal cinders' extent, quantity, or depth.

In recent years, as a result of railroad facility reconstruction and redevelopment projects near stations, these coal cinders are increasingly being excavated. Once excavated, coal sludge buried underground (including soil mixed with coal sludge) is classified as “cinders” under environmental laws and cannot be disposed of as waste soil. Furthermore, due to the unknown physical and chemical properties of the material, most of it has been disposed of as industrial waste. The majority of this excavated coal sludge ends up landfilled at final disposal sites, resulting in significant environmental impacts from both transport and disposal. Reducing the massive volume of final disposal coal cinders revealed through Sustainable Development Goals (SDGs)–driven projects across Japan is a critical issue.

This study aims to utilize excavated coal sludge as roadbed material for railroad structures[4]-[8]. According to design standards for railway structures, a Unconfined compressive strength of at least 1000 kN/m² after 28 days of curing is required for use as roadbed material. Therefore, this target strength was set, and the authors attempted to improve the excavated coal sludge-mixed soil (hereinafter referred to as “coal cinders”) by cement stabilization. This report evaluates the solidification characteristics of newly sampled coal cinders. The improved soil specimens were prepared by mixing the in-situ collected coal sludge with clay and blast furnace cement type B at specified proportions, setting various initial water content and curing them for a fixed period. We assessed the solidification characteristics by measuring the unconfined compressive strength of the specimens and also examined their compaction and cone index characteristics.

RESEARCH SIGNIFICANCE

The importance of this research lies in the fact that no research has been conducted to date on what to do with coal cinders that is excavated during redevelopment work. Clarifying the physicochemical properties of excavated coal cinders so that it can be used is also important in terms of environmental issues.

MAIN CHARACTERISTICS OF THE SAMPLE

The coal cinders used in this study were collected during excavation at a construction site on a railroad right-of-way. Photographs 1 and 2 show the conditions during sampling.

The main physical properties of the coal sludge and added clay are summarized in the table 1. The particle density of the coal sludge is 2.44 g/cm^3, which is lower than that of ordinary soil. This is likely because coal, which typically has a specific gravity of 1.2–1.5, lowers the density of the coal cinders when present. It is extremely difficult to determine the exact coal content, as many finely crushed coal fragments are mixed in.

Consistency tests (e.g., liquid limit) are conducted with samples that pass through a sieve according to JIS standards, meaning coal fragments larger than 0.425 mm are removed. Therefore, consistency testing is possible. It has also been previously reported that soils mixed with coal often yield “NP” when the soil type is sandy.

Photo 1 Coal cinders dug up at the construction site

Photo 2 Collected coal cinders sample

Table 1 Typical properties of coal cinders and added clay

Typical Soil properties		Coal cinders	Added clay
Soil particle density	ρ_s (g/cm^3)	2.44	2.87
Liquid limit	w_L (%)	NP	54.7
Plastic limit	w_P (%)	NP	33.7
Plastisity index	I_p (-)	NP	21.0
Natural water content	w_n (%)	3.17	4.65
Ignition loss	L_i (%)	16.71	5.85

Test Items and Conditions

The following experiments were carried out to understand the cement solidification characteristics of coal cinders.

(1)Unconfined compression test for cement-solidified soil, [9],[10] (Curing time 7 and 28 days)
(2) Soil compaction using a rammer, [11]
(Adjusted soil and improved soil, curing 7 days)
(3) Cone index for compacted soils, [12]
(Adjusted soil and improved soil curing 7 days)
(4) Permeability of saturated soil , [13]
(Adjusted soil and improved soil curing 7 days)

Note: adjusted soil refers to coal cinders with grain size adjustment.

Unconfined Compression Test of Cemented Soil

Specimens were prepared following the Japan Society of Geotechnical Engineers’ standard (JGS 0821) for stabilized soil specimens without compaction. Coal sludge passed through a 2.0 mm sieve was used to ensure compatibility with the Unconfined compression test specimen dimensions. Commercial powdered clay was added, and blast furnace cement type B was used as the solidifier.

Clay was added because the coal sludge alone did not exhibit sufficient strength when its clay content was low. Previous studies confirmed adequate strength when clay content was adjusted as a parameter.

Water was added to the clay, coal sludge, and blast furnace cement and mixed for about 10 minutes using electrical mixer to achieve a homogeneous mixture. An acrylic mold with a 35 mm diameter and 100 mm height was used. The bottom was sealed with a rubber stopper, and the specimen was filled in five layers, tapping each layer 100 times to expel air. After filling, the top was wrapped in plastic, and specimens were cured for 7 and 28 days at 20°C in a thermostatic chamber.

The cement and water were added based on the dry mass of the coal cinders (sludge–clay mixture). Cement addition rate and coal cinders addition rate were defined using following Equations (1) and (2). Test conditions are shown in Table 2.

$$a_w = \frac{m_s'}{m_g + m_s} \times 100 \ (\%) \quad (1)$$

$$D_w = \frac{m_g}{m_g + m_s} \times 100 \ (\%) \quad (2)$$

m_s' : Mass of blast furnace cement type B
m_s : Dry mass of clay
m_g : Dry mass of coal cinder mixed soil

Table 2 lists the tested combinations. Coal cinders addition rates ranged from 0 to 100%, and cement addition rates were 5%, 10%, 20%, and 35%.

Because the powdered clay had a water content of approximately 4.7%, water was necessary. Preliminary tests showed that initial water content below 30% made mixing difficult, while above 60% led to specimens that could not maintain shape. Thus, 50% was set as the initial water content.

Table 2 Test conditions for unconfined compression test of cemented soil

Condition	Symbol	Values
Coal cinders addition rate	D_w (%)	0～100
Cement addition rate	a_w (%)	5, 10, 20, 35
Initial water content	w_0 (%)	40, 50, 60
Water-cement ratio	w/c (%)	60
Curing time	Tc (days)	7, 28

Compaction Test by Ramming

We set the coal cinders and cement addition rate based on the unconfined compression test results and prepared the improved soil. Specimens cured for 7 days were adjusted to a maximum grain size of 19 mm and tested according to JIS A 1210. The mold used had a 10 cm diameter and 1000 cm^3 volume.

The average initial water content of the improved soil after curing was 53.4%, so compaction testing began at that water level. This exceeded the optimum water content of the improved soil, so the initial value was adopted as the optimum water content and maximum dry density.

Cone Index Test of Compacted Soil

Cone index tests were conducted on specimens prepared for the compaction test in accordance with JIS A 1228 (cone index test of compacted soil). Test conditions matched those in Table 2. Tests were performed on both cement-modified and uncemented coal cinders specimens.

For the cement-modified soil, a second test was conducted using samples that were compacted, broken into smaller pieces, and then re-compacted. This was to observe changes in strength upon repeated use.

Permeability Test for Compacted Soil

Permeability tests were conducted to evaluate the water permeability of the compacted soil. Both uncemented adjusted soil and cement-modified improved soil were tested. Given that cement-modified soil tends to absorb water and resist drainage, we tested its hydraulic conductivity. Because the soil contains clay, the falling head permeability test (as specified by JIS A 1218) was used.

EXPERIMENTAL RESULTS AND DISCUSSION

Unconfined Compression Test Results

The relationship between coal cinders addition rate and unconfined compressive strength was plotted for 5%, 10%, and 20% cement addition rates at 7 and 28 days. Each point represents the average of three specimens. While variation existed due to coal cinders content, general trends were identified.

For all conditions, strength increased more after 28 days than after 7 days. However, under high coal cinders content, the strength gains were smaller, and this difference between 7-day and 28-day values diminished. The strength increased with coal cinders addition up to a point and then decreased, more noticeably at higher cement contents. This is attributed to coal cinders acting as aggregate, which reduces clay content and therefore bonding strength.

From these results, 50% coal cinders content, 40% and 50% initial water content, and a 60% water–cement ratio were selected for subsequent tests, with cement addition ranging from 5% to 20%.

Unconfined compressive strength ranged from 350 to 5000 kN/m² depending on cement and coal cinders content. In particular, when the cement content is 20%, the strength is greatest when the coal ash content is 40%, and coal cinders can be considered to play the role of aggregate. Strength

increased linearly with cement addition for coal cinders (Figures 1 to 3). Comparisons to the target strength for roadbed use (q_u=1000 kN/m^2 at 28 days curing) showed that cement addition rates of 10% and 20% met the criteria under appropriate conditions.

From Figure 4, the target strength of curing 28days can be achieved when the cement addition ratio exceeds approximately 8%.

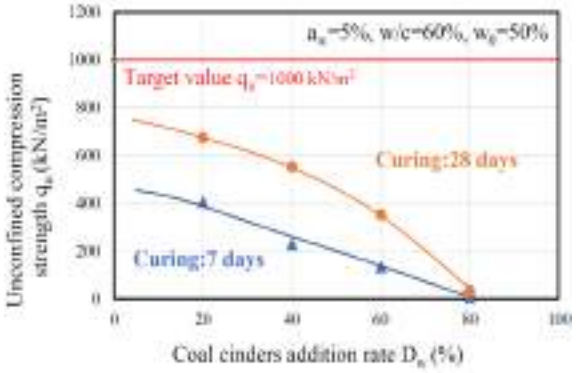

Figure 1 Relathionship between coal cinders addition rate and unconfined compression strength

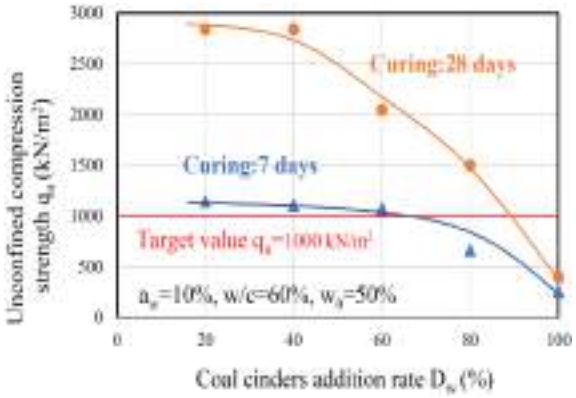

Figure 2 Relathionship between coal cinders addition rate and unconfined compression strength

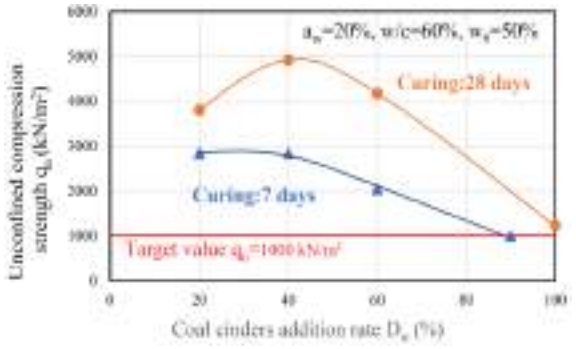

Figure 3 Relathionship between coal cinders addition rate and unconfined compression strength

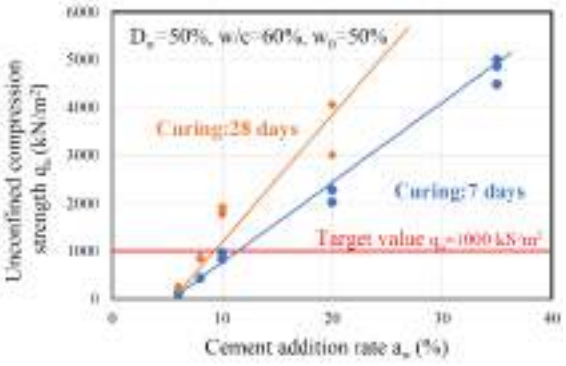

Figure 4 Relathionship between cement addition rate and unconfined compression strength

Compaction Test Results

Based on the results of the unconfined compression tests, sample soil was prepared for the compaction test and cone index test under the following conditions: 50% coal cinders addition rate, 60% water-cement ratio, 50% initial water content, and 7 days curing time.

Figure 5 shows the compaction curve alongside the zero air voids line. Conditions used: 10% cement, 50% coal cinders, and 7 days curing. Water content after 7 days was 48–53%, indicating that optimum water content (about 45–50%) had likely been reached. Maximum dry density was approximately 1.05 g/cm^3. Due to the presence of coal, dry density remained at lower values than in usual soils. Further compaction behavior will be studied under controlled drying conditions (e.g., air-drying cured specimens).

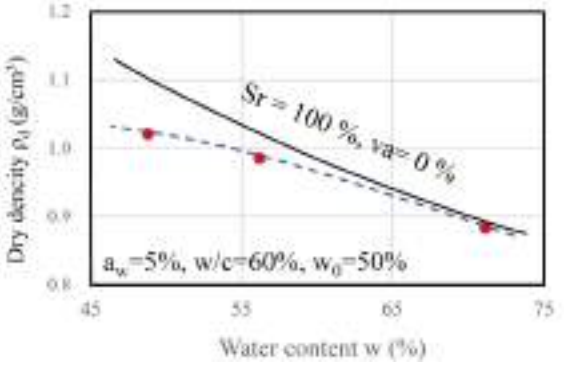

Figure 5 Compaction curve of cement solidified soil

Cone Index Test Results

Figure 6 shows cone index test results for the cement-modified improved soil and the grain-adjusted soil. The uncemented "grain-adjusted soil" was passed by sampled coal cinders through a 2.0 mm

sieve. It was compacted only coal cinders without cement. The cone index ratio in this figure shows the value divided by the cone index of the grain-adjusted soil. It indicates the rate of increase in the cone index due to cement solidification. Under the same conditions, the improved soil showed a cone index about 1.5 times that of the uncemented soil. After 7 days of curing, the strength was about 2400kN/m², three times the threshold of 800 kN/m² of cone index values, the second-class standard for construction-generated soil. It was confirmed that the improved soil is suitable as a backfill material.

In Figure 7, "2nd use to 4th use" refers to the repeated number of compacted specimens after the initial compaction of soil for the cone test. The specimen was broken up and re-compacted for the following cone index test. Reuse led to gradual loss of strength (cone index): the cone index fell by half after four cycles, though dry density remained stable. The cone index ratio shown in Figure 7 is defined as the cone index value for each measurement divided by the initial cone index and represents the rate of decrease in the cone index. The decrease in the cone index implies limitations in reusability and warrants further investigation.

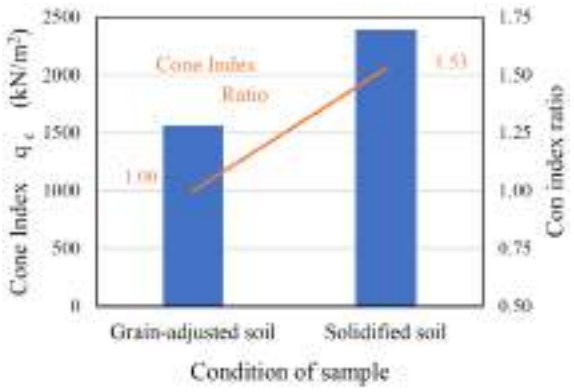

Figure 6 Result of cone index test
(Cone index and Cone Index ratio)

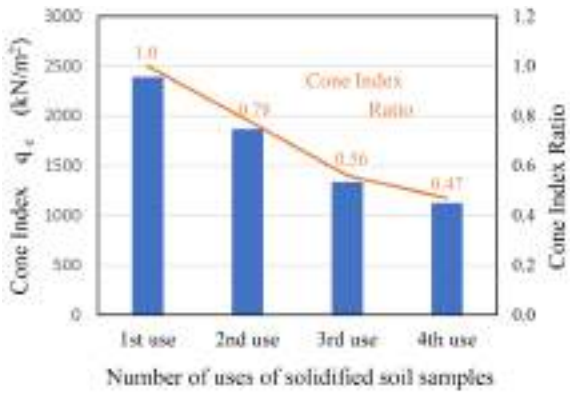

Figure 7 Result of cone index test
(Use repeated compacted sample)

Permeability Test Results

Permeability test results are shown in Table 3. While prior studies suggest permeability declines with smaller pore size as cement content increases, no significant difference was observed before and after treatment in this study [14].

Results matched other reports that permeability remains similar or slightly decreases [15]. Permeability is classified as “low” to “very low.” Since permeability depends on material composition and compaction density, future research will continue.

Table 3 Pearmeability test results

Sample	Permeability coefficient k	
Grain-adjusted soil	1.63×10^{-7}	m/s
Solidified soil	1.66×10^{-7}	m/s

CONCLUSIONS

From the above, the following conclusions were drawn:

1. Cement addition increased the strength of coal cinders. By adjusting cement addition rate, coal cinders content, and initial water content, the required uncofined compressive strength was achieved.
2. Compaction test results confirmed the existence of optimum water content and maximum dry density. Due to coal content, both dry and wet densities of the improved soil were relatively low.
3. The cone index for cement-modified improved soil met the criteria for displaced soil at construction under appropriate solidification conditions. However, repeated compaction tests showed a gradual decrease in the cone index, indicating care must be taken when considering reuse.
4. Permeability tests showed that hydraulic conductivity remained nearly constant regardless of cement modification.

ACKNOWLEDGMENTS

In preparing this paper, several laboratory compaction experiments and other tests were conducted by the Environmental Geotechnical Laboratory staff of the Department of Civil Engineering, College of Science and Technology, Nihon University. The authors would like to express gratitude to them.

CHARACTERISTICS OF FATAL WATER ACCIDENTS IN JAPAN AND THE IMPACT OF CHANGES IN THE AGE COMPOSITION OF THE POPULATION

Masaaki Kondo[1], Yusaku Mizoguchi[1] and Kaede Yoshida[1]

[1] Graduate School of Bioresources, Mie University, Japan

ABSTRACT

This study examines the characteristics of water accidents occurred in Japan from the 1970s to the 2020s, focusing specifically on accidents occurring in the sea, rivers, canals, lakes/marshes/ponds, swimming pools, and other water-related locations. It also analyzes the contribution of changes in Japan's population structure to the temporal trends in the number of fatalities from water accidents.

The results show that in the 1970s and 1980s, a high proportion of water accidents involved infants, preschoolers, and elementary school students, whereas in the 2010s and beyond, those aged 65 and older accounted for the majority. Additionally, in all periods, accidents occurring solely in the sea accounted for approximately 50%, and when combined with river accidents, they made up 70-80% of all accidents. Furthermore, regardless of the periods, fishing activities accounted for the majority of water accidents.

The relationship between accident ratios and population ratios reflects Japan's aging population and declining birthrate. When comparing the RMSE of accident ratios and population ratios for all water accidents and irrigation pond accidents, the RMSE for all water accidents was smaller than that for irrigation pond accidents. This suggests that population structure may influence the overall incidence of water accidents.

Keywords: Water accidents, Occurrence characteristics, Age distribution of population, and Changes in the times

INTRODUCTION

Background

According to the World Health Organization (WHO), approximately 300,000 people drown each year worldwide [1]. Water accidents occurring not only in Japanese waters but also in waters around the world are a serious problem. Since water bodies function as amenity-oriented riparian spaces, water accidents occur in natural waters such as oceans, rivers, lakes, and marshes, as well as in civil engineering structures such as maintained reservoirs and irrigation ponds, through daily life and leisure time.

Figure 1 shows the percentage of fatal water accidents that occurred in Japan in the most recent year, 2023, by location [2]. The scope of fatal water accidents covered by this paper is the entire range of accidents, specifically, accidents that occurred in the sea, rivers, irrigation canals, lakes/marshes/ponds, swimming pools, and others, as shown in Figure 1.

The number of fatalities in Japan in water accidents in general has been on a downward trend since the year the records began to be kept as shown in Fig.2. However, although the number seems to have bottomed out at around 800 in recent years, 743 people died in 2023, indicating that the number has not yet dropped to zero.

In this paper, water accidents refer to fatal accidents that occur near water, such as the sea, rivers,

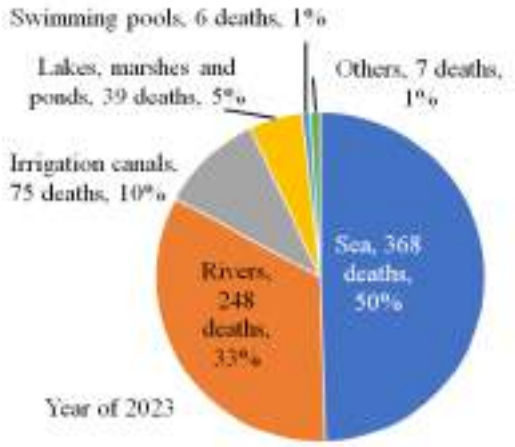

Fig.1 Percentage of water accidents by location in 2023 [2]

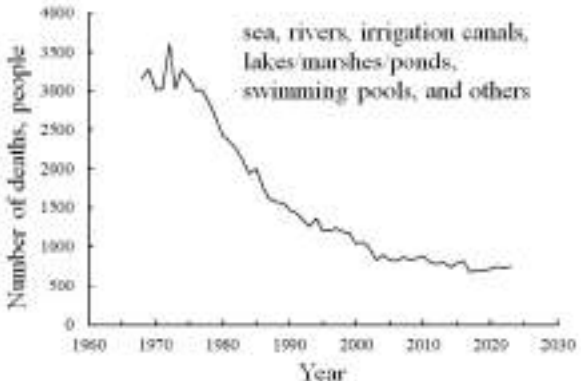

Fig.2 Yearly changes in the number of deaths from all types of water accidents

and irrigation canals. Focusing on fatalities, cases in which individuals were injured but survived the accident are not included.

Previous Studies

Since water accidents occur in a wide variety of locations, there are papers on the individual locations where accidents have occurred. However, there seem to be few studies on water accidents in general. Therefore, this section introduces examples of research on major individual locations where water accidents have occurred.

First, Nishi et al. [3] reported on the physical environment of offshore currents that can cause water accidents, based on the average velocity of offshore currents and the topography of sandbars that can easily generate offshore currents, through field observations along the coast of Miyazaki Prefecture. In July 1955, 36 female junior high school students from Tsu City, Mie Prefecture, drowned during swimming practice near Mie University due to longshore current [4].

Next, the River Foundation Research Institute reported on various risks inherent in rivers and water bodies, as well as risk countermeasures, by organizing accident characteristics for river accidents ([5,6]).

Furthermore, Okamoto et al. [7] conducted an interesting study on irrigation canals, elucidating the mechanism by which water accidents can occur even in canals with shallow water depths and low flow velocities.

Finally, there are some studies on irrigation ponds. While there have been few detailed studies of irrigation pond accidents, the Ministry of Agriculture, Forestry, and Fisheries (MAFF) [8] has published the number of accidents in its collection of irrigation pond safety case studies. Mizutani [9] investigated water accidents involving irrigation ponds, summarized the locations of fatal accidents, and classified accident patterns by age group. Hayashi et al. [10] conducted a questionnaire survey of local residents and reported on the relationship between their childhood experiences of swimming and playing in the water and their perception of irrigation ponds as dangerous. Yoshida et al. [11] collected data from newspaper articles and reported on the actual situation of water accidents in irrigation ponds. Kondo et al. [12] compared the past and the present in terms of water accidents in irrigation ponds, and pointed out the contribution of factors other than changes in population structure.

Purpose of this Study

Looking at the Police White Paper, which contains statistics on water accidents, it is clear that the deaths of children have been taken seriously in every era. Furthermore, looking at papers on accident prevention, I feel that many of them target children. In an official document titled “Statistics on Water Accidents in 2012,” it was first mentioned that approximately 40% of accidents involved elderly people. However, subsequent official documents did not continue to mention elderly people, leading us to believe that there is less concern for elderly people compared to children, and that there is little awareness of the aging population involved in accidents. The objectives of this study are as follows.

First, to summarize the trends in the occurrence of water accidents in Japan in general from the 1970s to the present day 2020s as accident characteristics. Next, the contribution of changes in Japan's population structure will be examined based on changes in the number of fatalities in water accidents over time.

Expected Effects of this Study

In Japan, many people used to die in water accidents in the past, as evidenced by the 3,160 fatalities in 1975. However, accidents have been reduced through various efforts on various fronts, including school education. We hope to explain the overall picture of water accidents in Japan to an international audience, so that the past, present, and history of accidents can be better understood.

METHOD

Data Used in the Analysis

The number of fatalities in water accidents and Japan's population are publicly available from government agencies, and these data were used. Specifically, data on the number of people who died or went missing due to water accidents from 1975 to 2023, based on the Police White Paper [13] and the Statistics on Water Accidents [14] published by the National Police Agency, was used.

In addition, population data from the 1970-2020 census were used [15]. The census is conducted every five years and covers everyone living in Japan.

As a supplementary explanation of the quality of data available from public institutions, data from public institutions tend to be limited in terms of content. One way to collect data from non-public institutions is to organize data from newspaper articles. Newspaper articles may provide useful information for analysis, such as the attributes of the deceased and the circumstances at the time of death. However, as in this paper, it requires a great deal of effort to obtain data from newspaper articles over a long period of time, such as about 50 years in the past, so we did not refer to newspaper articles in this paper. On the other hand, the River Foundation's efforts can

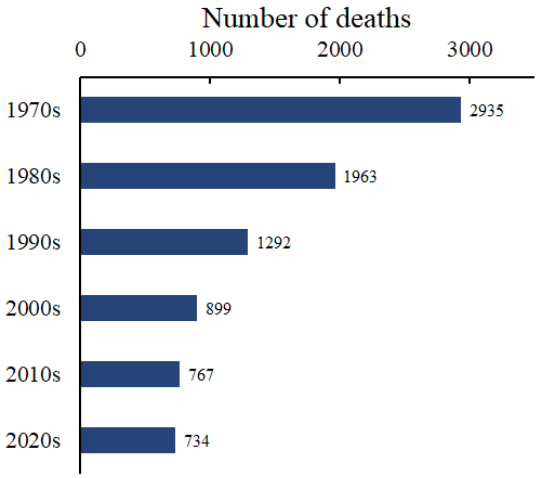

Fig.3 Changes in the number of deaths from all types of water accidents every 10 years

be cited as an example of an analysis that referred to such newspaper articles. In the River Foundation's report, Miyao et al. [5] collect data on water accidents in rivers by referring to newspaper articles as well as data from public agencies. Yoshida et al. [11] and Kondo et al. [12] also report on water accidents in irrigation ponds by organizing data from newspaper articles.

Analysis Method

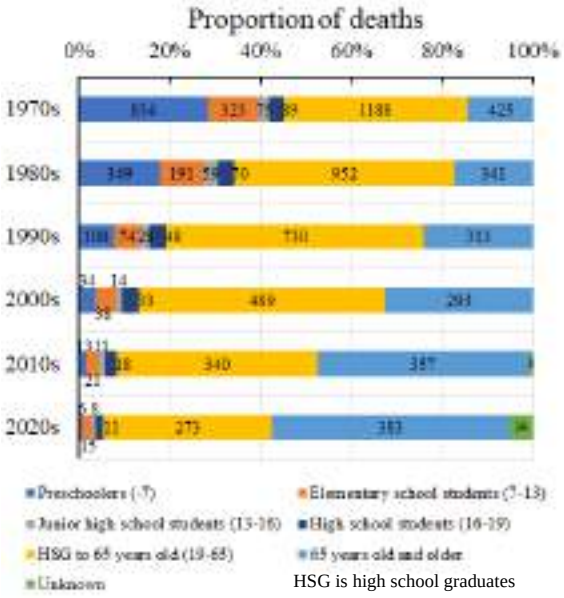
The acquired data were carefully examined, and basically a 10-year average was taken to organize the data by time period for discussion.

Water accident data were subject to changes in survey items since they were first recorded. For example, there was one major change with respect to age of occurrence, and supplemental calculations were made to reflect trends over several years.

When examining the population proportion and accident proportion, the Root Mean Squared Error (RMSE) shown in Equation 1 below was used as an indicator to determine the degree of distribution. Here, the population proportion is variable x and the accident proportion is variable y. The contribution of the population proportion to the accident proportion was determined by calculating the variation in the degree of departure from the equation y=x using Equation 1. In other words, the closer the distribution was to y=x, the better the fit to y=x, indicating that it was influenced by the population proportion, and conversely, the further the distribution was from y=x, the poorer the fit to y=x, indicating that it was not influenced by the population proportion.

$$RMSE = \sqrt{\frac{\sum_{i=1}^{N}(x_i - y_i)^2}{N}} \quad (1)$$

RESULTS AND DISCUSSION



HSG is high school graduates

Fig.4 Changes in the number of deaths from all types of water accidents every 10 years (by age group)

Characteristics of Water Accidents

This section identifies trends on the age of those who died as a result of an accident, the location where the accident occurred, and the conduct of the person when the accident occurred. Note that there is no information other than age, location, and conduct that can be obtained from official data. However, as explained in the "Section on Data Used", other information may be obtained by organizing newspaper article data.

The data were averaged and graphed by decade from the 1970s to the 2020s. Basically, the data is averaged over the 10-year period from XX00 to XX09, with the 1970s being the average over the 5-year period from 1970 to 1974 and the 2020s being the average over the 4-year period from 2020 to 2023. The reason for organizing the data by period is to make it easier to understand the occurrence of fatal accidents by summarizing them in decadal rather than yearly time series.

Trends in the number of fatalities in water accidents

Figure 3 shows the change in the number of fatalities in water accidents by period. In the 1970s, nearly 3,000 people died annually, but the number decreased exponentially, falling to around 1,300 in the 1990s, around 900 in the 2000s, and around 730 in the 2020s. The number of deaths decreased by 56% from the 1970s to the 1990s and by 18% from the 2000s to the 2020s. Thus, the number of cases, which was notably high, gradually declined significantly, with smaller declines from the 2010s to the 2020s.

Characteristics of age of occurrence in water accidents

Figure 4 shows the number of fatalities in water accidents as a percentage of the total number of fatalities by age of occurrence. The percentage of accidents involving infants, preschool children (under 7 years old), and elementary school students (7 years old to under 13) showed a decreasing trend. The percentage of accidents involving junior high and high school students (13 years old to under 16, 16 years old to under 19) has been small since the 1970s, while the percentage of accidents involving persons aged high school graduates to 65 (19 years old to under 65) has been on a downward trend. While the percentage of accidents for the previous age groups showed a decreasing trend, the percentage of accidents for those aged 65 and over continued to increase. Looking at the largest segments in the percentage of accidents, while in the 1970s and 1980s, infants, preschoolers, and elementary school students accounted for a large proportion of accidents, in the 1990s, the percentage of accidents for those aged 65 and older accounted for 24%, exceeding the 20% rate for high school students and younger. Furthermore, since the 2010s, people aged 65 and older have accounted for the majority of accidents.

According to the WHO, children under the age of five account for approximately 25% of drowning deaths worldwide [1]. The percentage of preschoolers who die in Japan has dropped to about 1%. Recent trends in Japan have clearly diverged from global trends.

Characteristics of location of occurrence in water accidents

Figure 5 shows the number of fatalities in water accidents by location, with the sea accounting for the largest proportion of fatalities from the 1970s to the 2020s, followed by rivers. The next largest number of fatalities occurred in irrigation canals and lakes/marsh/ponds, followed by swimming pools and others, in that order. Both oceans and rivers are the largest segment, and they occupied the top positions regardless of the time period. Irrigation canals, lake/marsh/ponds, swimming pools, and others showed a slight downward trend. As can be seen, accidents still occur most frequently in oceans and rivers. The sea alone accounts for about 50% of all accidents regardless of age, and the total of sea and rivers accounts for 70-80% of all accidents. The percentage of fatalities in irrigation canals and lake ponds is on a declining trend.

Characteristics of occurrence acts in water accidents

Figure 6 shows the number of fatalities in water accidents as a percentage of the number of fatalities per act of occurrence. It can be seen that while swimming and passing through show a decreasing

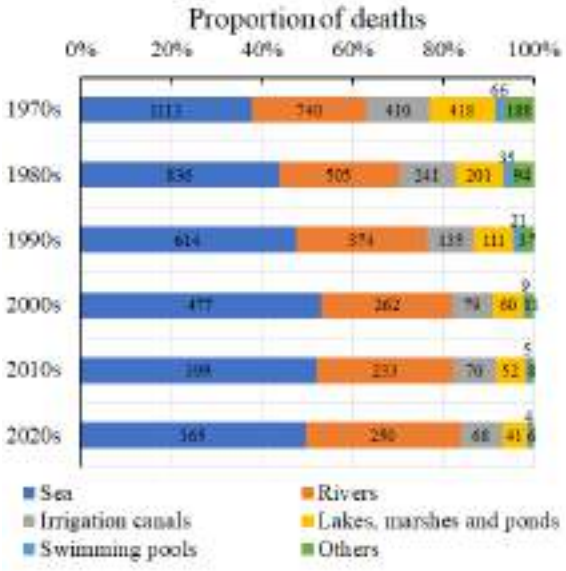


Fig.5 Changes in the number of deaths from all types of water accidents every 10 years (by location)

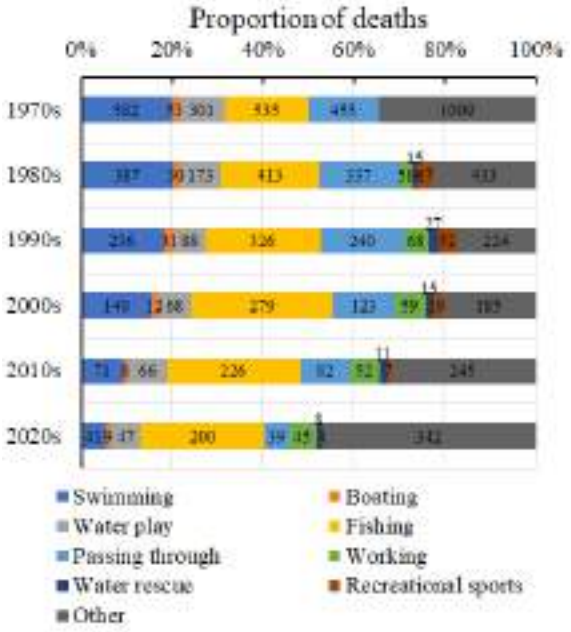

Fig.6 Changes in the number of deaths from all types of water accidents every 10 years (by behavior)

trend, water sports, fishing, working, and others remain unchanged or show an increasing trend. It is difficult to determine which are the largest segments, but the contemporary largest segments are others and fishing. Thus, regardless of the time period, angling for fish is in the majority. Others, despite being in the majority, are not detailed and require caution during the data collection phase.

Age		Middle year of each 10-year period			
Group	Range*	1985	1995	2005	2015
Under 10	00 - 10	13	10	9	8
10s	10 - 20	16	13	10	9
20 to 65	20 - 65	61	63	61	56
65 and older	65 -	10	15	20	27
Total		100%	100%	100%	100%

*) eg. 00 <= x < 10 years old

Trends in Japan's population numbers

Figure 7 illustrates the changes in the number of people in Japan, without averaging the data as a period, since the survey is conducted every five years. As Fig.7(a) shows, Japan's population increased from a little over 100 million in 1970 to a peak of 127 million in 2005, after which it began to decline. As Fig.7(b) shows, the birthrate began to decline in the late 1970s, and by 1990, the birthrate had dropped to 1.57, which is now considered a serious social problem.

Changes of Water Accidents in General

In order to examine the relationship by age group between water accidents and population, we reorganized the data on accident ratios and population ratios. That is, the accident ratio from the 1980s to the 2010s were re-compiled for the four main age groups as shown in Table 1. Specifically, the data were broken down into the following groups: elementary school students and younger, junior high and high school students, high school graduates and under 65 years of age, and 65 years of age and older. The purpose of grouping the data into major age groups is to better understand the data and to make it more useful for future measures. Table 1 shows the general school age range in Japan.

On the other hand, the reorganized population ratios are shown in Table 2. The data corresponding to the middle years of each age group were used for the population ratio to correspond to the accident ratios from the 1980s to the 2010s. For example, in the 1980s, the population counts for 1985 were used. In addition, the age groups in the population ratio were roughly matched to the age groups in the accident ratio. Specifically, the groups were divided into the following age groups: under 10 years old, teens (10 to 20 years old), 20 to 65 years old, and 65 years old or older.

The age ranges in Tables 1 and 2 do not match exactly in some places. This is because population data with fixed age intervals was used, while accident data with irregular age intervals was used. Therefore, a format that aligns as closely as possible with the accident data with irregular age intervals was adopted. Even with such data, it was determined that it is sufficient to draw general conclusions.

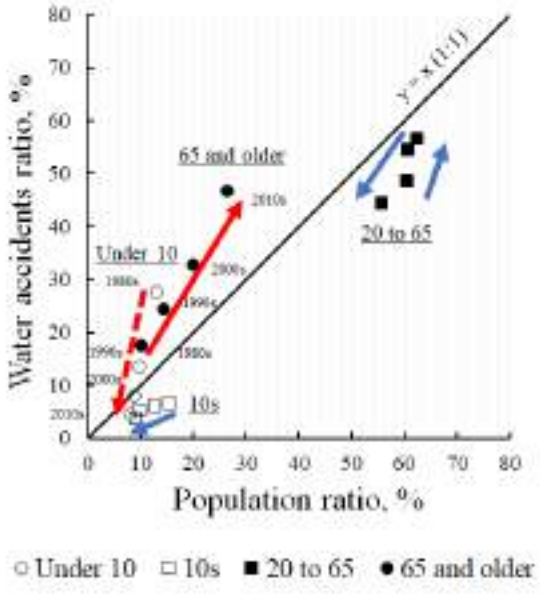

Fig.8 Age-specific population ratio vs. accident ratio by age group for all water accidents

Figure 8 plots the relationship between the percentage of population composition and the percentage of accident composition by age group for water accidents in general. For each age group, changes from the 1980s to the 2010s are plotted. The y=x line indicates a 1:1 relationship between the population proportion and the accident proportion; a plot above y=x means that the accident proportion is larger than the size of the population proportion; a plot below y=x means that the accident proportion is smaller than the size of the population proportion. This means that the accident ratio is smaller than the size of the population ratio.

Figure 8 illustrates the change from the 1980s to the 2010s. For children under 10 years old, which corresponds to preschool and elementary school students, accidents used to occur more frequently than the size of the population ratio, but in the modern era, the number of accidents has decreased significantly to match the size of the population ratio. For the 10s, which correspond to junior high and high school students, the accident ratio was smaller than the size of the population ratio both in the past and in the present, but both the population ratio and the accident ratio have decreased. For those aged 20 to 65, who were considered to be equivalent to those aged 18 to 65, unlike other age groups, there was no unidirectional progression, but only changes in the vicinity of a straight line. For those aged 65 and over, accidents have always occurred at a rate higher than the population size, but in modern times, the accident ratio has increased significantly to a level that does not match the population size.

Table 3 Comparison of population ratio vs. accident ratio for all water accidents and pond accidents by age group for all water accidents

Period	RMSE of water accidents in general	RMSE of water accidents in ponds
Case of 1980s	11.1	33.3
Case of 2010s	12.0	20.2
All cases of 1980s and 2010s	11.5	27.6

Among the four age groups, we focused on the two most characteristic age groups, those under 10 and over 65, which, unlike the other age groups, have changed significantly over time, and the direction of change is opposite to each other. In other words, for the under-10s, the population and accident ratios decreased significantly, and the intervals between the plots approached a straight line while decreasing; for the over-65s, the population and accident ratios increased significantly, and the intervals between the plots tended to move away from a straight line while increasing.

Comparison of Water Accidents in General and Irrigation Pond Accidents

Since Japan has become an aging society with a declining birthrate and the population composition ratio has changed, the relationship between the population ratio and the accident ratio is discussed in light of this change. In the data used in this study, the age groupings do not perfectly match the population ratio and accident ratio, but this was not judged to be a problem in the big picture. Focusing on the variation between the population and accident ratios, we compared water accidents in general with irrigation pond accidents, which are known to have changed over time, in order to examine and understand the characteristics of water accidents in general. In order to compare the variation, all age groups in the 1980's and 2010's were included.

Table 3 shows the results of the comparison of RMSE values for variability. The RMSE values for variability were RMSE = 28 for irrigation pond accidents and RMSE = 12 for accidents in general. The RMSE value for the all water accident was 0.5 times as small as that for the irrigation pond accident. In other words, the variability of the water accidents in general was smaller than that of the irrigation pond accidents. This was interpreted as indicating that

water accidents in general are highly correlated with the percentage of the population, and that the contribution of the population ratio is significant in accidents in general.

CONCLUSION

The number of fatal water accidents in Japan in general has been calculated as a 10-year average, basically from the 1970s to the 2020s, in order to better grasp changes over time. However, a downward trend has been observed in recent years.

The characteristics of the occurrence of water accidents in terms of age, location, and activity were identified. Specifically, while in the 1970s and 1980s, infants, preschool children, and elementary school children accounted for a large proportion of water accidents, since the 2010s, the majority of accidents have occurred among people aged 65 and older. In all periods, water accidents in the sea alone accounted for about 50% of all water accidents, and 70-80% when accidents in the sea are combined with those in rivers. Fatalities in irrigation canals and lake ponds are on the decline. Fishing is the most common activity involved in water accidents, regardless of the time period.

The relationship between the accident rate and the population rate shows the trend of Japan's declining birthrate and aging population. When the variation between accident rate and population rate was compared between water accidents in general and irrigation pond accidents, the variation for water accidents in general was smaller than that for irrigation pond accidents. This suggests a possible demographic effect for water accidents in general.

WHY IS SEEDLING'S REGENERATION OF *RHODODENDRON QUINQUEFOLIUM* POPULATION ON MT. RYUGATAKE NOT GOING WELL?

Mei Takeoka[1], Masaharu Sakakibara[2] and Michiko Masuda[3]

[1,2,3]Department of Civil Engineering, Nagoya Institute of Technology, Japan

ABSTRACT

In recent years, the famous population of *Rhododendron quinquefolium* in Mt. Ryugatake have been decreased, in the center of Japan. Mt. Ryugatake is loved by many people because of the beautiful scenery that is flowering of *R. quinquefolium*, so everyone will be recovering the species. Because of regeneration by seedlings has not occurred, there are concerns that the population of the species will decline. Mt. Ryugatake area is national park, surveys was restricted, and no precise research have been conducted. We therefore conducted field surveys to verify two hypotheses. One hypothesis is that the reason for the lack of seedling regeneration is that the deer are feeding on the plants, and the other hypothesis is that the lack of regeneration is due to the lack of an environment in which seedlings can emerge. To prevent feeding damage, we set up nets to prevent feeding damage and checked the number of seedlings with and without the nets, and found that feeding damage by deer was not the cause. In addition, the hypothesis that the environment is not suitable for seedlings was also denied by confirming the seedlings. We therefore compared the growth environment (pH, ignition loss, electrical conductivity, soil moisture, canopy openness) of *R. quinquefolium* in general with that of the species in Mt. Ryugatake, and found that the habitat of the species in Mt. Ryugatake had a high pH and was eutrophic. This suggests that seedling regeneration may not be going well.

Keywords: Deer Harvest, Seedling Regeneration, Environmental Condition, Conservation Activity

INTRODUCTION

From the perspective of distinctiveness, *Rhododendron quinquefolium* (commonly known as Shiroyashio) population on Mt. Ryugatake—located on the border between Inabe City in Mie Prefecture and Higashiomi City in Shiga Prefecture—is considered a high conservation priority. *R. quinquefolium* is an endemic deciduous shrub in the family Ericaceae, characterized by its whorled leaves and known as "Goyou-tsutsuji" due to its five-leaf arrangement. Although it is listed as a threatened species in some prefectures, it is generally widely distributed across main land of Japan and Shikoku island and is not considered globally endangered. However, the population that grows in a broad area on the gentle slopes near the summit of Mt. Ryugatake is exceptionally rare. The sight of its white blossoms stretching across the landscape has been likened to a flock of white sheep and draws many hikers each year. From a utilitarian perspective, the conservation of this population is also significant [1].

In recent years, concerns have arisen regarding the decline of this population, with many mature trees dying or falling, and a lack of seedling establishment indicating difficulties in natural regeneration. In conservation biology, especially in managing rare or endangered species, it is essential to understand the species' ecology, population dynamics, and factors affecting population size and distribution [2][3]. Various methods can be employed for population studies, including ecological data collection and long-term monitoring.

This study focuses on the reproductive process and regeneration of R. quinquefolium populations on Mt. Ryugatake. By investigating physical environmental conditions in areas where seedling recruitment is observed, we aim to identify the key factors affecting regeneration, thereby contributing to the conservation of this unique plant community. We formulated two hypotheses and conducted a study to test them. The first hypothesis is that the seedlings of *Rhododendron quinquefolium* are disappearing due to predation by deer. The second hypothesis is that the seedlings are unable to grow because the environmental conditions are unsuitable for their development. To verify these hypotheses, we carried out this research.

RESEACH SIGNIFICANCE

Natural environments that function as key tourism resources represent assets of considerable national importance. Nevertheless, the maintenance and management of natural vegetation present substantial challenges, and many national parks are currently confronted with serious ecological issues. In recent years, numerous large-scale civil engineering projects—such as landslide prevention, debris flow mitigation, and sediment control in river basins—

have been carried out under the framework of the National Resilience Plan. Although these public works are widely acknowledged to have significant ecological impacts, comprehensive long-term assessments of their influence on natural environments remain scarce. The formation of *R. quinquefolium* communities is hypothesized to be closely linked to large-scale slope failures caused by past geomorphological disturbances. This study seeks to highlight the necessity of long-term ecological evaluations concerning the potential impacts of future public infrastructure development under national resilience strategies.

MATERIALS AND METHODS

The Study Site

The study was conducted on Mt. Ryugatake, located on the border between Inabe City, Mie Prefecture, and Higashiomi City, Shiga Prefecture (N35°11’93’’, E136°44'51”). Mt. Ryugatake, classified as a deciduous broad-leaved forest zone, has an elevation of 1,099.6 meters. The forest limit is around 900 meters above sea level. The base of the mountain features deep valleys, such as those found in the Ugakei area, creating diverse natural environments. Near the summit, a broad area of naturally growing *R. quinquefolium* populations can be found. Two study areas were established near these growth zones: Plot 1 and Plot 2. Plot 2 consists of a large slope with limited human activity. In contrast, Plot 1 is located near a hiking trail and consists of gentle slopes separated from Plot 2. With permission from the Mt. Ryugatake Nature Conservation Promotion Committee and the Mt. Ryugatake Trail Maintenance Association, we installed eight quadrats in Plot 1 (Fig. 1).

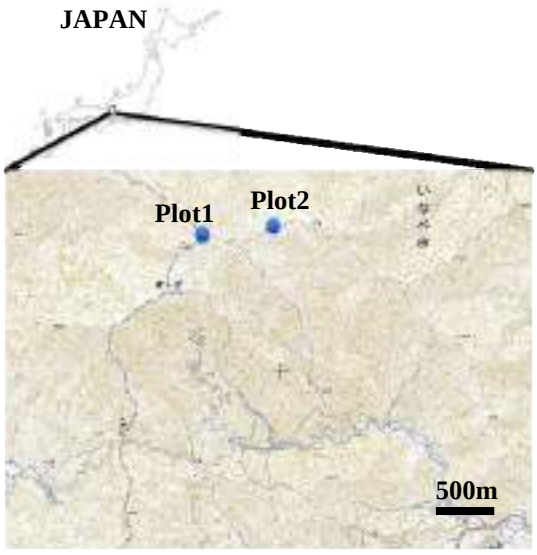

Fig.1 Map of research plots

Due to landscape protection concerns, permission for quadrat installation was not granted in plot 2; therefore, only physical environmental surveys were conducted there. In plot 1, four 1-meter square quadrats were installed perpendicular to the contour lines at 2-meter intervals, considering the impact of topsoil erosion. Another four quadrats were installed parallel to the contour lines at a 2-meter distance from the first set, forming eight quadrats in total (Fig. 2), where changes in seedling counts were recorded. Additionally, quadrats numbered 11, 13, 14, and 18 were equipped with deer-proof fencing to examine the effects of feeding damage.

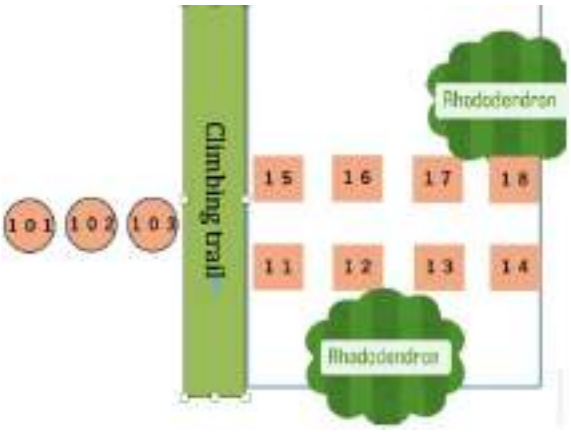

Fig.2 Quadrats layout of plot 1

Physical environmental data were collected at 17 locations. In addition to the eight quadrats in plot 1, three points near the hiking trail (without nearby *R. quinquefolium* trees) were selected as control sites. In plot 2, six survey points were set up at 2-meter intervals perpendicular to the contour lines. Two of these points were located where tree growth was assumed to be unaffected.

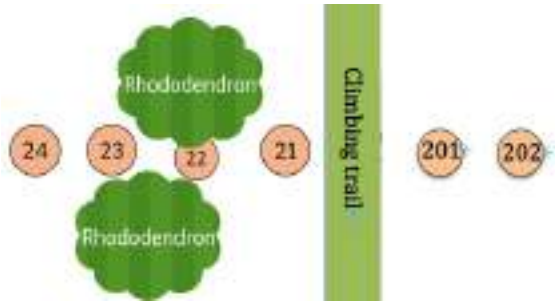

Fig.3 Sampling layout of plot 2

The Study Species

Rhododendron quinquefolium is an endemic deciduous shrub of the Ericaceae family, mainly distributed along the Pacific side of Japan (Fig. 4). It typically grows on rocky highland areas and forest interiors, reaching heights of 4 to 7 meters. Some trees have been found to be over 100 years old. Its leaves grow in whorls of five at the branch tips, hence

its Japanese name “Goyou-tsutsuji.” It produces one to three white flowers per branch tip from late May to early June, concurrently with leaf expansion. The flowers are funnel-shaped with five deep lobes and green spots on the petals, contributing to its elegant appearance [4]. Due to its beauty, it was chosen as the floral emblem of Princess Aiko.

Fig.4 Flower of *R. quinquefolium*

The Tree Ring Survey

To investigate whether the current *R. quinquefolium* individuals on Mt. Ryugatake established simultaneously in the past, a tree-ring survey was conducted. With permission from the Mt. Ryugatake Nature Conservation Promotion Committee and the Mt. Ryugatake Trail Maintenance Association, five fallen trees approximately 4–5 meters tall were sampled on 11th Dec. 2024. A segment of each tree trunk was cut approximately 10 cm above ground level using a saw. The cross-sections were sanded, and the number of rings was counted. The diameter of each section was also measured.

The Seedling Emergence Survey

To examine the correlation between physical environmental conditions and seedling emergence, monthly surveys were conducted in the eight quadrats installed in plot 1 from May to December. The number of emerging seedlings was counted and recorded during each visit (22th May, 5th, 19th Jun., 10th Jul., 6th Aug., 25th Sep., 17th Oct. and 11th Dec. in 2024).

Physical Environmental Survey

Light environment, soil pH, soil moisture content, loss ignition and electrical conductivity were measured every month in 2024 at each plots (19th Apr. 8th, 22nd May, 5th, 19th Jun., 10th Jul., 6th, 21st Aug., 17th, 25th Sep., 17th, 31st Oct. 14th Nov. and 11th Dec. in 2024).

Light is a crucial factor for plant germination and growth. For *R. quinquefolium* populations growing on ridges, good sunlight conditions are ideal. To assess the light conditions, canopy openness was measured at each survey point using a 360-degree camera (RICOH THETA S,). Photos were analyzed using CanopOn2 software [5]-[7], which calculates the proportion of open sky area in hemispherical images. Brightness thresholds were manually adjusted to accurately binarize the images, separating sky from non-sky areas.

Since members of the Ericaceae family prefer acidic soils, the pH of the soil at each survey point was measured using a soil tester. The probe was inserted vertically to a depth of approximately 2.5–3 cm into the topsoil.

Although most plants favor moist environments, *R. quinquefolium* is adapted to drier conditions. To assess this, the same soil tester was used to measure relative moisture levels in five stages: DRY+, DRY, NORMAL, WET, and WET+.

In December, soil samples were collected to a depth of 10 cm and dried at 80°C for 48 hours using a drying oven. Samples were wrapped in paper and weighed before and after drying with a precision balance. Soil moisture content W(%) was calculated using the following formula:

$$W = ((\text{wet weight} - \text{dry weight}) / \text{dry weight}) \times 100$$

Soil organic matter content, which correlates with nutrient levels, was determined via loss Ignition tests. The dried samples were ground and wrapped in aluminum foil, then incinerated at 600°C for 2 hours in a muffle furnace. The loss in mass was calculated using the following formula:

$$LI = ((\text{dry weight} - \text{ignited weight}) / \text{dry weight}) \times 100$$

To assess soil fertility, electrical conductivity (EC) was measured. Five grams of dried soil were mixed with 25 mL of distilled water and stirred for 15 minutes. The EC value of the supernatant was then measured using a conductivity meter.

RESULTS

Detailed experiments and surveys conducted in 2024 yielded the following results regarding the age of existing *R. quinquefolium*, seedling emergence, and physical environmental conditions. From May to November 2024, seedlings of *R. quinquefolium* have been observed in and around Quadrat 18 in Plot 1.

The Tree Ring Survey

The results for the tree-ring survey of the sampled *R. quinquefolium* trunks are shown in Table 1. Considering that the sampling was done at 10 cm or more above the ground, the actual tree ages are likely older than the number of rings counted. These results suggest that, regardless of trunk thickness, most *R. quinquefolium* individuals on Mt. Ryugatake are

likely over 100 years old

Table 1. Tree ring No. and diameter of 5 individuals

Sample No.	Tree ring No.	Diameter max(mm)	Diameter min(mm)
1	99	116	86
2	103	63	45
3	108	90	64
4	109	80	59
5	115	133	73

The Seedling Emergence Survey

Monthly changes in seedling counts from Quadrats 11 to 18 in plot 1 are shown in Table 2. Seedling counts tended to be lower in quadrats located near the hiking trail. Overall, the number of seedlings increased from spring to summer and decreased toward winter. There was no clear difference in seedling count trends between quadrats with or without deer-proof fencing, suggesting that feeding damage by deer may not significantly affect seedling regeneration

Physical Environmental Survey

Canopy openness measurements from April to December 2024 are shown in Fig. 5. Quadrats 11 and 15 near the hiking trail showed relatively high canopy openness. In contrast, other quadrats, including Quadrat 18 where seedlings were found, had lower openness levels compared to plot 2. Fig. 5 shows the box plot from April to December in canopy openness in plot 1 and 2. Openness decreases from May, when *R. quinquefolium* leaves emerge, and increases again around October when the leaves fall.

Table 2. The seasonal accumulation number of seedlings in each quadrat

Quadrat No.	M	J	J	A	S	O	N
11	0	0	0	0	0	0	0
12	0	0	0	2	3	3	3
13	2	3	3	3	3	3	3
14	45	45	45	45	45	45	45
15	0	0	0	2	2	2	2
16	0	0	0	0	0	0	0
17	18	24	40	58	58	58	58
18	20	23	27	33	33	33	33

Soil pH measurements from April to December 2024 are presented in Fig. 6. The soil at sites where *R. quinquefolium* grows was found to be weakly acidic (pH 5–7). Quadrat 18, where seedlings were observed, had relatively high pH values compared to other points. Soil pH decreased toward autumn and increased in winter.

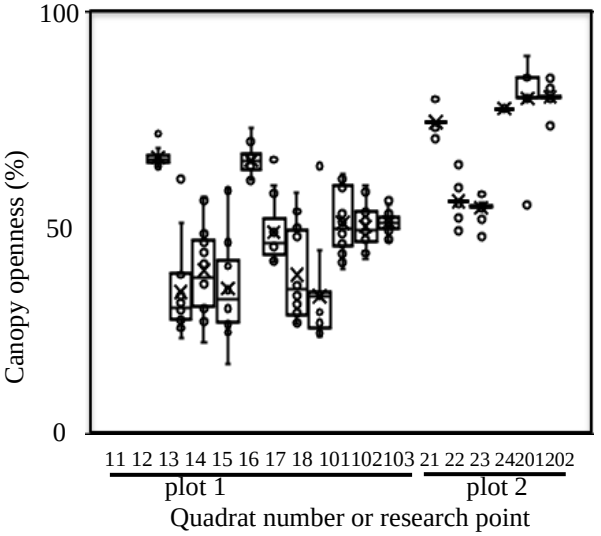

Fig. 5. Canopy openness at each point in plot1 and plot2 from April to December in 2024

Soil moisture data from April to December 2024 are shown in Fig. 7. Quadrat 16 had moisture levels 36% above average, while Quadrat 18 was 26% below average. Overall, plot 2 had moisture values 18% higher than plot 1. Quadrat 18 had the lowest moisture content, 28% below plot 1 average.

The December 2024 loss ignition results are shown in Fig.8. Quadrat 18 had the lowest loss ignition value among all surveyed points.

The electrical conductivity measurements from December 2024 are shown in Fig.9. The average electrical conductivity in plot 1 was 0.4408 mS/cm, compared to 0.1299 mS/cm in Aichi satoyama forest, a 3.39-fold difference. Quadrat 18 again showed the lowest EC value, 41% below the average for plot 1.

DISCUSSION

Although *R. quinquefolium* is widely distributed in Honshu and Shikoku, and many Ericaceae species share similar ecological characteristics, the population on Mt. Ryugatake forms a unique community that had not been extensively studied until now. Because the view of Mt. Ryugatake is so unique, and it is designated as a National Park, researches were severely restricted. Though some research has been done about gene [8], this investigation clarified the actual environmental conditions in which this distinctive community thrives. This section discusses the potential causes behind the poor regeneration of *R. quinquefolium* on Mt. Ryugatake. In general, failure in generational turnover can result from issues in seed production, germination, seedling establishment, or growth. As multiple seedlings were confirmed during this study, it is unlikely that seed production or germination is the limiting factor. Instead, unsuitable environmental conditions for seedling establishment and growth may be responsible for the population decline.

The survey points were placed perpendicular to contour lines. quadrat 18, where seedlings were found, is located on the downhill side of the slope in plot 1. Since *R. quinquefolium* often grows on rocky ridges where winds can exceed 15 m/s [9], strong winds may prevent seed settlement and seedling establishment on exposed ridges. Thus, seedlings may favor more sheltered, downslope areas for establishment.

The tree-ring survey results suggest that the current *R. quinquefolium* population originated from a past cohort that established simultaneously. Similar regeneration failures have been observed in other Ericaceae species. For example, the Ontsutsuji community at Funakubo in Tokushima Prefecture, designated a national natural monument, is also experiencing decline, and measures such as seedling conservation and planting are being considered [10]. However, these methods may not be desirable from the perspective of genetic diversity conservation [11].

Tree-ring analysis revealed that both thin and thick individuals with diameters ranging from 45 to 133 mm may be over 100 years old, suggesting a single cohort establishment more than a century ago. The same phenomenon was observed in Nepal at land slide area [12]. The landslide created an ideal environment for seedling regeneration, which led to simultaneous germination and the formation of population. The geology of Ryugatake is limestone, and there is a possibility of landslides due to the formation of doline.

While current seedling growth and generational turnover appear unlikely, the small sample size limits certainty. Previous research [13] found that a *R. quinquefolium* (4.2 m tall) was about 75 years old, suggesting that Mt. Ryugatake individuals are relatively older. To verify the timing of past regeneration, further studies using stable oxygen isotope dendrochronology are recommended.

The lack of significant difference in seedling numbers between fenced and unfenced quadrats suggests that feeding damege and trampling have little impact. We focus on differences in physical environmental conditions between quadrats with many seedlings (e.g., 14, 17, 18) and other points.

Seasonal variation in canopy openness indicates shading from May to October during leaf-out, followed by increased openness after leaf fall. Canopy openness in plot 1 is generally lower than in plot 2. Quadrats with low seedling presence (e.g., 11, 15) had high openness, while Quadrat 18 showed much lower openness, about half of that in plot 2

All points showed weakly acidic conditions suitable for *R. quinquefolium*. In plot 2, pH remained stable between 5 and 6, while some points in plot 1 exceeded pH 6. Although Quadrat 18 had higher pH, seedlings were still present. This may suggest a suboptimal environment possibly hindering growth.

Quadrat 18 showed particularly low soil moisture, which favors *R. quinquefolium* seedlings that prefer dry, well-drained soils. However, the overall high moisture levels in Mt. Ryugatake soils suggest that the environment may not be ideal for long-term growth.

The average loss ignition was higher than other that of mountain forest near here, indicating richer organic content. Since *R. quinquefolium* prefers nutrient-poor soils, such fertility may be unsuitable. However, Quadrat 18 had the lowest ignition loss, supporting the notion that seedlings establish better in nutrient-poor conditions

Electrical conductivity, which correlates with soil nitrate content, was significantly higher in Mt. Ryugatake than in the other Forest. This suggests an abundance of nutrients, which may hinder seedling establishment. The lowest electrical conductivity was observed in Quadrat 18, again indicating that *R. quinquefolium* prefers nutrient-poor conditions.

CONCLUSIONS

The first hypothesis was refused because of deer harvesting was not be observed. The second hypothesis was supported by the environmental research.

The current *R. quinquefolium* population on Mt. Ryugatake likely originated from a mass regeneration event in the past. Although multiple seedlings were observed, the environmental conditions appear unsuitable for their continued growth. Strong winds along the ridgeline may also hinder seedling establishment, favoring locations with less wind exposure. Since available dead trees for tree-ring analysis are limited, future investigations using stable oxygen isotope dendrochronology are recommended to verify the occurrence of past synchronous regeneration events.

To conserve the population, seedling environment should be improved by racking fallen leaves.

ACKNOWLEDGMENTS

We extend our sincere thanks to the Mt. Ryugatake Nature Conservation Promotion Committee and the Mt. Ryugatake Trail Maintenance Association for granting access to the study area and providing essential support during fieldwork. Our appreciation also goes to the members of the Conservation Ecology Laboratory at Nagoya Institute of Technology for their cooperation in field investigations and for their valuable advice during the writing of this thesis. Finally, we would like to thank all individuals who contributed in any way to this research.

ESTIMATING THE DISTRIBUTION OF WATER CHESTNUT LEAVES ON THE WATER SURFACE OF IRRIGATION PONDS USING THRESHOLD PROCESSING

Yusaku Mizoguchi[1] and Masaaki Kondo[2]

[1,2]Graduate School of Bioresources, Mie University, Japan

ABSTRACT

Water chestnut has the advantage of controlling eutrophication in reservoirs. However, when the water chestnut thrives and dies in large numbers, it causes foul odors and sludge. In this study, a method using image processing was investigated to understand the status of overgrowth of water chestnut in reservoirs. The method studied was threshold processing. Images were taken by a drone at a reservoir near the university from May to October. Six types of images with different characteristics such as leaf distribution and luminance were used for analysis. Six different thresholding methods were used, including Otsu's binarization and adaptive thresholding. The results showed that Otsu's binarization process gave good results for most of the image patterns. However, Otsu's binarization process was not accurate for images containing high luminance objects such as the sun. Based on these results, the Otsu binarization process, which was the best method, was used to estimate the distribution of the water chestnut from May to October for the entire reservoir.

Keywords: Water Chestnut, Image Analysis, Threshold Processing, Coverage Ratio

INTRODUCTION

Japan has approximately 200,000 irrigation ponds, which serve primarily as a vital water source for agriculture [1]. On the other hand, the deterioration of water quality and the excessive growth of vegetation in reservoirs have raised concerns about their impact on aquatic ecosystems [2]. Among these concerns, increasing attention has been directed toward water chestnut, a type of floating-leaf plant. Water chestnut is an annual aquatic plant that grows rapidly from spring to summer and has the potential to cover large portions of the water surface. Its proliferation has been reported to affect water quality parameters such as nutrient concentrations, chlorophyll a, and dissolved organic carbon (DOC) in reservoirs [3, 4]. As such, water chestnut is closely linked to the water environment of reservoirs, and understanding its distribution and growth patterns is essential for water quality conservation and vegetation management. Traditionally, the distribution of water chestnut has been surveyed through human observation and fieldwork. In recent years, however, aerial photography using unmanned aerial vehicles has gained attention. Drone-based imaging enables wide-area, high-frequency monitoring and significantly improves the efficiency of vegetation surveys [5, 6].

In this study, we estimated the distribution of water chestnut on the surface of irrigation ponds using aerial imagery captured by drones. Multiple thresholding methods were applied, and their extraction accuracy was compared and evaluated. The ultimate goal is to improve the accuracy of growth rate estimation for water chestnut under actual field conditions.

RESEARCH SIGNIFICANCE

This study is significant in that it enhances the efficiency and accuracy of vegetation monitoring in small water bodies such as reservoirs through the use of simple and reproducible image processing techniques. By utilizing drone-acquired imagery and thresholding methods, the approach is not only effective for water chestnut but can also be applied to other floating-leaf plants and aquatic vegetation. As such, it holds great potential as a practical tool for future plant management and the assessment of aquatic ecosystems.

METHOD

About The Survey Pond

The survey target pond, Osawa Pond, is an agricultural reservoir located in Tsu City, Mie Prefecture. Table 1 shows basic information about Osawa Pond. As shown in Figure 1, Osawa Pond is long and narrow, extending from east to west.

About The Image

How to photograph the surface of a reservoir

The images were captured using a drone equipped with a video camera. The drone is a DJI Phantom 3 Advanced. The video has a HD resolution of 1280 x 720 pixels and a frame rate of 60 fps. Filming was conducted during the daytime when weather conditions were favorable. The filming altitude was set at 10 meters to capture the water chestnuts clearly

and over a wide area. Three locations were selected for filming: upstream, midstream, and downstream. The reason for this was that, as shown in Figure 1, Osawa Pond is long and narrow from east to west and could not be captured entirely in a video. Filming took place from May to October 2021. The filmed videos were cut into still images for analysis. The cut images were 48 × 32 pixels in size.

Table 1 Basic information on Osawa Pond [7,8]

specifications	Value
embankment height (m)	10.1
embankment length (m)	260
effective storage capacity (m^3)	3.3×10^3
full water area (m^2)	8.5×10^4

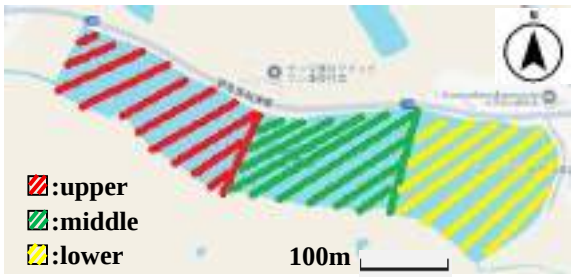

Fig.1 Shape of Osawa Pond (Source: https:/www.google.co.id/maps)

Features of analyzed images

Table 2 lists the characteristics of the images used in the analysis, while Figure 2 displays the corresponding images. Figure 2(a) depicts a case with a relatively small water chestnut coverage area, whereas Figure 2(b) shows a case with extensive coverage. Figure 2(c), the water surface appears cloudy green, making it difficult to distinguish the water chestnut. Figure 2(d) includes reflections of clouds on the water surface. Figure 2(e), the water surface appears whitish overall due to sunlight reflecting off the water chestnut. Figure 2(f) illustrates a condition where strong sunlight is reflecting directly off the water surface.

Two main reasons justify the selection of images with the characteristics listed in Table 2 for analysis. First, such image conditions were frequently observed across the dataset. Second, the degree of analytical difficulty was expected to vary depending on the image characteristics. Figures 2(a) and 2(b) were considered relatively easy to analyze, while Figures 2(c) to 2(f) presented more complex conditions such as water surface turbidity and light reflection making them more challenging to process.

For the analysis, six images were used, each corresponding to the characteristics described in Table 2(a) to 2(f).

Table 2 Image characteristics

(a) Less water chestnut
(b) More water chestnut
(c) Water surface is murky green
(d) Clouds are reflected on the water surface
(e) Leaves reflect sunlight
(f) Sun is reflected on the water surface

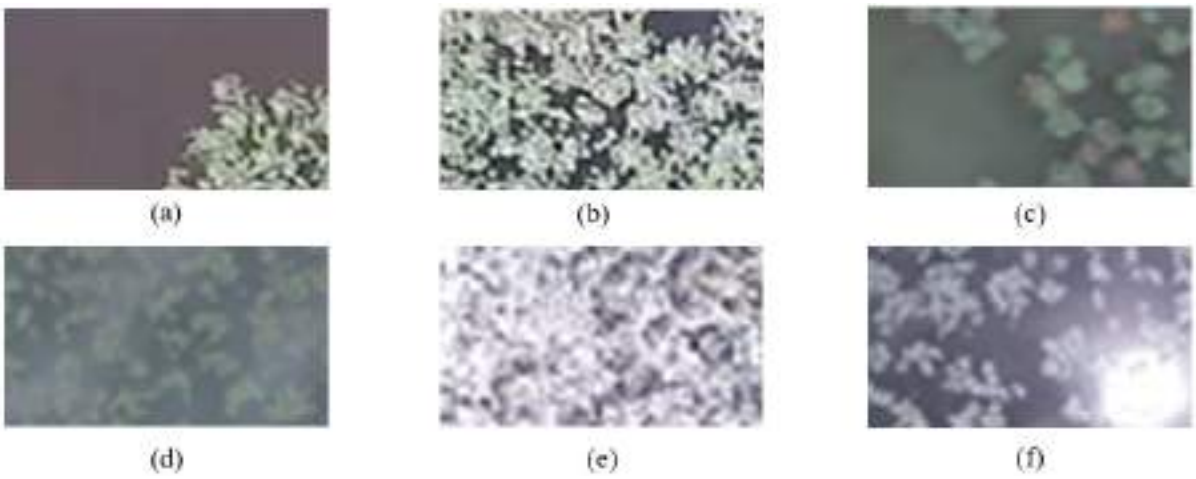

Fig.2 pixel images used for analysis (a) Less water chestnut (b) More water chestnut (c) Water surface is murky green (d) Clouds are reflected on the water surface (e) Leaves reflect sunlight (f) Sun is reflected on the water surface

About Analysis

The analysis was conducted in the following sequence: creation of ground truth images, application of thresholding methods, and evaluation of consistency between the ground truth and thresholded images.

Creating ground truth images

Ground truth images were created for the images shown in Figure 2. A ground truth image refers to an image in which water chestnut areas are visually identified and color labeled. The images were generated using the image editing software ImageJ. Areas visually recognized as water chestnut were filled in red, while all remaining regions were filled in black to complete the ground truth images, as shown in Figure 3.

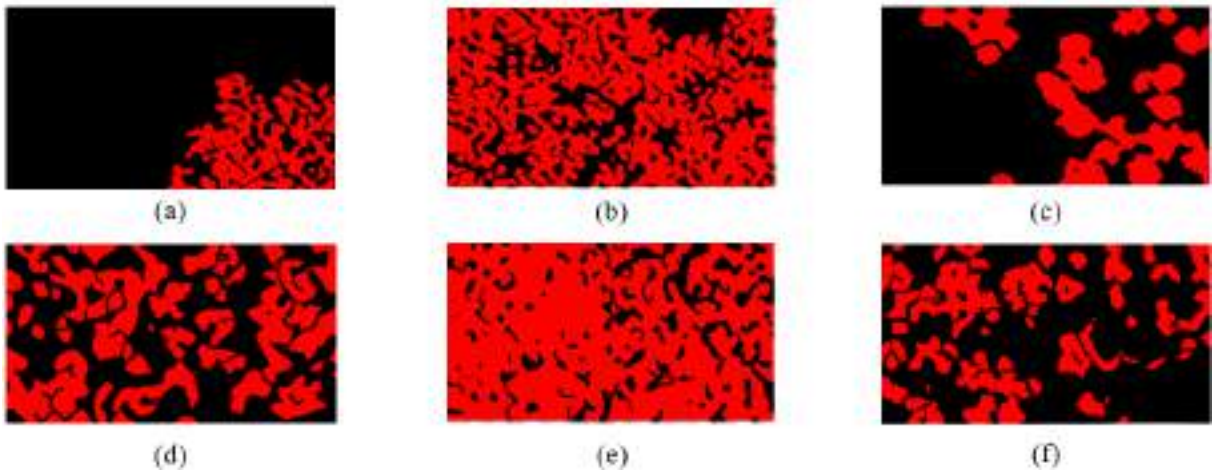

Fig. 3: List of ground truth images (a) Less water chestnut (b) More water chestnut (c) Water surface is murky green (d) Clouds are reflected on the water surface (e) Leaves reflect sunlight (f) Sun is reflected on the water surface

Application of threshold processing

Various thresholding methods were applied to analyze the images shown in Figure 2. The development environment used was Google Colab, and the implementation was carried out in Python. Six thresholding methods are listed in Table 3. The advantages of each method are summarized below.

Table 3(A): Otsu's binarization process automatically determines the threshold using the image histogram. It is effective for images with little noise. [9]

Table 3(B): The K-means method allows images to be divided into multiple areas by specifying the number of clusters.

Table 3(C): The method developed by Sezan is robust against uneven lighting and has been shown to be effective for the binarization of text images [10].

Table 3(D): Adaptive thresholding considers local variations in brightness within an image, allowing for effective binarization even under non-uniform lighting conditions.

Table 3(E): Minimum cross entropy thresholding enables high-precision clustering and identification and is suitable for statistical models. [11]

Table 3(F): Mixed Gaussian model fitting is effective when the data consists of multiple normal distributions. [12]

Table 3 Threshold processing used

(A)Otsu's binarization process
(B)K-Means method
(C)The method developed by Sezan
(D)Adaptive thresholding
(E)Minimum cross entropy thresholding
(F)Mixed Gaussian model fitting

Verification of consistency between ground truth images and threshold-processed images

The thresholded image was binarized, with black representing the water surface and white representing the leaves. For comparison with the ground truth image, the white areas were converted to red.

The consistency between the ground truth image and the thresholded image was evaluated using Intersection over Union (IoU). IoU was calculated using the following formula.

$$IoU = \frac{A \cap B}{A \cup B} \quad (1)$$

Here, A denotes the region of water chestnut in the ground truth image, and B denotes the region of water chestnut in the thresholded image.

RESULT AND DISCUSSION

IoU Between Thresholded Images And Correct Images

The average IoU values shown in Table 4 represent the mean performance of each thresholding method. In the method proposed by Cezan (C), thresholding could not be performed on image 2(d), which contains cloud reflections on the water surface. Accordingly, the (C)-(d) cell in Table 4 is left blank.

Overall, Otsu's binarization method demonstrated high accuracy. Specifically, it achieved the highest accuracy among the tested methods in Tables 4(a) and 4(b), and the second highest in Tables 4(c) and 4(d). Notably, Otsu's method was the only one to yield an average IoU exceeding 70%. This method is both highly accurate and effective for images with clear separation between objects and backgrounds. Therefore, it can be concluded that the favorable results obtained in this study were largely due to the application of Otsu's binarization method. In Table 4(f), none of the thresholding methods achieved an IoU greater than 50%. The image shown in Figure 2(f) contains strong sunlight reflection on the water surface, resulting in extremely high brightness values. This condition likely reduced the accuracy of all thresholding methods. Based on these findings, Otsu's binarization method appears to be the most suitable for analyzing reservoir water surfaces.

Table 4 IoU (%) of each thresholded image and correct image

	(a)	(b)	(c)	(d)	(e)	(f)	IoU average
(A)	91.65	89.91	71.03	67.02	75.01	25.78	70.07
(B)	80.14	84.52	71.37	66.99	74.68	26.21	67.32
(C)	15.73	81.90	26.41	-	87.15	33.22	48.88
(D)	10.44	67.82	26.71	50.20	67.57	36.31	43.18
(E)	53.12	70.88	48.20	66.61	59.60	42.63	56.84
(F)	58.98	85.28	60.27	67.09	77.14	22.74	61.92

(A), (B), (C), (D), (E), and (F) are as shown in Table 3, and (a), (b), (c), (d), (e), and (f) are as shown in Table 2.

Percentage Of Water Chestnut Coverage In Osawa Pond

We estimated the monthly coverage rate of water chestnut at three locations—upstream, midstream, and downstream—of Lake Osawa. One image per month was selected as reference material. The selected images were determined to capture representative vegetation conditions within the field of view of each water area and to contain sufficient information for identifying trends in coverage change. Each image covered an area of approximately 225 m².

Otsu's binarization method demonstrates high accuracy for images where the target object is clearly separated from the background, but its performance tends to decline under conditions influenced by external factors such as sunlight reflection. Therefore, binarization was performed after minimizing the influence of factors such as sunlight reflection in the images used for analysis. First, the target image was divided into eight segments both vertically and horizontally, and Otsu's binarization method was applied to each resulting section. After processing, areas exhibiting strong sunlight reflection or where water chestnut extraction was deemed inaccurate were excluded from the analysis. Subsequently, the proportion of pixels classified as water chestnut by the binarization method was calculated relative to the total number of pixels in the remaining image area. This proportion was used as the water chestnut coverage rate at each survey site for evaluation.

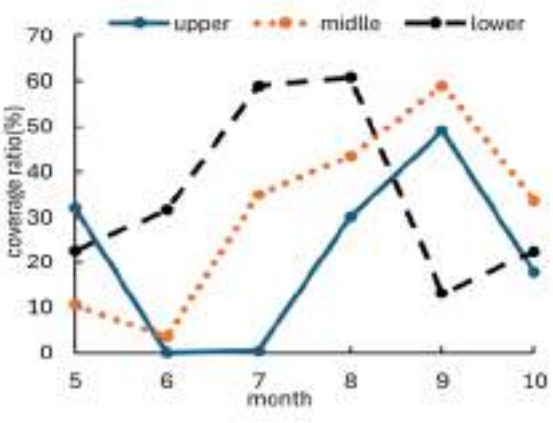

Fig. 4 The growth rate of water chestnut at various locations in Osawa Pond

The monthly coverage rates of water chestnut at each location are presented in Figure 4. In the upper reaches, proliferation was observed in May, but

coverage remained very low in June and July, followed by a steady increase through September, when it peaked. The exact cause of the sudden decrease in water chestnut coverage in June and July remains unknown. In the middle reaches, coverage gradually increased from May to September and declined in October, confirming the ecological cycle of water chestnut, which thrives in summer and dies off in winter. In the lower reaches, unlike the upper and middle sections, peak coverage occurred in July and August, followed by a decrease in September. Possible causes include the outflow of water chestnut and natural die-off.

CONCLUSIONS

In this study, to efficiently assess the proliferation of water chestnut in reservoirs, we applied multiple thresholding methods to drone-acquired aerial images and compared their accuracy. The analysis revealed that Otsu's binarization method exhibited the highest consistency among the tested methods, with an average IoU exceeding 70%. This confirms its effectiveness in environments with clear contrast between the target object and background, such as irrigation ponds.

Furthermore, using Otsu's method, we calculated the monthly coverage rate of water chestnut in the upper, middle, and lower reaches of Osawa Pond, thereby clarifying the temporal variations in the proliferation trends and growth cycle of water chestnut. In particular, in the middle reaches, the proliferation of water chestnut increased significantly from May to September, reflecting its typical ecological pattern of active summer growth and winter dieback. The results of this study demonstrate that simple and reproducible image processing techniques can streamline and quantify vegetation monitoring in small water bodies. This approach is also considered applicable to the management and assessment of other floating-leaf plants, including invasive aquatic species beyond water chestnut, in the future. Future challenges include mitigating external factors that may reduce the accuracy of image analysis, such as sunlight reflection and turbidity on the water surface. It will be necessary to consider the implementation of preprocessing techniques to suppress or correct these effects, as well as the adoption of AI-based deep learning methods for image recognition.

ABSTRACT

Following the Fukushima Daiichi Nuclear Power Plant accident, decontaminated waste was generated as highly radioactive removed soil. For the final disposal of such wastes, it is necessary to establish volume reduction of waste and Cesium (Cs) stabilization technology. One of the treatment processes could be done by concentrating the Cs using Cs adsorbent like mordenite. The objective of this study is to investigate Cs leaching behavior and immobilization mechanism of the solidified body of Cs adsorbed mordenite. Solidified bodies of cement or geopolymer (cylinder with 2 cm diameter and 4 cm height) were prepared. Leaching tests evaluated its Cs leaching characteristics by the ANSI 16.1 test method. In addition, changes in Cs leaching behavior due to freezing and thawing of specimens and contact with seawater were evaluated as an estimated severe condition in a disposal site. As a result, it was clarified that the Cs leaching was mainly controlled by two factors, Cs desorption rate between mordenite and pore water, and Cs diffusion through the pores of the solidification body. The Cs leaching rate was not affected by freezing and thawing, but increased with seawater immersion. The Cs leaching rate was kept as low as below 0.5% even after 60 days of immersion in seawater, and the leached Cs concentration in a solvent can be estimated within the order of the standard in environmental water. The results indicate that mordenite and its solidification can be a reasonable way of final disposal that retains Cs for a long period.

Keywords: Cesium, Leaching test, Final disposal, Hazardous waste

INTRODUCTION

In Japan, decontamination waste was generated due to the Fukushima Daiichi Nuclear Power Plant accident. This waste contains radioactive cesium (Cs) and its disposal method for them is determined according to its radioactivity as follows. The waste with 8,000 Bq/kg or less can be disposed of in a conventional controlled landfill [1]. Waste with 8,000 to 100,000 Bq/kg can be landfilled after taking appropriate treatment such as solidification [2]. Waste exceeding 100,000 Bq/kg is currently stored at a temporary storage facility in Fukushima Prefecture, but is scheduled for final disposal by 2045, within 30 years from the start of storage [2].

Volume reduction of decontamination waste by thermal treatment is ongoing, especially for the fraction of the waste exceeding 100,000 Bq/kg. The waste is incinerated, and then treated by a melting process at 1700°C by adding calcium chloride ($CaCl_2$) to accelerate Cs volatilization [3]. The Cs-containing fly ash generated here is not suitable for final disposal because its radioactivity exceeds 150,000 Bq/kg, and Cs is water-soluble [4]. For the final disposal of the melting fly ash (MFA), it's preferable to immobilize Cs in the MFA.

Various methods have been developed for the immobilization of Cs and further volume reduction of MFA [2]. One of them is done as follows. MFA is washed with water to transfer Cs to the liquid phase, and Cs is recovered in the liquid phase with Prussian blue (PB). Then, the Cs-adsorbed PB is decomposed and transferred to the liquid phase again, and the Cs in the solution is adsorbed on mordenite [5].

Cs adsorbed mordenite may release Cs in water due to ion exchange with non-adsorbed alkali metal ions, and thus it should be solidified with cement or geopolymer. For the final disposal, the long-term Cs leaching mechanism from the solidified body of mordenite adsorbing Cs must be revealed. In this study, the leaching test was conducted and the Cs leaching characteristic was investigated considering its leaching mechanism. Several severe conditions assumed to promote the Cs leaching rate in the final disposal site were also applied.

MATERIALS

Mordenite is known for its high cation adsorption capacity. In this study, natural mordenite (UniSelect UR3103Z, Ataka Asano Co. Ltd., Japan) was used as the Cs adsorbent. It was produced in Miyagi Prefecture, Japan. And its grain sizes were from 1.9 to 2.3 mm. The chemical composition obtained from energy dispersive spectrometry using FE-SEM (JSM-

Table 1 Elemental composition of the mordenite (mol%)

7200F, JEOL, Japan) analysis is shown in Table 1. The composition was calculated as relative concentration.

Preparation of Cs adsorbed mordenite

The composition of the decomposed PB solution is adjusted based on the report of the on-site examination [6]. But, in this study, a 30 times higher concentration was made compared to the actual data reported. Table 2 shows the concentration.

Cs adsorbed mordenite was prepared with the following method. Cs_2SO_4 (Wako reagent, Fujifilm Wako Chemicals, Osaka, Japan), $Na_4[Fe(CN)_6]\cdot 10H_2O$ (Wako reagent, Fujifilm Wako Chemicals, Osaka, Japan), and $K_4[Fe(CN)_6]\cdot 3H_2O$ (Wako guaranteed reagent, Fujifilm Wako chemicals, Osaka, Japan) were dissolved in distilled water to achieve the concentration shown in Table 2. Stable isotope Cs-133 was used in this study. The mordenite was immersed in this simulated solution at a liquid-to-solid ratio of 5 mL/g, and agitated at 200 rpm. After 30 minutes of immersion, the mordenite was removed, thoroughly washed with distilled water to remove non-adsorbed ions, and then dried at 60°C. After the adsorption process, the immersing solution was sampled, filtered with 0.45 μm membrane filter (A045A025A, Advantec, Japan) and the Cs concentration was quantified using an ICP-MS (ICP-MS-QQQ, Agilent technology, USA).

More than 99% of Cs in the initial immersion solution was adsorbed onto the mordenite. The amount of adsorbed Cs was 765 mg-Cs/kg-mordenite.

Mordenite solidification and accelerated weathering (freezing and thawing)

The Cs adsorbed mordenite was solidified using cement and geopolymer. The cement (Portland blast-furnace slag blended cement type B, JIS R5211:2019, Taiheiyo Cement Co. Japan) was mixed with water at a water-to-cement ratio of 0.6. Then, Cs adsorbed mordenite was added to the cement paste at 40 wt%. The geopolymer (hereafter GP) was prepared by mixing Na solution (NaOH (Wako guaranteed reagent, Fujifilm Wako Chemicals, Osaka, Japan): 24.7 g, sodium silicate solution (Wako reagent, Fujifilm Wako Chemicals, Osaka, Japan): 105 g and distilled water: 86.8 g) and metakaolin (MK-11-SF-8, SOBUECLAY, Japan): 133 g.

Then, the mixed paste was set in the molds created by a PTFE tube (2 cm in diameter, 4 cm in height) and then sealed with parafilm (PM-996, Bemis, USA). The molds were sealed and cured in a humid environment at 30°C for 9 days until demolding.

To reproduce freezing and thawing of solidified bodies in the final disposal site, some samples underwent freeze-thaw treatment. It was done using an incubator (MIR-554-PG, PHC, Japan) with a 300-cycle of -10°C for 3 hours and 20°C for 2 hours.

METHODOLOGY

Leaching test for the solidified bodies

For investigating Cs leaching behavior, leaching tests were conducted according to the ANSI 16.1 test method [7], replacing the solvent at an interval determined in advance. To keep the solvent homogeneous, agitation at 200 rpm was applied to the solvent. The solvent temperature was maintained at 25°C using a water bath. The solidified bodies were immersed in the solvent with the solid-to-liquid ratio at solvent volume (cm^3) / sample surface area (cm^2) = 10 (cm).

The solvent was sampled at solvent replacement and filtered with a 0.45 μm membrane filter. The elemental composition was measured by the ICP-MS, and the amount of leached Cs per solvent replacement was calculated. The cumulative leached Cs was calculated as a summation of the incremental leached Cs of each solvent replacement.

Table 3 shows the leaching test conditions. The solvent was changed after the first 6 hours, then every other day until the 7th day, and then weekly thereafter. Seawater was prepared by dissolving artificial seawater powder (Instant Ocean, Aquarium Systems, USA) in distilled water at 35.0 g/L. Seawater was used as a solvent with a dilution factor of 1 and 10. The major elemental composition of the artificial seawater obtained from ICP-OES (ICPE-9000, SHIMADZU, Japan) analysis was Na: 9600 mg/L, Mg: 1000 mg/L, Ca: 331 mg/L, K: 247 mg/L.

XRD and SEM analysis

When the solidified bodies above were immersed in seawater, precipitation was formed on the surface. To determine the composition of the precipitates, X-ray diffraction (XRD) and scanning electron microscopy and energy dispersive spectrometry (SEM-EDS) analysis were conducted.

The specimens for the SEM-EDS and XRD analysis were prepared as follows. Cement or geopolymer solidified bodies were immersed in distilled water or seawater for 28 days, and dried in a vacuum dryer (FDU-1200, EYELA, Japan). To observe the cross-section, the solidified body was cut and impregnated with epoxy resin, which was later polished. Carbon spattering was performed to prevent charge-up. Then, back scattering electron image (BSE) and EDS analysis were conducted using FE-SEM (JSM-7200F, JEOL, Japan) at accelerating voltage: 15 kV, working distance: 9.6 mm.

A portion of the precipitate was scraped off with a knife and ground with a mortar, then analyzed by XRD (Smart lab, Rigaku, Japan). XRD analysis was conducted using Cu-Kα1 radiation with tube voltage: 45 (kV), tube current: 200 (mA), step size: 0.01° (2θ), and a scan rate of 4°/min.

RESULTS AND DISCUSSION

Cs leaching behavior from the solidified body of Cs adsorbed mordenite

Figure. 1 shows the cumulative leaching ratio of Cs from the cement or GP solidified body. When the solidified bodies were immersed in DW, only 0.12-0.14% of Cs was leached until the 133 days of immersion. Cs leaching is promoted when the solidified bodies are immersed in seawater. Freezing and thawing didn't show a significant difference in Cs leaching. Though these trends are common for both cement and GP solidified bodies, Cs leaching from the cement solidified body immersed in seawater is remarkably suppressed after 7 days of immersion compared with that of the GP solidified body.

Difference in Cs leaching behavior between cement and GP solidified bodies

It is reported that non-weathered cement paste has little cation adsorption capacity, and when soluble CsCl is solidified with cement, almost all of the Cs is eluted within several tens of days [8].

GP has cation adsorption capacity due to its aluminosilicate matrix [9], and thus is expected to suppress Cs leaching compared to the cement solidified body.

However, as shown in Fig. 1, the Cs leaching behavior from cement and the GP solidified body was similar. The similarity is thought to be caused by the low Cs desorption from the mordenite to the pore solution in the solidified body.

Influence of seawater on Cs leaching and surface precipitation

When the solidified body is immersed in seawater, the ion exchange equilibrium on the mordenite surface changes as the seawater penetrates into the pore solution, and the Cs concentration of the pore solution increases because of Cs desorption compared to the distilled water immersion. This leads to an increase in the Cs leaching flux due to the enhanced concentration gradient between the solvent and the pore solution.

The Cs leaching from the cement solidified body immersed in seawater shows inflection at 7 days of immersion. This must be caused by the precipitates on the cement solidified body. As shown in Fig. 2 (a),

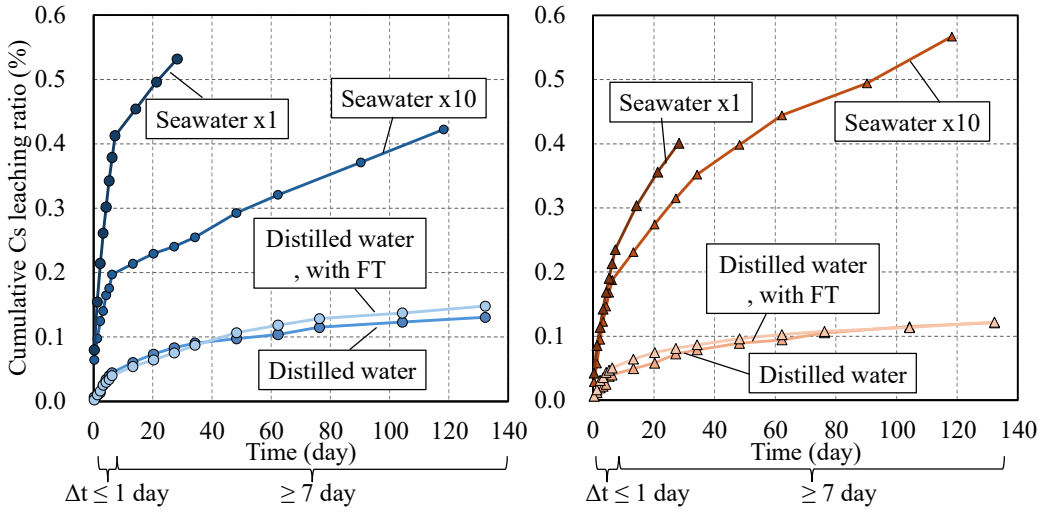

Figure. 1 Cumulative Cs leaching ratio for cement solidified body of Cs adsorbed mordenite (left) and GP solidified body (right)

precipitation as thick as 10 μm formed on its surface of the cement solidified body immersed in seawater. Calcite (outer layer) and brucite (interlayer) were observed using the EDS (Table 4 (a)) and XRD. Cs diffusion is thought to be suppressed in the denser layer of brucite and calcite, and Cs leaching flux to the outside decreases.

On the other hand, for the GP solidified body immersed in seawater, only a fragment of precipitation was measured on the surface as shown in Fig. 2 (b). It was calcite due to the EDS (Table 4 (b)) and XRD analysis. Though there is a possibility that a part of the precipitates fell during the drying process for SEM analysis, the influence on Cs leaching behavior like the cement solidified body was not observed for the GP solidified body as shown in Fig. 1.

Cs leaching pass-way for cement or GP solidified body of Cs adsorbed mordenite

In the solidified body of Cs adsorbed mordenite, granular mordenite (1.9 ~ 3.3 mm) is scattered. Cs leaching from the solidified body is expected to proceed by the path shown in Fig. 3. Firstly, Cs on the mordenite is released to the pore solution by ion exchange with alkali metal ions in the solution, and then transferred by diffusion in the solidified body through the pores.

Each of cement and GP has pores in the diameter of nm to mm [10]. The composition of the pore solution of cement is considered to be a highly ionic

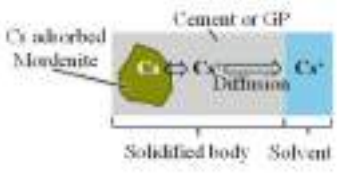

Figure. 3 Schematic diagram of Cs leaching pass-way from solidified Cs adsorbed mordenite.

solution composed mainly of Na and K in cement [11]. The pore solution of GP can contain Na^+ ions from the dissolution of NaOH remaining unreacted in the GP paste. On the surface of Cs adsorbed mordenite, a fraction of the Cs is desorbed by ion exchange between the Na and K in the pore solution and Cs on mordenite. Since mordenite selectively adsorbs Cs, the desorption ratio remains low even in solvents with high ionic strength.

When Cs adsorbed mordenite prepared in the previous section which is not solidified was immersed in the artificial seawater (Na: 9600 mg/L, Mg: 1000 mg/L) for 24 hours, the liquid phase Cs concentration was about 116 μg/L and the Cs desorption ratio was 0.73%. Though this solution does not accurately reproduce the pore solution of the solidified body, the low desorption ratio indicates that the low Cs leaching ratio from the solidified body is mainly determined by the Cs desorption ratio of the Cs adsorbed mordenite.

The Cs desorbed in the pores transfer through the pores by diffusion with a concentration gradient. Both cement and GP are porous materials, so Cs transfer is suppressed by the amount of voids, bending, and connectivity of the pores in the cement/GP. On the outer surface of the solidified body, Cs leaches to the solvent by the concentration gradient between the pore solution and the solvent.

Determination of apparent diffusion coefficients

When the Cs leaching from the solidified body is controlled by the concentration gradient in the pore solution, the Cs leaching is calculated as follows [12].

The Cs concentration in the solidified body is expressed as Eq. 1 by Fick's 2nd law, assuming the body is a semi-infinite medium [12].

$$\frac{C}{C_0} = erf\left(\frac{x}{2\sqrt{D_a t}}\right) \quad (1)$$

Here, D_a is the apparent diffusion coefficient (m^2/s), C is the concentration in the solidified body (mg/m^3), and C_0 is the initial concentration in the solidified body (mg/m^3). The leaching flux $J(t)$ (mg/(m^2·s)) at the surface of solidified body (x = 0) can be expressed as follows:

$$J(t) = -D_a \frac{\partial C}{\partial x}\Big|_{(x=0)} = C_0\sqrt{\frac{D_a}{\pi t}} \quad (2)$$

The amount of leaching per unit area up to a certain time (A (mg/m^2)), is obtained by integrating this flux with respect to time.

$$A = \int_0^t J(t)\,dt = 2C_0\sqrt{\frac{D_a t}{\pi}} \quad (3)$$

The cumulative leaching ratio can be obtained by dividing the amount of leached from the total surface area up to the target time by the initial content. If the surface area of the solidified body is S (m^2) and the volume is V (m^3), then:

$$\text{Cumulative leaching ratio} = \frac{AS}{C_0 V} = 2\left(\frac{S}{V}\right)\sqrt{\frac{D_a t}{\pi}} \quad (4)$$

In the experiment, the amount of leached at n^{th} solvent replacement interval is defined as A_n (mg), and the cumulative leaching amount is calculated as $\sum A_n$ (mg). Then it is divided by the initial amount (A_0 (mg) = C_0V), and the following relation is derived.

$$\frac{\Sigma A_n}{A_0} = 2\left(\frac{S}{V}\right)\sqrt{\frac{D_a t}{\pi}} \quad (5)$$

That is, the cumulative leaching ratio is proportional to the square root of time.

Figure. 4 shows the plot of the cumulative leaching ratio and the root of the immersion time. In all cases, the leaching ratio increases linearly up to 7 days of immersion (day$^{0.5}$=2.6), suggesting that Cs leaching was controlled by diffusion in the solid phase during this period.

The D_a obtained from the slope of the regression line up to 7 days immersion are indicated in Table 5. For both cement and GP solidified bodies, D_a of Cs are ranged around 10^{-18} m^2/s in distilled water and 10^{-17} to 10^{-16} m^2/s in seawater. Freezing and thawing didn't affect the D_a.

The Cs leaching D_a from the cement solidified body of Cs adsorbed mordenite was 10^{-18} m^2/s, though the D_a from cement with soluble CsCl is reported to range around 10^{-12} m^2/s [13–15]. The D_a in cement with soluble CsCl is 6 orders of magnitude larger than that of the cement solidified body of Cs adsorbed mordenite. The difference in D_a between cement solidified body of Cs adsorbed mordenite and cement containing soluble Cs is mainly due to Cs adsorption by the mordenite because there should be no significant difference in the connectivity of pore in cement paste itself.

Table 5 Apparent diffusion coefficient (D_a (m^2/s)) for each solidified Cs adsorbed mordenite. DW: Distilled water, SW: Artificial seawater

Solidification	Solvent	Freezing & thawing	D_a (m^2/s)
Cement	DW	No	4.1E-18
Cement	SWx10	No	6.3E-17
Cement	SWx1	No	3.3E-16
Cement	DW	Yes	3.5E-18
GP	DW	No	2.7E-18

GP	SWx1	No	1.1E-16
GP	DW	Yes	3.1E-18

CONCLUSIONS

The leaching tests were conducted for cement- or geopolymer-solidified bodies containing Cs-

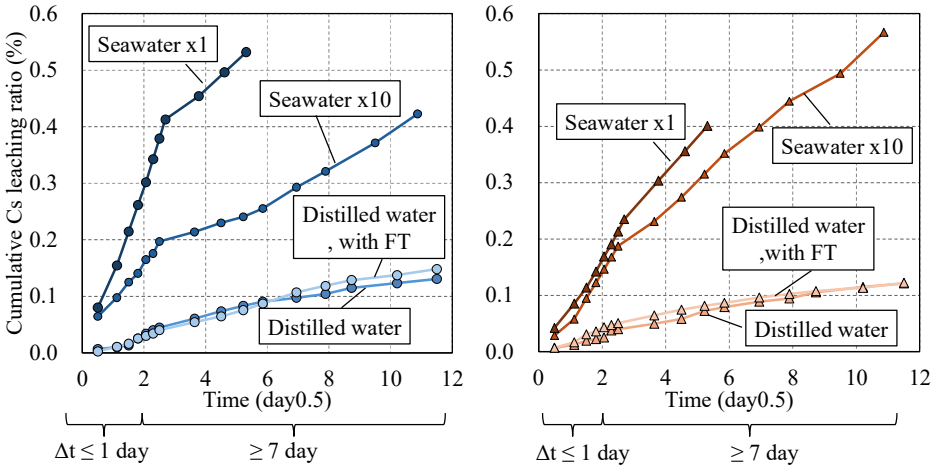

Figure. 4 Cumulative Cs leaching ratio from solidified body of Cs adsorbed mordenite vs square of immersion time (left: cement solidified body, right: GP solidified body)

adsorbed mordenite. The results indicate that Cs leaching primarily occurs through a two-step process involving Cs desorption from mordenite followed by diffusion through the pores of the solidified bodies. Due to the selective Cs adsorption by mordenite, the overall Cs leaching ratio remains significantly suppressed. Therefore, the D_a of the solidified bodies showed a significantly small value ranged in 10^{-18} to 10^{-16} m^2/s. Furthermore, freezing and thawing at temperatures of −10°C and 20°C were found to have no appreciable effect on the leaching behavior. In contrast, immersion in seawater led to an approximate fourfold increase in Cs leaching compared to distilled water. Nevertheless, even under seawater exposure conditions, the cumulative Cs leaching ratio remained as low as approximately 0.5% after 30 days of immersion. These findings suggest that the solidification of Cs-adsorbed mordenite solidified with cement or geopolymer offers a promising approach for the long-term Cs immobilization in the final disposal site.

ABSTRACT

Dyes are widely used in the textile industry and pose significant environmental concerns. Although various methods are available for the removal of dyes from wastewater, many of these techniques have notable limitations. Among them, chemical coagulation and the electrocoagulation process have shown promise, with electrocoagulation emerging as an attractive alternative for the treatment of textile wastewater. The objective of this study is to investigate the performance and determine the optimum operating conditions of electrocoagulation using aluminum (Al) electrodes for the decolorization of reactive dyes. The results showed that batch electrocoagulation studies were effective in treating reactive dyes, achieving a decolorization efficiency of 74.60%. The operational parameters—initial dye concentration of 100 mg/L, reaction time of 50 minutes, and initial pH of 6 significantly influenced the decolorization process. The optimum conditions identified in the batch studies were then applied to continuous flow electrocoagulation experiments. The continuous flow electrocoagulation system, operated under varying flow rates (8, 12, and 16 mL/min) and initial dye concentrations (75, 100, and 125 mg/L), achieved decolorization efficiencies ranging from 47.76% to 57.95%. The highest decolorization efficiency was observed at a flow rate of 8 mL/min and an initial dye concentration of 75 mg/L. These results demonstrate that continuous flow electrocoagulation system is an effective and promising technique for the removal of reactive dyes from textile wastewater.

Keywords: Electrocoagulation, Reactive dye, Continuous flow system, Decolorization

INTRODUCTION

The textile industry is a significant contributor to environmental pollution, largely due to the high volume and complex composition of its dye-laden wastewater, particularly from reactive dyes. These water-soluble dyes are difficult to remove from wastewater, making them persistent pollutant.

Various techniques have been developed to remove soluble dyes from wastewater; however, each method presents certain drawbacks. Biological treatment processes are often hindered by the toxic effects of dyestuffs on microorganisms [1], while advanced oxidation processes require the addition of chemicals, which may generate secondary pollutants [2]. Among these methods, the electrocoagulation (EC) process has emerged as a promising alternative for treating textile wastewater. Electrocoagulation is considered simple, reliable, and cost-effective, as it operates without the need for additional chemicals and produces less sludge [3,4].

The aim of this study is to evaluate the efficiency of aluminum-based electrocoagulation for the decolorization of soluble reactive dye solutions and to determine the optimal operating conditions through batch experiments. The insights gained from the batch studies are subsequently applied to design and assess a continuous-flow electrocoagulation system. The performance of the continuous-flow electrocoagulation system is investigated under varying flow rates and initial dye concentrations, with the goal of optimizing its application for textile industry wastewater treatment. Ultimately, this work lays the groundwork for scaling up and integrating electrocoagulation technology into existing wastewater treatment facilities, enhancing the industry's environmental performance and sustainability.

RESEARCH SIGNIFICANCE

This research addresses a critical environmental challenge in the textile industry by developing an electrocoagulation (EC) system capable of effectively decolorizing soluble reactive dyes, which are among the most persistent pollutants in textile wastewater. The proposed continuous flow electrocoagulation system offers a promising, cost-effective, and environmentally friendly alternative to conventional decolorization methods, with the potential to achieve high decolorization efficiency, reduce chemical usage, and minimize sludge production. This study bridges the gap between laboratory-scale treatment and practical industrial applications and integrating electrocoagulation technology into existing wastewater treatment facilities, enhancing the

industry's environmental performance and sustainability.

MATERIALS AND METHODS

Reactive Dye Solution Preparation

The reactive dye was supplied by Sivasumpan Co., Ltd, Thailand. A stock solution with a concentration of 1,000 mg/L was prepared, and the desired experimental solutions were obtained by diluting this stock to the required initial concentrations. The maximum absorbance wavelength (λ_{max}) of the reactive dye solution was determined by scanning the solution using a UV-Visible spectrophotometer (GENESYS™ 20, USA) and was found to be 430 nm.

Batch Electrocoagulation Experiment

The batch electrocoagulation (EC) experimental setup is shown in Fig. 1, featuring an aluminum electrode configuration. Each setup included four parallel electrodes two anodes and two cathodes made of aluminum plates with dimensions of 46 × 55 × 3 mm. The electrodes were prepared by first washing with acetone to remove surface grease. Residual impurities on the aluminum surfaces were then eliminated by immersing the electrodes for 5 minutes in a freshly prepared solution consisting of 100 cm^3 of 35% HCl and 200 cm^3 of 2.80% hexamethylenetetramine aqueous solution, followed by drying and weighing[5]. The total effective electrode area was 192 cm^2, with an inter-electrode spacing of 11 mm, connected to a DC digital power supply.

A 1,000 mL beaker was used as an electrocoagulation reactor. The experiments were carried out to identify the optimal conditions for the electrocoagulation process by varying the initial reactive dye concentration (20–100 mg/L), solution pH (4–12, adjusted with 0.1 M NaOH and 0.1 M HCl), reaction time (20–60 minutes), and a constant applied voltage of 20 V. Each experiment was conducted with 600 mL of reactive dye solution and a stirring speed of 200 rpm.

Continuous Flow Electrocoagulation Experiments

The optimum conditions obtained from the batch electrocoagulation experiments were used to design the continuous flow electrocoagulation experimental setup shown in Fig. 2. The continuous electrocoagulation system comprises two compartments: the first is a rectangular reactor with a volume of 0.4 L, equipped with four aluminum electrodes; the second is a pyramid-shaped sedimentation tank with a volume of 1.0 L. Trials were conducted by operating the continuous flow electrocoagulation system under varying flow rates and dye concentrations to determine the optimal conditions for practical industrial application

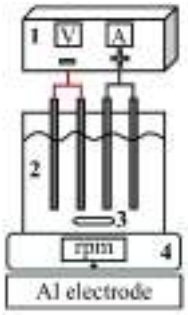

Fig.1 Schematic of batch electrocoagulation experimental sets (1) DC power supply, (2) electrocoagulation cell, (3) magnetic bar-stirrer, (4) digital magnetic stirrer.

Data Analysis

The reduction of reactive dye concentrations was measured and calculated by using equation given below. The reduction in reactive dye concentration was measured and calculated using Eq. (1) below, where C_0 and C_t represent the inlet and outlet reactive dye concentrations from the continuous flow electrocoagulation system, respectively.

$$R(\%) = \frac{C_o - C_t}{C_o} \times 100 \qquad (1)$$

RESULTS AND DISCUSSION

Batche Electrocoagulation Experiments

Effect of initial concentration

The batch electrocoagulation experimental set up was carried out to find the optimum conditions for electrocoagulation by varied initial reactive dye concentration, reaction time and initial pH solution and investigated their effect on decolorization efficiency of reactive dye.

Table 1 Effect of Initial Reactive Dye Concentration on Decolorization Efficiency and Removal Rate (mg/g Al) in Electrocoagulation

initial concentration (mg/g)	Decolorization efficiency (%)	Removal rate (mg/g of Al)
20	87.39	862.13
40	73.74	1,451.31
60	67.67	2,049.05
80	58.09	2,357.85
100	54.28	2,848.67

The effect of the initial reactive dye concentration was investigated over a range of 20–100 mg/L, as presented in Table 1. The results indicate that the decolorization efficiency decreased significantly from 87.39% to 54.28% as the initial dye concentration increased from 20 to 100 mg/L, respectively. In contrast, the dye removal rate per unit mass of aluminum increased substantially, rising from 862.13 to 2,848.67 mg/g Al, with the highest value observed at an initial concentration of 100 mg/L.

A primary mechanism for reactive dye removal in electrocoagulation is the adsorption of dye molecules onto the metal hydroxide flocs formed during the process. According to Faraday's law, the quantity of metal ions released into the solution remains constant for a given current and treatment time, regardless of the initial dye concentration. Consequently, the amount of flocs generated is fixed, limiting the available adsorption sites for dye molecules. Therefore, decolorization efficiency depends on whether the amount of flocs produced is sufficient to adsorb the total dye present [6,7].

Based on these findings, an initial dye concentration of 28 mg/L was selected as the optimum for subsequent experiments to ensure effective and comparable electrocoagulation performance.

Effect of reaction time

The effect of varying electrolysis reaction time on decolorization efficiency of reactive dye is presented in Fig. 3. It can be observed that the decolorization efficiency increased significantly with longer reaction times. This trend is attributed to the relationship between reaction time and the production rate of Al^{3+} ions from the aluminum electrode; the decolorization efficiency is directly dependent on the concentration of hydroxyl and metal ions generated at the electrodes [8]. As reaction time increases, more metal ions and hydroxyl ions are released, leading to the formation of greater amounts of hydroxide flocs, which enhance the adsorption of dye molecules [9].

However, extending the electrolysis time beyond an optimum point results in only marginal improvements in decolorization efficiency while incurring higher energy and electrode consumption [10]. This is associated with increased charge loading, which can affect the electrocoagulation performance for decolorization [11], and may reduce the extent of cathodic reduction and the generation of fresh coagulant flocs [12].

As shown in Fig. 3, the maximum reactive dye removal efficiency of $74.60 \pm 0.17\%$ was achieved at an electrolysis time of 50 minutes. Therefore, a reaction time of 50 minutes was selected as the optimum duration for subsequent experiments.

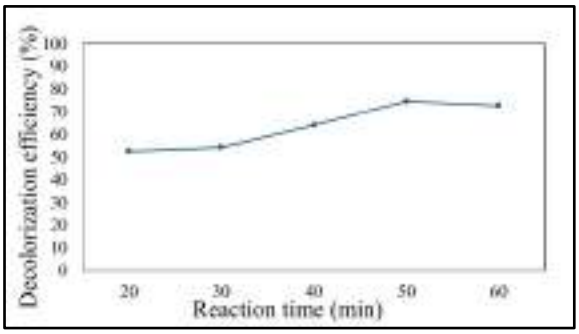

Fig. 3 The effect of reaction time on decolorization efficiency of electrocoagulation.

Effect of initial pH

To investigate the effect of the initial pH of the reactive dye solution on decolorization efficiency, batch experiments were conducted by adjusting the initial pH within the range of 4 to 12. The influence of pH on the electrocoagulation process is illustrated in Fig. 4. The results showed that an increase in the initial pH led to a decrease in decolorization efficiency, with the highest decolorization efficiency of 73.41% observed at an initial pH of 6.

In electrocoagulation for wastewater treatment, pH plays a crucial role in determining treatment performance [11]. For aluminum electrode systems, higher decolorization efficiencies are typically achieved within a pH range that favors the formation of $Al(OH)_3(s)$. These $Al(OH)_3(s)$ flocs have large

surface areas, which facilitate rapid adsorption of dissolved organic compounds and effective entrapment of colloidal particles. [13] also reported that the predominant aluminum species in solution varies with pH: Al^{3+} is the major species between pH 4 and 9.5, while $Al(OH)_3(s)$ becomes dominant within this range, enhancing coagulation efficiency.

The optimal conditions initial reactive dye concentration of 100 mg/L, reaction time of 50 minutes, and an initial pH of 6 were used as the basis for designing the continuous flow electrocoagulation experiment.

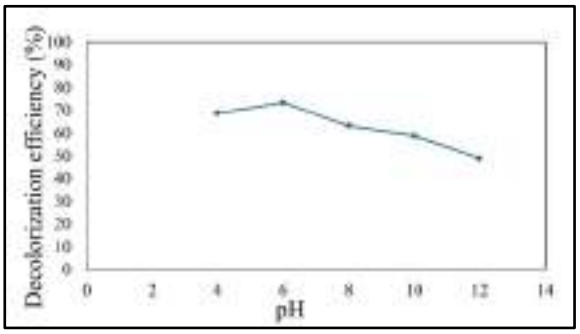

Fig. 4 The effect of initial pH on decolorization efficiency of electrocoagulation

Continuous Flow Electrocoagulation Experiment

The continuous flow system was operated at varying flow rates (8, 12, and 16 mL/min) and initial dye concentrations (75, 100, and 125 mg/L). The corresponding decolorization efficiencies are presented in Table 2. An increase in flow rate and initial dye concentration led to a decrease in decolorization efficiencies, which ranged from 48.50% to 57.95%. The optimal inlet flow rate was determined to be 8 mL/min, corresponding to a residence time of approximately 75 minutes in the continuous flow electro coagulation system and achieving the highest decolorization efficiency of 57.95%.

The findings of this study indicate that continuous-flow electrocoagulation (EC) is a promising technology for textile wastewater treatment; however, scale-up presents specific challenges. In large reactors, maintaining uniform current distribution and adequate mixing can be difficult, potentially reducing treatment efficiency. Electrode passivation and increased sludge generation require management strategies such as periodic polarity reversal, mechanical cleaning, and integration with effective sludge handling units. Fluctuations in influent dye concentration, pH, and conductivity in real industrial effluents necessitate automated control of current density and hydraulic retention time. Modular reactor configurations can provide operational flexibility, while coupling electrocoagulation with downstream biological or membrane processes can enhance overall pollutant removal and system robustness. Addressing these considerations is essential to translate laboratory-scale performance into reliable, cost-effective industrial applications.

Table 2 Decolorization efficiencies of reactive dyes using a continuous flow electrocoagulation system

Flow rate (ml/min)	Initial concentration (mg/L)	Decolorization efficiency (%)
8	100	57.83
12	100	54.08
16	100	50.79
16	75	57.95
16	125	47.76

Under the bench-scale conditions used in this study (I = 0.14 A, t = 45 min, V = 12.5 V, reactor volume = 0.6 L), aluminum electrode consumption calculated by Faraday's law was approximately 58.7 $g \cdot m^{-3}$ (≈0.059 $kg \cdot m^{-3}$), corresponding to a material cost of about 0.15 $USD \cdot m^{-3}$ at current aluminum market prices. The measured voltage resulted in an energy demand of ~2.19 $kWh \cdot m^{-3}$, equivalent to ~0.26 $USD \cdot m^{-3}$ at an average electricity tariff of 0.12 $USD \cdot kWh^{-1}$. Thus, the estimated direct operational cost for energy and electrode consumption was ~0.41 $USD \cdot m^{-3}$, excluding labor, maintenance, capital depreciation, and sludge handling. The electrocoagulation process generates sludge composed primarily of coagulated dye–metal hydroxide complexes, which requires dewatering (e.g., filtration or centrifugation) and environmentally compliant disposal. Where feasible, beneficial reuse for example, as a raw material in cement or brick manufacturing can reduce disposal costs and environmental impact. Pilot-scale trials are recommended to validate these cost estimates and optimize sludge management strategies for full-scale application.

To further advance the practical application of continuous-flow electrocoagulation, several research directions are recommended. Building on the promising results of this study, future research should focus on pilot-scale implementation of continuous-flow electrocoagulation systems to evaluate their performance under actual textile industry wastewater conditions. Long-term studies investigating operational stability, electrode durability, and maintenance requirements will be critical to ensure sustained treatment efficiency. Furthermore, comparative assessments of electrocoagulation with other advanced treatment technologies, such as membrane filtration and advanced oxidation processes, are recommended to better understand

their relative advantages, cost-effectiveness, and environmental impacts. These steps will support the practical adoption and optimization of sustainable wastewater treatment solutions in the textile industry.

CONCLUSIONS

The batch electrocoagulation system demonstrated effective decolorization of soluble reactive dyes, achieving a maximum decolorization efficiency of 73.41% at an initial dye concentration of 100 mg/L, an initial pH of 6, and a reaction time of 50 minutes. The insights gained from the batch experiments were subsequently used to design and evaluate a continuous-flowelectrocoagulation system, which achieved decolorization efficiencies ranging from 48.50% to 57.95%. These findings indicate that integrating electrocoagulation technology into existing wastewater treatment processes can enhance the textile industry's environmental performance and contribute to greater sustainability.

ABSTRACT

Reservoirs are crucial for sediment control and raw water supply, yet integrated assessments of their infrastructure resilience and water quality are still rare, especially in tropical, erosion-prone areas. This study evaluates the resilience and water quality of four reservoir systems at Universitas Andalas, located in the upstream Batang Kuranji watershed: PNP, LPPM, Arsip, and the Nurul Ilmi–Siratal Mustaqim (NI–SM) system. Methods include erosion and sediment yield estimation (USLE/MUSLE), sediment transport analysis (us), peak discharge modeling (Muskingum), and laboratory water quality testing. Results show that the NI–SM system had the most extended lifespan (3.02 years) and lowest SDR (49%), indicating better sedimentation resistance. The Siratal Mustaqim 2 reservoir reduced peak discharge by 26.23% and delayed flow by 20.96 minutes. Water quality tests revealed excess levels of iron, color, and TSS, particularly upstream, surpassing national standards. These results suggest runoff significantly contributes to water quality degradation. In conclusion, reservoir resilience is determined by sediment control, hydraulic performance, and water quality protection, emphasizing the need for integrated watershed management and ongoing monitoring.

Keywords: Reservoir, Erosion, Sedimentation, Infrastructure Resilience, Water Quality

INTRODUCTION

Infrastructure resilience and water quality are strategic issues in the management of water resources in upstream watershed areas, including the Andalas University campus region located within the Limau Manis and Batu Busuk sub-watersheds, as illustrated in Figure 1. This area serves both as an educational center and a conservation zone, equipped with a reservoir system for flood control, raw water supply, and sediment mitigation. Resilience to sedimentation, the ability to maintain water quality, and the effectiveness in reducing and delaying flood peak discharges are the primary indicators of infrastructure resilience [1–7].

Fig. 1. Map of the Batang Limau Manis and Batu Busuk Sub-Watersheds, Batang Kuranji Watershed.

This study assesses four reservoir systems: single (Politeknik Negeri Padang [PNP], Lembaga Penelitian dan Pengabdian kepada Masyarakat [LPPM]), series (Arsip 1–3), and series-parallel (Nurul Ilmi 1–2, Siratal Mustaqim 1–2 [NI-SM]) using the USLE–MUSLE approach for sedimentation, the Muskingum method for flood routing, and water quality testing. This integrated analysis of physical resilience and water quality, rarely conducted in erosion-prone tropical regions [8–9], aims to support sustainable land conservation, sediment management, and raw water supply.

RESEARCH SIGNIFICANCE

This study highlights the importance of an integrated evaluation of reservoir infrastructure resilience (the ability of infrastructure to function and survive in the face of and recover from various shocks, threats, or disturbances) and water quality in managing sedimentation, flooding, and raw water resources within Andalas University. The novelty of this research lies in the simultaneous integration of USLE–MUSLE analysis, SDR, Flood Routing, and water quality assessment to evaluate the structural and functional performance of reservoirs. These findings offer strategic contributions to land conservation planning, reservoir infrastructure design, and the sustainable management of water quality in tropical regions.

RESEARCH METHODS

This study employs an integrated quantitative approach to assess the resilience of reservoir systems in the upstream area of the Batang Kuranji watershed, with a focus on sediment control, raw water supply, and runoff mitigation [10–13].

Reservoir Storage Capacity Contour Method

Reservoir capacity calculation is the initial step in estimating the effective lifespan (period during which a reservoir can function before its storage capacity is significantly reduced by sedimentation), conducted using a contour-based method derived from topographic data :

$$\boldsymbol{V = \Delta H\ (n-1)\frac{\sum_{i=1}^{n} Li}{n}} \quad (1)$$

Where:

- $\boldsymbol{V}$ - reservoir storage capacity (m^3/s),
- $\boldsymbol{\Delta H}$ - contour interval (m),
- n - number of contour lines,
- $\boldsymbol{Li}$ - inundated area at the i-th contour line (m^2)

Rainfall Intensity

The 30-minute rainfall intensity analysis was conducted using the Talbot, Sherman, and Ishiguro methods, which are commonly used in hydrology to describe the intensity–duration relationship of rainfall [14–15]. The main objective is to obtain the average intensity at the 30th minute in order to calculate rainfall erosivity (ei), which forms part of the R factor in the USLE model.

Talbot method

This method is widely used for estimating rainfall intensity due to its simplicity and ease of application, particularly in short-term hydrological analyses. Rainfall intensity using the Talbot method is calculated using the following formula:

$$I = \frac{a}{t+b} \quad (2)$$

$$a = \frac{[\sum(I.t)]\,[\sum(I^2)] - [\sum(I^2.t)][\sum(I)]}{N[\sum(I^2)] - [\sum(I)][\sum(I)]} \quad (3)$$

$$\boldsymbol{b} = \frac{[\sum(\boldsymbol{I})]\,[\sum(\boldsymbol{I}.\boldsymbol{t})] - \boldsymbol{N}\,[\sum(\boldsymbol{I^2}.\boldsymbol{t})]}{\boldsymbol{N}[\sum(\boldsymbol{I^2})] - [\sum(\boldsymbol{I})][\sum(\boldsymbol{I})]} \quad (4)$$

Where:

- $\boldsymbol{I}$ - rainfall intensity (mm/hour)
- t - rainfall duration (hours)
- $\boldsymbol{a}$ - empirical constant representing the theoretical maximum intensity for short durations
- $\boldsymbol{b}$ - empirical constant that adjusts the curve shape based on the square root of time, determining the slope of intensity reduction
- $\boldsymbol{N}$ - number of data points

Sherman method

This method is an empirical approach for estimating rainfall intensity based on duration and is generally applied to short-duration rainfall events. Rainfall intensity using this method is calculated with the following formula:

$$\boldsymbol{I} = \frac{\boldsymbol{a}}{\boldsymbol{t^n}} \quad (5)$$

$$\boldsymbol{\log a} = \frac{[\sum(\boldsymbol{\log I})]\,[\sum((\boldsymbol{\log t})^2)] - [\sum(\boldsymbol{\log t}.\ \boldsymbol{\log I})][\sum(\boldsymbol{\log t})]}{\boldsymbol{N}[\sum((\boldsymbol{\log t})^2)] - [\sum(\boldsymbol{\log t})][\sum(\boldsymbol{\log t})]} \quad (6)$$

$$\boldsymbol{n} = \frac{[\sum(\boldsymbol{\log I})]\,[\sum(\boldsymbol{\log t})] - \boldsymbol{N}\,[\sum(\boldsymbol{\log t}.\ \boldsymbol{\log I})]}{\boldsymbol{N}[\sum((\boldsymbol{\log t})^2)] - [\sum(\boldsymbol{\log t})][\sum(\boldsymbol{\log t})]} \quad (7)$$

Where:

- $\boldsymbol{I}$ - rainfall intensity (mm/hour)
- t - rainfall duration (hours)
- $\boldsymbol{a}$ - constant representing rainfall intensity at t = 1 hour; defines base intensity level
- $\boldsymbol{n}$ - exponent controlling the rate of intensity decline with increasing duration; reflects temporal rainfall distribution
- $\boldsymbol{N}$ - number of data points

Ishiguro method

This method is an empirical model specifically designed to represent short-duration rainfall events, typically lasting less than 2 hours.

$$\boldsymbol{I} = \frac{\boldsymbol{a}}{\sqrt{\boldsymbol{t}}+\boldsymbol{b}} \quad (8)$$

$$\boldsymbol{a} = \frac{[\sum(\boldsymbol{I}.\sqrt{\boldsymbol{t}})]\,[\sum(\boldsymbol{I^2})] - [\sum(\boldsymbol{I^2}.\sqrt{\boldsymbol{t}})][\sum(\boldsymbol{I})]}{\boldsymbol{N}[\sum(\boldsymbol{I^2})] - [\sum(\boldsymbol{I})][\sum(\boldsymbol{I})]} \quad (9)$$

$$\boldsymbol{b} = \frac{[\sum(\boldsymbol{I})]\,[\sum(\boldsymbol{I}.\sqrt{\boldsymbol{t}})] - \boldsymbol{N}[\sum(\boldsymbol{I^2}.\sqrt{\boldsymbol{t}})]}{\boldsymbol{N}[\sum(\boldsymbol{I^2})] - [\sum(\boldsymbol{I})][\sum(\boldsymbol{I})]} \quad (10)$$

Where:

- $\boldsymbol{I}$ - rainfall intensity (mm/hour)
- t - rainfall duration (hours)
- $\boldsymbol{a}$ - empirical constant representing the theoretical maximum intensity for short durations
- $\boldsymbol{b}$ - empirical constant that adjusts the curve shape based on the square root of time, determining the slope of intensity reduction
- $\boldsymbol{N}$ - number of data points

Flood Discharge

Runoff in this study refers to the portion of rainfall that flows over the land surface and contributes to streamflow, estimated using the Rational Method [14-15].

$$\boldsymbol{Qp} = \boldsymbol{0,278\,.\,C.I.A} \quad (11)$$

Where:

- Qp - peak flood discharge (m^3/s)
- C - runoff coefficient
- I - rainfall intensity during time of concentration (mm/hour)
- A - catchment area (Ha)

Erosion

Soil loss due to surface erosion was estimated using the USLE [10-13] model, which accommodates the calculation of both average annual erosion rates and event-based erosion. Soil loss at each reservoir site is estimated through the multiplication of five key parameters. Can be calculated using the following formula :

$$\boldsymbol{A} = \boldsymbol{R} \times \boldsymbol{K} \times \boldsymbol{LS} \times \boldsymbol{C} \times \boldsymbol{P} \quad (12)$$

Where:

- $\boldsymbol{A}$ - average annual soil loss (tons/ha/year)
- $\boldsymbol{R}$ - rainfall erosivity factor (MJ·mm/ha·hr·year)
- $\boldsymbol{K}$ - soil erodibility factor (tons·ha·hr/ha·MJ·mm)
- $\boldsymbol{LS}$ - slope length and steepness factor
- $\boldsymbol{C}$ - cover and land use factor
- $\boldsymbol{P}$ - conservation practice factor

Sedimentation

Sediment volume resulting from surface runoff was estimated using the MUSLE approach, which replaces the rainfall erosivity factor (R) in the USLE model with hydrological parameters, namely runoff volume (V) and peak discharge (Qp) [10-13].

$$\boldsymbol{Sed} = \boldsymbol{11.8} \times \left(\boldsymbol{Q} \times \boldsymbol{q_{peak}} \times \boldsymbol{A}\right)^{\boldsymbol{0.56}} \times \boldsymbol{K} \times \boldsymbol{C} \times \boldsymbol{P} \times \boldsymbol{LS} \quad (13)$$

Where:

- $\boldsymbol{Sed}$ - estimated sediment yield (tons)
- $\boldsymbol{Q}$ - runoff volume (m³)
- $\boldsymbol{q_{peak}}$ - peak flood discharge from runoff (m³/s)
- $\boldsymbol{A}$ - catchment area (km²)
- $\boldsymbol{K}$ - soil erodibility factor
- $\boldsymbol{C}$ - land cover and land use factor
- $\boldsymbol{P}$ - soil conservation practice factor
- $\boldsymbol{LS}$ - slope length and steepness factor
- $\boldsymbol{11.8}$ - conversion and calibration coefficient for results in tons

Sediment Delivery Ratio (SDR)

This study employed the empirical approach of the United States Department of Agriculture (USDA) based on catchment area size. This estimation is essential for assessing the actual sediment load that affects reservoir capacity, resilience, and effective lifespan.

$$SDR = 0.472 \times A^{-0.125} \quad (14)$$

Where:

- SDR - sediment delivery ratio
- A - catchment area (km2)

Flood Routing

As part of the infrastructure resilience analysis, this study applies the Flood Routing method to evaluate the reservoir's ability to reduce peak discharge (maximum instantaneous flow at the watershed outlet during a storm event) and delay flood peak time (time difference between the occurrence of the maximum inflow and the maximum outflow hydrograph at the reservoir or watershed outlet) [3]. The method used is the Muskingum :

$$\boldsymbol{C_0} = \frac{-\boldsymbol{KX}+\boldsymbol{0.5\Delta t}}{\boldsymbol{K}-\boldsymbol{KX}+\boldsymbol{0.5\Delta t}} \quad (15)$$

$$\boldsymbol{C_1} = \frac{\boldsymbol{KX}+\boldsymbol{0.5\Delta t}}{\boldsymbol{K}-\boldsymbol{KX}+\boldsymbol{0.5\Delta t}} \quad (16)$$

$$\boldsymbol{C_2} = \frac{\boldsymbol{K}-\boldsymbol{0.5\Delta t}}{\boldsymbol{K}-\boldsymbol{KX}+\boldsymbol{0.5\Delta t}} \quad (17)$$

$$\boldsymbol{Q_{out,t+1}} = \boldsymbol{C_0 I_{t+1}} + \boldsymbol{C_1 I_t} + \boldsymbol{C_2 O_t} \quad (18)$$

where :

- $Q_{out,t+1}$ - outflow discharge at time t+1
- I_t - inflow discharge at time t
- I_{t+1} - inflow discharge at time t+1
- O_t - outflow discharge at time t
- Δt - time interval between two observations (Δt)
- K - storage constant represents the travel time of water through the reach
- X - weighting factor typically ranges between 0 and 0.5; describes the relative influence of inflow and outflow on storage
- C_0, C_1, C_2 - numerical weights derived that distribute inflow and outflow in the flood routing process

DATA ANALYSIS

This section presents the results of primary and secondary data analysis from the upstream area of the Batang Kuranji watershed to support erosion estimation and the evaluation of reservoir effective lifespan as an indicator of infrastructure resilience.

Reservoir Storage Capacity

Table 1. Reservoir Storage Capacity

System	Reservoir	Storage Capacity (m^3)	Sub-Total (m^3)
Single	PNP	2,418	2,418
	LPPM	445	445
Series	Arsip 1	1,392	3,020
	Arsip 2	522	
	Arsip 3	1,106	
Series-Parallel	Nurul Ilmi 1	1,141	18,370
	Nurul Ilmi 2	1,176	
	Siratal Mustaqim 1	1,653	
	Siratal Mustaqim 2	14,400	
	Total		24,253

The single reservoirs, PNP and LPPM, have capacities of 2,418 m³ and 445 m³, respectively; the series system (Arsip) has a combined capacity of 3,020 m³; while the series-parallel system (NI-SM) possesses the largest capacity at 18,370 m³, with a total capacity of 24,253 m³, as shown in Table 1.

Rainfall Data

Short-term rainfall analysis was conducted using 5-minute interval data over 120 minutes at four stations (PNP, LPPM, Arsip, and NI–SM). Over the 10-day observation period, 15 data intervals were recorded, with Period 1 (January 21, 2025) identified as the worst-case scenario due to the highest rainfall intensity as shown in Table 2.

Table 2. Rainfall Data

No	Time (minutes)	Rainfall Intensity (mm)			
		PNP	LPPM	A	NI-SM
1	0	0.0000	0.0000	0.0000	0.0000

22	105	0.6018	0.7967	0.8033	0.8950
23	110	0.5047	0.6043	0.8966	0.7007
24	115	0.2977	0.3955	0.8024	0.6001
25	120	0.1973	0.2968	0.7043	0.4950
Accumulation		52.0000	54.0000	52.1000	53.5000

Soil Data

Table 3. Soil Test Results

No	Parameter	A Sample	NI-SM Sample
1	% silt	28.650	34.510
2	% clay	31.710	42.150
3	% fine sand	18.770	23.340
4	% organic matter (a)	6.660	8.827
5	soil structure class (b)	3.000	3.000
6	permeability class (c)	5.000	5.000
7	bulk density	0.874	0.858

To determine the soil erodibility factor (K) in the USLE framework, a soil characterization study was performed using both physical and chemical soil properties. Data obtained from the upstream zone representing the catchment area of the Arsip (A) Series and NI-SM Parallel Series Reservoir served as the reference for evaluating baseline erosion susceptibility, as detailed in Table 3.

RESULTS AND DISCUSSION

This study integrates rainfall intensity and flood discharge analyses to estimate erosivity and runoff, supporting calculations of erosion rates, sediment volume, and SDR to evaluate reservoir lifespan as a resilience indicator. The Muskingum method assessed hydraulic effectiveness in reducing and delaying peak discharge, while water quality testing evaluated the reservoirs' suitability as raw water sources and their role in sustainable water resource conservation.

Rainfall Intensity

Short-term rainfall intensity was analyzed using the Talbot, Sherman, and Ishiguro methods based on the highest recorded rainfall data, across durations of 5 to 720 minutes. All methods showed decreasing intensity with longer durations, reflecting their distinct characteristics. The average 30-minute intensity (I_{30}) was 33.29 m³/s, relevant for runoff and erosion analysis, as shown in Table 4.

Table 4. Rainfall Intensity

Time (minutes)	Rainfall Intensity (m^3/s)		
	Talbot	Sherman	Ishiguro
5	37.14	34.49	55.77

Flood Discharge Analysis

Table 5. Flood Discharge Analysis Results

t	QPNP	Q_{LPPM}	Q_A	Q_{NI-SM}
(hour)	(m^3/s)	(m^3/s)	(m^3/s)	(m^3/s)
0.25	0.44	0.02	0.13	0.27
0.49	2.27	0.00	0.00	0.00
0.50	2.25	0.00	0.04	0.68
0.75	1.47	0.00	0.02	0.40
1.00	0.96	0.00	0.01	0.24
1.50	0.48	0.00	0.00	0.12
2.26	0.20	0.00	0.00	0.00
Total Q (m^3/s)	1.47	0.03	0.12	0.49
VDR (m^3)	5,289.71	116.32	434.63	1777.57
TDR (mm)	5.17	11.08	8.81	5.51

Flood discharge analysis using the Rational Method provided VDR (volume direct runoff), TDR (total direct runoff), and Qp (peak discharge) values as inputs for MUSLE-based sediment load estimation. The PNP reservoir showed the highest, while the LPPM and Arsip systems had lower values. The NI–SM series-parallel system recorded a notable combined flow, reflecting variations in runoff control capacity among the reservoirs as shown in Table 5.

Infrastructure Resilience Analysis

Reservoir infrastructure resilience was analyzed using three main indicators: the SDR, effective lifespan, and hydrological response through Flood Routing. These indicators provide a comprehensive overview of the reservoir's resistance to sedimentation and extreme hydrological pressure.

Erosion, sedimentation, and reservoir lifespan analysis

The effective lifespan of a reservoir, indicating its resilience to sedimentation, is calculated from the ratio of initial storage capacity to annual sediment volume, based on erosion, sediment yield, SDR (PNP: 66%, LPPM: 72%, Arsip: 61%, NI–SM: 49%) and bulk density where a lifespan exceeding about 10-20 years is considered resilient in this regional context. Results show the PNP and Arsip reservoirs have the shortest lifespans, indicating high siltation risk, while LPPM and NI–SM have longer lifespans but remain vulnerable without proper land management, as shown in Table 6.

Table 6. Erosion, Sedimentation, and Reservoir Lifespan Analysis Result

Parameter	Reservoir			
	PNP	LPPM	A	NI-SM
	USLE			
Erosion per Event (tons/event)	286.50	186.38	458.01	281.22
Annual Sediment (tons/year)	1,520.06	532.67	3,968.08	12,490.64
Annual Erosion (tons/ha/year)	1,739.74	609.65	4,541.56	14,295.83
Reservoir Lifespan (years)	1.59	0.84	0.76	1.47
	MUSLE			
Sediment Yield (tons/event)	1,484.18	14.82	159.03	443.13
Annual Sediment (tons/year)	1,698.68	203.50	2,184.18	6,086.12
Reservoir Lifespan (years)	1.42	2.19	1.38	3.02

Flood routing

Flood Routing analysis was calculated using the Muskingum method, with no single standard specific to the watershed conditions. Table 7 demonstrates that series and series-parallel reservoir systems are more effective in reducing peak discharge and delaying flood peak time than single reservoirs. The Arsip system achieved a 25.56–39.92% reduction with a 12.92-minute delay, while the NI–SM system recorded a 26.23% reduction and a 20.96-minute delay, supported by sequential reservoir flow. In contrast, single reservoirs like LPPM and PNP showed lower effectiveness, with reductions of 40% and 0.54% and minimal delays, underscoring the superior performance of tiered systems in flood control.

Table 7. Reduction and Delay of Flood Peak Discharge Muskingum Method

System	Reservoir	Reduction (%)	Delay (minutes)
Single	PNP	0.54	0.32
	LPPM	40.00	0.00
Arsip Series	Arsip 1	25.56	5.96
	Arsip 2	31.34	5.96
	Arsip 3	39.92	12.92
Nurul Ilmi – Siratal Mustaqim Series-Parallel	Nurul Ilmi 1	11.32	5.96
	Siratal Mustaqim 1	17.63	5.96
	Nurul Ilmi 2	23.73	20.96
	Siratal Mustaqim 2	26.23	20.96

Water Quality Analysis

Table 8. Water Quality Test Results

Parameter	Test Results		Water Quality Standard	Unit
	Sample A	Sample NI-SM		
Color	8.50	12.80	10	Pt-Co Unit
Total Dissolved Solids (TDS)	91.70	62.60	300	mg/L
Temperature	25.00	25.10	± 3	oC
pH	6.87	6.54	6.5 – 8.5	-
Dissolved Iron (Fe)	1.79	0.877	0.2	mg/L
Dissolved Oxygen (DO)	5.53	5.53	-	mg/L
Total Suspended Solids (TSS)	3,600.00	245.00	-	mg/L
Total Hardness (CaCO3)	112.00	52.00	NA	mg/L

Laboratory tests from upstream and downstream reservoirs shown in Table 8, explain that temperature, pH, and TDS met quality standards based on the Indonesian Ministry of Health Regulation Number 2 of 2023. However, dissolved iron exceeded the 0.2 mg/L limit, and NI–SM also surpassed the color threshold, indicating organic matter or fine particulates. TSS levels dropped from 3,600 mg/L upstream to 245 mg/L downstream, reflecting effective sedimentation, so further water quality improvements are needed.

CONCLUSION

This study evaluated the resilience of four reservoir systems in the upstream Batang Kuranji watershed based on sedimentation, hydrological

performance, and water quality. USLE and MUSLE analyses identified the NI–SM system as the most resistant to sedimentation, with the longest effective lifespan (3.02 years) and the lowest SDR value (49%), while the Arsip reservoir had the shortest lifespan (0.76 years). Flood routing results showed that tiered systems (Arsip and NI–SM) were more effective in reducing and delaying peak discharge, with the NI–SM system achieving a 26.23% reduction and a 20.96-minute delay, compared to only 0.54% reduction by the PNP reservoir. Water quality analysis indicated compliance for parameters like temperature, pH, TDS, and DO, but elevated levels of iron, color, and TSS especially upstream highlighted runoff-related contamination. However, the findings are limited to the local scale of the upstream Batang Kuranji watershed, with model parameters that may vary under different tropical conditions. Future studies should integrate broader pollutant parameters, long-term monitoring, and climate–land use scenarios to strengthen reservoir resilience strategies in tropical regions and the implementation of parallel–series reservoir systems as a more effective option for future reservoir design.

ACKNOWLEDGMENT

We thank the Department of Civil Engineering, Andalas University, and the Department of Water Resources and Construction Development, West Sumatra Province, for their support and permission, and the GEOMATE Journal for facilitating the dissemination of this study.

ABSTRACT

This study compares composite materials using synthetic resin matrices and bio-resin matrices derived from plant sources, with foam core layers of Lantor Soric made from recycled PET plastic added in 1, 2, 3, and 4 layers. The bending behavior and morphology of the materials were evaluated using Scanning Electron Microscopy (SEM). Results show that increasing the number of foam core layers enhances the strength and flexibility of the composite materials, with the 4-layer foam core composite exhibiting the highest strength. Additionally, composites using bio-resin matrices demonstrate superior bending properties compared to those using synthetic resin matrices. SEM analysis reveals strong bonding between the resin and foam core, with no delamination, indicating a well-integrated structure and efficient resin distribution. The materials used, including flax fibers, bio-resin matrices, and the Lantor Soric core made from recycled PET, are all environmentally friendly, reducing reliance on petroleum-based resources and minimizing environmental impact. This approach aligns with global sustainability efforts by reducing greenhouse gas emissions and supporting the circular economy, providing a promising alternative for producing high performance, eco-friendly composite materials that meet both performance and environmental goals.

Keywords: Bio-resin matrix, Sandwich composite, Natural reinforced composite, Flexural properties, Morphology

INTRODUCTION

Composite materials are among the most rapidly growing and evolving material groups today. They have gained widespread popularity across various industries, including aerospace, automotive, sports, and construction, all of which demand materials with specialized properties. Due to their superior characteristics compared to conventional materials such as exceptional mechanical strength, remarkable lightness, and resistance to harsh environmental conditions composite materials have become a crucial choice for structures requiring an optimal balance between weight and strength [1-2]. Notable applications include complex structural components of aircraft wings and fuselages, wheels and landing gear assemblies, energy efficient automotive body panels, and high-performance sports equipment such as tennis rackets and carbon fiber bicycles. These examples underscore the potential and significant role of composite materials in modern industries [3-5].

Although synthetic composite materials such as carbon fiber, glass fiber, and Kevlar fiber, along with petroleum-based matrices, are key to modern material development due to their outstanding mechanical properties, their production and end-of-life disposal have significant environmental impacts. These include greenhouse gas emissions, non-biodegradable waste accumulation, and the release of toxic substances into ecosystems [6-7]. These issues have driven researchers to explore alternative materials, such as natural reinforcement fibers, which are considered a highly promising replacement for synthetic materials [8]. Natural fibers offer advantages in sustainability, including the use of renewable resources, environmental friendliness, and reduced carbon dioxide emissions during production [9]. A notable example is flax fiber, which possesses excellent mechanical properties, enhances composite strength, and can effectively replace certain synthetic fibers.

Meanwhile, the development of bio-matrix, or naturally derived matrices, is equally important. These matrices are often extracted from plants, such as starch or lipid extracts [10-11]. Research indicates their compatibility with natural fibers like flax fibers, this combination yields promising results in terms of both mechanical properties and sustainability. Furthermore, Bio-matrix materials can meet the demands of various industries, including automotive, construction, and sports equipment, which seek to balance performance with environmental responsibility. The growing trend of incorporating natural materials into composites reflects a strong commitment to advancing circular economy principles and sustainable design, which are key directions for the future of composite materials [12-13].

Another important approach in the development of composite materials is the enhancement of performance through particle additives, which help increase strength, flexibility, and compatibility between the matrix and reinforcing fibers. Additionally, improving the mechanical properties of composites also involves the use of lightweight cores in sandwich composites [14]. Inserting a core between the surface layers of the composite sheet enhances thickness and reinforces load-bearing performance, such as bending and shear forces. These cores come in various types, depending on the requirements, including cores made from natural wood, foam, or synthetic materials like aramid. Notably, honeycomb shaped cores have become more popular due to their structure, which effectively distributes forces and provides a lighter alternative to conventional block shaped cores [15-16]. Currently, environmentally friendly cores, such as the Lantor Soric core made from recycled PET plastic with a honeycomb structure, are being developed. This type of core offers notable advantages in flexibility and durability. In addition to meeting sustainability goals, this core shows high potential for use with both synthetic and bio-matrix matrix materials [17].

In this research, the compatibility between the Lantor Soric core and two types of matrices, namely synthetic resin matrices and bio-resin matrices was tested with a focus on flexural mechanical strength. The inclusion of flax fibers in the composite material helps improve its strength and long-term sustainability from an environmental perspective. The obtained data will help understand the potential of this new composite material and promote the development of materials that meet both performance and sustainability requirements in the industry. Scanning electron microscopy (SEM) was used to analyze the structure of the Lantor Soric core in terms of core-matrix adhesion. The SEM data will help understand the material's behavior and support the development of high performance, durable, and eco-friendly composite materials.

MATERIALS AND METHODS

Materials

The composite materials employed in this study incorporate flax fibers obtained from Linum usitatissimum, which are well known for their high specific strength-to-weight ratio, biodegradability, and cost-effectiveness [1]. Compared to other natural fibers such as jute and hemp, flax offers a more favorable balance between mechanical performance and sustainability, making it one of the most promising reinforcements for lightweight composites. Recent studies have further highlighted that the mechanical and damping properties of flax fiber composites are strongly influenced by processing conditions and structural design [2].

Two resin matrices were selected: a synthetic epoxy resin, chosen for its superior mechanical properties and resistance to environmental factors, and a plant-based bio-resin, employed to reduce environmental impact while improving interfacial compatibility with the hydrophilic flax fibers.

To enhance flexural performance, a recycled PET-based foam core (Lantor Soric) was incorporated. This lightweight core increases composite thickness and flexural stiffness without significantly increasing weight, while simultaneously promoting sustainability through the reuse of waste-derived resources. A summary of the materials used in this investigation is presented in Fig 1.

Fig.1 Detailed Materials Overview.

Fabrication

The production of composite materials in this study utilizes the Vacuum Infusion Process, a technique that uses a vacuum system to press the components together while injecting the matrix into the prearranged reinforcement fibers and core. The reinforcement fibers are laid in the same direction at 0 degrees, layered in 3 layers. A Lantor Soric core, made from recycled PET plastic, is inserted in the middle to increase thickness and enhance the bending properties of the material. Additionally, three layers of flax fibers are placed on the top and bottom to improve strength and load-bearing efficiency. The material size before trimming is 220x100 mm^2, which will be cut to the appropriate size according to the test standards. Afterward, the surface is covered with Peel ply to prevent resin bonding to the surface and topped with infusion net to ensure the resin spreads evenly during injection. The matrix is mixed with a hardening agent in the correct ratio according to the technical data before undergoing a degassing process to remove any air trapped in the matrix, preventing air

bubbles in the composite structure. The matrix is then drawn into the vacuum system, where the fibers and core are neatly arranged, with the matrix infusion process taking approximately 15 minutes. Afterward, the entire structure is placed in an oven for about 6 hours to allow the resin to cure and acquire excellent mechanical properties.

Materials Testing

The sandwich composite materials, after forming and curing, are trimmed to meet standard dimensions for the bending test. The specimens are 200 mm in length and 15 mm in width, with thickness varying based on the core layers. The bending test follows ASTM C 393/C 393M standards with a 150 mm support span and a loading head speed of 2 mm/min, conducted using a LLOYD LD100 universal testing machine (100 kN capacity). Each specimen is tested 5 times for accuracy. Two groups are tested: one with synthetic resin matrices and 4 core configurations (20 specimens), and another with bio-resin matrices and the same 4 core configurations (20 specimens), totaling 40 specimens. Further details are in Table 1.

Table 1 Designed method for experimental study.

Matrix Type	Core layer	Name	Width (mm)	Thickness (mm)
Synthetic resin matrix	1 Core	S1C	15±0.2	5.02 ± 0.2
	2 Core	S2C		7.72 ± 0.2
	3 Core	S3C		10.33 ± 0.2
	4 Core	S4C		13.42 ± 0.2
Bio-resin matrix	1 Core	B1C		5.33 ± 0.2
	2 Core	B2C		7.70 ± 0.2
	3 Core	B3C		9.92 ± 0.2
	4 Core	B4C		12.21 ± 0.2

Facing Stress

The stress that occurs is mainly concentrated at the surface layers rather than the core. The stress calculation is based on an equation similar to the calculation of bending stress for a simple beam. The equation used for the calculation is shown in the following Eq.1

$$\sigma = \frac{P_{max} S}{2t(d+c)b} \quad (1)$$

Where: σ is the facing stress (MPa), Pmax is the maximum force prior to failure (N), S is the span length (mm), t is the facing thickness (mm), d is the sandwich thickness (mm), c is the core thickness (mm), b is the sandwich width (mm).

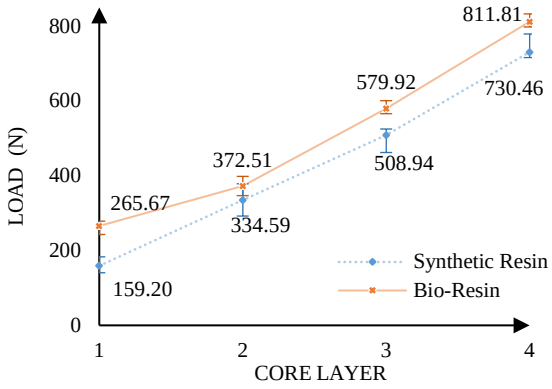
Morphology

Scanning Electron Microscopy (SEM) was used to examine the fracture surfaces, focusing on the failure behavior of reinforcing fibers and the interfacial compatibility between the resin matrix and flax fibers. In preparing the specimens for SEM, the tested samples are cut to an appropriate size (< 5 mm) to fit the SEM sample holder. The fracture surfaces are examined without further polishing to preserve the natural fracture characteristics. For nonconductive samples, a thin layer of gold is applied using a Sputter Coater to enhance electrical conductivity and reduce charge accumulation. Each specimen is then securely mounted on an aluminum stub with conductive carbon tape before being placed in the SEM chamber for imaging and further analysis

RESULTS

Behavior under bending load

The bending properties tested using the universal testing machine show that the specimen's response to the applied force results in the maximum load occurring at the specimen with the core layer of 4 and a core thickness of 10 mm. The maximum load distribution is measured at 811.81 N for the structure using a bio-resin matrix. For the synthetic resin matrix, the maximum load occurs at the specimen with the core layer of 4 and a core thickness of 10 mm, yielding a value of 730.46 N. These results, including both the applied load and the displacement during the tests, are summarized in Fig. 2. From the bending test results, it was found that the load-bearing strength for the structure with the core layer of 4 was more efficient than other core layers, and the bio-resin matrix provided better performance than the synthetic resin matrix across all tested core layers.



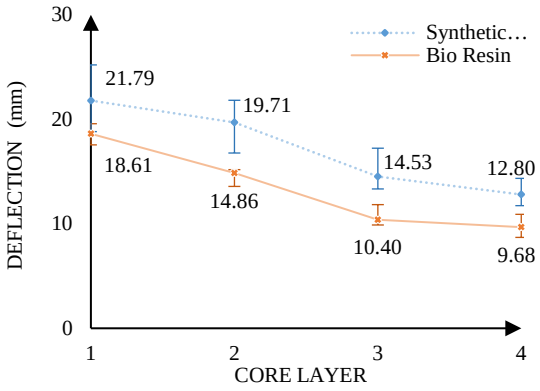


Fig.2 Load and Deflection distribution

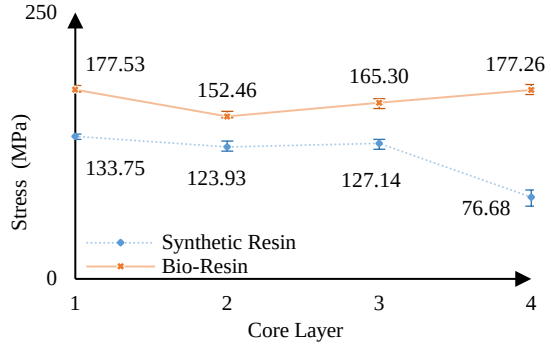
Flexural Strength

The stress values for the specimens were determined following the equation outlined in the ASTM C 393/C 393M standard. The test results show that the maxi-mum stress in the specimens with a bio-resin matrix is generally higher than that of the synthetic resin matrix, indicating better performance in terms of load-bearing capacity and resistance to stress. The stress in the specimens with a bio-resin matrix ranged from 152.46 MPa to 177.53 MPa, with the B1C and B4C specimens showing a maximum stress of approximately 177 MPa. In contrast, the specimens with a synthetic resin matrix had lower stress values, ranging from 76.68 MPa to 133.75 MPa. This difference indicates that the bio-resin matrix not only has better load-bearing properties but also demonstrates superior stress distribution, resulting in greater overall strength and resistance to applied forces. The bio-resin matrix's enhanced ability to distribute stress, especially between the core and surface layers, makes it more effective in maintaining the structural integrity under load compared to the synthetic resin matrix. All this information is summarized in Fig. 3.



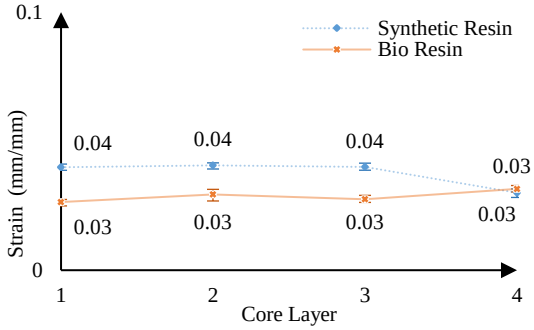


Fig.3 Facing stress and strain distribution.

Modulus Analysis

The flexural modulus, evaluated in sandwich composite structures subjected to bending tests, shows that the specimen with 1 core layers and a core thickness of 2.5 mm. provides the highest flexural modulus for specimens made with a bio-resin matrix, reaching 10.67 GPa. Meanwhile, the specimen with 1 core layers and a core thickness of 2.5 mm. provides the highest flexural modulus for specimens made with a synthetic resin matrix, reaching 9.99 MPa. When comparing the two types of matrices in Fig. 4, the bio-resin matrix demonstrates better suitability, resulting in a higher flexural modulus than the synthetic resin matrix

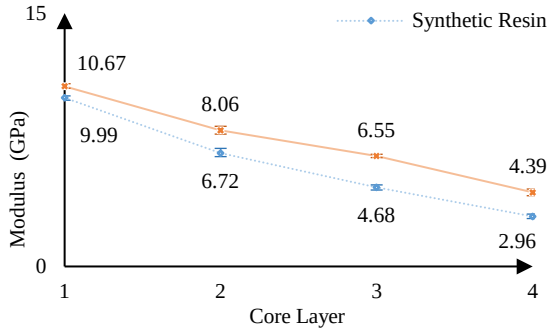

Fig.4 Modulus of flexural in different core layer.

Morphology Comparison between Bio-Epoxy Resin and Synthetic Epoxy Resin

The morphology of the sandwich structure was analyses using scanning electron microscopy (SEM) to examine areas damaged during testing and assess the compatibility between flax fibers and the two types of matrices. The analysis revealed that flax fibers formed with the bio-resin matrix exhibited damage characterized by fibers pulling away from the matrix. The breakage was clean and smooth, suggesting strong bonding between the fibers and the matrix, which facilitated clear separation of the fibers, as illustrated in Fig. 5(a).

In contrast, flax fibers formed with the synthetic

resin matrix, as shown in Fig. 5(b)., demonstrated damage where the fibers were torn and fragmented. The breakage exhibited rough, jagged edges, resembling tearing and separation from the matrix, indicating weak adhesion, which led to the fibers breaking into pieces.

Fig.5 SEM Fracture of fiber.

CONCLUSION

This study investigated the mechanical performance and sustainability of composite materials reinforced with bio-epoxy resin and a recycled PET-based core. The results demonstrate that increasing the number of foam core layers improves the structural strength and flexibility of the composites, with the four-layer core configuration exhibiting the highest mechanical performance. Additionally, composites using bio-resin matrices outperformed those with synthetic resin matrices in flexural tests, highlighting their potential as a sustainable alternative.

Scanning Electron Microscopy (SEM) analysis revealed strong adhesion between the resin matrix and core, with minimal signs of delamination, indicating efficient bonding and material integration. The bio-resin composites showed smoother fiber breakage, signifying enhanced compatibility between the resin and natural fibers, whereas synthetic resin composites displayed fiber fragmentation, suggesting weaker adhesion.

Overall, this research supports the feasibility of bio-resin-based composites as a sustainable and high-performance alternative to traditional petroleum-based composites. By incorporating renewable materials such as flax fibers and recycled PET cores, these composites contribute to reducing environmental impact while maintaining desirable mechanical properties. This study aligns with global efforts toward sustainable material development, promoting circular economy principles and reducing dependence on non-renewable resources. Future research should explore further optimization of bio-resin formulations and the long-term durability of these composites in real world applications.

ABSTRACT

The Seto Inland Sea, known for its highest biological productivity in the world, has experienced a substantial decline in critical coastal vegetated ecosystems such as tidal flats and algal beds. This degradation primarily resulted from extensive land reclamation projects during Japan's period of rapid economic growth. In recent years, the loss of algal beds has been further exacerbated by marine environmental changes driven by global climate change, including rising sea temperatures, contributing to the spread of isoyake (barren grounds). Simultaneously, long-standing efforts to reduce terrestrial nutrient inputs—particularly nitrogen and phosphorus—as eutrophication countermeasures have unintentionally accelerated oligotrophication in coastal waters, further inhibiting the regeneration of algal beds. To address this issue, we developed and deployed artificial reef structures made from porous materials, specifically designed to promote the establishment of macroalgal communities. Long-term field monitoring has demonstrated that these structures facilitate not only algal colonization but also the settlement of epifaunal organisms, thereby contributing to the restoration of high-biodiversity algal bed ecosystems. This study presents a quantitative evaluation of the annual variation in the biomass of attached organisms on these structures, confirming their high ecological functionality and effectiveness in supporting algal bed regeneration.

Keywords: Seaweed bed, Seto inland sea, Coastal ecosystem, Porous material

INTRODUCTION

In the context of global climate change mitigation, increasing attention has been directed toward blue carbon, which is the carbon sequestration capacity of marine ecosystems [1,2]. Compared to terrestrial green carbon ecosystems, blue carbon ecosystems exhibit a 3- to 10-fold higher CO_2 absorption capacity per unit area [3], along with the potential for long-term carbon storage [4]. Despite their significance, these ecosystems are increasingly threatened by anthropogenic development and the impacts of climate change [5]. In particular, the Seto Inland Sea has experienced pronounced degradation of its macroalgal beds [6,7].

This study reports on restoration efforts targeting macroalgal beds through the deployment of artificial reef structures—hereinafter referred to as macroalgal bed creation reefs—developed at Kagawa University [8]. This study evaluates the effectiveness of the porous materials used in these structures as substrates for promoting macroalgal growth and the colonization of epibiotic organisms. Although the biocompatibility of porous materials has been previously documented [9], this research presents a long-term evaluation of their ecological functionality under field conditions.

RESEARCH SIGNIFICANCE

This study quantitatively demonstrates that the newly developed seaweed bed creation reefs utilizing porous materials function as a source of food organisms. This approach enables the visualization and evaluation of the food supply function, which has been difficult to achieve with conventional seaweed bed restoration techniques, thereby contributing to a quantitative understanding of the ecosystem services provided by seaweed beds. The findings offer new guidance for the advancement of seaweed bed restoration technologies and the multifunctional management of coastal ecosystems.

Furthermore, the implementation of such multifunctional artificial reefs may play a vital role in enhancing coastal resilience by simultaneously supporting biodiversity, improving fishery productivity, and contributing to carbon sequestration. As coastal areas worldwide continue to face increasing anthropogenic pressures and climate-induced stressors, integrative restoration approaches like this hold promise for scalable and sustainable ecosystem management solutions.

MATERIALS AND METHODS

Experimental Sites

Field experiments were conducted at two coastal sites near Kamano Fishing Port and Shinoo Fishing Port, both situated in Ajicho, Takamatsu City, Kagawa Prefecture, Japan (Figure 1).

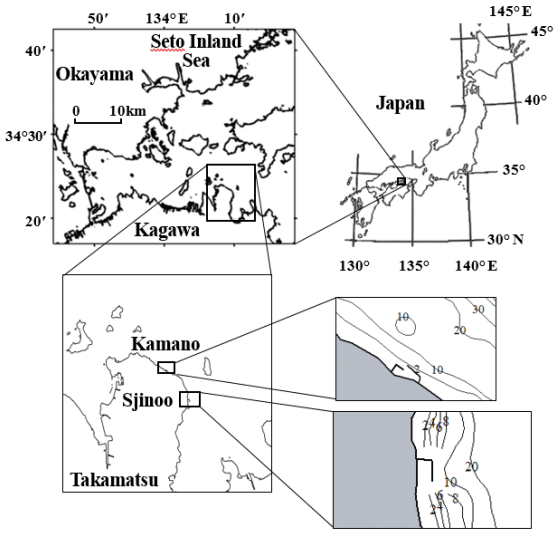

Figure 1. Locations of the Survey Sites

A total of 72 artificial seaweed bed reefs were deployed: 25 units in the Kamano area and 47 units in the Shinoo area (Figure 2).

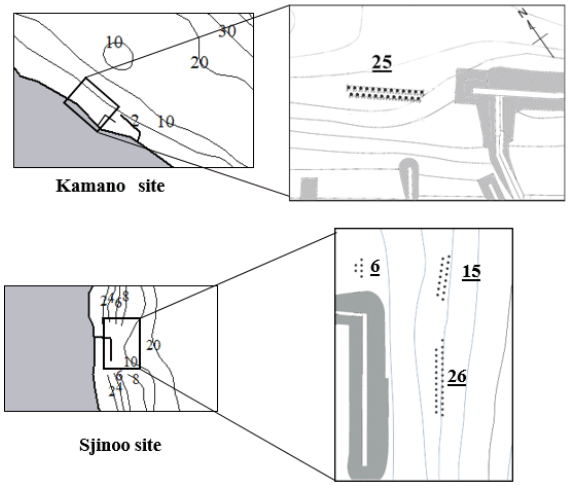

Figure 2. Locations of the Survey Sites and Reef Deployment Details
Numerical values indicate water depth (m), while underlined numbers denote the number of artificial seaweed bed reef units.

Artificial Seaweed Bed Reefs and Porous Structures

The artificial reef structures feature a two-tiered design: the lower tier functions as a stable foundation and helps to regulate local water flow, while the upper tier, referred to as the "roof," serves as a substrate for seaweed attachment and growth. The roof section is perforated with multiple holes to facilitate the transplantation of parent algae and is designed to accommodate the attachment and detachment of modular protruding components manufactured separately (Figure 3).

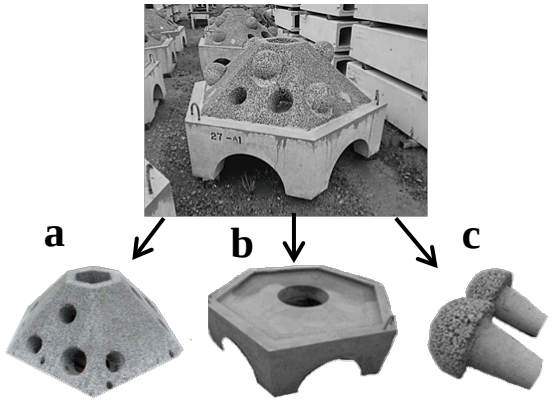

Figure 3. Structural Components of the Artificial Seaweed Bed Reef

(a) Porous roof section
(b) Concrete foundation section
(c) Porous protruding component

The roof and protruding components are constructed from porous materials, engineered to serve as a favorable substrate for the attachment of seaweeds and other marine organisms. Once deployed, the sloped roof design interacts with tidal currents to reduce silt accumulation on its surface. Additionally, the protruding components generate complex vortices that promote the settlement of seaweed spores and zoospores transported by the flow (Figure 4).

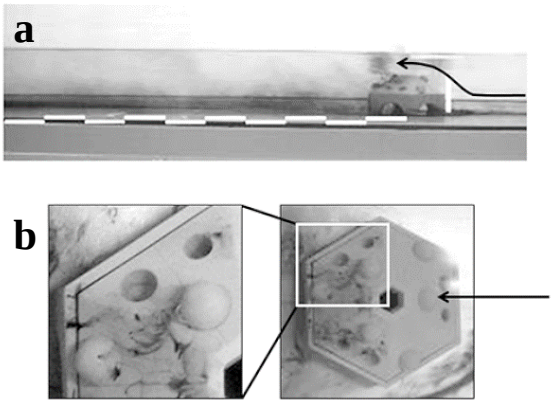

Figure 4. Flow Conditions Surrounding the Structure
(a) Side view; (b) Top view. Arrows represent the direction of water movement.

The porous substrate exhibits a void ratio of approximately 20–30%, promoting the production of prey organisms that attract fish and other marine life [10], and thus serving as a potential feeding ground for higher trophic-level organisms (Figure 5). The structure is named “Marine Mash” due to the mushroom-like appearance of its protruding components.

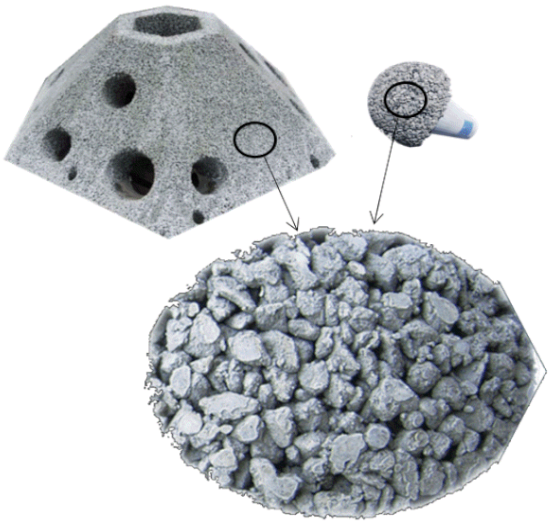

Figure 5. Porous Substrate Structure

Blocks for Sessile Organism Recruitment Experiments

Multiple sampling blocks (experimental units) were deployed on the roof section of artificial seaweed reef beds. These blocks measured either 18×18×6 cm or 30×30×6 cm (length × width × height). All attached organisms retained on a 1-mm mesh sieve were identified, and both the number of individuals and the biomass for each species were quantified.

As control units, three material types were utilized: natural stone reefs (20×20×20 cm), concrete plates (30×30×6 cm), and steel plates (30×30×2 cm). Organisms adhering to the surfaces of these control materials were measured similarly. Results were converted to values per unit volume (m
3) for annual comparisons across different substrate types.

Among the collected sessile organisms, three phyla—Mollusca, Annelida, and Arthropoda—were selected as preferred prey organisms due to their potential as food sources for fish and other marine animals. Statistical analyses were performed to examine differences in their occurrence.

Assessment of Algal Growth Conditions

Algae within a defined area (50 × 50 cm) on the artificial seaweed bed reef were harvested from their attachment base, and their dry weight was measured to estimate the standing crop per unit area (m^2). Sampling was conducted in March, corresponding to the peak period of algal growth. For comparison, algal biomass was also measured on natural stone reefs located adjacent to the artificial structures.

Assessment of Epiphytic Organism Occurrence

Epiphytic organisms residing on the surface of algal thalli attached to the artificial seaweed bed reefs were collected concurrently with algal biomass sampling. Their wet weight (g) was quantified per unit wet weight (kg) of algal thalli to evaluate the relative abundance of epiphytic organisms.

RESULTS

Occurrence of Sessile Organisms on Porous Materials

Figure 6 presents the annual variation in biomass (kg/m^3) of preferred prey organisms among the sessile communities that developed on porous substrates, in comparison with those on other materials such as stone, concrete, and steel.

DISCUSSION

Occurrence of Preferred Prey Organisms on Porous Substrates

The porous substrate exhibited significantly higher biomass of preferred prey organisms compared to other materials. An ANOVA conducted to assess differences in the mean biomass of preferred prey organisms between the experimental group (porous substrate) and the three control groups revealed a highly significant effect ($F=161$, $P<0.01$). Post hoc tests further confirmed significant differences between the porous substrate and each of the control groups ($P<0.01$). These findings strongly indicate that the porous substrate supports a substantially greater biomass of preferred prey organisms than commonly used reef materials such as natural stone, concrete, and steel.

Algal Growth Assessment

A paired t-test comparing algal biomass between the experimental reef structure "Marine Mash" and the control reef (stone-based) revealed a statistically significant difference ($t(12) = 12.475$, $P < 0.01$). The exceptionally small p-value ($P = 3.13 \times 10^{-6}$)) indicates that this observed difference was highly unlikely to have occurred by chance. These findings strongly suggest that the porous substrate incorporated into the Marine Mash reef structure effectively promotes algal growth.

Epiphytic Fauna on Algal Surfaces

A paired t-test comparing the biomass of epiphytic organisms on algae between the experimental reef structure 'Marine Mash' and the control reef (stone-based) revealed a statistically significant difference ($t(9) = 9.3$, $P < 0.01$), and the exceptionally small p-value ($P = 6.51 \times 10^{-6}$) indicates this difference was highly unlikely to have occurred by chance, strongly suggesting that the porous substrate incorporated into the Marine Mash reef structure effectively promotes the development of epiphytic fauna on algal surfaces.

CONCLUSIONS

In this study, we assessed the bio-attractive properties of a porous substrate incorporated into the seaweed bed restoration reef, Marine Mash, by examining the occurrence of preferred prey organisms, macroalgae, and epiphytic organisms as ecological indicators.

1. The results revealed that the porous substrate exhibited a significantly greater attraction of preferred prey organisms compared to conventional reef materials such as stone, concrete, and steel (ANOVA, $F = 161$, $P < 0.01$). These findings indicate that the porous substrate has strong potential as a material for improving the feeding environment for fish.
2. A statistically significant difference in algal biomass was observed between the Marine Mash reef and conventional stone reefs ($t(12) = 12.475$, $p = 3.13 \times 10^{-8}$). The extremely low p-value provides strong evidence that the porous substrate markedly enhances algal attachment and growth.
3. A significant difference in the abundance of organisms attached to the surfaces and interstices of macroalgal thalli was also detected between the experimental and control sites ($t(9) = 9.3$, $p = 6.51 \times 10^{-6}$), indicating that the porous substrate contributes to increased biodiversity and biomass of algae-associated communities.

These results provide strong evidence for the high efficacy of seaweed bed restoration techniques employing porous substrates in enhancing feeding habitats and promoting ecological diversity. The findings underscore the potential applicability and scalability of this method as a viable technology for coastal ecosystem restoration. In addition, the restoration of blue carbon ecosystems and the enhancement of carbon sequestration capacity through seaweed bed establishment are identified as key areas for future research, with significant implications for global environmental sustainability.

Future Challenges and Potential Applications

This study demonstrated that seaweed bed restoration reefs incorporating porous substrates significantly enhance the presence of preferred prey organisms, macroalgae, and epiphytic organisms. Moving forward, the following challenges and potential applications should be addressed to advance the development of this restoration approach.

First, it is necessary to verify the long-term effectiveness of the porous substrate through extended monitoring. This study's evaluations were conducted over a limited period, and the effects of biological community succession and physical degradation over time remain unclear. Additionally, to clarify the influence of seasonal variations and regional differences on the bio-attraction effect, it is essential to assess reproducibility under diverse environmental conditions.

Another challenge lies in advancing functional evaluation. For instance, assessing the extent to which biotic communities induced by porous substrates contribute to the restoration of fishery resources and carbon sequestration requires system-level analysis using ecosystem models that incorporate energy flow and material cycling.

In terms of potential applications, integrating this approach with **coastal ecosystem restoration** and **blue carbon policies** is of particular importance. Notably, this aligns well with international targets like **United Nations Sustainable Development Goals (SDGs) 14 'Life Below Water' and 13 'Climate Action'** [10], and holds promise for implementation as a nature-based solution [11–12].

The Intergovernmental Panel on Climate Change (IPCC) has recognized the carbon sequestration capacity of blue carbon ecosystems—such as seaweed beds, seagrass meadows, and mangroves—as a Nature-based Solution (NbS) contributing to greenhouse gas emission reduction [13]. Accordingly, this study's findings hold international significance as a strategic approach that simultaneously promotes coastal ecosystem restoration and climate change mitigation.

The fabrication of artificial reef materials from regional resources, including industrial by-products, demonstrates high compatibility with the local production for local consumption paradigm. This synergistic approach is anticipated to both lessen environmental burdens and engender favorable regional economic multipliers. Future efforts must encompass a thorough assessment of the scientific and societal importance of these initiatives, alongside the systematic accretion of knowledge pertinent to domestic and international policy development and environmental assessments. Additionally, actively investigating opportunities for engagement within international frameworks is a key consideration.

ACKNOWLEDGMENTS

This research has been continuously conducted with the generous cooperation of the Aji Fisheries Cooperative Association, to whom we express our sincere gratitude, and we also extend our heartfelt thanks to Professor Emeritus Tsuneo Honjo, Professor Emeritus Kuninao Tada, and Professor Kazuhiko Ichimi for their valuable advice on the environmental issues of the Seto Inland Sea; this study was supported by JST Japan, Grant Number JPMJPF2306.

SOLVING OPTIMAL RESERVOIR OPERATIONS PROBLEMS WITH A GENETIC ALGORITHM AND KEPLER OPTIMIZATION ALGORITHM

Teerapat Moonlaong[1], Rittayut Gonthong[2], Nonthaphong Phonphuak[3], Anongrit Kangrang[4] and Anujit Phumiphan[5]

[1,2,5] School of Engineering, University of Phayao, Phayao, Thailand; [3] Faculty of Engineering, Rajabhat Mahasarakham University, Mahasarakham, Thailand; [4] Faculty of Engineering, Mahasarakham University, Mahasarakham, Thailand.

ABSTRACT

Reservoir rule curves are essential for long-term operation and flood control. This study proposes an alternative approach using GA and KOA integrated with a simulation model to optimize flood control rule curves. The approach was applied to the NOR in northeastern Thailand, using two objective functions: minimizing average excess water and minimizing frequency of excess water. The efficiency of the optimized rule curves was evaluated using historical, 1,000 synthetic, and projected inflow data, focusing on water shortage and excess conditions in terms of frequency, magnitude, and duration. Results indicate that the proposed GA and KOA models outperformed existing rule curves in reducing excess water under both current and future scenarios, enhancing long-term flood management.

Keywords: Water Infrastructures, Non-Construction Reservoir Management, Rule Curves, Genetic algorithm, Kepler Optimization Algorithm.

INTRODUCTION

Many countries face challenges in managing water resources, which are essential for human well-being. These challenges are intensified by climate and land use changes [1]. Effective management requires both structural measures and non-structural tools within a suitable organizational framework [2].

Reservoir operation rule curves (RORC) offer a cost-effective, non-structural approach to optimizing reservoir management by balancing multiple, often conflicting objectives. RORC define upper and lower bounds for monthly water storage to stabilize reservoir levels, mitigate flood risks, and prevent shortages. Effective implementation ensures sufficient water supply under normal conditions, minimizes deficits during droughts, and reduces downstream impacts during floods [3-4]. However, their performance may decline over time or with changing data, necessitating periodic optimization and adjustment [5-7].

Several optimization techniques, such as dynamic programming and simulated annealing, have been applied to optimize RORC; however, they often suffer from limitations like sensitivity to initial conditions and convergence to local optima. This study explores two alternative methods—Genetic Algorithm (GA) and Kepler Optimization Algorithm (KOA)—known for their robustness in solving complex, multi-objective problems in water resource management. GA is a widely used population-based metaheuristic inspired by natural selection. It utilizes selection, crossover, and mutation operators to evolve solutions across generations, offering strong global search capabilities without requiring gradient information. Conversely, KOA is a recent physics-based algorithm grounded in Kepler's laws of planetary motion. It treats solutions as orbiting bodies influenced by gravitational pull toward the best-known solution, enabling efficient exploration and fast convergence while avoiding local optima.

This article advocates for an alternative approach integrating GA and KOA with a reservoir simulation model (RSM) to optimize flood RORC in flood control regions. The study applied the proposed models to determine the optimal flood RORC for the Nam-Oon Reservoir (NOR) in Northeastern Thailand. The search methods were guided by two objective functions: minimizing average excess water and reducing the frequency of excess water.

RESEARCH SIGNIFICANCE

This study integrates the GA and KOA into reservoir rule curve development, presenting an innovative approach to overcome limitations of conventional methods. By employing adaptive optimization for excess water management, the research enhances long-term flood mitigation. Results indicate improved reservoir performance under current and projected inflow conditions, offering a scalable and transferable framework for flood-prone regions. This approach advances reservoir operation by linking simulation models with robust optimization techniques.

METHODOLOGY

Research Area

The study was conducted in 2021–2022 at the Nam-Oon Reservoir (NOR), located in Sakon Nakhon province within Thailand's Songkham Basin (Fig. 1). NOR supports an irrigation area of 32,480 hectares, with a storage capacity of 520 million cubic meters (MCM) and an average annual inflow of 404.835 MCM. Inflow data were collected over a 28-year period (1994–2021).

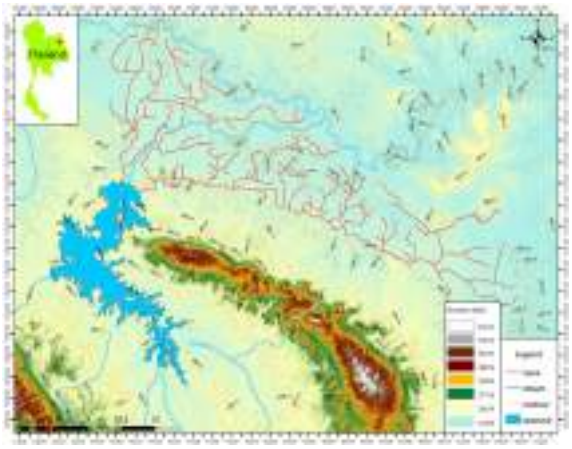

Fig. 1 The geographic location of the NOR.

Model for the Simulation of Reservoir Operation

The reservoir system was modeled using the water balance principle, incorporating hydrological data, reservoir characteristics, water demand, and related information. Available water was calculated using Equation (1), based on this principle. Monthly water release was assessed considering available resources, release requirements, operational rules, and the defined RORC (Fig. 2).

$$W_\tau = S_{\tau-1} + I_\tau + P_\tau - E_\tau \quad (1)$$

The equation delineates the computation of the water resources accessible during the month τ, while considering various influencing factors. W_τ signifies the water availability for the month τ, whereas $S_{\tau-1}$ indicates the volume of water retained at the termination of the month $\tau - 1$, which is initially established at the maximum capacity of the reservoir. The computation is derived from the influx into the reservoir (I_τ), the volume of precipitation recorded during the month (P_τ), and the average evaporation losses incurred throughout the month (E_τ).

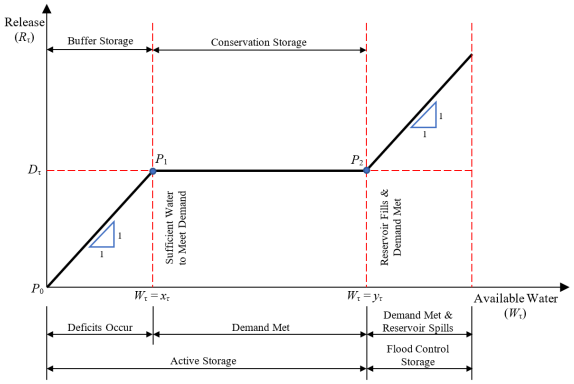

Fig. 2 Standard water allocation criteria

Subsequently, the monthly water release rate (R_τ) was determined to calculate water scarcity and excess water levels. These levels are represented by the average yearly excess water amount (the initial objective function in the search procedure) and the yearly frequency of excess water (the second objective function utilized during the search procedure), as shown in Equations (2) and (4), respectively. In these equations, x_τ refers to the lower RORC during month τ while y_τ denotes the upper RORC during month τ .

$$\text{Min } Avg_i = \left(\frac{1}{n} \sum_{v=1}^{n} Sp_v \right) \quad (2)$$

$$\text{if } R_\tau > D_\tau; \text{ Then } Sp_v = \sum_{v=1}^{n} (R_\tau - D_\tau) \quad (3)$$

$$\text{Min } Fre_i = \left(\frac{1}{n} \sum_{v=1}^{n} Sf_v \right) \quad (4)$$

In this equation, Avg_i represents the average amount of excess water per year during iteration *i*, Sp_v denotes the excess water during year *v*, where releases exceed the target demand, Fre_i is the frequency of excess water, Sf_v indicates the number of annual floods, which is the year when releases exceed the target demand, D_τ represents the monthly goal demand from the reservoir, which is determined by utilizing data from previous studies and calculating the water demand in the downstream area. The variable *i* represents the iteration number.

Genetic Algorithm (GA)

The GA, introduced by John Holland in the 1970s [8], is a population-based optimization method inspired by natural selection. It iteratively improves

candidate solutions (chromosomes) through selection, crossover, and mutation. The process begins by defining the objective function, constraints, and bounds, followed by the initialization of a random population. Each chromosome is evaluated for fitness, and the fittest individuals are selected to produce offspring via crossover and mutation. The new population replaces the previous one, and the cycle continues until convergence or stopping criteria are met. The best-performing chromosome is then selected as the optimal solution.

Kepler Optimization Algorithm (KOA)

The KOA is a physics-based metaheuristic inspired by Kepler's laws of planetary motion, used for solving complex optimization problems. It treats candidate solutions as orbiting bodies influenced by gravitational forces, with their positions updated according to Keplerian dynamics to converge toward the optimal solution. The process begins by defining the objective function, constraints, and search space, followed by initializing a population of candidate solutions with associated orbital parameters. Each solution is evaluated for fitness, and the best-performing one serves as the central gravitational focus. Positions and velocities are updated iteratively, with boundary checks and fitness evaluations performed at each step. This process continues until convergence or stopping criteria are met, and the best solution is selected as the optimal result.

GA Incorporating RSM

The GA–RSM integration begins by initializing reservoir parameters, including storage capacity, water levels, and monthly demands. A population of chromosomes, each with 24 decision variables (12 upper and 12 lower RORCs), is generated. The RSM simulates monthly releases, and objective functions—average annual excess water and its frequency—are evaluated. Genetic operations (selection, crossover, mutation) produce new generations, and the process repeats until convergence or a predefined limit is reached. The best-performing chromosome is selected as the optimal RORC. Fig. 3 illustrates the GA–RSM optimization framework.

KOA Incorporating RSM

The KOA–RSM integration begins by initializing reservoir parameters such as capacity, water levels,

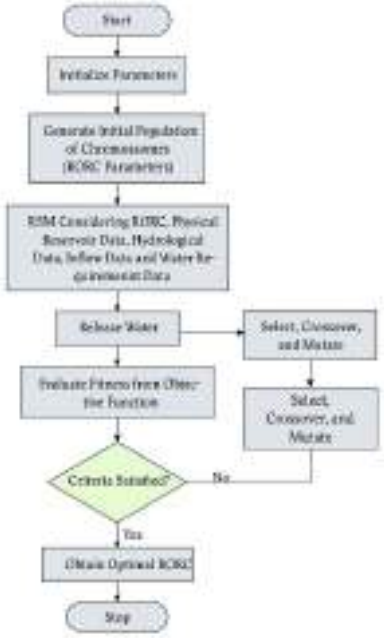

Fig. 3 GA incorporating RSM to search for optimal RORC.

and monthly demand. A population of agents, each representing 24 decision variables (monthly upper and lower RORCs), is generated. The RSM simulates monthly releases based on these RORCs, and performance is evaluated using objective functions that minimize average excess volume and frequency. Fitness scores guide updates of agent positions and velocities via Keplerian dynamics toward the best-known solution. This process iterates until convergence or a defined stopping criterion is reached. The optimal RORC is selected from the best-performing agent. Fig. 4 illustrates the KOA–RSM framework.

Assessment of the Obtained RORC

The RORCs were evaluated using GA, KOA, and RSM under various inflow scenarios. Historical data over 28 years supported the RSM, while 1,000 synthetic inflow events were generated using the HEC-4 model. HEC-4 applies statistical methods to simulate inflows from single or multiple runoff stations, estimating missing data through inter-station correlations. Synthetic inflows are based on statistical parameters—mean, standard deviation, and skewness—with a 1% adjustment to the mean. The evaluation assessed the frequency, magnitude, and duration of water surplus and shortage conditions [9].

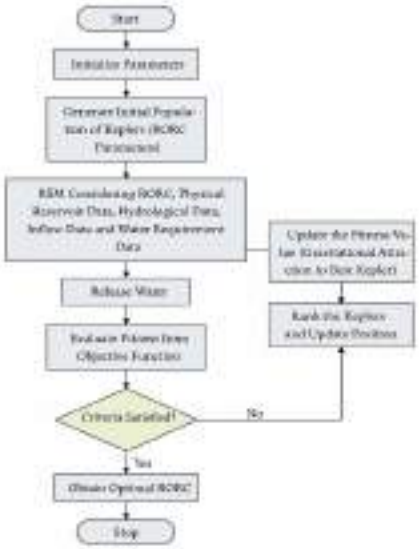

Fig. 4 KOA incorporating RSM to search for optimal RORC.

RESULTS

Optimal RORCs

Fig. 5 presents the optimal RORCs from the GA and KOA models, optimized to minimize annual excess water using historical and projected inflow data. The resulting curves (GA-Avg., KOA-Avg.) follow seasonal patterns similar to the existing RORC (RC1-Existing), with higher lower bounds from March to July and higher upper bounds from June to September, supporting increased storage. In contrast, KOA-Avg. upper RORCs are lower during October and November, enabling greater releases for improved flood control.

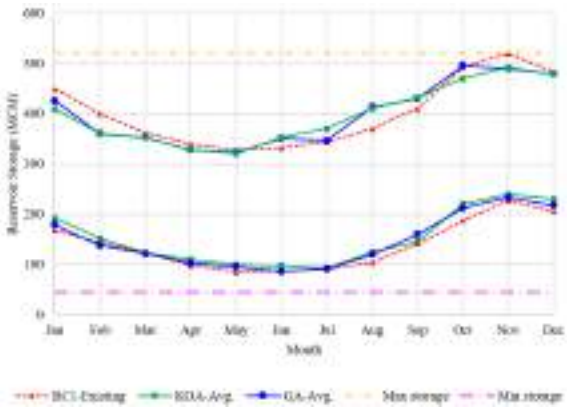

Fig. 5. Optimal RORCs for the NOR based on minimizing average excess water.

Fig. 6 presents the optimized RORCs for the NOR, derived by minimizing the frequency of excess water using historical inflow data. The optimized curves (GA-Fre., KOA-Fre.) show patterns similar to the existing RORCs. Notably, the lower RORCs from GA-Fre. and KOA-Fre. exceed the current values from January to June, while the upper RORCs are lower than the existing curve in July.

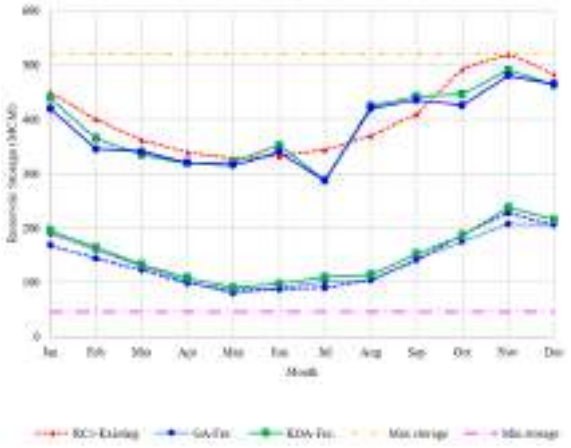

Fig. 6. Optimal RORCs for the NOR based on minimizing excess water frequency.

Efficiency of the Obtained RORCs

Table 1 summarizes the performance of optimized RORCs evaluated using 28 years of historical inflow data for the NOR. The RORC from the ABC-CA model (RC5-Avr_ABC-CA), optimized for average excess water, demonstrated the best results—showing the lowest water scarcity (0.464 times/year, 19.926 MCM/year, 1.684 years) and excess water (0.627 times/year, 85.641 MCM/year, 2.00 years). Overall, the optimized RORCs outperformed the existing rule curves in reducing both water scarcity and excess under historical conditions.

Table 2 presents the results from 1,000 synthetic inflow scenarios based on historical data for the NOR. The KOA-optimized RORCs (KOA-Fre.), aimed at minimizing average excess water, achieved the lowest levels of water scarcity (16.271 ± 7.224 MCM/year) and excess water (66.221 ± 17.001 MCM/year). In contrast, the existing RORCs showed the highest values, indicating lower effectiveness under simulated conditions.

Table 1 Excess water and water scarcity in the NOR based on 28 years of historical inflow data.

Situation	RORC	Frequency (times/year)	Volume (MCM)		Time period (year)	
			Average	Maximum	Average	Maximum

DISCUSSION

The newly derived RORCs and the existing RORCs (Figs. 6 and 7) show similar patterns, influenced by seasonal inflow and consistent hydrological conditions, consistent with previous studies [10]. The updated lower RORCs are higher than the current ones during the dry season, promoting water conservation by reducing discharge during low inflow periods. In contrast, the new upper RORCs exceed the existing curves from June to September, supporting higher storage and

reducing unnecessary releases. Conversely, from October to November, the new upper RORCs are lower, allowing increased releases to create storage buffer capacity, thereby enhancing flood management potential.

The results in Tables 1 and 2 show that the ABC-CA RORCs, optimized using historical inflow data, yielded the lowest occurrences of water scarcity and excess compared to other RORCs. This outcome aligns with previous studies [11,12], where historical data was similarly utilized in the optimization process. A comparative analysis between the proposed GA and KOA approaches and other optimization methods is essential to further validate their effectiveness.

CONCLUSIONS

This study applied the GAA and KOA, integrated with an RSM, to identify optimal RORCs using two objective functions. The resulting RORCs exhibited similar patterns due to seasonal inflow and consistent search conditions, with notable differences during the rainy season. RORCs optimized to minimize average excess water using historical inflow data proved more effective in reducing excess water events under both historical and synthetic inflow scenarios compared to other RORCs.

This study demonstrates the application of GA and KOA, integrated with a simulation model, to optimize flood control RORCs. The optimized RORCs outperformed existing curves in mitigating flood risks. These findings provide a useful reference for researchers developing flood control strategies for reservoirs in flood-prone areas.

ABSTRACT

Shelter planning following an earthquake is a critical component of disaster response and management, directly influencing the affected populations. Strategic shelter allocation must consider factors such as population density, infrastructure vulnerability, and accessibility to optimize emergency response efforts. This research introduces SELENA V7.0 (SEismic Loss EstimatioN using a logic tree Approach), an advanced open-source risk assessment tool designed to estimate potential physical damage and human losses from seismic events. Developed by NORSAR and the University of Alicante, this software has been used to enhance emergency planning through scenario-based risk analysis.

The tool examines the anticipated seismic damage in the seven provinces of Nepal resulting from a probabilistic seismic hazard assessment (PSHA)-based design earthquake with a 475-year return period, reference to a 10% probability of exceedance in 50 years. Fragility models are integrated with GIS-based spatial analysis to assess seismic risk across the provinces. The approach also supports identifying optimal shelter locations based on predicted infrastructure damage and accessibility constraints.

The study outcomes are evaluated in terms of structural damage, economic losses varying from 0 to 1 billion Euros, number of homeless populations ranging from 2,330 to 57,463, and other relevant impact parameters as discussed in the results. The findings will equip policymakers and emergency planners to develop more effective shelter strategies, ultimately improving disaster resilience by providing critical evidence demonstrating how integrated technical and policy approaches can significantly enhance disaster resilience and emergency response effectiveness in seismic regions.

Keywords: Seismic Risk Assessment, Disaster Response, Shelter, SELENA Software.

INTRODUCTION

Earthquakes are among the most devastating natural hazards, causing serious threats to life, infrastructure, and economic stability. Globally, natural disasters have resulted in over $2.97 trillion in economic losses and affected more than 4 billion individuals over the past two decades [1]. Nepal is one of the countries most affected by earthquakes due to its sensitive location in the Himalayan region. It's located at the collision boundary of the Indian and Eurasian tectonic plates, which is particularly vulnerable to seismic activity. The 2015 Gorkha earthquake, with a magnitude of 7.8, caused over 8,700 deaths and 20,000 injuries, extensive infrastructure damage, and the collapse of more than 500,000 buildings [2, 3].

In such disasters, shelter intervention becomes a critical humanitarian need. However, the effectiveness of shelter responses is often hampered by poor planning, delays in implementation, and inadequate integration with critical infrastructure [4]. Damage to road networks and bridges frequently limits access to shelters and impedes the delivery of emergency assistance [4]. This demonstrates the necessity for proactive shelter planning strategies.

International frameworks such as the Sphere Standards and the Sendai Framework provide valuable guidance for shelter response and disaster risk reduction [5, 6]. Nevertheless, these are often general and lack the integration of technical seismic risk assessment tools required for precise, context-specific planning [7, 8].

To address this gap, this study utilizes the SELENA tool, a globally adaptable, open-source software designed to model seismic risk by simulating building damage, human losses, and economic impacts [9, 10]. Through integration with QGIS tools, this tool enables spatial analysis of seismic impact, helping identify priority zones for shelter deployment. This paper applies SELENA to the Nepalese context to demonstrate a replicable, evidence-based framework for optimizing post-earthquake shelter placement. By bridging engineering-based risk modeling with humanitarian planning standards, the study contributes to more resilient and strategic emergency shelter planning in seismically active regions.

RESEARCH SIGNIFICANCE

This study uniquely combines seismic risk modeling with humanitarian shelter planning using SELENA, integrating probabilistic analysis, infrastructure accessibility, and international standards. It aids decision-makers in identifying vulnerable zones and optimizing shelter placement, thereby advancing strategic disaster preparedness and fostering more resilient post-earthquake responses in high-risk regions.

LITERATURE REVIEW

Effective disaster response requires an integrated approach combining engineering, policy, social, and humanitarian. Various international frameworks guide post-earthquake shelter planning, but challenges persist in aligning them with real-world application, especially in terms of infrastructure limitations and technical risk assessments.

The minimum standards in the humanitarian response 'Sphere handbook' provide widely accepted humanitarian guidelines for shelter design, including a minimum living space of 3.5 m^2 and 4.5-5.5 m^2 in cold areas. fire safety distances of 3 m between shelters, and site planning of 30 m of fire breaks in each 300 m of built-up area of the camp. However, they often lack structural engineering detail, especially regarding seismic resilience [5]. In parallel, the Sendai Framework for Disaster Risk Reduction (2015–2030) highlights infrastructure resilience, risk governance, and stakeholder coordination but is primarily policy-oriented and lacks prescriptive engineering content [6].

From the engineering point of view, Eurocode 8 (EN 1998-1) offers a rigorous standard for designing earthquake-resistant structures across Europe. It includes parameters such as base shear calculations, ductility considerations, and provisions for masonry structures. Nonetheless, its application in low-resource or humanitarian contexts is limited due to complexity and high implementation costs.

Rohwerder has also highlighted numerous operational gaps in post-disaster shelter response, including delays due to land ownership disputes, lack of integration with water/sanitation networks, and poor coordination between civil engineers and humanitarian agencies [7, 8]. The experience in Nepal after the 2015 earthquake revealed that many displaced populations depended on non-engineered shelters, with limited oversight on structural safety [1, 3].

Seismic risk assessment involves various methods and concepts, which are visually summarized in Figure 1. A keyword co-occurrence map was generated from 1,225 Scopus-indexed publications (2016–2020; data collected 30 April 2025), highlighting “risk assessment” as the central and most interconnected term. It is closely linked with key concepts such as “seismic risk,” “fragility curves,” and “structural dynamics,” reflecting the multidisciplinary integration of engineering, hazard modeling, and decision-making. Emerging terms like “machine learning” and “uncertainty” indicate a growing trend toward data-driven, probabilistic approaches, while keywords such as “building codes,” “retrofit,” and “masonry buildings” emphasize practical considerations in infrastructure resilience and seismic preparedness.

In terms of simulation tools used to estimate expected losses, SELENA was not commonly featured, as few studies have adopted this approach. In this study, SELENA V7.0 has been applied as a robust tool for simulating structural damage, human losses, and economic losses under seismic conditions [9, 10]. Unlike tools such as HAZUS, which focus on the U.S. context, SELENA is globally adaptable and uses fragility curves and capacity spectrum methods to estimate damage at varying levels of intensity [9, 10]. Its integration with QGIS further supports spatial analysis for decision-making in emergency response.

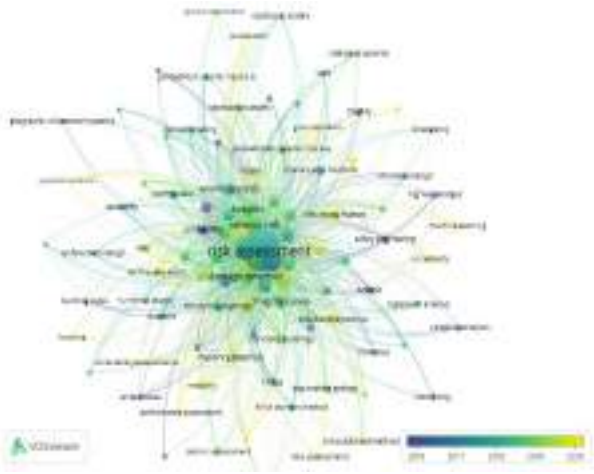

Figure 1 Keyword mapping of seismic risk from Scopus (Source: authors)

Global Applications of SELENA in Seismic Risk Modeling

Despite SELENA's potential, its real-world adoption has been concentrated in focused case studies across different countries:

Algeria: Bellalem et al. [11] applied SELENA to model seismic scenarios in downtown Blida, one of Algeria’s most seismically active regions. By simulating four distinct earthquake scenarios, they observed mean damage ratios (MDRs) reaching up to 90% in some cadastral zones. Their study also highlighted the sensitivity of this tool to ground motion prediction equations (GMPEs) and performance point methods such as MADRS and I-

DCM, helping authorities identify high-risk areas and prioritize retrofitting initiatives.

China: Yang et al. [13] estimate building damage and casualties in primary schools across 15 counties impacted by the 2008 Wenchuan earthquake using the software. The study demonstrated SELENA's capability to function effectively in data-limited environments. By combining probabilistic models with CSM, they visualized varying damage distributions and identified vulnerabilities among unreinforced structures. it further validated these outcomes by comparing damage levels across regions, reinforcing the model's consistency.

Norway: In Oslo, Lindholm et al. [10] conducted seismic risk modeling using SELENA, supported by detailed data on subsoil properties and building typologies. The study simulated a hypothetical M6.5 earthquake on the Oslofjord fault and successfully mapped potential economic and structural losses. The comprehensive urban dataset enhanced the precision of the outputs, underscoring its utility for seismic risk planning in well-documented European urban centers.

Romania: In Bucharest, Armaș et al. [14] used SELENA to simulate the impacts of a repeat of the 1977 Vrancea earthquake. They applied the Improved Displacement Coefficient Method (I-DCM) to assess 358 buildings, identifying unreinforced masonry structures with timber floors as highly vulnerable. Spatial maps produced using GIS and SELENA revealed MDRs up to 32%, alongside significant economic loss projections. These outputs informed both emergency preparedness and long-term urban mitigation strategies.

Nepal: Two studies demonstrate SELENA's critical role in assessing seismic risk in Nepal. Vineetha and Rajaram [15] modeled a hypothetical Mw 8.4 earthquake across eleven districts, estimating losses up to €0.6 million and predicting 1,000–5,000 casualties. They identified brick masonry structures as most vulnerable and earthquake magnitude as the dominant factor influencing loss. Additionally, this study expands upon that analysis by using SELENA to assess the Koshi Province, revealing more than 57,000 displaced individuals, over 900 fully collapsed buildings, and economic losses exceeding €158 million. Spatial analysis in QGIS further enabled shelter planning based on infrastructure proximity and accessibility challenges.

Global Modeling: On a broader scale, Martins and Silva [16] developed a global database that can used as inputs for SELENA of fragility and vulnerability functions for over 500 building classes as part of the GEM Foundation's risk assessment initiatives. Their work demonstrated SELENA's value in standardizing global seismic risk modeling and guiding multi-regional disaster resilience planning.

These diverse applications confirm SELENA's strength as a globally adaptable and analytically rigorous tool. Whether in data-rich urban centers or resource-constrained regions, the software has proven effective for estimating structural vulnerability, casualty potential, and economic losses—supporting both local interventions and international disaster risk reduction strategies.

RESEARCH METHODOLOGY

This study integrates seismic risk modeling with spatial analysis to support evidence-based post-earthquake shelter planning in Nepal. The methodological framework is built on the application of the SELENA V7.0 simulation software and QGIS for geospatial analysis. The process involves three main stages: risk modeling, spatial mapping, and shelter site evaluation.

Seismic Risk Simulation Using SELENA

SELENA was employed to simulate the probabilistic analysis effect of earthquake across Nepal's seven provinces, as shown in Table 1. It estimates building damage, casualties, and economic losses by combining datasets such as: Seismic hazard inputs, derived from regional ground motion prediction models [2], Building typologies, obtained from OpenQuake and categorized by structural characteristics [16], Population distribution, adjusted for occupancy patterns at different times of day [1], Soil classification, using Vs30 values to account for local amplification effects [2,15], Fragility and capacity curves, sourced from global vulnerability databases and GEM standards [17]. SELENA applies the Capacity Spectrum Method (CSM) and a logic tree structure to capture uncertainties in both hazard and vulnerability models [9,10]. Outputs include damage states (none, slight, moderate, extensive, and complete), projected displacement, casualties, and direct economic losses per region.

Spatial Analysis with QGIS

Simulation results were imported into QGIS 3.36.2, a Geographic Information System (GIS) used to visualize and analyze the spatial distribution of earthquake impacts [18]. QGIS enabled layering of SELENA outputs to identify high-risk areas and infrastructure exposure. Key visualized data included: Damage distribution and collapse densities by administrative region, Estimates of displaced populations and homeless individuals [16], economic losses and number of injuries. This mapping was essential in guiding shelter planning by highlighting accessible and high-need zones.

Table 1 Administrative regions level 1 of Nepal include 7 Geounits and relevant building stock (source: The Open Quake Platform, accessed: 01 April 2025)

Region Name	ID	Number of buildings
Bagmati	NP-P3	1108047
Gandaki	NP-P4	1064718
Karnali	NP-P6	948806
Lumbini	NP-P5	634612
Madhesh	NP-P2	612709
Province 1 (Koshi)	NP-P1	266458
Sudur Paschim	NP-P7	630546

Shelter Site Identification and Planning (Figure 8)

The city of Biratnagar, located in Koshi Province as shown in the Figure 2, was selected for focused shelter planning due to its high vulnerability as shown by SELENA outputs. Satellite imagery and infrastructure data were used to locate and assess potential shelter areas. Each site was evaluated using the Sphere Standards [5], which define A minimum area of 3.5 m² per person for emergency shelters, Spatial layout guidelines for safety, privacy, and WASH services, Accessibility standards for emergency response logistics and mobility. Shelter capacity was calculated using available free area based on critical infrastructure evaluation in the area, and WASH needs (water points and latrines) were estimated based on Sphere's recommended ratios. Road access and redundancy were also considered to ensure rapid deployment and minimize logistical delays [4,6].

Figure 2 Administrative region level 1 of Nepal with seven provinces (Source: authors)

RESULTS

This study used SELENA V7.0 and QGIS 3.36.2 to assess seismic vulnerability and improve guidance of shelter planning and response across Nepal's provinces. The results highlight spatial patterns of seismic hazard, building damage, human casualties, economic losses, and shelter requirements. The findings support evidence-based decisions for disaster preparedness and emergency response.

Seismic Hazard and Ground Motion

Figure 3 illustrates the spatial distribution of amplified peak ground acceleration (PGA) across Nepal. Probabilistic analysis revealed that provinces like Bagmati and Gandaki exhibit the highest PGA values (0.375 – 0.6 g), indicating elevated seismic hazard levels. This distribution aligns with Nepal's tectonic profile and underscores the need for targeted risk reduction in central regions.

Figure 3 Spatial distribution of amplified PGA values across Nepal's provinces from probabilistic seismic analysis (Source: authors).

Structural Damage Assessment

SELENA simulations estimated building damage across 20 taxonomies and four damage states. Damage maps (Figure 4) show that Koshi, Bagmati, and Madhesh provinces consistently report the highest counts of slightly, moderately, extensively, and completely damaged buildings. For example, complete collapse in Koshi exceeded 900 buildings, pointing to urgent retrofitting needs. In contrast, western provinces like Karnali and Sudur Paschim reported minimal damage, reflecting lower hazard exposure and/or smaller urban footprints.

Figure 4 Number of completely damaged buildings for all taxonomies (Source: authors).

Displacement and Homelessness

As shown in Figure 5, the projected number of homeless individuals is highest in Koshi and Madhesh, with up to 57,000 people will be displaced.

Figure 5 Spatial distribution of the homeless population across provinces of Nepal (Source: authors).

driven by building collapse and dense urban populations. These figures directly inform emergency shelter planning and resource allocation, especially in provinces with limited resilience capacity.

Casualty and Injury Estimates

The number of injury projections across three critical time frames, which are 2:00 A.M., 10:00 A.M., and 5:00 P.M. Nighttime injuries are significantly higher due to residential occupancy. At 2:00 A.M., Koshi, Madhesh, and Bagmati show the greatest injury rates. During the daytime, injuries are less due to population dispersion, but the ratio rises again by 5:00 P.M. as people return home. These trends emphasize the importance of time-sensitive emergency medical planning. Figures 6 illustrate the highest peak hour of injuries at midnight.

Figure 6 Total number of injuries at 2:00 A.M (Source: authors)

Economic Loss Estimates

The direct economic losses were estimated using a probabilistic methodology that incorporates damage probabilities, structural typologies, and spatially distributed exposure. The total economic loss was calculated using this formula from the tool's manual [10]:

$$L_{eco} = C_r \times \Sigma_{i=1}^{N_{OT}} \ \Sigma_{j=1}^{N_{BT}} \ \Sigma_{K=1}^{N_{DS}} \times A_{i,j} \times P_{j,k} \times C_{i,j,k} \qquad (1)$$

Where:

N_{OT} - Number of occupancy types,

N_{BT} - Number of building typologies,

N_{DS} - Number of damage states ds,

Cr - Regional cost multiplier (currently set to 1.0, but it can have different values for each geographical unit in order to take into account the geographic cost variations),

$A_{i,j}$ - Built area of the model building type j in the occupancy type i (in m^2)

$P_{j,k}$ - Damage probability of a structural damage k (slight, moderate, extensive, or complete) or model building type j,

$C_{i,j,k}$ - Cost of repair or replacement (per m^2) in the provided input currency of structural damage k for occupancy type i and model building type j (provided by input files elossi.txt).

Figure 7 presents estimated direct economic losses per province. Koshi Province shows the highest losses, between €140 million and €158 million, followed by Madhesh and Bagmati. In contrast, Karnali and Sudur Paschim reflect lower financial impacts (under €21 million), corresponding to smaller urban exposure. These disparities stress the need for region-specific investment in mitigation and response capacity.

Figure 7 Estimated economic losses by province from seismic events (in Euros) (Source: authors).

OPERATIONALIZING SHELTER PLANNING IN SEISMIC EMERGENCY SCENARIOS

Effective shelter planning and response in seismic regions requires deep knowledge of the international frameworks, such as the Sendai Framework, Eurocode 8, and Sphere Standards. In the practical field, locally adapted strategies. While these frameworks promote resilience, risk reduction, and community engagement, their implementation often faces barriers in resource-constrained settings. This

research demonstrates that integrating advanced seismic risk tools like SELENA with context-specific data enables a multi-dimensional understanding of infrastructure vulnerability and access, essential for emergency shelter planning.

This study applied its findings to a real-world example in Biratnagar, the urban center most affected in Koshi Province. The evaluation of post-earthquake emergency response capacity was conducted by generating a 200-meter resolution map using satellite imagery from Google Earth as shown in Figure 8. This map served as the foundation for evaluating the spatial distribution of critical infrastructure and available open spaces, thereby identifying suitable locations for the deployment of emergency shelters. The analysis yielded three potential shelter areas, designated A1, A2, and A3, with respective areas of 80,404 m², 42,800 m², and 37,140 m², respectively. Furthermore, the analysis identified six critical infrastructure buildings, including hotels, the Morang campus, Sagarmatha Secondary School, the Ganesh Temple, and other schools. In the event of a seismic

occurrence, critical infrastructures may be mobilized if they have been designed to resist such events and to provide seismic resilience for the surrounding population. The following map illustrates the locations in question.

Figure 8 plan of proposed shelter area based on critical infrastructure in Biratnagar, Koshi Province (Source: authors).

Emergency plan for Biratnagar:

An emergency WASH and shelter plan for the three designated areas in Biratnagar was developed based on Sphere Standards, which recommend a minimum of 3.5 m² per person and include 3 m spacing requirements between shelters to ensure safety and privacy. In an emergency camp, each shelter with a 3-meter buffer on all sides requires approximately 54 m². By using this living area for shelter, Area A1 with 80,404 m² can host 1,488 shelters for 7,440 people as the shelter can host one household of 5 family members. Area A2 with 42,800 m² can support 829 shelters for 4,145 people, and Area A3 of 37,140 m² can accommodate 719 shelters for 3,595 people. Corresponding water point and latrine needs were also calculated using Sphere ratios—1 water point per 250 people and 1 latrine per 20 people. Water points must be accessible within 500 meters of all shelters, and latrines should include gender-sensitive and accessible options. The table below summarizes the shelter capacity and WASH requirements for each area. Table 2 summarizes the emergency plan can done in the three identified sites.

Table 2 The summary of emergency WASH and Shelters needed based on the area.

Area	Total Area (m²)	Shelters	People Capacity	Water Points	latrines
A1	80,404	1,488	7,790	30	372
A2	42,800	829	4,145	17	207
A3	37,140	719	3,595	15	180

Prototype shelter design:

Drawing on the author's field experience in emergency shelter programs, particularly with the IOM Shelter and Non-Food Items sector, a practical and scalable prototype shelter is proposed for post-earthquake housing in the selected area. In line with Sphere Association [5], guidelines and humanitarian shelter standards, the design features a 3 × 6 meter structure intended to accommodate a family of five members. The material proposed for the shelter is wood as a primary material due to its environmental sustainability, recyclability, and proven seismic resilience. Wood's flexibility allows the structure to absorb shock during seismic events, making it especially suitable for disaster-prone regions, while its lightweight and simple structure supports rapid assembly, relocation, and long-term usability, aligning with sustainable construction principles that emphasize locally sourced, low-impact materials [17]. This design balances immediate emergency needs with principles of environmental responsibility and structural safety, supporting both short-term humanitarian assistance and long-term recovery efforts as it can be easily upgraded. Figures 9 and 10 illustrate the prototype's plan and longitudinal section.

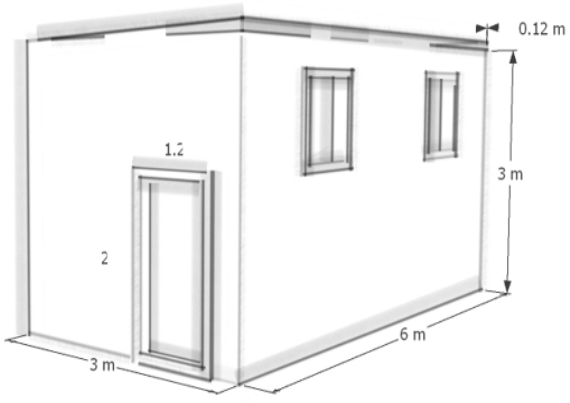

Figure 9 Shelter prototype (Source: authors).

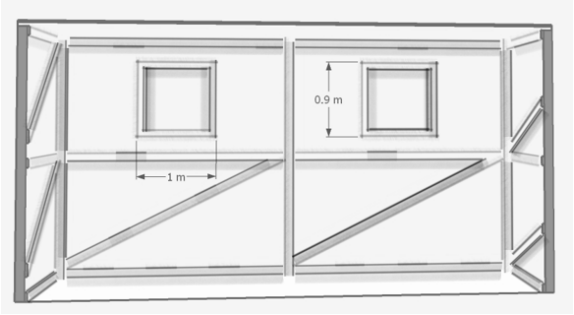

Figure 10 Shelter prototype longitudinal section (Source: authors).

DISCUSSION

This study aimed to evaluate post-disaster shelter response sustainability and infrastructure resilience interventions in earthquake zones, with a particular emphasis on the civil engineering, technology, and policy-making functions. with simulation tools and case studies, a complex interaction of technical, organizational, and contextual factors shapes disaster preparedness, response, and recovery. The findings confirm that while global disaster risk reduction frameworks—such as the Sendai Framework, Eurocode 8, and the Sphere Standards—provide valuable guidance, gaps remain in operationalizing these standards within resource-constrained, high-risk settings. Eurocode 8 emphasizes structural safety but lacks social context; the Sphere Standards focus on dignity and access but fall short on seismic resilience; and FEMA's models offer technical depth yet are difficult to apply outside well-resourced environments. These limitations highlight the need for a multidisciplinary approach that blends structural engineering principles, humanitarian needs, and geospatial risk analysis.

Using the SELENA simulation platform and QGIS visualization tools, the study presented a probabilistic assessment of seismic risk across Nepal. The results showed clear regional disparities in hazard exposure, structural vulnerability, and expected damage. Provinces such as Koshi, Bagmati, and Madhesh consistently demonstrated the highest levels of damage, displacement, and economic loss, particularly under nighttime scenarios when residential occupancy peaks. These findings underscore the value of temporal and spatial vulnerability analysis in guiding time-sensitive emergency planning and targeted retrofitting.

The simulation also revealed an east-to-west gradient in seismic intensity and building collapse, closely aligned with tectonic fault zones and population densities. Economic loss estimates further emphasized this regional variation, with Koshi alone expected to incur up to €158 million in direct damages. These high-risk areas demand not only technical upgrades and engineering interventions but also robust planning strategies that account for infrastructure access, road network redundancy, and service delivery.

A real-world application of the study's findings in Biratnagar demonstrated how simulation outputs can directly inform emergency shelter planning. By identifying open spaces, calculating capacity under Sphere Standards, and evaluating access to critical infrastructure, the study proposed a shelter strategy that is both context-sensitive and scalable. The shelter prototype—based on sustainable materials and seismic resilience—offers an adaptable solution that balances emergency needs with long-term recovery goals.

Ultimately, the study affirms that technical capacity exists to model and address seismic risk comprehensively. However, effective implementation requires greater institutional coordination, investment in local capacity, and mainstreaming of disaster-resilient design into planning systems. Integrating data-driven tools like SELENA into local policy and engineering practice can bridge the gap between analysis and action—ensuring safer, more sustainable shelter responses in future seismic emergencies.

CONCLUSION

The research assesses seismic risk and shelter planning in Nepal by utilizing tools like SELENA V7.0 and GIS-based spatial analysis. It is focused on simulating earthquake impacts on 7 provinces of Nepal, zones like Koshi, Bagmati, and Madhesh, which are approximated to experience the highest number of damages. For instance, Koshi is single-handedly anticipated to experience economic loss of up to €158 million and leave over 57,000 individuals homeless due to the building collapse. Three potential shelter sites in Biratnagar that would accommodate approximately 7,440 people were also identified in the research, based on Sphere Standards for shelter and WASH planning. These findings emphasize the variation in vulnerability across regions and demand mitigation at the local level, resilient infrastructure retrofits, and data-driven emergency planning in order to foster resilience and community recovery. These findings can support policymakers in making evidence-based decisions for prioritizing shelter allocation, refining urban emergency plans, and investing in region-specific seismic risk mitigation strategies.

Future Directions

Building Future research should expand on these findings by applying advanced seismic assessment methods, such as deterministic analysis and SELENA–MATLAB integration, to improve accuracy and validate the research findings.

Incorporating site-specific ground response analysis, as emphasized by Labar et al. [19], will enhance shelter prototype reliability in varied soil conditions. Strengthening transportation networks and leveraging GIS, drones, and real-time monitoring can improve emergency access and coordination, particularly in low-resource areas. Culturally informed shelter designs and aftershock performance testing will further ensure relevance and resilience. Finally, multi-disciplinary collaboration and institutionalized planning are essential for building communities that can withstand and recover from seismic events.

RECOVERY OF METALLIC IRON FROM ILMENITE BY THE PROCESS OF MECHANOCHEMICAL TREATMENT, ACID LEACHING AND ELECTRODEPOSION

Takaaki Wajima[1]

[1]Graduatee School of Engineering, Chiba University, Japan

ABSTRACT

In recent years, space development has become more active and plans have been made to construct a base for space development on the Moon. However, approximately 1 million dollars may be required to transport 1 kg of material from the earth to the Moon, and there is a need to develop some necessary materials from resources on the Moon. Lunar sand and regolith are abundant on the surface of the moon and contain ilmenite ($FeTiO_3$), including iron. Smelting of ilmenite on Earth is a direct reduction method or sulfuric acid method, but these methods require energy at high temperatures and pressures. In this study, we attempted to recover metallic iron from ilmenite using a novel process consisting of a mechanochemical treatment, acid leaching, and electrodeposition. Mechanochemical treatment is a low-energy process that accelerates changes in the crystal structure and chemical reactions by mechanical energy such as friction and impact forces on the sample, which are likely to work well in a lunar environment. Ilmenite can be converted into soluble salts by mechanochemical treatment with sodium hydroxide, and ferric ions can be extracted into a hydrogen chloride solution. Metallic iron can be recovered using electrodeposition.

Keywords: Ilmenite, Metallic Iron, Mechanochemical treatment, Acid leaching, Electrodeposition

INTRODUCTION

In recent years, space development has become more active and plans have been made to construct a base for space development on the Moon. With the space industry currently booming, space development is rapidly advancing around the world, and the "Artemis Project," which aims to send a manned mission to Mars and is led by NASA and major countries such as Japan, Canada, Australia, and the European Union, plans to construct a lunar base by 2030 to serve as a base for manned activities. However, if the building materials to be used for the lunar base are transported by rocket from the earth, it will cost a huge amount of money (1.2 million dollars/kg) [1]; therefore, it is necessary to develop new building materials using resources that exist on the moon based on the in situ resource utilization (ISRU) concept of local procurement of useful extraterrestrial materials on extraterrestrial celestial bodies [2, 3]. Therefore, attempts have been made to produce construction materials from lunar resources [4-6].

Iron (Fe) is a transition element with atomic number 26 and is a metallic element. Iron is an important material in modern architectural and civil engineering structures and is used in a wide variety of applications because of its strength, durability, and workability. Iron is produced from iron ore, coal, and limestone, which are biogenic in origin and do not exist in the moon. Therefore, we focused on the ilmenite ($FeTiO_3$) contained in regolith, which is abundant on the Moon as an iron resource. The smelting of ilmenite on Earth can be achieved by the direct reduction method or sulfuric acid method, but these methods require energy at high temperatures and pressures, as well as reducing agents and chemicals that are difficult to obtain on the Moon. Therefore, we attempted to recover iron from ilmenite by mechanochemical treatment with sodium hydroxide dissolved in a hydrogen chloride solution to be deposited by electrodeposition, which is considered to be available on the lunar surface. Mechanochemical treatment causes changes in the crystal structure and the promotion of chemical reactions in the sample by mechanical energy, such as frictional and impact forces [7].

The objective of this study was to convert iron into soluble alkali salts by the mechanochemical reaction of ilmenite, a poorly soluble mineral, with sodium hydroxide and to dissolve it in hydrochloric acid to obtain a solution in which iron can be electrolytically deposited.

RESEARCH SIGNIFICANCE

This study was based on cost considerations for the future development of the lunar base using resources on the Moon, for local production on the Moon, in order to minimize the resources that need to be transported from Earth. For this purpose, in this study, we attempted to recover iron metal from simulated lunar rock sand using a process consisting of mechanochemical treatment, acid leaching, and

electrodeposition, which are known to be able to be performed on the lunar surface, although these tests must be performed under earth conditions.

EXPERIMENTAL METHODS

Mechanochemical Treatment

Ilmenite (Sigma-Aldrich) (0.8 g) and sodium hydroxide (NaOH) (Wako) (0.1 - 0.8 g) were placed in a zircon container (80 mL) together with zircon grinding balls (10 mm diameter, 25 pieces) so that the ilmenite, sodium hydroxide, and grinding balls occupied 1/3 of the container in that order. The mechanochemical treatment was performed at a rotational speed of 200–600 rpm and treatment time of 0–180 min. After the mechanochemical treatment, the grinding balls were placed in a tea strainer, the sample powder was sieved, and the sample in the container was collected by scraping it off with a spatula.

After mechanochemical treatment with sodium hydroxide containing 0.2 g, samples were added to 1.0 mol/L hydrochloric acid (20 mL) in a 50 mL centrifuged tube, and the tube was shaken for 2 h. After shaking, centrifugation was performed, the supernatant solution was filtered, the pH of the filtrate was measured using a pH meter (LAQUA F-72, HORIBA), and the concentrations of Fe and Ti in the filtrate were determined using atomic absorption spectrometry (AAnalyst 200, Perkin Elmer). After the determination, the dissolved amount was calculated using Equation (1).

$$E = \frac{C \bullet V}{M \bullet m} \qquad (1)$$

where E: dissolved amount (mmol/g), C: metal concentration (mg/L), V: solution volume (L), M: atomic weight (mg/mmol), m: sample weight (g). The mineral phases of the prepared samples and residues were determined by powder X-ray diffraction (XRD) (D8 ADVANCE, Bruker AXS).

As a comparison sample for solubility, a mechanochemically treated sample of ilmenite (0.8 g) alone and a sample of ilmenite (0.8 g) and sodium hydroxide (0.2 g) well mixed in a mortar were prepared.

Acid Leaching and Electrodeposition

The amount of metal dissolved in hydrochloric acid in mechanochemically treated ilmenite was examined during the acid leaching stage. For the treated samples, a mixture of ilmenite (0.8 g) and sodium hydroxide (0.2 g) was treated using a planetary ball mill at a rotation speed of 600 rpm for 120 min.

The sample (0.1 - 1.0 g) was placed in 0 - 1.0 mol/L hydrochloric acid (10 mL) in a 50 mL centrifuge tube and shaken for 2 h. After shaking, the tube was centrifuged and the supernatant was filtered through a membrane filter. The pH of the filtrate was measured, the concentrations of Fe and Ti in the filtrate were determined using an atomic absorption spectrometer, and the dissolved amount was calculated using Equation (1). The mineral phases of the prepared samples and residues after acid leaching were determined by XRD.

The leachate after acid leaching of mechanochemically treated ilmenite (0.2 g) with 1 mol/L hydrochloric acid solution for 0.5 hour was subjected to electrodeposition to precipitate iron metal. The pH of the leachate was 0.3, and the concentrations of Fe and Ti in the leachate were 136 mg/L and 140 mg/L, respectively. The leachate (2 mL) with or without the addition of oxalic acid dihydrate ($(COOH)_2 \cdot 2H_2O$) (0.2 g) was poured into the cell (10 mm× 20 mm× 20 mm), and two carbon electrodes (Φ2 mm× 25 mm) set at 10 mm intervals were placed so that they were immersed 10 mm, and a 5 V DC current was applied to the carbon electrode to observe the electrode.

RESULTS AND DISCUSSION

The metal dissolution amounts of the samples mechanochemically treated with different amounts of NaOH are shown in Figure 1. The rotation speed was 200 rpm and the processing time was 60 min. The dissolution amounts of the raw materials were 0.080 mmol/g for iron and 0.081 mmol/g for titanium, the solubilities of the mixtures were 0.081 mmol/g for iron and 0.084 mmol/g for titanium, and those of the mechanochemically treated samples without sodium hydroxide addition were 0.089 mmol/g for iron and 0.088 mmol/g for titanium, indicating that mechanochemical treatment of ilmenite or mixing of ilmenite and sodium hydroxide alone does not make ilmenite soluble.

The solubility of Fe and Ti increased as the amount of sodium hydroxide added increased up to 0.2 g and then decreased. The maximum dissolved amounts of Fe and Ti were 1.56 mmol/g (23.7 %) and 1.63 mmol/g (24.8 %), respectively. The XRD patterns of the mechanochemically treated samples with different amounts of sodium hydroxide and the residue after dissolution in hydrochloric acid are shown in Figure 2. It should be noted that the sample with 0.8 g of sodium hydroxide could not be measured by XRD because of the large amount of unreacted sodium hydroxide, and the sample showed deliquescence. The peak of ilmenite was observed in all samples after mechanochemical treatment, and the peak of the sodium salt of ilmenite was observed in the sample with 0.2 g of sodium hydroxide added. The following reaction could have occurred via a

mechanochemical treatment:

$FeTiO_3 + 2NaOH \rightarrow Na_2FeTiO_4 + H_2O$ (2)

In the sample after dissolution in hydrochloric acid, only the ilmenite peak was observed, indicating that Na_2FeTiO_4 was dissolved in hydrochloric acid as follows:

$Na_2FeTiO_4+6HCl \rightarrow FeCl_2+TiOCl_2+2NaCl+3H_2O$ (3)

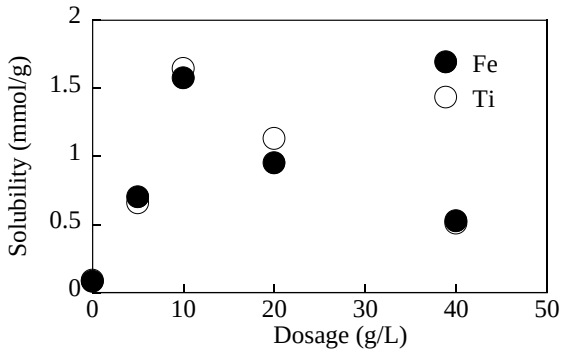

Fig.1 The metal dissolution amounts of samples mechanochemically treated with different amounts of sodium hydroxide addition

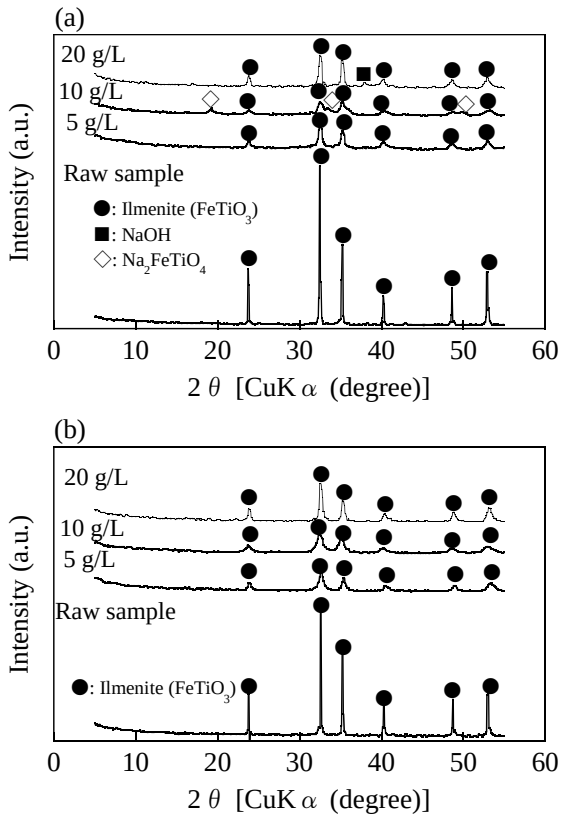

Fig.2 XRD patterns of (a) mechanochemically treated samples with different amounts of sodium hydroxide and (b) the residue after dissolution in hydrochloric acid

Figure 3 shows the amount of metal dissolved in the mechanochemically treated samples at different rotational speeds. It is noted that the amount of sodium hydroxide added was set to 0.2 g and the processing time to 60 min. The higher the rotation speed, the greater is the amount of metal dissolved. At 600 rpm, the dissolved amounts of iron and titanium were 2.09 mmol/g and 2.06 mmol/g, respectively. The XRD patterns of the mechanochemically treated samples at different rotation speeds and the residue obtained after dissolving each sample in a hydrochloric acid solution are shown in Figure 4. The peak intensity of the sodium salt in the mechanochemically treated sample increased with increasing rotation speed. After hydrochloric acid dissolution, only the ilmenite peak was observed. The reaction between ilmenite and sodium hydroxide was accelerated by increasing the rotation speed and the amount of soluble sodium salt.

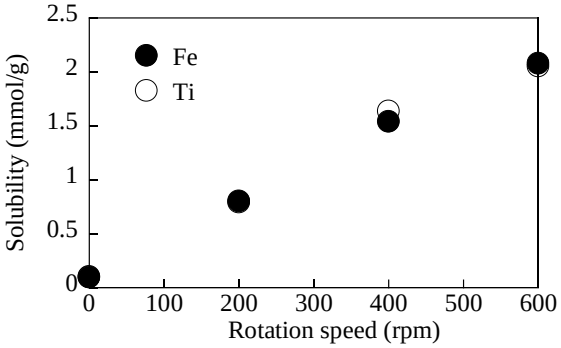

Fig.3 The amount of metal dissolved in the mechanochemically treated samples at different rotation speeds

Figure 5 shows the amount of metal dissolved by mechanochemical treatment at different treatment times. The amount of sodium hydroxide addition was 0.2 g and the rotation speed was set at 600 rpm. The amount of dissolution increased with increasing processing time, and became constant after 120 min. After120 min of processing, the dissolution amounts were 2.34 mmol/g for iron and 2.30 mmol/g for titanium. The XRD patterns of the mechanochemically treated samples and the residue after dissolution of each sample are shown in Figure 6. The sodium salt of ilmenite was formed after 30 min of treatment, and the sodium salts of iron and titanium were formed at 90 min by the following reaction:

$Na_2FeTiO_4 + 4NaOH \rightarrow Na_4FeO_3 + Na_2TiO_3 + 2H_2O$

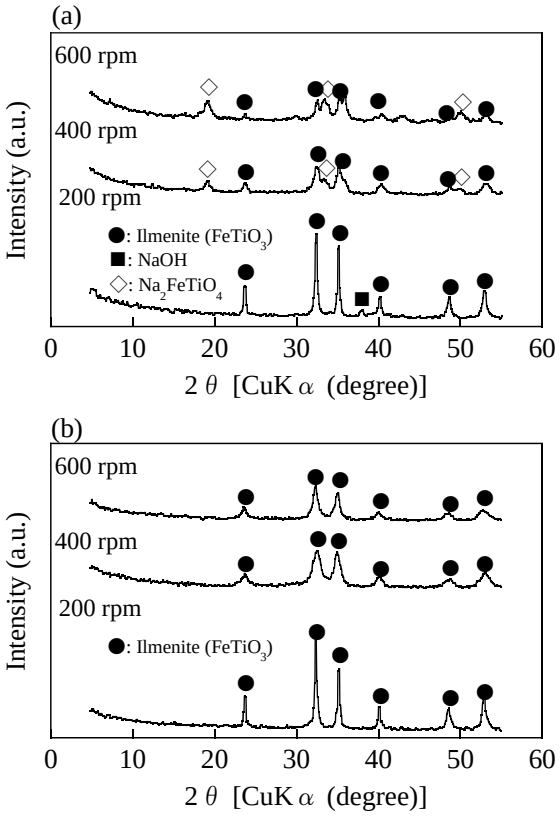

Fig.4 The XRD patterns of the mechanochemically treated samples at different rotation speeds and the residue after dissolving each sample in hydrochloric acid solution

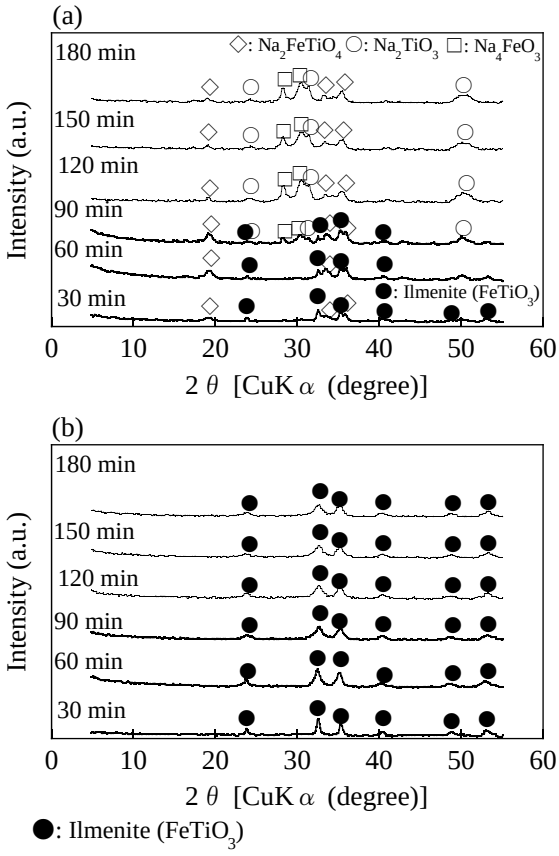

Fig.6 XRD patterns of (a) mechanochemically treated samples at different times and (b) the residue after dissolution of each sample

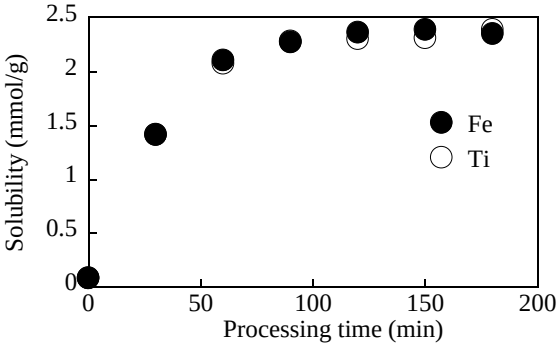

Fig.5 The amount of metal dissolved by mechanochemical treatment at different treatment times

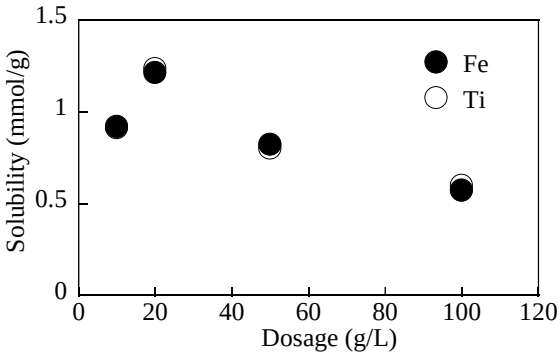

Fig.7 The amount of metal dissolved by adding the amount of sample into 1 mol/L hydrochloric acid solution

Figure 7 shows the amount of metal dissolved by adding the sample to 1 mol/L hydrochloric acid solution. It is noted that the pH of leachate remained at strong acidity (0.4 - 0.6). Iron and titanium were most soluble at an addition rate of 20 g/L, with iron and titanium at 1.21 mmol/g and 1.23 mmol/g, respectively. The amount of dissolution decreased above 50 g/L.

Figure 8 shows the amount of metal dissolved in the solution and the pH of the solution with various concentrations of hydrochloric acid. As hydrochloric acid concentration increased, the amount of dissolved metal increased from 0.1 mol/L and the pH of the solution dropped steeply with hydrochloric acid concentration of 0 - 0.1 mol/L.

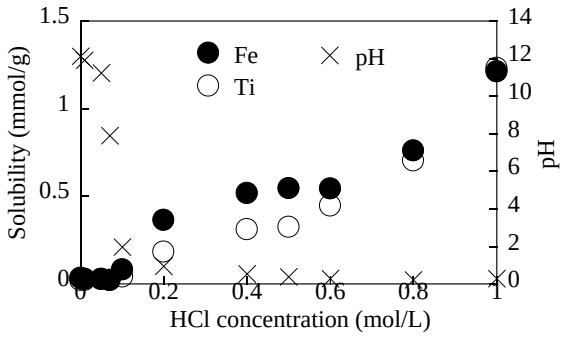

Fig.8 The amount of metal dissolved into the solution and pH of the solution with various concentration of hydrochloric acid

Figure 9 shows the amount of dissolution by leachate pH, and Figure 10 shows the XRD patterns of the residue after sample dissolution at HCl concentrations of 0, 0.2, 0.5, and 1.0 mol/L (pH of 12.24, 1.06, 0.61, and 0.24, respectively). The amount of dissolved material increased with a decrease in pH. The sodium salts of ilmenite, iron, and titanium did not dissolve at basic and neutral pH, but began to dissolve below pH 2. It is considered that the sodium salt dissolved in HCl at a lower pH, and the amount of dissolved metal increased.

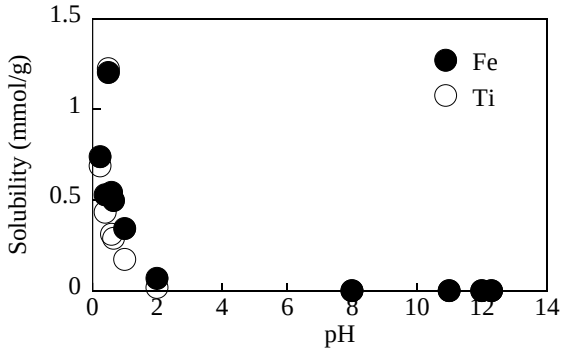

Fig.9 The amount of dissolution by pH of leachate

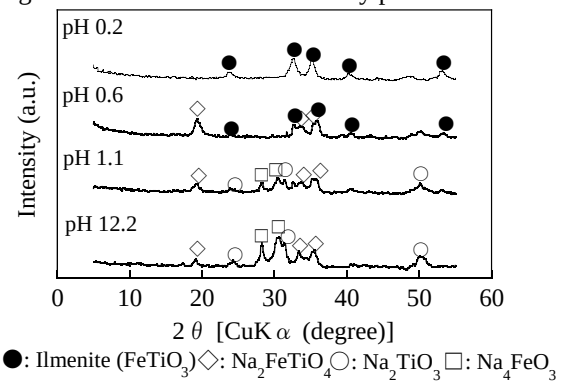

Fig.10 XRD patterns of the residue after sample dissolution at various HCl concentrations

Figure 11 shows photographs of the (a) carbon electrode before electrodeposition, (b) anode and (c) cathode after electrodeposition in leachate without oxalic acid, and (d) anode and (e) cathode after electrodeposition in leachate with oxalic acid. It should be noted that bubbles formed at both electrodes during the electrodeposition. There was no change in the original electrode for the anodes and cathodes in the leachate without oxalic acid (Fig. 11 (a), (b), (c), (e)), but precipitation was observed on the surface of the electrode at the anode in the solution with oxalic acid addition (Fig. 11 (d)). It was confirmed that the precipitate was metallic iron by energy dispersive X-ray spectroscopy (EDS). These results suggest that metallic iron can be recovered from ilmenite via mechanochemical treatment with NaOH, acid leaching, and electrodeposition.

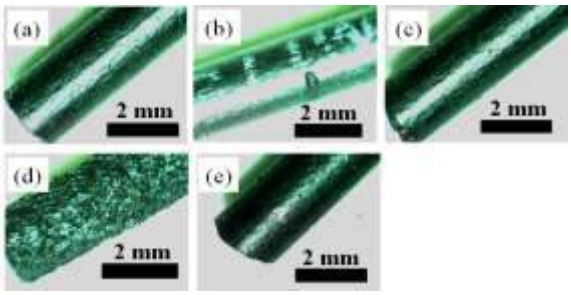

Fig.11 The photos of (a) carbon electrode before electrodeposition, (b) anode and (c) cathode after electrodeposition in leachate without oxalic acid, and (d) anode and (e) cathode after electordeposition in leachate with oxalic acid

CONCLUSIONS

In this study, we attempted to recover metallic iron from ilmenite-containing lunar regolith, abundantly present on the lunar surface, using a novel process consisting of mechanochemical treatment with sodium hydroxide, acid leaching with hydrochloric acid, and electrodeposition. Ilmenite can be converted into a soluble salt by mechanochemical treatment with sodium hydroxide at a rotation speed of 600 rpm for 120 min, and ferric ions were extracted into a hydrogen chloride solution under conditions where it became strongly acidic after dissolution. Metallic iron can be recovered via electrodeposition with the addition of oxalic acid.

ABSTRACT

The safety of railway is crucial for railway transportation. With the advancement of digital technologies and the widespread use of mobile mapping systems, LiDAR-acquired 3D point cloud data offers a robust foundation for railway inspection. This paper addresses the challenge of inspecting ballast railway facilities by proposing an integrated method that combines deep learning-based semantic segmentation with Multi-scale Geometric Feature Enhancement (MGFE), and a kind of automatic sleeper distance calculation. First, multi-scale geometric features are introduced to enhance the point cloud dataset, thereby improving the performance of model to identify various ballast railway components. Based on this strategy, we employ three deep learning algorithms: PointNet++, PointNet++ MSG, and GACNet to perform semantic segmentation on ballast railway facilities, and we compare the segmentation performance before and after MGFE. Subsequently, sleeper information extracted from the segmentation results is clustered by the DBSCAN algorithm, and a sleeper distance calculation method is developed to assess the railway's structural health. Experimental results show that dataset MGFE significantly improves segmentation performance: on high-quality point cloud dataset of ballast railway, all models achieve overall accuracies above 90% and mIoU exceeding 80%. Moreover, the DBSCAN-based method accurately measures the distance between adjacent sleepers, showing strong correlation with actual measurements.

Keywords: Ballast railway, Point cloud, Semantic segmentation, MGFE, Deep learning

INTRODUCTION

Railway safety is of paramount importance to national transportation networks, serving as both the lifeline of national economies and a crucial guarantee for public travel. Regular inspection and maintenance of railway infrastructure constitute the fundamental safeguards for ensuring the operational safety of trains [1]. Traditional railway inspection methods primarily rely on manual patrols and rudimentary mechanical equipment, which are not only time-consuming and labor-intensive but also suffer from strong subjectivity, limited detection precision, difficulties in quantitative assessment, and interference with operational lines. Particularly for ballast railway structure inspection, traditional methods struggle to efficiently acquire comprehensive and accurate health status information.

In recent years, with the rapid development of digital technologies and the widespread application of mobile mapping systems, three-dimensional point cloud data acquired by Light Detection and Ranging (LiDAR) has provided new technical means for railway facility inspection. Point cloud data captures the geometric features of complex structures with millimeter-level precision, offering advantages such as high accuracy, high density, comprehensive coverage, and non-contact acquisition. Compared with traditional two-dimensional images, three-dimensional point clouds can more completely represent the spatial structures and geometric relationships of railway facilities, bringing revolutionary changes to the field of railway inspection [2]. Mobile mapping systems combined with LiDAR technology can rapidly collect data at normal train operating speeds, significantly improving inspection efficiency while reducing impact on railway operations.

However, point cloud-based ballast railway facility inspection still faces numerous technical challenges. From the inherent characteristics of point cloud data, its irregular, unordered, and high-dimensional nature makes processing complex. Unlike structured two-dimensional image data, point clouds lack fixed structures and clear neighborhood relationships, making traditional convolutional neural networks difficult to apply directly [3]. Additionally, high-density point clouds often contain tens of millions of sampling points, resulting not only in high storage and transmission costs but also in substantial computational burden. Furthermore, field-collected point cloud data frequently introduces noise and data gaps due to factors such as equipment

vibration, uneven reflection, or partial occlusion, affecting the reliability of subsequent analyses.

Moreover, the ballast railway environment contains a variety of components, such as rails, sleepers, ballast, and fasteners, which are not only complexly arranged but also similar in geometric features, increasing the difficulty of accurate classification. Particularly, some critical small components, such as fasteners, are often not prominent in point cloud representations and are easily misclassified or completely overlooked [4]. Natural environmental factors along railway lines, such as vegetation intrusion, water accumulation, and sediment deposition, further increase the complexity of point cloud data, creating additional obstacles for accurate detection. Most importantly, the precise measurement of key geometric parameters, such as sleeper spacing, depends on high-quality semantic segmentation results, requiring algorithms to not only distinguish different components but also accurately locate their spatial positions, which places higher demands on point cloud processing technology [5].

To address these challenges, this paper proposes an integrated method for semantic segmentation of railway ballast railway components that combines deep learning-based semantic segmentation with MGFE, and develops an automatic sleeper distance calculation method. First, a multi-scale geometric feature enhancement method is proposed. By calculating and integrating geometric features such as normal vector variation rate, curvature, and verticality into the original point cloud data, the ability of segmentation models to recognize various ballast railway components is significantly improved, especially for structures with similar shapes and small volumes. Then, based on the enhanced point cloud data, the performance of three deep learning algorithms (PointNet++, PointNet++ MSG, and GACNet) in ballast railway facility segmentation is evaluated. The performance differences before and after enhancement are compared and analyzed, quantitatively validating the effectiveness of the proposed method. A DBSCAN clustering-based automatic sleeper distance calculation method is designed. This method extracts sleeper information from segmentation results, determines spatial positions through density clustering, and achieves accurate measurement of adjacent sleeper distances, providing quantitative basis for ballast railway health status assessment.

RESEARCH SIGNIFICANCE

This study proposes a deep learning-based framework that integrates multi-scale geometric feature enhancement and semantic segmentation for ballast railway inspection using LiDAR point clouds. By introducing six geometric features of different radius and evaluating three segmentation models—PointNet++, MSG, and GACNet—the method significantly improves classification accuracy for complex railway components. Furthermore, a DBSCAN-based approach enables high-precision automatic calculation of sleeper spacing, achieving a mean absolute error of only 2.65 mm. The results demonstrate the capability of extracting both semantic and geometric information from unstructured point clouds, providing accurate, efficient support for railway infrastructure analysis and maintenance planning.

METHODS

Framework

Fig. 1 illustrates the overall technical framework of our proposed method, which consists of three main modules: data preprocessing and feature enhancement, deep learning-based semantic segmentation, and automatic sleeper distance calculation.

In the first stage, we calculate six multi-scale geometric features (normal change rate, first-order moments, neighbor point count, roughness, surface change, and verticality) to enhance the point cloud dataset. These features capture local geometric characteristics crucial for distinguishing various railway components with similar appearances.

The second stage performs semantic segmentation using three deep learning architectures: PointNet++, PointNet++ MSG, and GACNet. These networks are trained to classify each point into predefined categories including Rail, Ballast, Side ballast, Sleeper, Edge sleeper, Side sleeper, Sided edge sleeper, Fastener, and Noise. We employ cross-entropy loss with weighted regularization to address class imbalance issues. Performance evaluation compares segmentation results between models trained on original and feature-enhanced point clouds.

The final stage focuses on automatic sleeper distance calculation based on segmentation results. Points classified as sleepers undergo DBSCAN clustering to identify individual sleepers. Geometric centers are calculated for each cluster, followed by sequential ordering along the railway direction. Distances between adjacent sleepers are then computed using a vector-based approach, providing quantitative measurements for structural health assessment.

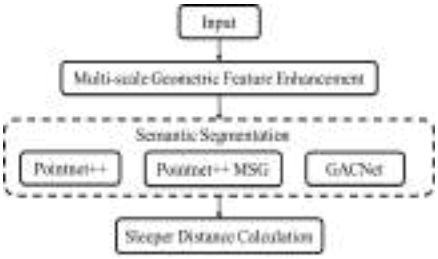

Fig. 1 Technical framework flow diagram

Multi-scale Geometric Feature Enhancement

Point cloud data of ballast railway contains complex structures with similar geometric appearances. To improve the discriminative ability of deep learning models, we propose a novel multi-scale geometric feature enhancement (MGFE) approach that integrates six geometric features into the original point cloud data. For each point, we compute features at multiple scales to capture both local details and broader structural contexts.

To the best of our knowledge, this is the first study to systematically introduce a comprehensive set of six geometric features—normal change rate, first-order moments, roughness, surface variation, verticality, and neighbor density—at multiple spatial scales for ballast railway point cloud enhancement. Unlike previous methods that either rely on raw coordinates or apply limited geometric descriptors, our MGFE framework offers a richer and more discriminative feature space, enabling improved segmentation performance especially for geometrically ambiguous and small-scale components.

For each point p_i with neighborhood $N_k(p_i)$, we perform Principal Component Analysis (PCA) to obtain eigenvalues λ_1, λ_2, λ_3 and corresponding eigenvectors $\vec{v}_1$, $\vec{v}_2$, $\vec{v}_3$ of the covariance matrix. The normal vector $\vec{n}_i$ at point p_i is defined as the eigenvector corresponding to the smallest eigenvalue: $\vec{n}_i = \vec{v}_1$, as shown in Fig.2. Based on this analysis, we calculate six geometric features:

(1) Normal Change Rate (NCR): Measures the consistency of normal vectors within a neighborhood, helping identify edge points and surface transitions:

$$\mathrm{NCR}_i = \frac{1}{|N_k(p_i)|}\sum_{p_j \in N_k(p_i)} \left(1 - \left|\vec{n}_i \cdot \vec{n}_j\right|\right) \quad (1)$$

(2) First-order Moments (FOM): Captures the spatial distribution of points relative to the tangent plane:

$$\mathrm{FOM}_i = \frac{1}{|N_k(p_i)|}\sum_{p_j \in N_k(p_i)} \left|\vec{n}_i \cdot \left(p_j - p_i\right)\right| \quad (2)$$

(3) Roughness**:** Quantifies local surface variation as the distance from each point to the best-fitting plane:

$$\mathrm{Roughness}_i = \lambda_1 \quad (3)$$

(4) Surface Variation (SV): Represents local curvature as the ratio of smallest eigenvalue to sum of all eigenvalues:

$$\mathrm{SV}_i = \frac{\lambda_1}{\lambda_1+\lambda_2+\lambda_3} \quad (4)$$

(5) Verticality: Measures alignment with the vertical direction, useful for distinguishing horizontal structures from vertical ones:

$$\mathrm{Verticality}_i = 1 - |\vec{n}_i \cdot \vec{v}_v| \quad (5)$$

Where $\vec{v}_v$ = [0, 0, 1] represents the vertical direction vector. This value approaches 0 for horizontal surfaces (like sleepers) and 1 for vertical surfaces (like rail sides).

(6) Number of Neighbor Points (NNP)**:** Provides density information within a fixed radius *r*.

To capture features at different scales, each feature using two neighborhood sizes were computed: small (r = 2cm), and large (r = 10cm). These multi-scale features are concatenated with the original coordinates to form the enhanced feature vector.

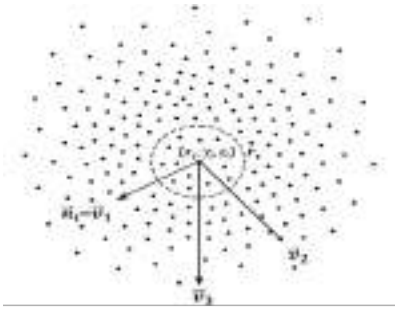

Fig. 2 How to feature calculation method of point cloud

Deep Learning Semantic Segmentation

Building upon the enhanced point cloud data, three deep learning networks were implemented for semantic segmentation: PointNet++, PointNet++ MSG, and GACNet.

PointNet++ [6]

PointNet++ processes point clouds hierarchically through four key steps: sampling representative points, grouping neighboring points, extracting local features using shared MLPs, and propagating features back to all original points. This hierarchical approach enables PointNet++ to capture geometric details at different levels, essential for distinguishing various railway components. The architecture consists of four set abstraction layers followed by four feature propagation layers with a final softmax classification layer.

PointNet++ MSG [6]

PointNet++ with Multi-Scale Grouping (MSG) extends the standard PointNet++ by addressing density variations in point clouds. Its key innovation is gathering points at multiple scales using different neighborhood sizes simultaneously. Features from these scales are extracted independently and concatenated, enhancing the model's ability to capture both fine details (fasteners) and larger structures (rails, sleepers), making it suitable for complex railway environments.

GACNet [7]

Graph Attention Convolution Network (GACNet) models point clouds as graphs with attention mechanisms. Each point connects to its nearest neighbors, with learnable attention weights applied to focus on the most relevant parts of local structures. By employing multi-head attention, GACNet captures diverse aspects of point relationships, effectively modeling intricate spatial connections between railway components.

Loss function

To address class imbalance, a weighted cross-entropy loss function L was employed [8]:

$$L = -\sum_{i=1}^{N} \sum_{c=1}^{C} w_c y_{ic} \log(\hat{y}_{ic}) \quad (6)$$

where N is the number of points in the training batch, C is the total number of semantic classes, $y_{ic} \in \{0,1\}$ is the one-hot encoded ground truth label indicating whether the *i-th* point belongs to class c, $\hat{y}_{ic} \in [0,1]$ is the predicted probability that the *i-th* point belongs to class c, w_c is the weight assigned to class c.

Automatic Sleeper Distance Calculation

This section presents a systematic approach for automatic sleeper distance calculation based on the semantic segmentation results obtained from the deep learning models.

DBSCAN Clustering Algorithm

After obtaining semantic segmentation results, the points classified as sleepers are extracted for further processing. To identify individual sleepers from these clusters, we apply the Density-Based Spatial Clustering of Applications with Noise (DBSCAN) algorithm.

DBSCAN is a widely used density-based clustering method that groups nearby points into clusters based on two parameters[9]:
ε: the neighborhood radius that defines how close points must be to each other to be considered part of the same cluster, minPts: the minimum number of points required to form a dense region. This algorithm starts from a randomly selected point and expands the cluster by recursively including all points within ε-neighborhoods that meet the minPts criterion. Points in low-density regions are treated as outliers.

Unlike algorithms such as K-means, DBSCAN does not require the user to specify in advance how many clusters are present in the data. Instead, it automatically determines the number of clusters based on the spatial distribution of points. This property is particularly beneficial in our application, as the number of visible sleepers in the point cloud may vary due to occlusion, incomplete scanning, or field conditions. DBSCAN can robustly detect each sleeper as a separate cluster, even when the spacing is irregular or some parts are partially missing.

Sleeper Distance Calculation

Following the successful clustering of individual sleepers, a vector-based approach is employed to calculate the distances between adjacent sleepers. The procedure consists of the following key steps:
Geometric Center Calculation: For each identified sleeper cluster C_i, its geometric center G_i is computed as the average position of all points within the cluster.
(1) Railway Direction Determination: The principal direction of the railway track is determined through Principal Component Analysis (PCA) on the set of all sleeper centers, with the dominant eigenvector representing the line direction.
(2) Center Determination: Sleeper centers are projected onto the railway direction vector and sorted to establish their sequential ordering along the track.
(3) Distance Computation: The distance between adjacent sleepers is calculated by projecting the vector between consecutive sleeper centers onto the railway line direction vector.

Fig. 3 illustrates the DBSCAN clustering process and the subsequent distance calculation. This approach accounts for potential deviations in sleeper orientation and provides precise measurements even when sleepers are not perfectly perpendicular to the railway direction. The calculated distances serve as quantitative indicators for evaluating railway structural health.

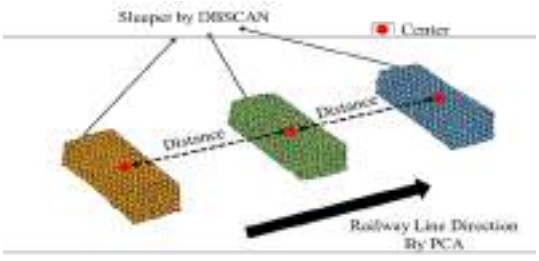

Fig. 3 DBSCAN clustering process and distance calculation

EXPERIMENTAL RESULTS

Experimental Setup

The experiments were conducted using a comprehensive point cloud dataset of ballast railway sections. The dataset was acquired using a mobile mapping system equipped with a high-precision LiDAR scanner mounted on a dedicated inspection vehicle. Data collection was performed at a speed of 30 km/h to maintain high point density while ensuring operational efficiency, as shown in Fig. 4(a).

The dataset covers approximately 500 meters of standard-gauge ballast railway track, including both straight sections and curved segments with varying radii. The total dataset contains approximately 205 million points. Points in the dataset were manually annotated into nine categories: Rail, Ballast, Side ballast, Sleeper, Edge sleeper, Side sleeper, Sided edge sleeper, Fastener, and Noise, as shown in Fig. 4(b).For validation purposes, the dataset was divided into training and testing sets with an 78.2:21.8 ratio, ensuring that both sets contained representative samples of all railway components across various track sections.

The deep learning models were implemented using the PyTorch framework (version 2.4.0) with CUDA 11.8 support. All experiments were conducted on a workstation equipped with an NVIDIA RTX 4090 GPU (24GB memory), Intel Core i9-14900K CPU, and 64GB RAM.

For model training, the following hyperparameters were utilized: Batch size: 12; Learning rate: 0.001 with cosine annealing schedule; Optimizer: Adam with $\beta_1 = 0.9$, $\beta_2 = 0.999$; Weight decay: 0.0001; Number of epochs: 200.

To address class imbalance, the weighted cross-entropy loss function described in Section 3.3.4 was employed with weights inversely proportional to class frequencies.

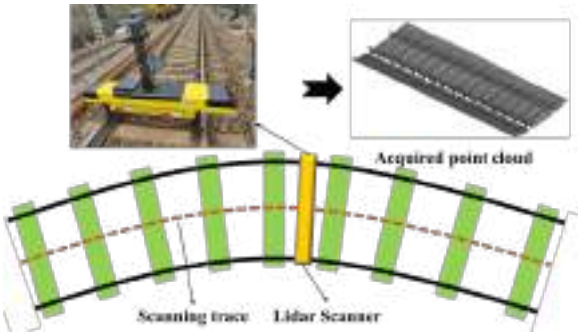
To comprehensively evaluate the performance of crack detection, we employed several standard metrics widely used in semantic segmentation tasks. For each class, true positives (TP), false positives (FP), and false negatives (FN) were calculated. Based on these values, the Intersection over Union (IoU) was computed as:

$$IoU = \frac{TP}{TP+FP+FN} \quad (7)$$

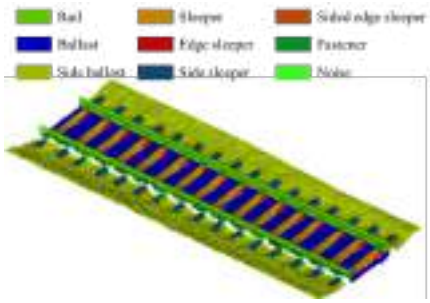
Semantic Segmentation Results

Feature Enhancement Effect Analysis

The efficacy of the proposed multi-scale geometric feature enhancement methodology was systematically evaluated through comparative analysis of segmentation performance metrics before and after feature MGFE across all three deep learning architectures: PointNet++ (PLUS), PointNet++ MSG (MSG), and GACNet.



(a) How to acquire the point cloud data



(b) Acquired point cloud data

Fig. 4 Data acquisition and dataset examples

As illustrated in Fig. 5, qualitative visual assessment between enhanced (E) and non-enhanced (NE) point cloud segmentation results demonstrates significant improvements attributable to MGFE. In the ballast railway section exemplar, all three architectures exhibit markedly enhanced segmentation fidelity with feature enrichment, particularly evident in small-scale components such as fasteners and transitional regions between distinct railway structural elements. The second exemplar further corroborates these observations, with enhanced models generating more precise segmentation boundaries.

Quantitative performance evaluation presented in Fig. 6 substantiates these qualitative assessments through intersection-over-union (IoU) metrics across

all railway component categories. For the PLUS architecture (Fig. 6(a)), geometric feature enhancement yielded substantial performance improvements across all semantic classes, with particularly pronounced enhancements observed in geometrically complex and small-scale components: fasteners (31.4% to 91.1%), sided edge sleepers (16.1% to 53.3%), and side sleepers (27.3% to 97.1%). The mean IoU metric increased substantially from 41.6% to 84.9%, representing a 43.3 percentage improvement.

Analogous performance enhancements were observed with the MSG architecture (Fig. 6(b)), which demonstrated significant IoU improvements particularly for ballast (87.6% to 97.2%) and side sleepers (56.0% to 97.4%). The overall mean IoU metric improved from 71.3% to 87.1%, constituting a 15.8 percentage point increase in segmentation accuracy.

The GACNet architecture (Fig. 6(c)) exhibited superior baseline performance compared to the other models but nevertheless benefited significantly from feature enhancement, with mean IoU increasing from 73.2% to 87.8%. Notably substantial improvements were observed in sided edge sleepers (31.1% to 63.3%) and noise point classification (61.7% to 76.1%), categories that present inherent challenges due to their spatial distribution characteristics and geometric ambiguities.

The experimental results conclusively demonstrate that the incorporation of multi-scale geometric features significantly enhances the discriminative capacity of point cloud deep learning architectures to differentiate between morphologically similar railway components, particularly in complex environments characterized by variable point densities and complex structural arrangements.

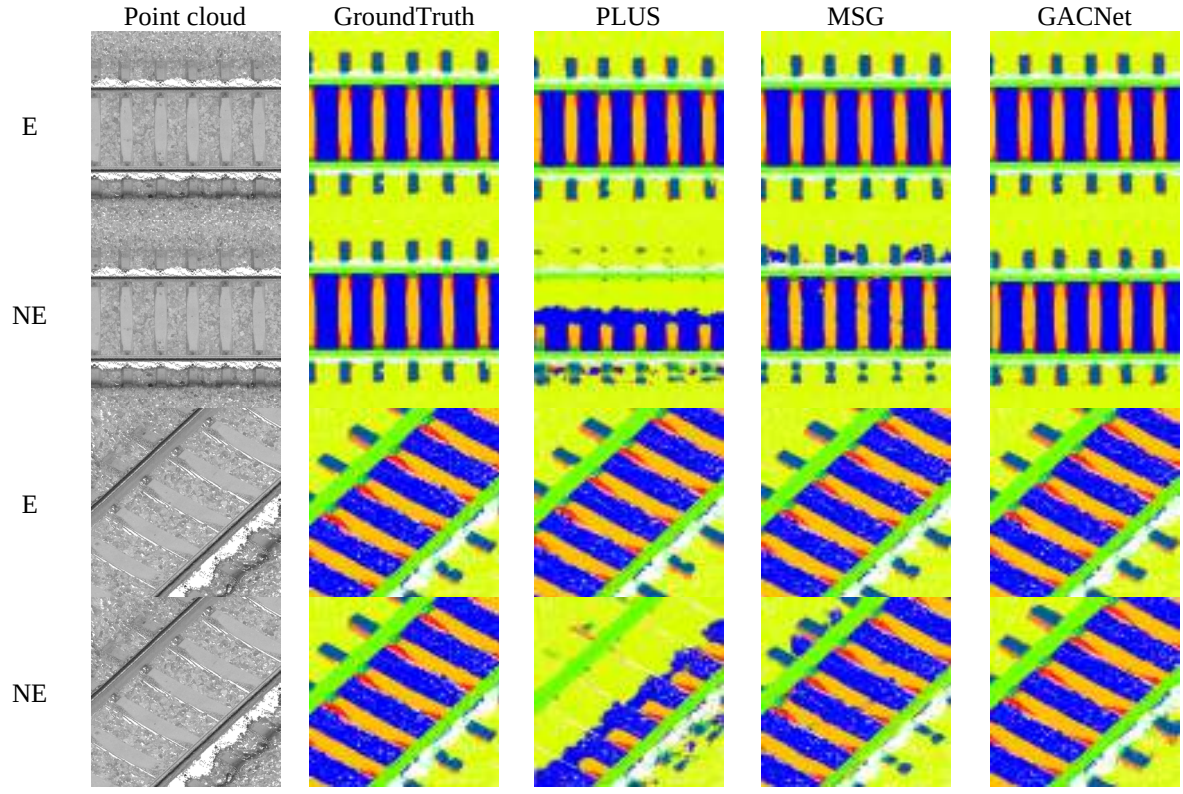


Fig. 5 Visualization of typical scene segmentation results, comparing original methods and proposed method

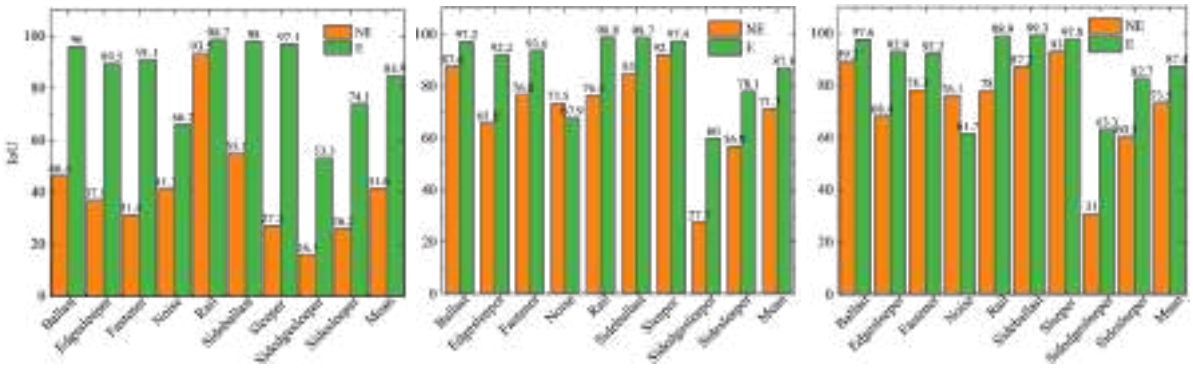

(a) PLUS (b) MSG (c) GACNet

Fig. 6 Performance comparison of three algorithms on original and enhanced point clouds

The comparative analysis presented in Fig. 7 illustrates the IoU performance metrics of the three deep learning architectures (PLUS, MSG, and GACNet) across nine railway component categories following multi-scale geometric feature enhancement.

For ballast segmentation, all three models achieve high accuracy with GACNet (97.6%) and MSG (97.2%) outperforming PLUS (96%). In edge sleeper classification, GACNet (92.9%) and MSG (92.2%) show similar performance, both surpassing PLUS (89.5%).

Side ballast classification shows GACNet (99.3%) slightly outperforming MSG (98.7%) and PLUS (98%). The most substantial performance differences appear in sided edge sleeper detection, where GACNet (63.3%) significantly outperforms MSG (60%) and PLUS (53.3%).

For standard sleepers, all models achieve excellent results with minimal variation (97.1-97.8%). In the side sleeper classification, GACNet (82.7%) demonstrates superior performance compared to MSG (78.1%) and PLUS (74.1%).

Overall, GACNet achieves the highest mean IoU (87.4%), closely followed by MSG (87.1%), with PLUS showing lower mean performance (84.9%).

The results indicate that while each model has specific strengths in certain categories, GACNet generally provides the most consistent performance across the majority of railway components.

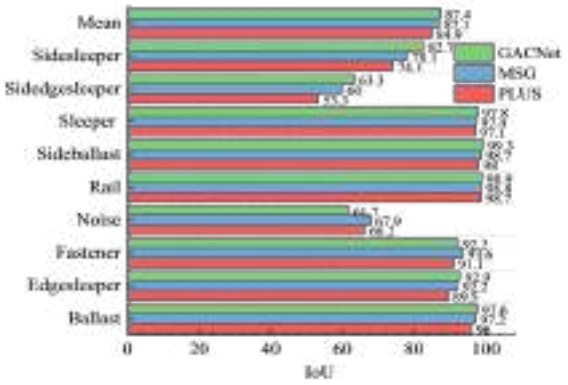

Fig. 7 Performance comparison of three algorithms

Sleeper Distance Calculation Results

Distance Measurement Accuracy

To evaluate the accuracy of the automatic distance measurement, a total of 83 sleeper distances were calculated from the point cloud data and compared with onsite measured reference values. The measured distances ranged from 0.5377 m to 0.6774 m, with an average distance of 0.6151 m.

Table 1 summarizes the statistics of these on site measured measurements. The measurements indicate that the average sleeper distance is 615.1 mm with a standard deviation of 22.5 mm, which falls within the expected range for standard ballast railway construction. The variation in distances (ranging from 577.7 mm to 677.4 mm) reflects the real-world conditions of the railway track.

Table 1 Statistics of sleeper distance measurement

Statistical Measurement	Value
Mean Distance	615.1 mm
Deviation of Distances	22.5 mm
Minimum Distance	537.7 mm
Maximum Distance	677.4 mm
Range	99.7 mm

Comparison of Deep Learning Models for Distance Calculation

Table 2 presents the error statistics for distance measurements based on segmentation results from each of the three deep learning models (with feature enhancement). In addition, Figure 7 visualizes the distance computation results, where the sleeper is marked as green, and the calculated geometric centers and distance are shown along the railway line.

Among the three models, GACNet achieved the highest accuracy in sleeper distance calculation with a mean absolute error (MAE) of 2.65 mm, which is 39.5% lower than MSG and 72.8% lower than PLUS. This significant improvement can be attributed to superior ability of GACNet to precisely segment sleeper boundaries, particularly at the interface between sleepers and ballast, which is critical for accurate clustering and center point calculation.

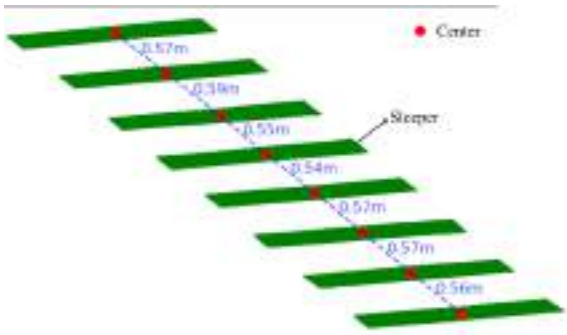

Fig. 8 Visualization of Sleeper Distance Calculation results

Table 2 Sleeper distance by point cloud

Statistical Measurement(mm)	PLUS	MSG	GACNet
MAE	9.76	4.38	2.65
RMSE	11.38	5.12	3.24
Standard Deviation	5.87	3.15	2.07
Maximum Error	18.92	10.47	6.18

CONCLUSION

This study proposed an integrated deep learning-based framework for the semantic segmentation and automatic sleeper distance measurement of ballast railway infrastructure using high-density LiDAR point cloud data.

By introducing a multi-scale geometric feature enhancement strategy, the discriminative capability of raw point clouds was significantly improved, enabling more accurate classification of morphologically similar railway components.

Comparative experiments demonstrated that MGFE led to substantial performance gains across all three evaluated models—PointNet++, PointNet++ MSG, and GACNet—with GACNet achieving the highest mean IoU of 87.8%.

Furthermore, a DBSCAN-based clustering method combined with a vector projection algorithm was developed to automatically compute sleeper distances. Experimental results on a 500-meter real-world dataset confirmed the accuracy and robustness of this approach, with GACNet-based results yielding a mean absolute error of only 2.65 mm.

These findings demonstrate the practical potential of integrating semantic segmentation with geometric measurement for efficient and accurate railway condition assessment. While the current framework performs well under ideal acquisition conditions, its dependence on high-density data and manually tuned parameters highlights opportunities for improvement.

ACKNOWLEDGMENTS

This work is supported by the National Key Research and Development Program of China (2024YFE0214600). The authors would like to express their sincere gratitude to the technical staff who assisted with the field data collection in the railway tunnel. The authors also acknowledge the computing resources provided by Hokkaido University that made the extensive computational experiments possible.

CONVERSION OF WASTE GLASS FIBER REINFORCED PLASTICS USING MOLTEN ALKALI HYDROXIDES

Nobuyuki Kawagoe[1] and Takaaki Wajima[1]

[1]Graduate School of Science and Engineering, Chiba University, Japan

ABSTRACT

Glass fiber reinforced plastics (GFRP) is a composite material of glass fiber and thermosetting resin with high strength, used in a wide range of applications, and its waste is increasing. Due to the high fire resistance, it is difficult to incinerate, and most of it is currently disposed of in landfills. This study investigated the decomposition mechanism of waste GFRP in molten alkali hydroxide to convert GFRP into geopolymer material. Waste GFRP used in this study contains 67 % resin including calcium carbonate as fillers, and glass fiber and others. The sample was immersed in the molten alkali hydroxide with NaOH : KOH = 1:0, 3:1, 1:1, 1:3 and 0:1, and heated at 200 - 600 ℃ for 1.5 h. Molten alkali hydroxide after dissolving GFRP (fused GFRP) was mixed with fly ash and water, and dried at 60 ℃ for 24 h to form geopolymer material. Regardless of types of molten alkali hydroxide, glass fiber dissolved into molten alkali hydroxide at 300 ℃. Resin components also dissolved into molten alkali hydroxide at 200 - 300 ℃ and gasification occurred over 400 ℃. The mixture of fused GFRP which was heated at 300 ℃ after adding GFRP into alkali hydroxide with NaOH: KOH = 1:1, 1:3, and 0:1 (molten hydroxide : GFRP = 4:1), fly ash, and water could be converted into a geopolymer solid with compressive strength, equivalent to half the strength of Portland cement. It was revealed that waste GFRP can be dissolved in molten alkali hydroxide, and fused GFRP can be converted into a geopolymer material by adding fly ash and water.

Keywords: GFRP, Molten alkali hydroxide, Fly ash, Geopolymer

INTRODUCTION

Glass fiber reinforced plastics (GFRP) is a composite material of glass fiber and thermosetting resin with high tensile and compressive strength, and is used in various fields, including ships, aircraft, leisure goods, and other markets. Its market size is about 47.1 billion USD in 2023 [1]. In addition, its demand is expected to continue to grow in the future. On the other hand, the amount of waste GFFP is increasing.

Due to the high fire resistance, GFRP is difficult to incinerate, and most of it is currently disposed of in landfills. In Japan, more than 90 % of waste GFRP is disposed of in landfills [2]. However, increased landfill disposal costs have caused social problems such as illegal dumping [3]. Mechanical, thermal, and chemical methods have been suggested as recycling technologies for GFRP [4,5]. For the mechanical method, GFRP was ground to powder as a raw material for new composite materials, but glass fiber's physical properties decrease, leading to low market value [6]. For the thermal method, resin components in GFRP was decomposed by heating between 300 to 500 ℃ for several hours, consuming much energy [7], and the recovered glass fiber was cheap. For the chemical method, solvents were used to break down the resin components to generate hazardous wastewater, required for further processing [8]. The glass fiber recovered by chemical method possess higher strength compared to thermal method. In addition, recovered glass fibers from thermal or chemical process are relatively inexpensive, and still face cost-related limitations in practical applications [8]. Therefore, new recycling technology for GFRP is desired.

A geopolymer (GP) is an amorphous silicate paste, generally formed by the reaction of alkali silica liquid and alumina-silica powder. In comparison with Portland cement, GP cement has higher heat and acid resistance, and the CO_2 gas generated in the manufacturing process can be reduced [9,10]. In addition, GP materials can be used as an environmental purifier, such as water purification, soil improvement, deodorant and so on, with cation exchange capacity [11,12].

In a previous study, waste GFRP is pyrolyzed with sodium hydroxide to be powdered without mechanical crushing, glass fiber is transformed into soluble alkali silicate material to be extracted into water, and resin in GFRP is decomposed to fuel gasses, such as hydrogen and methane [3]. Crushed rock sand is solubilized by fused alkali hydroxide and converted into geopolymer material with high acid resistance, and heat resistance [13–17]. From these results, the new recycling process can be suggested that resin in GFRP dissolve and gasify, glass fiber in GFRP solubilized and converted into geopolymer material.

In this study, the decomposition mechanism of waste GFRP in the molten alkali hydroxide was investigated to be converted into GP material.

RESEARCH SIGNIFICANCE

GFRP has high heat resistance and durability, but it is leading to difficulties in processing crushing or incineration to be disposed. Therefore, most of waste GFRP is disposed of in landfills. This study proposes a new potential process to convert resin and glass fiber in GFRP into fuel gases, hydrogen and methane, and geopolymer using molten alkali hydroxide, respectively. This is a zero-emission process and convert into clean energy sources, hydrogen and methane gas, and environmentally harmonious material, geopolymer material.

EXPERIMENTAL

Sample

Waste GFRP used in this study was generated in Japan. Figure 1 shows the appearance of waste GFRP sample for the experiment. It was cut into 1.5 × 1.5 × 0.2 cm.

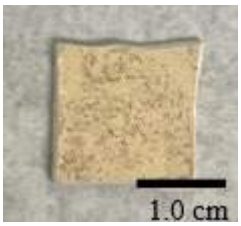

Fig.1 The appearance of waste GFRP sample

Figure 2 shows the XRD pattens of waste GFRP obtained by an X-ray diffraction apparatus (XRD) (D8 ADVANCE, Bruker AXS). The peak of calcite ($CaCO_3$) (used in GFRP as a filler) and quartz (SiO_2) were observed.

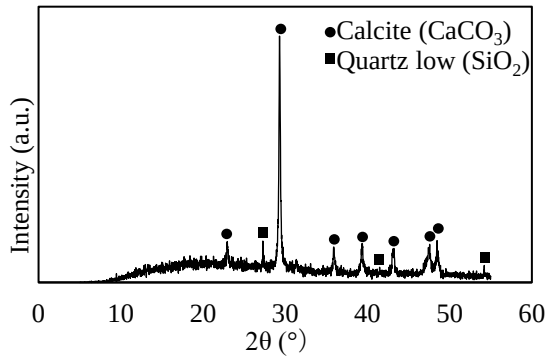

Fig. 2 XRD pattern of waste GFRP

Figure 3 shows the change in weight and heat flow concerning the temperature change of the sample by thermogravimetry/ differential thermal analyzer (TG-DTA) (STA-6000, Perkin Elmer). There are two weight decreases. The first one is 31.3 % weight reduction around 300 - 400 ℃, and heat flow indicates an endothermic reaction, causing the thermal decomposition of epoxy resin. The other one is 16.0 % reduction around 700 ℃, and heat flow indicates an endothermic reaction, causing decarbonation of calcium carbonate. From these results, it can be expected that the weight ratio of epoxy resin, calcium carbonate, and glass fiber and others in the sample is 32%, 35 %, and 33 %, respectively.

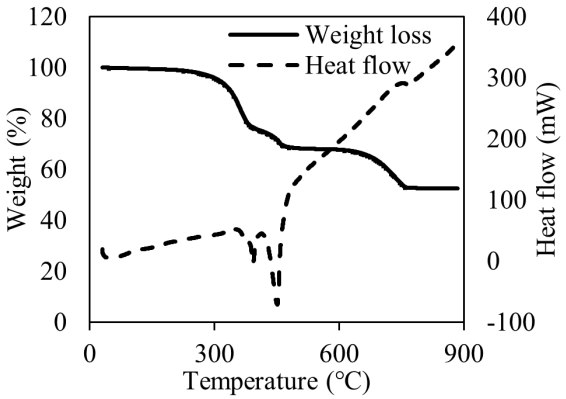

Fig. 3 TG-DTA analysis of waste GFRP

Decomposition Behavior of Waste GFRP in Molten Alkali Hydroxides

Figure 4 shows the experimental flow for the decomposition of waste GFRP in molten alkali hydroxides. The alkali hydroxide (60 g) mixing NaOH : KOH = 1:0, 3:1, 1:1, 1:3, 0:1 (weight ratio) was added into the stainless reactor (φ 4 × 25 cm), and was heated at 400 ℃ for 90 min (including 30 min of temperature rising time) with nitrogen flow (20 mL/min) to prepare alkali hydroxide with different alkali ratio. After heating and cooling to room temperature with nitrogen flow (20 mL/min). The sample (1 g) was packed in a mesh stainless bag with a stainless-steel ball (φ = 1.0 cm); the ball was placed on the sample to prevent it from floating in the molten alkali hydroxide. This bag was added to the reactor on the prepared alkali hydroxide and heated at 200 - 600 ℃ for 90 min (including 30 min of temperature rising time) in nitrogen atmosphere. During heating, generated gas through the condenser to condense condensable gases was collected by a gas pack and the component ratio in the collected gas was analyzed by a gas chromatograph (GC-8A, SHIMADZU), and the total amount of generated gas was calculated using Eq. (1).

$$S_g = V \frac{C_g}{C_T} \quad (1)$$

S_g : the amount of generated gas (mL), C_g : the concentration of specific gas measured by the

detector (ppmV), C_T: the concentration of total gas (ppmV), V: the amount of the total gas generated (mL)

After heating, the reactor was cooled to room temperature, 8 mol/L nitric acids (300 mL) were added into the reactor to dissolve the alkali hydroxide and filtrated. The weight of the residue after drying was measured, and the residual ratio was calculated using Eq. (2).

$$R = \frac{W}{W_0} \times 100 \quad (2)$$

R: the residual ratio (%), w: the weight of residue (g), w_0: the weight of GFRP sample (g)

The silicon concentration in the filtrate was measured by an inductively coupled plasma optical emission spectrometer (ICP-OES, Avio500, Perkin Elmer) to calculate silica concentration, and the dissolved glass fiber was calculated using Eq. (3).

$$S_{SiO_2} = \frac{C_{SiO_2}}{W_0} V \quad (3)$$

S_{SiO_2}: the amount of dissolved glass fiber from 1 g of GFRP (g/g), C_{SiO_2}: the measured silica concentration (g/L), V: the amount of solution (L)

The organic carbon concentration in the filtrate was measured by a total organic carbon meter (TOC-L, SHIMADZU), and the dissolved resin carbon was calculated using Eq. (4).

$$S_{toc} = \frac{C_{toc}}{W_0} V \quad (4)$$

S_{toc}: the amount of dissolved total organic carbon (TOC) from 1 g of GFRP (g/g), C_{toc}: the measured total organic carbon concentration (g/L)

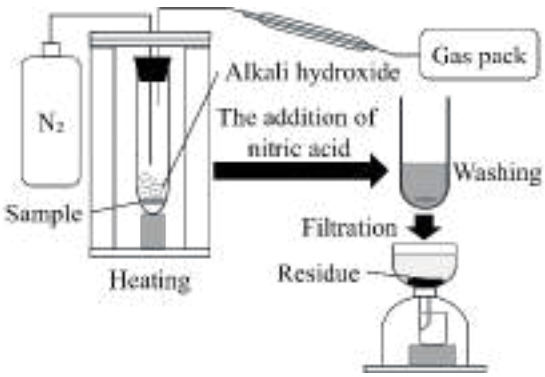

Fig. 4 Experimental flow for GFRP decomposition

As a comparison, GFRP sample without alkali hydroxide was heated at 200 - 600 ℃ for 90 min (including 30 min of temperature rising time) with nitrogen flow (20 mL/min) as pyrolysis.

The potassium hydroxide (60 g) was heated at 400 ℃ for 90 min (including 30 min of temperature rising time) in the reactor (φ 4 × 25 cm) with nitrogen flow. After heating and cooling to room temperature, the GFRP sample (1 - 25 g) was added into the reactor and heated at 300 ℃ for 90 min (including 30 min of temperature rising time) with nitrogen flow. During heating, generated gas was collected by a gas pack, and the amount of total gas was calculated, and the residual ratio, the dissolved glass fiber, and the dissolved resin carbon after heating were calculated using Eq. (1) - (4), respectively.

Geopolymer From Molten Fused GFRP

Figure 5 shows the experimental flow of preparing a geopolymer from molten fused GFRP. The alkali hydroxide mixing NaOH: KOH = 1:1, 1:3, 0:1 (weight ratio) was heated at 400 ℃ for 30 min (including 10 min of temperature rising time) in a crucible and collected from crucible after heating and cooling to room temperature. Powder sample of waste GFRP (3 g), was added to the bottom in the crucible, and the prepared alkali hydroxide (12 g) was added on the GFRP powder. The crucible was heated at 300 ℃ for 75 min (including 15 min of rising time). After heating and cooling to room temperature, the alkali hydroxide after adding waste GFRP (fused GFRP) was mixed with water and fly ash (Ⅴ types) in the ratio of 4 - 6 : 4 - 6 : 10 : 22, and this mixture was filled into a circular mold (φ 4 × 0.3 cm) and was dried in a drying oven at 60 ℃ for 24 h. The strength test of the cured product was measured using the method of previous study [17]. Chemical composition of fly ash used in this experiment is shown in Table 1.

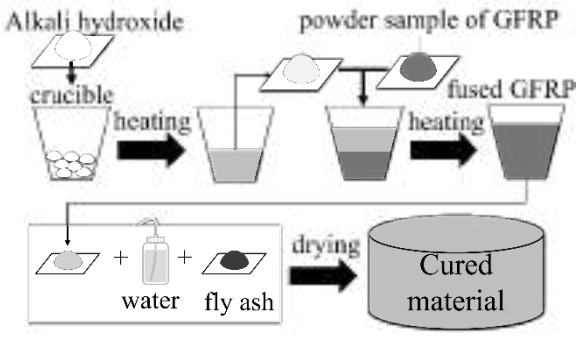

Fig 5. Experimental flow of geopolymer preparation

Table 1 Chemical composition of fly ash

Compound	Weight (%)
SiO_2	54.99
AlO_3	20.79
Fe_2O_3	10.7
CaO	5.13
TiO_2	2.37
Others	6.02

RESULTS AND DISCUSSION

Decomposition Behavior of Waste GFRP in Molten Alkali Hydroxides

Figure 6 shows the residual ratio of waste GFRP heating at 200 - 600 ℃ in molten alkali hydroxide. The residual ratio of pyrolysis is also shown in this graph. In the pyrolysis, the residual ratio was decrease at 200 - 400 ℃ and remain about 70 % at 400 - 600 ℃, meaning that only resin was decomposed to remain glass fiber and fillers. At 200 ℃, the alkali hydroxide did not melt, and the sample could not be immersed in the molten alkali hydroxide with NaOH: KOH = 1:0 and 3:1. On the other hand, alkali hydroxide with NaOH : KOH = 1:3, and 0:1 melted, the sample was immersed, and the weight ratio decreased to 40 - 60 %. At higher 300 ℃, the residual ratios were lower than 20 % regardless of type of alkali hydroxides. Furthermore, at 300 ℃, the higher the weight ratio of KOH in molten alkali hydroxide, the lower the residual ratio, suggesting that KOH has higher ability to decompose GFRP than NaOH.

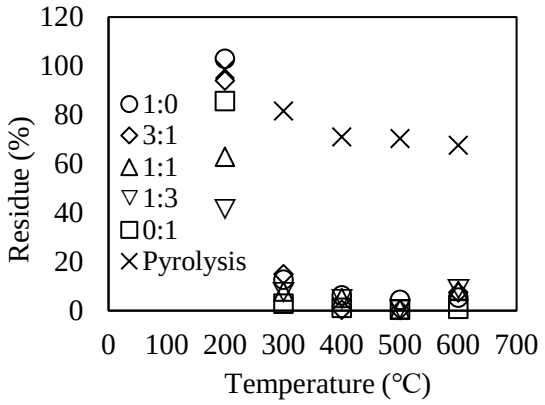

Fig. 6 Residual ratio of waste GFRP

Figure 7 shows the residue after heating with alkali hydroxide with NaOH: KOH = 1:3 at (a) 200 ℃ and (b) 300 ℃. At 200 ℃, the residue retained its original shape with a slightly smaller size compared to that before the treatment, and the fiber-like structure was observed on the surface. At 300 ℃, the residue was completely pulverized, and its weight was 0.075 g. It is noted that no Si component was included in the residue at 300 ℃, analyzed by XRF analysis, indicating that glass fiber dissolved in molten alkali hydroxide.

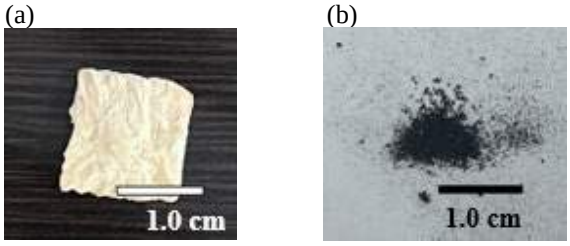

Fig.7 Appearance of residues after heating molten alkali hydroxide with NaOH : KOH = 1 : 3 at (a) 200 ℃ and (b) 300 ℃

Figure 8 shows the dissolved glass fiber in molten alkali hydroxide. Dissolved glass fiber was lower than 0.1 g/g at 200 ℃, while it was 0.2 g/g above 300 ℃, regardless of type of alkali hydroxide. This result is consistent with the trend of residue. It suggests that almost all glass fiber dissolved in molten alkali hydroxide above 300 ℃ with the following reaction;

$$SiO_2 + 2NaOH \rightarrow Na_2SiO_3 + H_2O \quad (5)$$

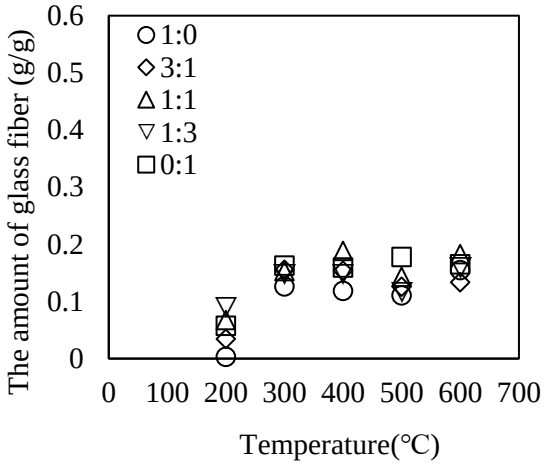

Fig. 8 The amount of dissolved glass fiber in molten alkali hydroxide

Figure 9 shows the dissolved resin carbon in molten alkali hydroxide. The dissolved resin was larger in alkali hydroxide with the higher KOH ratio. The dissolved resin carbon increased from 200 to 300 ℃ and decreased above 300 ℃. The dissolved resin carbon at 300 ℃ in alkali hydroxide with NaOH: KOH = 1 : 1, 1 : 3, and 0 : 1 were about 0.3 g/g, indicating that almost resin in GFRP dissolved in molten alkali hydroxide. It suggests that the large amount of resin component dissolved at 300 ℃.

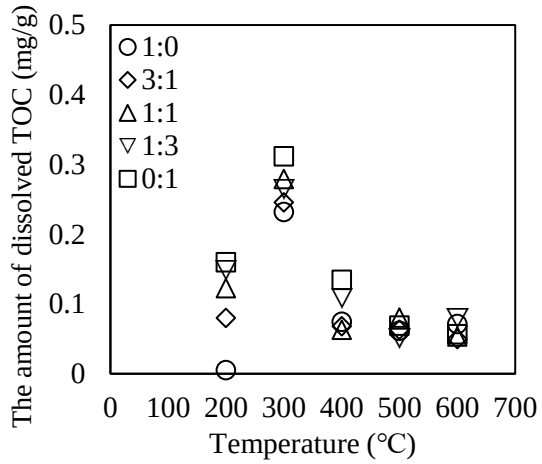

Fig. 9 The amount of dissolved resin carbon

Figure 10 shows the generated amount of gases (H_2, CH_4). It is noted that CO and CO_2 did not detect in gas phase, but carbonate ion was detected in molten alkali after dissolving in distilled water. Molten alkali hydroxide may dissolve CO and CO_2, preventing them from emitting in the gas phase. The gas amounts of H_2 and CH_4 increased significantly above 400 ℃, meaning that the resin gasified above 400 ℃. The amount CH_4 gas was larger in alkali hydroxide with the higher KOH ratio.

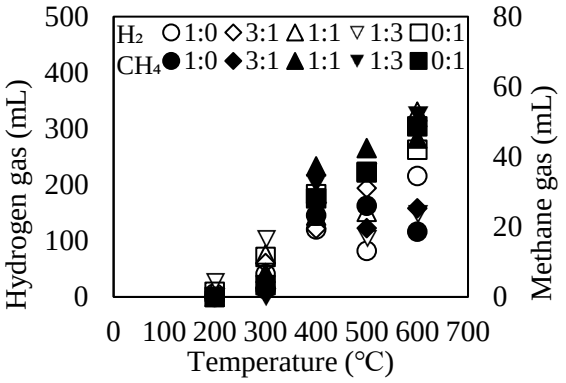

Fig. 10 The amount of generated gas (H_2, CH_4)

From the results of Fig. 9 and Fig. 10, for the decomposition behavior of resin in GFRP; it was assumed that the resin is dissolved at 300 ℃, while the resin is gasified above 400 ℃.

Sample addition dependence of decomposition behavior of waste GFRP in molten alkali hydroxides

Figure 11 shows the residual ratio of waste GFRP heating at 300 ℃ in molten potassium hydroxide with different addition of GFRP. The residual ratio was constant when the amount of waste GFRP addition was 0.1 - 0.35 g/g, and increased when the amount of waste GFRP addition was more than 0.35 g/g addition. This result implies that molten potassium hydroxide could dissolve 80 % of the GFRP up to 0.33 g/g.

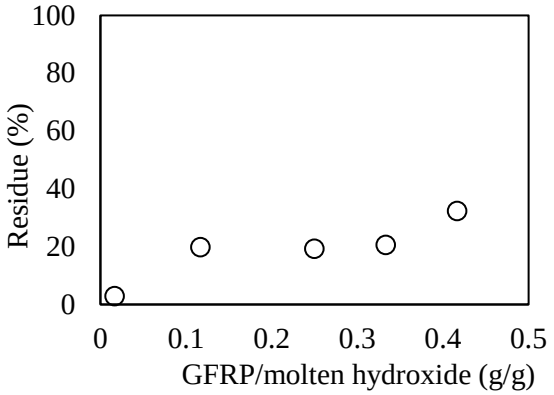

Fig. 11 The residual ratio of waste GFRP in KOH at 300 ℃

Figure 12 shows the dissolved glass fiber and resin in molten potassium hydroxide. The dissolved resin was almost constant (0.02 - 0.42 g/g) while the dissolved glass fiber was almost constant (0.02 - 0.25 g/g) and decreased above 0.33 g. These results imply that whole glass fiber can be dissolved up to GFRP/molten hydroxide = 0.25 g/g while the resin was dissolved up to 0.5 g/g.

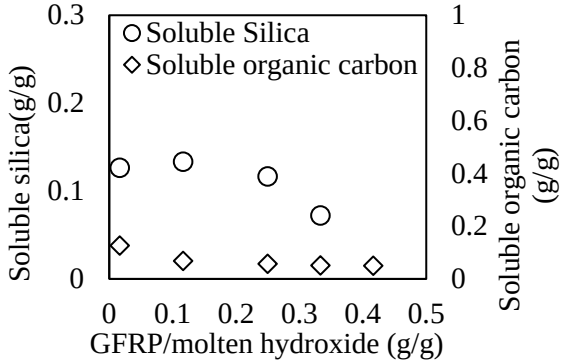

Fig. 12 The amount of dissolved glass fiber and resin components in KOH at 300 ℃

From the results of Fig. 12 and Fig. 13, it is suggested that GFRP can be processed up to 0.25 g/g in KOH at 300 ℃.

Geopolymer From Fused GFRP

Table 2 shows the compressive strength of the solids prepared on various mixing conditions. The solid didn't harden using more than 6 g of water. The solid of fused GFRP : water : fly ash = 3 : 2 : 8 was obtained the hardest product. The compressive strength of solid using 4 g of water was lower than

that of 5 g of water. It suggests that an excessive amount of water leads to being solidified incompletely. As the amount of fly ash added increased using 4 g of water, the compressive strength initially increased, and decreased above 18 g of fly ash addition.

Table 2 The compressive strength of the obtained solid

Water [g]	Fly ash [g]	Strength [N]
4	10	18
4	12	58
4	14	77
4	16	150
4	18	21
4	20	-
5	10	×
5	12	×
5	14	×
5	16	34
5	18	51
5	20	27

×: broke during demolding, -: not performed

Figure 13 shows the appearance of the hardest solid (fused GFRP: water : fly ash = 3 : 2 : 8). The surface of it was smooth. It is noted that the gray powder on the surface is thought to be the fly ash that was insufficiently mixed.

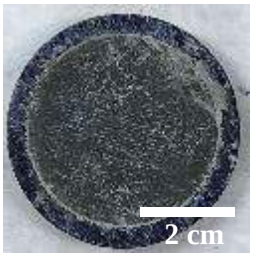

Fig. 13 The appearance of the hardest solid

Table 3 The compressive strength of the solid

NaOH : KOH	1:1	1:3	0:1	Cement
Strength [N]	113	204	104	550

Table 3 shows the compressive strength of the solids with different NaOH : KOH ratio with the compressive strength of Portland cement as a comparison. The solids were prepared from the mixture of fused GFRP : water : fly ash = 3 : 2 : 8, based on the results shown in Table 2. The solid of NaOH : KOH = 1 : 3 was obtained the hardest product, and its compressing strength was approximately half as high as that of Portland cement.

HAZARD MANAGEMENT

Sodium hydroxide and potassium hydroxide are highly corrosive, especially at elevated temperatures, and careful selection of experimental apparatus is required. In this study, stainless steel vessels were used as reaction containers. Since molten alkali hydroxides pose significant health risks, experiments were conducted with caution while wearing gloves, safety goggles, and lab coats. In addition, due to their strong hygroscopicity, alkali hydroxides were stored in a sealed and dry condition and opened only immediately before use.

CONCLUTION

In this study, the decomposition behavior of resin in molten alkali hydroxide and the feasibility of converting the fused GFRP after processing GFRP into geopolymer cement were investigated. The results showed that both the resin and glass fiber in GFRP dissolved in molten alkali hydroxide above 300 °C. The dissolved resin was converted into gases such as hydrogen and methane above 400 °C. GFRP could be processed up to 0.25 g/g in molten potassium hydroxide at 300 °C. After treatment, adding water and fly ash to the fused GFRP yielded a solid product. The solid of fused GFRP (NaOH : KOH = 1 : 3) : water :fly ash = 3 : 2 : 8 was the hardest product. It was 204 N, corresponding to 37 % of Portland cement, when the geopolymer was synthesized from a fused GFRP with NaOH : KOH = 1:3.

This method enables treatment at a relatively lower temperature (300 °C) and shorter reaction time than that of conventional thermal decomposition methods, which typically operate at around 500 °C for several hours. Therefore, a significant reduction in energy consumption can be expected.

The typical landfill disposal costs for a controlled landfill in Japan is approximately 100,000 yen per ton (2024). In this study, it was demonstrated that one ton of potassium hydroxide can process approximately one-fourth by weight of GFRP. The market price of industrial-grade potassium hydroxide in Japan is around 250,000 yen per ton (2025), meaning that the chemical cost alone is more than 10 times higher than that of landfill disposal. To enhance the economic feasibility of the alkali-based treatment process, it is essential to optimize the reaction conditions to reduce reagent consumption and to increase the added value of byproducts such as geopolymer materials.

POLICY IMPACT EVALUATION ON LAND PRICE: A CASE STUDY OF THE LOCATION OPTIMIZATION PLAN IN HACHIOJI USING PROPENSITY SCORE MATCHING

Kaichen He [1], Toru Nagahara [1] and Shinya Inazumi [1]

[1] Shibaura Institute of Technology, Japan

ABSTRACT

This study employs propensity score matching methodology to quantitatively assess the effects of Japan's Location Optimization Plan (hereafter LOP) on residential land price dynamics, with explicit consideration of disaster risk factors. While previous research has examined urban planning policies and land-use regulations as primary determinants of land price fluctuations, the interaction between disaster risk and policy intervention on land values remains under-explored. Land price stability is crucial for disaster risk management and urban policy since it ensures fair property values and fair investment, also affects urban planning and construct of infrastructure. This research addresses this gap by analyzing the causal effects of policy implementation using statistical matching techniques. Data from Hachioji City, where the LOP has been continuously implemented for over a decade, are compared to other densely populated areas within Tokyo Prefecture. Through the application of both nearest neighbor matching and kernel matching techniques, the analysis effectively isolates policy effects from confounding variables. As result, changing of the land prices in Hachioji City decreased by 6,911.11 JPY/m² compared to other areas in Tokyo. This study validates the effectiveness of propensity score matching for rigorous policy evaluation and provides empirical insights for future urban planning and disaster risk management strategies.

Keywords: Location Optimization Plan, Hachioji city, Land price dynamics, Disaster risk assessment, Propensity score matching

INTRODUCTION

In recent years, Japan has experienced escalating geotechnical disaster risks due to intensifying climate change and heightened seismic activity. The increasing frequency of landslides and liquefaction phenomena triggered by extreme precipitation and earthquakes has resulted in severe human and economic losses. This situation underscores the urgent need for policy frameworks that can effectively assess and mitigate disaster risks.

Previous studies, such as those by Sakamoto [1] and Daniel et al. [2], have demonstrated that disaster risk significantly influences land prices and may cause substantial property value depreciation. However, comprehensive analytical models incorporating both disaster risk factors and urban planning policies into land price analysis remain limited. Additionally, increased population density and inappropriate land use patterns in high-risk areas are exacerbating disaster impact severity, issues that remain systematically underexplored.

Compounding these challenges, empirical evidence from Nomura Real Estate [3] indicates that public awareness of disaster risk remains insufficient, despite the high probability of major seismic events directly affecting the Tokyo metropolitan area. In response to this context, the authors' preliminary research employed hedonic pricing methodology to model land prices in the Tokyo Bay area during 2022-2023, revealing growing market sensitivity to geotechnical risk impacts on property values. However, the influence of disaster risk perception and LOP implementation on land price dynamics remains inadequately characterized.

The LOP represents a national urban policy initiative in Japan designed to promote compact and sustainable urban development. Although the policy framework theoretically excludes high-risk areas such as landslide-prone zones from designated residential promotion areas, it lacks enforceable legal authority. Moreover, designating new residential zones outside existing urban planning frameworks often entails substantial infrastructure investments and logistical challenges.

This study examines the effectiveness of the LOP in stabilizing land prices while accounting for disaster risk factors through propensity score matching methodology. Specifically, the analysis evaluates residential area attributes that balance accessibility and disaster resilience, thereby providing empirical foundations for policy recommendations. Among Tokyo Prefecture's municipalities, Hachioji City represents the sole case with continuous LOP implementation for over a decade, making it an optimal empirical setting for this causal analysis.
This study quantitatively evaluates the impact of LOP on residential land prices using propensity score matching. By providing empirical evidence of policy effects, the research addresses a gap in quantitative policy evaluation and offers a replicable framework for future studies. The findings serve as a

valuable reference for policymakers aiming to assess and improve urban development initiatives.

STUDY AREA AND DATA

This study focuses on Hachioji City, located in western Tokyo Prefecture, as the primary analytical case (Fig.1) , which is the only municipality with continuous LOP implementation since 2014. (Neighboring cities, such as Fussa, adopted similar policies only recently and were therefore excluded.) Hachioji is the largest city in western Tokyo but has experienced population decline and aging since the early 2000s. These demographic changes have led to increased infrastructure burdens and a rise in vacant properties, complicating urban management. The city's LOP designates residential promotion areas based on proximity to public transportation, sufficient projected density (≥40 persons/ha), and adequate infrastructure, while systematically excluding landslide warning zones and industrial districts. However, exceptions exist, and the ongoing population decline continues to challenge sustainable management. Fig.2 shows the distribution of changes on land prices between treatment and control Groups in from 2014 to 2024.

In this research, official land price data from the Ministry of Land, Infrastructure, Transport and Tourism (MLIT) [4] and population density datasets from the National Spatial Planning database [5] were used.Densely populated areas within Hachioji were classified as the treatment group, while similar areas in other Tokyo municipalities served as the control group. Propensity score matching was applied to compare land price changes before (2013–2015) and after (2022–2024) LOP implementation. Only locations with complete data across this period were included, resulting in 507 observation points (93 in Hachioji, 414 in other cities). Land price values were averaged for the pre- and post-policy periods. Table 1 shows the mean difference in Land Price Changes Between Treatment and Control Groups

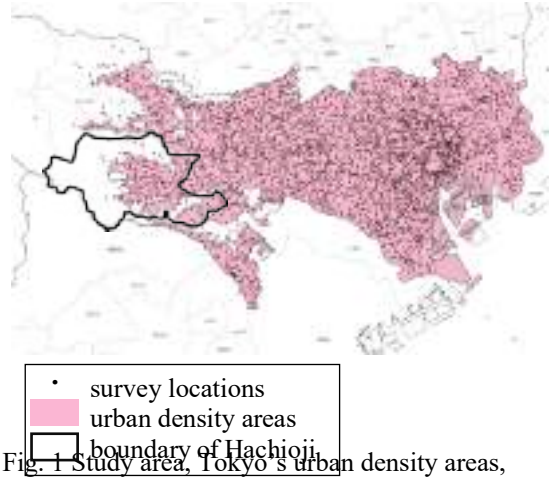

Fig. 1 Study area, Tokyo's urban density areas, land price survey locations and the boundary of Hachioji City.

METHODOLOGY

The Propensity Score Matching (PSM) method is a statistical technique widely used to address selection bias in observational studies, particularly when treatment and control groups differ in background characteristics. In cases where randomized controlled trials are not feasible, such as policy evaluations where municipalities self-select into treatment conditions, PSM offers a robust framework to estimate causal effects by balancing covariates.

The central idea behind PSM is to estimate the probability (propensity score) that each unit (in this case, a geographical location) receives treatment, conditional on observed covariates. This score is then used to match treated and untreated units with similar characteristics, effectively mimicking randomized experimental conditions. Let $T \in \{0,1\}$ represent treatment status, and X be a vector of observed covariates. The propensity score e(X) is defined as Eq. (1):

$$e(X)=P(T=1 \mid X) \quad (1)$$

In this study, "treatment" refers to the implementation of the LOP. Since the policy is not randomly assigned, traditional methods such as Difference-in-Differences (DID) are inapplicable. Instead, PSM is employed to identify treatment effects by matching regions with similar observable attributes.

To account for potential confounding factors, a probit model is constructed using covariates that significantly influence treatment assignment. The main explanatory variables include land area, availability of water, gas, and sewer infrastructure, road width, distance to the nearest station, land use zoning type (land use zoning types are further categorized into residential, commercial, and industrial classes according to Japanese planning codes), building coverage ratio, floor-area ratio, population density, and land-use zones. Using Eq. (2):

$$P = \alpha T + \sum X\beta + \varepsilon \quad (2)$$

The influence of observed regional attributes, including population and locational characteristics, on land price variations is examined quantitatively.

The analysis applies one-to-one nearest neighbor matching within a common support region, ensuring that matches are made only between units with overlapping propensity scores. Matching is performed using the psmatch2 function in STATA 13, which estimates the Average Treatment Effect on the Treated (ATET) and Average Treatment Effect (ATE).Fig.3 shows the process for analyzation of Propensity Score Matching in this research.

The counterfactual refers to a hypothetical scenario in which an individual or unit experiences a treatment or outcome that did not actually occur. Specifically, it involves conceptualizing both the outcome that would result if the unit received the treatment (in this study, the policy intervention of the LOP) and the outcome if it did not, even though only one of these outcomes can be observed (Fig.4).

In essence, the counterfactual represents a hypothetical comparison: what would the dependent variable have been if the control group had received the policy intervention, or conversely, if the treatment group had not received it? Since it is fundamentally impossible to observe both potential outcomes for the same unit simultaneously, the unobserved outcome must be estimated using statistical methods.

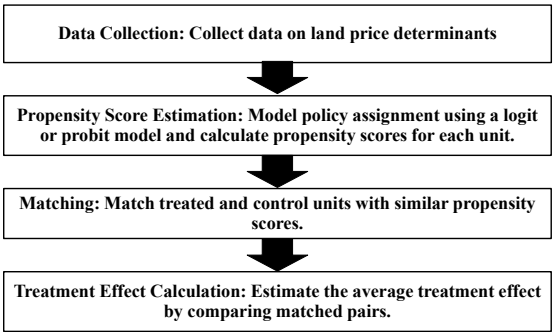

Fig.3 Analytical Process for Propensity Score Matching in Land Price Policy Evaluation

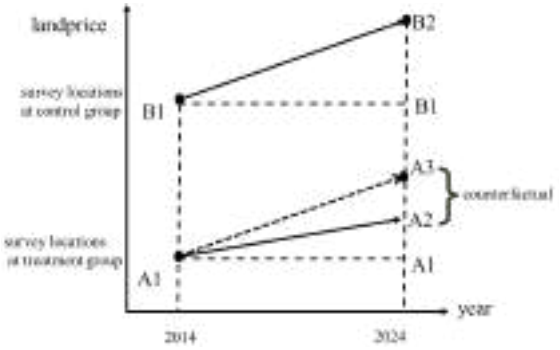

Fig.4 Concept of counterfactual

This approach enables the estimation of counterfactual outcomes by comparing each treated unit with its matched counterpart in the control group. The difference between observed and counterfactual land prices represents the causal policy effect.

Nearest Neighbor Matching (NNM)

Nearest Neighbor Matching pairs each treated unit with the control unit that has the closest propensity score. First, units in both groups are sorted by propensity scores. Then for each treated unit, the control unit with the smallest absolute difference in score is identified. The treatment effect is calculated as the difference in outcomes (land prices) between matched pairs. In practice, the nearest neighbor matching method involves the following steps. First, the propensity score e(X) is estimated using statistical models such as logistic or probit regression. This enables the calculation of each unit's probability of receiving treatment based on observed covariates (see Eq. (3)).

$$d(i,j)=|e(X_i)-e(X_j)| \quad (3)$$

Table 2 The result of Nearest Neighbor Matching

Teffect psmatch (NNM)	
Number of observations	507
Treatment model	logit
Price difference (Policy ATE)	
Coef	6911.11
Std.Err	1668.25
z	4.14
P>|z|	0
95%Conf.	10180.82
	3641.41

In Eq. (3), i refers to a unit from the treatment group and j to a unit from the control group. The covariate distance d functions as an indicator of similarity between matched units from both groups.

Next, the distance between covariates of treated and control units is computed. Based on the estimated propensity scores, this covariate distance is calculated using Eq. (4). For each individual i in the treatment group, a specific individual j* from the control group is selected to minimize the covariate distance between them.

$$j^*=\arg\min_{j\in\{T=0\}} d(i,j) \tag{4}$$

Matching is then performed by selecting, for each treated unit i, the control unit j with the smallest distance value, as shown in Eq. (4). Once matching is complete, the Average Treatment Effect (ATE) is estimated using Eq. (5), which calculates the average difference in outcomes between matched treated and control units.

$$ATE=\frac{1}{N}\sum_{i=1}^{N}\left(Y_i^{(1)}-Y_i^{(0)}\right) \tag{5}$$

In this context, $Y_i^{(1)}$ and $Y_i^{(0)}$ represent the outcomes for treated and untreated conditions, respectively, and N denotes the number of matched pairs in the sample.

The analysis revealed that as a policy effect of the LOP, changing of the land prices in Hachioji City decreased by 6,911.11 JPY/m² compared to those in other areas (Table 2). This result quantitatively demonstrates the specific impact of the policy on land values.

Kernel Matching (KM)

Kernel Matching (KM) is a variant of the propensity score matching method that operates under the assumption that no exact match with identical propensity scores exists in the sample. It is designed to estimate causal effects from observational data by adjusting for covariate imbalances between treatment and control groups.

In kernel matching, each treated unit is compared not with a single control unit but with all control units, using kernel-based weights that reflect the closeness of their propensity scores. This approach allows for the estimation of potential outcomes by assigning greater weight to control units with more similar scores and less weight to those further away.

A key feature of kernel matching is its ability to adjust the trade-off between matching precision and bias through bandwidth selection. By tuning the bandwidth parameter, researchers can optimize the balance between variance and bias while utilizing the entire sample, thus improving estimation accuracy. Following the approaches suggested in Markus Frölich's [6] and Gadisa Muleta and Takele Mebratu's [7] studies, bandwidth of 0.1 was chosen in my analysis.

Using kernel-weighted matching, the potential outcome $Y_i^{(0)}$ for each treated individual i, that is, the outcome that would have been observed had the individual not received the treatment, is estimated according to Eq. (6). For each treated unit i, similar control units j are identified, and their observed outcomes Y_j are weighted based on a kernel function. A weighted average of these outcomes is then computed to approximate the counterfactual outcome for unit i in the absence of treatment.

$$\widehat{Y}_i^{(0)}=\frac{\sum_{j\in\{T=0\}} K(d(i,j))Y_j}{\sum_{j\in\{T=0\}} K(d(i,j))} \tag{6}$$

This approach leverages information from all control units, assigning higher weights to those with propensity scores closer to that of the treated unit, thereby improving the precision of causal inference. Fig.5 shows theBalance check of Propensity score matching(the variable twozhongzhuan represents the Second-Class Medium-to-High-Rise Residential Zone, popu denotes population density. onejvzhu refers to the First-Class Residential Zone, onedizhuan indicates the First-Class Low-Rise Residential Zone. youseki and kenpei correspond to floor-area ratio and

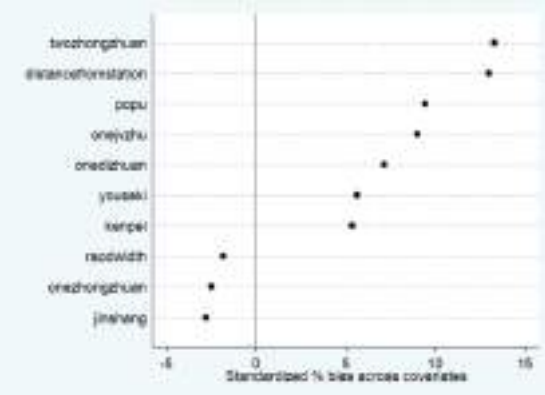

Fig.5 Balance check of Propensity score matching

building coverage ratio, respectively. onezhongzhuan represents the First-Class Medium-to-High-Rise Residential Zone, and jinshang refer to the Neighborhood Commercial Zone.)

The results of Kernel Matching compared that as the Average Treatment Effect on Treated (ATT) of the LOP with unmatched cases, shows land prices in Hachioji City decreased by 6,485.96 JPY/m² compared to those in other areas (Table 3).

Table 3 The result of Kernel Matching

Variable price difference(KM)		
sample	unmatched	ATT
Treated	3186.38	3390.26
Controls	16445.09	9876.21
Difference	-13258.71	-6485.96
Std.Err.	2239.83	2392.74
R stat	-5.92	-2.71

RESULTS AND DISCUSSION

The results obtained in this study demonstrate that the LOP has a statistically significant stabilizing effect on land prices in Hachioji City. Specifically, the nearest neighbor matching analysis revealed that, compared to other regions in Tokyo Prefecture, the average land price in Hachioji was 6,911.11 JPY/m² lower, controlling for confounding variables. Similarly, kernel matching yielded a comparable estimate of 6,485.96 JPY/m². Although the latter method excludes some outliers and exhibits greater estimation variance due to model complexity, the consistency of these results strengthens the conclusion. Based on these empirical findings, the discussion can be summarized into four key points:

Policy Effectiveness

The LOP appears to have contributed to land price stabilization in Hachioji by aligning urban development with planned zoning and infrastructure frameworks. The relatively modest land price fluctuations in the city suggest a balanced real estate market, possibly attributed to controlled urban expansion and green space preservation. Additionally, local urban development strategies, such as urban center formation in the Moto-Hachioji area and environmentally integrated development in Hachioji New Town, may have enhanced the city's attractiveness and sustainability.

Limited External Investment and Underlying Factors

Despite the policy's stabilizing benefits, Hachioji faces challenges in attracting external investment compared to Tokyo's central wards. Factors including insufficient transportation infrastructure (e.g., narrower roads, greater distance to stations), aging housing stock, and population decline have constrained real estate market dynamism. Low demand and high vacancy rates threaten efficient land utilization. Addressing these challenges requires targeted infrastructure investments, tourism promotion, and urban renewal strategies that leverage the city's natural and cultural assets.

Data Limitations and Analytical Improvements

The study's reliance on six-year matched data restricted the sample size to 507 observations. While measures were taken to ensure data consistency, missing values and potential selection bias remain analytical concerns. Future research should utilize longer time-series data and incorporate broader socioeconomic variables including employment, educational access, healthcare availability, and business activity. This would enable more comprehensive understanding of land price dynamics and policy impacts.

Furthermore, key covariates such as road width and station distance exhibited significant differences between Hachioji and other regions. On average, road width in Hachioji is approximately half that of other Tokyo areas, while station distance is twice as long. These factors may suppress price volatility, indicating a stabilizing yet growth-limiting effect.

Prospects and Policy Implications

To revitalize Hachioji and similar suburban areas, more comprehensive urban planning interventions are necessary. For example, national land valuation maps published annually by the National Tax Agency demonstrate rising land values around Hachioji

Station, suggesting growing accessibility and development potential. Building on this trend, future initiatives should include public transportation enhancement, district-level land use reorganization, and strategic tourism resource utilization.

CONCLUSIONS

This study demonstrates the measurable impact of urban planning policies on real estate markets through rigorous propensity score matching analysis. The empirical evidence confirms that the LOP contributes to land price stabilization in Hachioji City, with both nearest neighbor matching and kernel matching methods yielding consistent results. The policy's effectiveness in promoting compact urban development while maintaining land value stability represents a significant finding for disaster-prone urban areas facing demographic challenges.

The insights gained from Hachioji provide a methodological template for evaluating similar policies in other Japanese municipalities and internationally, particularly those confronting demographic decline and disaster vulnerability. The study validates the application of propensity score matching methodology for urban policy evaluation and offers evidence-based foundations for future urban planning strategies that balance accessibility, sustainability, and disaster resilience.

RADIAL JOINT PERFORMANCE IN SHIELD TUNNELS UNDER LARGE DEFORMATION: A COMPARATIVE STUDY USING EXPERIMENTAL AND NUMERICAL APPROACHES

Quoc Viet Tran[1], Kosuke Kawata[1] and Nobuharu Isago[1]

[1]Department of Urban Environmental Sciences, Tokyo Metropolitan University, Japan

ABSTRACT

The number of tunnels has seen a significant increase in urban areas. However, the behavior of radial joints of shield tunnel structures during large deformations remain underexplored. To address this gap, this study aims to deepen our understanding of radial joint behavior under bending moments and their subsequent impacts on damage mechanisms in shield tunnel linings during a strong seismic event. This study employes two primary tests: joint bending test, which assesses the behavior of joint elements, and shearing test, which simulates the effects of earthquakes on tunnel models. Both tests are conducted using experimental and numerical analysis methods. The experimental analysis uses small-scale models, while the numerical analysis utilizes the beam-spring method. Our findings indicate that segmental joint behavior under positive bending tests exhibits three distinct stages, each with different rates of rotational displacement. Conversely, negative bending tests demonstrate constant stiffness. Additionally, the tunnel model collapses during the shearing experiment when a joint reaches a 50-degree opening angle. Furthermore, once the shield tunnel subjects to a prescribed displacement reach half its diameter, both cross-sectional and rotational deformation increase significantly. Importantly, numerical models employing the beam-spring method accurately simulate the behavior of radial joints in a shield tunnel, including cross-sectional deformation and joint rotation, when subject to a specified amount of deformation.

Keywords: Earthquake, Shield tunnel, Radial joint, Beam-spring

INTRODUCTION

The rapid increase of shield tunnels in urban areas is attributed to their safety during excavation and minimal environmental disruption. Their discontinuous structure, comprising segments and joints, makes them susceptible to deformation from surrounding ground movement. Due to this reason, it can easily deform with surrounding ground when it is subject to large shearing deformation. As a result, this structure is generally more earthquake-resistant than tunnels constructed by other methods [1]. Past major earthquakes have caused damage to some shield tunnels Southern Hyogo [2] and Niigata [3], raising concerns about extreme strong seismic events in the future. Nankai Trough earthquake [4] is an example. Although previous studies have investigated the seismic performance of shield tunnels, insufficient attention has been given to radial joints, potentially affecting accurate seismic performance evaluation. Therefore, it is crucial to study the influence of radial joints on shield tunnel behavior under large deformations.

In experimental research on shield tunnel models, seismic loads can be simulated using either dynamic or static methods. While the dynamic action is simulated by shaking table method by many past studies [5–7], the static method offers a simpler approach that still yields accurate results [8]. In shield tunnels, monitoring joint openings is crucial. Large joint openings can signal concrete crushing in the lining and potential water leakage [9]. Therefore, this study utilizes the static method due to its effectiveness in measuring joint opening angles and cross-section deformation. This approach simplifies testing and isolated the effect of radial joints by applying a prescribed static horizontal load to a small-scale single-ring shield tunnel model.

In shield tunnel numerical simulation research, two classic design methods are the modified routine modelling and the beam-spring modelling. The former method, based on the routine method, assumes that the lining is a ring with uniform bending stiffness [10]. In this method, the decrease of the bending stiffness at the joint is considered as the decrease of the ring. Moreover, although the effect of the joints is considered, the joint opening cannot be obtained due to the continuous assumption [11]. On the other hand, the beam–spring method simplifies the main section of the segment to a circular arc beam or a linear beam frame in a 2D model, connected by radial joints modeled by rotating springs [12]. This approach considers the shield tunnel model to be discontinuous, which is closer to its real characteristic. The past study [13] uses the beam-spring model to calculate the magnitude of external loads and then assign them as distributed loads directly on the models. In that research, soil surrounding the tunnel model is considered as an external force, and its actions are converted into external forces. Another approach

considers the ground as a series of two-direction springs [14]. However, these approaches cannot transfer the effect of large horizontal deformation to the tunnel model. To address this limitation, surface elements are used to simulate soil because of its ability to transfer the external deformation to tunnel models. The combination of surface elements and the beam-spring method is utilized in this study to reproduce the physical experiments.

In this paper, both experimental and numerical methods are conducted to observe the influence of radial joints on the behavior of shield tunnel models under large deformation.

RESEARCH METHOD

This study observes the behavior of tunnel models using two methods: physical experiments, which utilized small-scale shield tunnel models and simulated soil material, and numerical modeling, which employes the beam-spring method. Each method consists of bending tests and shearing tests.

All experiments are conducted at least 3 times, and results that differ from the others are eliminated to remove human error.

Physical Experiment

The experimental models in this paper are 3D printed from plastic. The outer diameter is 100mm, and the thickness is 4mm because the height of the segments is around 4% of the outer diameter [8]. Joints are produced at the same time and from the same material as the segments, resulting in a strong connection. The property of this material is shown in Table 1. The completed tunnel models consist of 6 equal segments. Fig.1 illustrates the actual tunnel model, and blue letters represent joints' names.

To evaluate the behavior of a single joint, bending tests are conducted. The test model, shown in Fig.2, includes two segments connected by one joint. Since joints are mainly subjected to bending moments [15], two types of bending tests are performed to extract its properties under both positive and negative bending moments. For the positive bending test (the left image in Fig.2), the model is placed on a flat surface, and a horizontal constraint is applied to the left side to constrain the structure in three degrees of freedom. The frictional coefficient between the flat surface and segment material is about 239.3×10^{-3}. To simulate the distributed force on the model, the weight is approximated as 30 vertical concentrated forces. The total force is increased at a constant rate of 40 grams per 10 seconds until the model collapses. Regarding the negative bending test (the right image in Fig.2), the experimental model is also set up to constrain the model in three degrees of freedom. The horizontal force is applied by connecting the weight to the lowest point of the left segment by a non-stretchable string. Then, this weight increases at the same rate as the positive bending test until the model ruptured. In both types of experiments, a camera records the model's behavior at each load level. Image analysis is used to analyze the data by tracking the displacement of 4 targets marked at the beginning and ending positions of each segment. The outcomes of these experiments include the magnitude of the opening or closing angle at the joint position at each load level. Both positive and negative moment values at the joint are calculated conventionally using the method of section.

Table 1 Material property

Segment model (3D printer Wood PLA Filament)	
Elastic modulus (kN/mm²)	1.0
Unit weight (kN/mm³)	6.5×10^{-9}
Simulated soil material (Aluminum alloy)	
Internal friction angle (deg)	30.0
Cohesion (N/mm²)	0.0
Elastic modulus (kN/mm²)	0.7×10^{-3}
Unit weight (kN/mm³)	21.8×10^{-9}

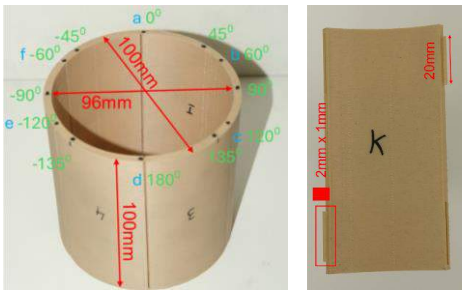

Fig.1 Tunnel model (segment and joint)

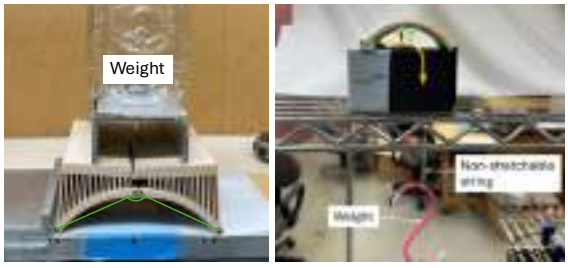

Fig.2 Positive and negative bending test model

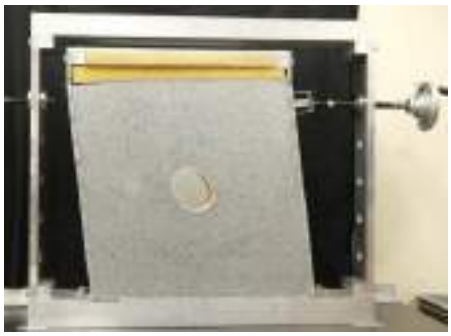

Fig.3 Shearing test model

The shearing test simulates a shield tunnel lining surrounded by soil under a large seismic event beyond the usual conditions. Shearing deformation is applied to simulate the effect of a large earthquake. The tunnel model is placed in a tank filled with simulated soil material, the properties of which are shown in Table 1. The simulated soil material is selected to achieve a realistic soil-to-lining stiffness ratio which is about 1429. To illustrate, the ratio of the tunnel lining's elastic modulus to that of aluminum alloy is comparable to the ratio between precast reinforced concrete and weak sand, which ranges from 480 to 3900. A shearing deformation is then applied gradually to the loading rod (1 mm every 30 seconds) to simulate the effects of large displacement (Fig.3) until the tunnel model collapses. A camera records the model's behavior throughout the test. This study tracks the movement of 12 targets (Fig.1) using image analysis to observe the deformation of cross-section and opening-closing angles. This method is chosen over using strain gauges [7]. Eight targets are marked every 45 degrees because maximum hoop deformation of the model tunnel under horizontal deformation is located at the conjugate 45° [16]. The remaining 4 targets are marked at the joint positions specifically to measure the joint opening-closing angles.

Numerical Analysis

This numerical analysis is conducted to verify the applicability of the 2D beam-spring method to simulate the performance of radial joints when the tunnel is subjected to large deformation. In this paper, segments are represented as beams, and the joints between these segments are modeled as rotational springs. Soil in this analysis is simulated using surface elements. The material properties used in this model are presented in Table 1.

Fig.4 illustrates the numerical joint bending test model, which aimed to evaluate numerical joint properties. The joint properties are determined as rotational spring properties based on experimental joint bending test results. The model simulating the positive bending moment is subjected to three external forces, including gravity, vertical forces and friction. The model simulating the negative bending moment is also under gravity, horizontal force and friction at the end target of the right segment. Loads are input as loading, while moment value and rotational angle are input piecewise linearly as the spring material's property. Finally, the combined positive and negative path of joint spring property is assigned to numerical shearing test models.

The numerical shearing test model (Fig.5) provides the rotational displacement of joints and deformation of the cross-sectional tunnel model. These factors can effectively reflect the performance of radial joints. While the variation of 2 major axes (Fig.5) reflects the cross-sectional deformation, the disparity of opening or closing angle is computed from the coordination of targeted nodes. Then, these results are compared to the experimental one.

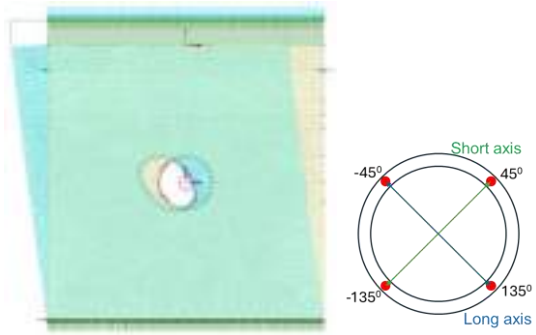

Fig.5 Numerical shearing test and layout of major axes

RESEARCH RESULT

Joint Bending Test

All bending test cases collapse due to joint slippage, not cracking segments.

In positive bending test, the capacity of the experimental model in the first, second, and third cases is 1768 grams, 1488 grams, and 1448 grams, respectively. Fig.6 presents the moment-θ relationship from both experimental and numerical bending tests. Although the capacities of the three experiment cases are different, their trends closely match. The joint stiffness is similar in cases 2 and 3 but higher in case 1. Therefore, the moment-θ relationship of case 3 is used as the input for the numerical bending test model. The joint behavior in the positive bending tests shows three main stages. Initially, from the starting point to an 8-degree joint opening, the angle increases at a rate of about 6.3 N*mm/degree. Subsequently, between 8 and 12 degrees, the rate of rotational displacement increases 1.5 times compared to the first stage. Beyond a 12-degree rotational angle, the deformation speed is negligible, reaching 1.8 N*mm/degree.

In the negative bending test, the capacities of 3 trials are similar at about 430 grams. The relationship

between bending moment and closing rotational angle (Fig.7) is nearly linear in all three cases at the ratio of 7.5 N*mm/degree. The second trial is chosen as the reference one.

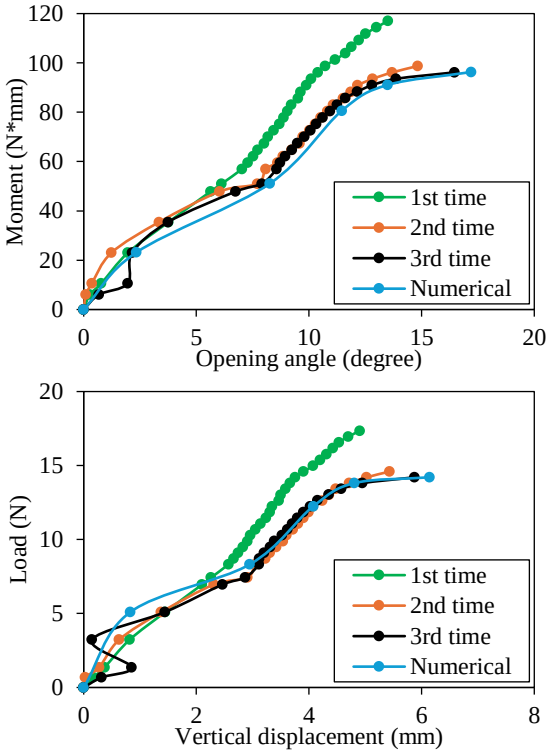

Fig.6 Rotational and vertical displacement results of positive bending tests

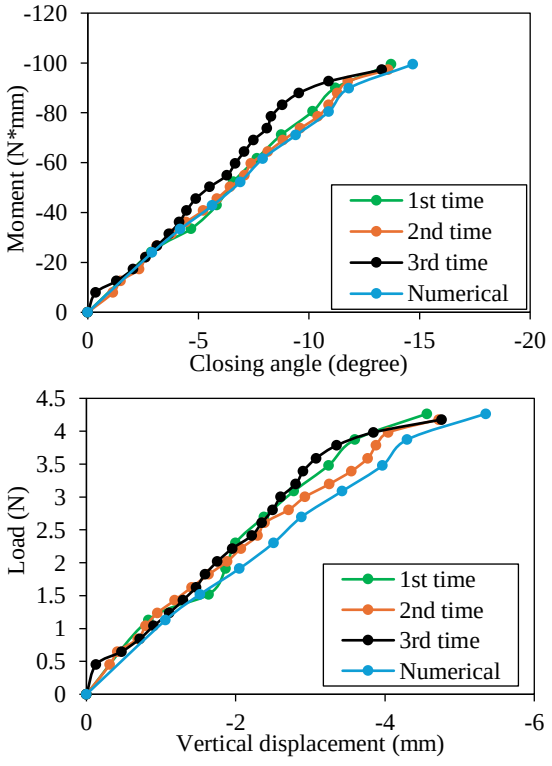

Fig.7 Rotational and vertical displacement results of negative bending tests

The experimental joint properties of the reference case are input to the numerical bending test models with corresponding load levels. Fig. 6 and Fig. 7 show that differences between the results of 2 methods are minor. Therefore, these joint stiffness graphs are combined and then input into the numerical shearing test model for reproducing this test.

Shearing test

The first trial collapses when the shearing displacement reached 72mm; the second at 73mm, and the third at 76mm. Although there are slight differences in the capacity of the three experimental cases, they are negligible. Results from the first and second cases are closer to each other compared to the third one, so the first one is chosen as the reference. Fig.8 shows the deformed shapes of the tunnel model just before collapsing. All these cases collapse because of the slippage of joint b.

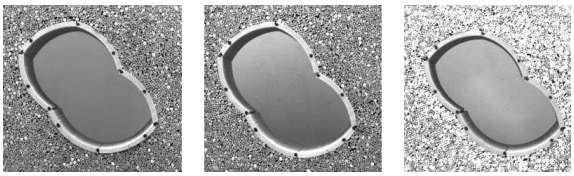

Fig.8 Deformed shapes of the tunnel model in three experimental cases just before collapsing

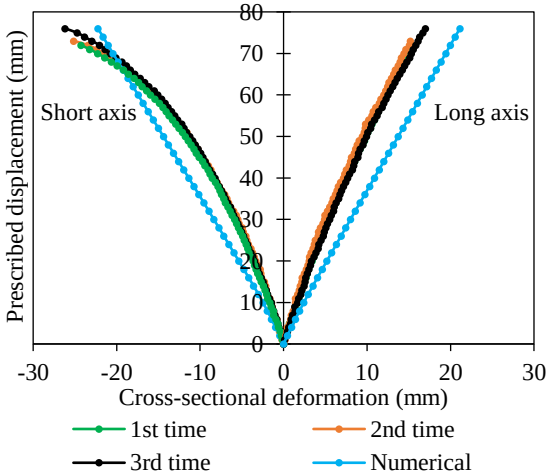

Fig.9 Disparity between the lengths of the major axes from experimental and numerical results

Fig.9 compares the disparity between the lengths of the major axes obtained from 3 experiment times and numerical results. In the reference trial, the deformation of the short axis is greater than that of the long axis. The deviation between these axes is only under 20% until the prescribed displacement of 50mm. Beyond 50mm, this value rapidly rises and reaches 60%.

Since the numerical model could not collapse, the maximum displacement applied to the reference case (72mm) is also applied to the numerical model.

As for the cross-sectional deformation (Fig. 9), for

the long axis, both experimental and numerical results are nearly linear. Regarding the short axis, while the disparity in the experimental length exhibits a curve pattern, the numerical outcome is linear. From the initial state up to 50mm of prescribed displacement, the difference rate between the results of the two methods is between -3.0% and 4.0%, relative to the model's outer diameter. Beyond 50 mm, this rate increases, but maximum value is about 4.5%.

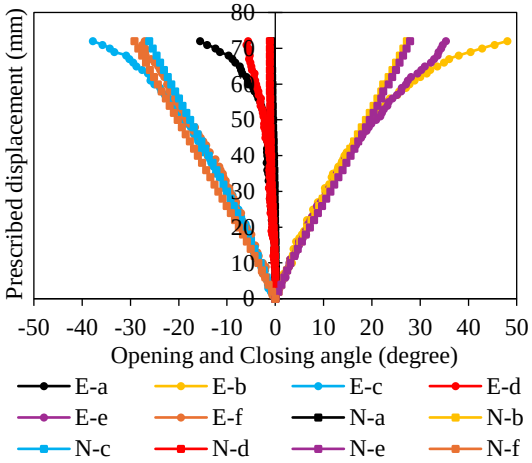

Fig.10 Comparison of Opening-Closing angle between experimental and numerical results.

Fig.10 compares the rotational deformation of 6 joints (joint names are shown in Fig.1) between the experimental reference case and numerical analysis. In Fig.10, E and N stand for Experimental and Numerical, respectively. Overall, their deformation trends are similar. Numerical results are linear. Most experimental results behave linearly from the initial, and non-linearly from the given displacement of 50mm, except for joint f. For the remaining joints, rotational differences between the two methods are minor when the prescribed displacement is under 50mm, but these differences increased rapidly beyond that point. From the initial to 50mm of prescribed displacement, the variation between the results of the two methods is between -2.2 degrees and 1.3 degrees. Beyond 50 mm, this rate begins increasing significantly, and the maximum variation is about 20.7 degrees at joint b.

DISCUSSION

The joint bending tests indicate that the model collapse is due to joint slippage, not segment cracking. Joint behavior in positive bending tests exhibit three distinct stages. The first stage displays a rotational displacement rate that is lower than the second stage, but higher than the third. In negative bending tests, the relationship between displacement and closing angle is nearly linear. This outcome is consistent with the previous finding [17], which shows that the stiffness of segmental joints under bending moment could be divided into 3 stages with different values. However, the mentioned paper does not study the relationship between negative moments and rotational angle, as well as the stiffness order of 3 stages.

The results from the shearing experiment show that all three tunnel models collapse due to the failure of joint b. This result could be predicted from its rotational deformation because the amount of opening angle joint b is 50 degrees, which is much more than the others. As for cross-section deformation, the deviation between the main axes (long axis minus short axis) remains low until the prescribed displacement reached 50mm. For rotational joint deformation, at most joints, the initial deviations are minor but increased rapidly from the given displacement of 50mm. The deformation begins increasing more rapidly once the prescribed displacement reaches half of the outer diameter of tunnel models.

The numerical models' results closely match the experimental outcomes. The bending test shows the similarity between experimental and numerical results through vertical and rotational deformation comparison. In shearing tests, while numerical models deform linearly, experiment models provide non-linear results. However, most differences are minor or acceptable, particularly when the given displacement is under 50mm, equivalent to 50% of the tunnel's diameter. Beyond this point, the accuracy decreases significantly. Therefore, this model can effectively reproduce the behavior of radial joints when shield tunnels are subjected to medium deformation (under half of the outer diameter).

CONCLUSION

In this study, we aim to find out the behavior of radial joints when the shield tunnel models are subjected to a large deformation. To achieve this, bending and shearing experiments are conducted using both experimental and numerical methods. The conclusions of this study include:

- Firstly, the behavior of joints under positive bending tests exhibits three distinct stages, each stage is characterized by a unique rate of rotational displacement. The first stage displays the lowest rate of rotational displacement, followed by the third stage, and the second stage exhibits the highest rate. Therefore, engineers should avoid radial joints reaching the third stage during the joint design process. In contrast, negative bending tests demonstrated a nearly linear relationship between the bending moment and closing angle.
- Secondly, the shearing experiments result in the collapse when any joint reached a 50-degree opening angle. The current joint type needs some modifications to prevent it from reaching the limit opening angle, or it should be replaced by other joint

structures. Furthermore, once the shield tunnel is subjected to prescribed displacement reaches half of its diameter, cross-sectional and rotational deformation increases significantly. In addition, for early alerts, sensors should be installed to detect when joints enter the third stage, or the magnitude of deformation approaches this value.

- Finally, numerical models employing the beam-spring method have accurately simulated the behavior of radial joints via cross-section and joint rotational deformations. The discrepancies between the numerical model and experimental behavior are generally minor and acceptable, particularly when the given displacement remains below a specific value. This method could be used for further research focusing on radial joints' behavior.

Although some good results are obtained, there are some limitations that worth of further studies. First, the maximum opening angle of the bending test (18 degrees) is much lower than that of the joint in the shearing test (50 degrees). It leads to significant disparity arises when the rotational displacement exceeds the limit of input spring stiffness. Second, the axial joint spring also impacts the behavior of radial joints, but it is ignored in this study. Third, although experimental small-scale models are employed to simulate the behavior of full-scale shield tunnels, only the length ratio and the ratio of elastic modulus between materials are maintained while other dynamic similitude parameters are not taken into account. We are trying to solve some of the above problems.

ABSTRACT

Vegetation control is important for the conservation of mountain trails, access to alpine areas, and the safety of hikers. However, in Japan, mountain trails are often obstructed by bamboo grass because of its vigorous growth. This study aimed to identify effective methods to control the regrowth of bamboo grass along mountain trails after cutting. We focused on Nagaone trail in the Kiso Mountains, Central Japan, where the bamboo grass was cut in 2020. Nineteen survey plots were set along the trail at elevations ranging from 1500 to 1900 m, with a quadrat (2 m long × the trail width) established at each site. The cutting height in 2020 and the culm height and density in 2022 were measured. Bamboo grass on the trailside slope was also measured because it obstructed the trail, and elevation, trail gradient, and slope gradient were recorded as the habitat environment. The results indicated that residual living bamboo grass on the trailside slope was significantly positively correlated with both regrowth on the trail and the density of the leaning culm from the trailside after 2 years. Cutting height was significantly positively correlated with the density of the regrowing culm and influenced by the trail gradient, but not the culm density or height. Thus, the growth of bamboo grass on the trailside slope and the cutting height appear to be critical for the regrowth of bamboo grass on the trail. This finding could lead to more effective methods to control the regrowth of bamboo grass along mountain trails.

Keywords: Mountain trail, Bamboo grass, Regrowth, Cutting

INTRODUCTION

Bamboo grass, including many species of the genera *Sasa* and *Sasaella* (Poaceae), often becomes dominant on the forest floor in montane and subalpine zones in Japan [1]. Generally, bamboo grass species show longevity and monocarpy, often surviving from several decades to a hundred years with simultaneous mass flowering and withering at the end of the generation before recovering from seeds [2,3]. Bamboo grass forms a large population with thick elect culms, which prevents the invasion or survival of other plants from outside [4,5]. In addition, underground rhizomes contribute to the tight binding of soil, which helps prevent soil erosion [6].

The relatively fast expansion of the bamboo grass population has been reported. Sparse populations of bamboo grass were found to have become a dominant species with almost 100% coverage on a slope along a highway 12 years after the suspension of traffic [4]. The annual expansion rates of tall-type (*Sasa borealis* Makino et Shibata) and small-type bamboo grass (*Sasa nipponica* Makino et Shibata and Sasaella ramosa Makino) have been estimated to be 117 m^2 and 50 m^2 per year, respectively [7].

Such growth characteristics are beneficial for revegetation and soil protection, but often become harmful. One of the typical cases where bamboo grass needs to be suppressed is mountain trails. On mountain trails, overuse by hikers causes widening of the trail and soil erosion through the deterioration of trailside vegetation; however, this can be mitigated by bamboo grass [6]. By contrast, the underuse of mountain trails can lead to the excessive growth of bamboo grass, which also creates difficulties in terms of maintaining the trail [5]. It has been reported that only 1%–2% of sunlight reaches the ground surface under bamboo grass populations [8], and the trace after cutting bamboo grass (i.e., the renewed trail) remains as dark as it was before cutting because the trail width is extremely narrow compared with the entire bamboo grass population [5]; the ground surface of the renewed trail would remain too dark for the survival of other plants, causing the condition of bare ground to continue [5].

On the other hand, bamboo grass has the ability to transport storage substances through underground rhizomes within the population [9], which implies that the regrowth of bamboo grass on mountain trails would be supported by the residual living part of the population on the trailside. Cutting and removing bamboo grass rhizomes is known to be an effective method to restrain regrowth [10], but is not recommended because it enhances the risk of erosion. Thus, the control of bamboo grass on

mountain trails is distinct from the large-scale cutting of forest floors in forestry, and consequently, little information has been available to date.

Given this background, in the present study, we aimed to establish a research area where bamboo grass had covered the mountain trail abandoned for decades. Two years after cutting, we investigated the regrowth of the bamboo grass and environmental factors and analyzed their relationships with the objective of developing more effective methods to control the regrowth of bamboo grass for the conservation of mountain trails.

RESEARCH SIGNIFICANCE

The significance of the study is that it aims to contribute to the conservation of mountain trails, where vegetation can become excessively thick as a result of underuse. This issue involves the existence of the large living part of bamboo grass populations after cutting, which can transport storage substances to the stubble on the trail through rhizomes. Based on the analysis of the regrowth and environmental factors, we discuss effective cutting methods to control the regrowth of bamboo grass for the conservation of mountain trails.

METHODS

Research Area

The research area in the present study was Nagaone trail (from an elevation of 1500 m to 2532 m), which leads to a peak on the ridge running from Mt. Shogi-gashira in the north of the Kiso Mountains, Central Japan (Fig. 1). Nagaone trail has not been very popular among general hikers because it passes through two research forests, Oguro Research Forest of Kami-ina Agricultural High School and Nishikoma Research Forest of Shinshu University. Recently, this trail became nearly abandoned after accessibility worsened following bridges across the Ogurogawa River (at elevations of 1420 m and 1500 m) being washed away by repeated floods. The convenience of hiking the trail also worsened because the roof of the mountain hut near the middle of the trail (at an elevation of 1900 m) collapsed as a result of heavy snowfall.

Fig.1 Topographical map of around the research area (Nagaone trail). Black solid lines indicate other mountain trails.

The vegetation around the trail consists of an afforested larch forest in the montane zone (the lower area up to the elevation of 1600 m), and a mixed forest of conifers and deciduous trees in the subalpine zone (the upper area). Bamboo grass, mainly *Sasa senanensis* Rehder, is distributed in the area up to an elevation of about 1900 m.

Establishment of Survey Plots

To recover Nagaone trail, we cut bamboo grass on the trail by human power in 2020. The tools used for cutting work were a long-handle sickle, a billhook, and pruning shears (Table 1). The trail before the cutting conducted in 2020 had become almost completely obstructed and unrecognizable because of the growth of thick bamboo grass (Fig. 2 (A)). The long-handle sickle was the most effective cut tool for cutting the bamboo grass, but the cut culms and leaf blades remained scattered on the trail (Fig. 2 (B)) and the cutting section of the culm often became sharp, which can be dangerous for hikers. By contrast, the pruning shears required a lot of time

Table 1 Properties of the tools used for cutting bamboo grass

Tools	Cutting edge length (cm)	Handle length (cm)	Efficiency of cutting work
Long-handle sickle	27.0	118.0	High but rough
Billhook	17.5	32.0	(Middle)
Pruning shears	4.8	9.0	Low but careful

Fig. 2 States of the trail before and after the cutting work in 2020. A: Before cutting, B: After cutting with a long-handle sickle, C: After cutting with pruning shears. Length of the red and white striped pole = 2 m.

and effort, but the harvested culms and leaf blades were often thrown off the trail because of the necessity to grasp them before cutting (Fig. 2 (C)). Moreover, the cutting section of the culm became blunt, which is safer for hikers. The efficiency of the cutting with a billhook and the resultant state of the trail were somewhere between those of the long-handle sickle and pruning shears. After confirming the efficiency of each tool, the tools were allotted to three persons (one tool per person), and the cutting work was performed through collaboration.

In 2022 (2 years after the cutting), 19 survey plots were established to examine the regrowth of the bamboo grass. The locations of the plots were determined at regular intervals of approximately 50 m. The size of the quadrat in each plot was 2 m long × the trail width. The conditions of each survey plot are shown in Table 2.

Table 2 Conditions of the location at each survey plot

No.	Elevation (m)	Slope direction	Trail gradient (°)	Width of trail (m)
1	1498	E	6.8	0.50
2	1510	NW	6.8	0.56

Measurement and Analysis of the Regrowth of Bamboo Grass

For the survey of the regrowth of the bamboo grass on the trail at 2 years after cutting, aboveground bamboo grass (hereafter “regrowing culm” on the trail, Fig. 3 (A)) was harvested with pruning shears and measured in the summer of 2022. The culm height and diameter at the base were recorded after harvesting. In addition, the culm along the trailside leaning over the trail (hereafter “leaning culm”, Fig. 3 (A)) was counted at each plot because it also obstructed the trail. The density of the leaning culm was calculated as the number of culms divided by the longitudinal length of the trail (2 m for each plot), as they existed linearly along the trail, unrelated to the trail width.

Regarding the environmental factors that could affect the regrowth of the bamboo grass, we considered the geographical conditions and residual living bamboo grass. Concerning the geographical conditions, we recorded the elevation, slope direction, trail gradient, and slope gradient for each plot at the same time the plot was established.

Concerning the residual living bamboo grass, the height of the remaining stubble on the trail was measured at the time of harvesting. The height of the remaining stubble was measured by examination of the basal part of each harvested culm. This height was considered to provide an estimation of the cutting height in 2020. However, after inspecting the data, we reached a reasonable conclusion using the maximum value for each plot to avoid underestimation, as some of the stubble had been already dead and decayed before the survey. The reason we were unable to design the cutting height experimentally in 2020 was that the work of cutting the thick population of bamboo grass and recovering the trail was excessively difficult, and the future regrowth on the trail was unknown immediately after cutting.

Besides, both the culm height and density of the bamboo grass along the slope of the trailside were measured at the time of harvesting. The culm height and density along the trailside slope at each plot, which was left intact in 2020, considered to be associated with the storage mass to invest in the regrowth of bamboo grass on the trail after cutting.

The relationships between these environmental factors and the regrowth of bamboo grass on the trail were analyzed using Pearson’s correlation coefficient.

Fig. 3 States of the trail before and after the cutting work in 2022. A: Before cutting, B: After cutting (both at plot No. 2). Length of the red and white striped pole = 2 m.

RESULTS

Regrowth of Bamboo Grass

Among the 19 survey plots, bamboo grass appeared in 17. Two plots (Nos. 11 and 16) and their trailside slopes were devoid of bamboo grass. The

diameter at the base showed no significance among plots (analysis of variance, F-test), and the mean diameter ± standard deviation of all 17 plots was 3.73 ± 0.92 mm.

Table 3 shows the estimated cutting height and regrowth of the bamboo grass. The estimated cutting height was 0–56 cm. Regrowing culms were observed in all 17 plots, with a density of 1.3–7.1 culms/m^2 and a height of 24–147 cm. The density of the leaning culms, mostly from the uphill slope, was 0.0–18.5 culms/m.

Table 3 Regrowth of bamboo grass on Nagaone trail at 2 years after cutting for each survey plot

No.	Estimated cutting height (cm)	Regrowing culm on the trail		Learning culm
		Density per m^2	Height (cm)	Density per meter

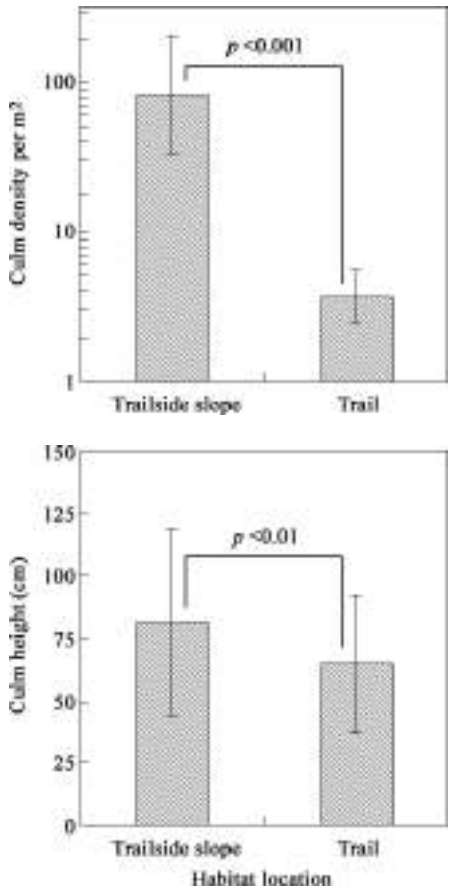

Fig. 4 Culm density and height of bamboo grass on the trailside slope (natural growth left intact) and Nagaone trail (regrowth at 2 years after cutting). The line on each bar indicates the range of ±1 standard deviation (n = 17).

All 17 plots and trailside slopes could be considered replications of the regrowth of bamboo grass on the trail after cutting and leaving natural growth intact, respectively. Fig. 4 shows the results of a comparison of culm density and height between the plots and trailside slopes. The culm density was significantly larger on the trailside slope than on the trail (84.0 vs. 3.9 culms/m^2 on average, respectively; Tukey's honestly significant difference (HSD) test, $p < 0.001$. The culm height was also significantly larger on the trailside slope than on the trail (81.0 vs. 64.8 cm, respectively; Tukey's HSD test, $p < 0.01$).

Relationships between Environmental Factors and the Regrowth of Bamboo Grass

Table 4 shows the relationships between environmental factors and the regrowth of bamboo grass. Regarding the factor of geographical conditions (Table 4 (A)), significant negative correlations were found between the trail gradient and regrowing culm density, between elevation and regrowing culm height, and between elevation and leaning culm density (around r = –0.5, $p < 0.05$, F-test). Although trail width was also planned to be an environmental factor, it was excluded from the analysis because it was considered an outlier (1.15 m at plot No. 9, Table 2) and therefore to disturb the correlation.

Regarding the factors related to the residual living bamboo grass (Table 4 (B)), the culm density in the trailside slope was significantly positively correlated with regrowing culm height and leaning culm density (around r = 0.7, $p < 0.01$, F-test), the culm height on the trailside slope was significantly positively correlated with regrowing culm height (r = 0.914, $p < 0.001$, F-test), and the estimated cutting height was significantly positively correlated with regrowing culm density (r = 0.689, $p < 0.01$, F-test).

Concerning the relationships between the regrowing culm density, height on the trail, and leaning culm density, significant positive correlations were observed (r = 0.5–0.6, $p < 0.05$, F-test).

Table 4 Relations between environmental factors and the regrowth of bamboo grass (Pearson's correlation coefficient, r; n = 17)

Factors	Regrowing culm on the trail		Learning culm
	Density per m^2	Height (cm)	Density per meter
(A) Geographical conditions			
Elevation	ns	-0.515*	-0.538*
Trail gradient	-0.487*	ns	ns
Slope gradient	ns	ns	ns
(B) Residual living bamboo grass			
Culm density	ns	0.648**	0.713**
Culm height	ns	0.914***	0.427
Cutting height	0.689**	ns	0.439

*Correlation coefficients less than $p < 0.1$ are shown. *, **, and *** denote significance at $p < 0.05$, 0.01, and 0.001, respectively. Culm density and height were measured on the trailside slope, and cutting height was estimated at 2 years after cutting.*

The factors related to the residual living bamboo grass were more important than those of the geographical conditions because the former can be controlled by cutting work, whereas the latter cannot. Table 5 shows the relationships with the factors related to the residual living bamboo grass. Regarding the factors of geographical conditions (Table 5 (A)), culm height was significantly negatively correlated with elevation ($r = –0.516$, $p < 0.05$, F-test), and trail gradient was significantly negatively correlated with estimated cutting height ($r = –0.571$, $p < 0.05$, F-test). The factors related to the residual living bamboo grass were not influenced by the slope gradient.

Regarding the relationships between the factors related to the residual living bamboo grass (Table 5 (B)), a significant correlation was detected only between the culm density and height on the trailside slope ($r = 0.567$, $p < 0.05$, F-test).

Table 5 Relations with the factors related to residual living bamboo grass (Pearson's correlation coefficient, r; n = 17).

Factors	D	H	C
(A) Geographical conditions			
Elevation	-0.414	-0.516*	ns
Trail gradient	ns	ns	-0.571*
Slope gradient	ns	ns	ns
(B) Residual living bamboo grass

Culm height (H)	0.567*	1	
Cutting height (C)	ns	ns	1

*Correlation coefficients less than $p < 0.1$ are shown. * denotes significance at $p < 0.05$.*
Culm density and height were measured on the trailside slope, and cutting height was estimated at 2 years after cutting.

DISCUSSION

Cutting Work

Concerning the cutting work, the culms and leaf blades of bamboo grass are recommended to be removed from the trail after cutting so as not to hide the trail [5]. Besides, the surface roughness of bamboo grass is considerably minute even 2 years after cutting (R_{max} around 0.01 mm, unpublished data by the authors). Surface roughness is reported to be related to the coefficient of friction between material and snow [13]; therefore, failing to remove scattered culms and leaf blades would increase the risk of a snowslide or falls by hikers.

On the other hand, the steep cutting sections of culms are also detrimental to the safety of hikers and cutting-work operators. It is recommended first to cut culms effectively using a long-handle sickle or billhook, and then to make the cutting section blunt with pruning shears and remove the harvested culms and leaf blades from the trail.

Regrowth of Bamboo Grass

Bamboo grass was observed to regrow on the trail at 2 years after cutting. However, the density of the bamboo grass on the trail was still far lower than that on the trailside slope. By contrast, the culm height on the trail appeared to have already become close to that on the trailside slope, even though there was a significant difference between them (Fig. 4). The bamboo grass population on the trail would scarcely be distinguishable from the population on the trailside slope if the culm density were left to increase in the near future. Because dwarfing of bamboo grass is one of the signs of animal damage, primarily by sika deer [11], the damage caused by cutting was considered to disappear after 2 years.

Among the geographical condition factors, elevation and trail gradient had a negative influence on the regrowth of bamboo grass (Table 4 (A)). However, because these factors are uncontrollable, this implies a favorable habitat for bamboo grass. Most bamboo species (subfamily Bambsoidae, containing bamboo grass) are distributed in tropical areas, and the species group of bamboo grass is distributed in northern areas [1]. High elevation, i.e., low temperatures, deep snow, and short growing periods, are considered to restrain the growth of bamboo grass. Trail gradients are not supposed to be related to temperature, but may be unfavorable for producing erect culms or rhizome growth.

The culm density and height on the trailside slope were positively correlated with not only the regrowth of bamboo grass on the trail, but also leaning culms (Table 4 (B)). Although we had considered that the gap on the trail after cutting would increase the growth of leaning culms from the

trailside, no negative correlation was observed between them, and both were encouraged by the trailside population. This suggests that bamboo grass can transport storage substances from adjacent trailside populations through rhizomes [9]. To date, most of the literature on controlling the growth of bamboo grass focuses on forestry on a large scale, not leaving bamboo grass intact in experimental plots. Therefore, considering the absence of residual living populations with abundant storage substances, reports that bamboo grass is suppressed for many years after large-scale cutting or the application of chemicals are reasonable [7,8,12]. On the other hand, the positive correlation observed between cutting height and regrowing culm density was considered to have been caused by the remaining lateral buds: shooting from lateral buds gives bamboo grass a broom-like branching form, which has been reported as a sign of animal damage, primarily by sika deer [11]. Cutting at a high position tends to leave many lateral buds intact, which can lead to rapid regrowth from the residual culm itself, photosynthesis, and increased storage substances, thereby encouraging the production of new culms on rhizomes, in addition to the support received from the trailside population.

Concerning the factors that affect the regrowth of bamboo grass on the trail, if we suppose that the population on the trail before cutting corresponded approximately to that of bamboo grass on the trailside slope, then it is important to consider that the cutting height was not influenced by the culm density or height, but rather, by the trail gradient (Table 5). The reason behind this relationship is unclear in the present study, but it seemed easier for the cutting-work operators to see and reach the base of the culms on a steep compared with a gentle slope. This finding suggests that attention should be paid to the slope gradient during cutting work, as opposed to cutting at a high position on a gentle slope and flat land.

On the other hand, the negative correlation with elevation (Table 5 (A)) showed similar relationships in Table 4 (A), implying a favorable habitat for bamboo grass: high elevation would decrease the growth of natural bamboo grass populations. The positive correlation observed between culm height and density (Table 5 (B)) is therefore reasonable because each indicates the growth of the population.

However, missing the important data, such as the height and density of bamboo grass before cutting in 2020 in each survey plot, would undermine the quality and reliability of the results in the present study. Hereafter, survey plots should be established before the population of bamboo grass on the mountain trail becomes too thick.

CONCLUSIONS

In the present study, we established a research area where bamboo grass had covered a mountain trail abandoned for decades. Two years after cutting, the regrowth of bamboo grass and environmental factors were investigated and their relationships were analyzed.

Concerning cutting work, it is recommended to cut effectively with a long-handle sickle or billhook at first, and then to make the cut sections blunt with pruning shears and remove the harvested culms and leaf blades from the trail for the safety of hikers and cutting-work operators themselves. Concerning the regrowth of bamboo grass on the trail after cutting, the results were as follows.

(1) The residual living population of bamboo grass on the trailside slope was significantly positively correlated with both the regrowth on the trail and the leaning culm density from the trailside after 2 years, probably because of the transportation of storage substances through rhizomes.

(2) The cutting height was significantly positively correlated with the regrowing culm density, probably because of the increase in storage substances caused by the rapid regrowth from lateral buds on residual culm.

(3) Concerning the factors related to the regrowth of bamboo grass, the growth of the population on the trailside slope was influenced by elevation, and the cutting height was influenced by the trail gradient, but not by the culm density or height.

In conclusion, monitoring the growth of bamboo grass on the trailside is important: low cutting or recutting at shorter intervals is needed if the growth of the trailside population is vigorous. In addition, monitoring the slope gradient is important to avoid cutting at a high position on gentle slopes and flat land.

EFFECT OF DIFFERENT GRAYSCALE CONVERSION METHODS ON ROUGHNESS MEASUREMENT USING BINARIZATION

Nozomu Urahata[1], Kenji Okajima[1] and Seiya Nagaoka[1]

[1]Graduate school of Bioresources, Mie University, Japan

ABSTRACT

Currently, roughness deterioration of concrete is a problem in agricultural canals in Japan. Roughness is caused by abrasion from water and sand flowing through the canals. Rough concrete surfaces impede water flow, so it is necessary to measure roughness. Previously, we showed that it's possible to measure roughness using binarization and lighting, by analyzing the shadows on the concrete surface. In binarization, RGB images are converted to grayscale images and then to binary images. However, previous studies have only examined one conversion method for converting to grayscale images. The objective of this study was to clarify the impact of different grayscale conversion methods on measurements. The analysis revealed that there were large differences in the coefficient of determination between the previously used grayscale conversion method and the newly examined conversion method in some cases. Additionally, it was found that there exists a conversion method with a higher coefficient of determination than the previous one, suggesting the potential for improved measurement accuracy.

Keywords: Roughness of concrete, Binarization, Grayscale conversion, Collimated light

INTRODUCTION

Currently, concrete roughness deterioration is a problem in Japan's agricultural canals, which have a total length of 400,000 km. Roughness is caused by abrasion from water and sand flowing through the canals. A rough concrete surface impedes water flow, causing a decrease in flow velocity and a rise in water level. Furthermore, as abrasion progresses and the surface becomes rougher, the cross-sectional area of the concrete decreases, which affects the durability of the canal. Therefore, roughness is measured, and the canal is repaired accordingly. Several quantitative measurement methods for roughness have been established. The arithmetic mean roughness R_a is used as an evaluation index for the roughness of canal concrete. The following three measurement techniques for R_a have been established.

First, there is the laser distance meter [1]. This method reads the unevenness of the concrete in 0.1 mm increments and converts it into roughness. Roughness is obtained as line information and is highly accurate. However, since the obtained roughness is line information and the measurement is precise, it takes time, making it unsuitable for measuring extensive canals.

Second, there is the profile gauge [2]. This method involves pressing multiple connected needles against the concrete to read the unevenness and convert it into roughness. It is an inexpensive and simple measurement method. However, like the laser distance meter, the roughness is obtained as line information with a resolution of approximately 150 mm, and analysis currently takes time.

Third, there is aerial ultrasonic [3]. This method involves irradiating concrete with ultrasound and measuring roughness based on the strength of the reflected wave's voltage. Unlike laser distance meters and profile gauges, this method can measure the roughness of a 160 mm diameter area, making it more efficient than the two methods mentioned above. However, it is not widely used because of the large variation in sensors and the effort required for calibration.

While these measurement techniques have been established, the Ministry of Agriculture, Forestry and Fisheries guidelines [4] stipulate that the evaluation method for roughness is non-quantitative visual inspection.

Our research, therefore, aims to develop a quantitative and more efficient roughness measurement method than existing techniques. We have shown the possibility of quantitative and efficient roughness measurement by using binarization, one of the image processing, and collimated light [5]. The measurement method involves first irradiating light onto the concrete surface from the side in darkroom and then capturing the shadows created by the unevenness of the surface with a camera. Binarization is used to extract shadow area from the captured image. The measurement principle is that the larger the arithmetic mean roughness R_a, the larger shadow area (%) that appear on the concrete surface.

In binarization, an RGB image (24-bit) represented by three colors is converted into a grayscale image (8-bit) represented by a gradient from white to black, and finally converted into a binary image (1-bit) represented by only two colors, white and black. Previous studies [5] have used the

National Television Standards Committee (NTSC) method shown in equation (1) for grayscale conversion.

$$Y = 0.2989\,R + 0.5870\,G + 1.140\,B \quad (1)$$

Y: luminance value, *R*: red value, *G*: green value, *B*: blue value. The NTSC is included as a default in many image libraries and is commonly used.

On the other hand, this study has only used equation (1) so far. Since RGB images store three color values per pixel, there are many other methods for converting to the luminance value Y besides the above (1) equation. Therefore, the validity of the equation has not been examined, and there may be more accurate equations available. Thus, the objective of this study is to clarify the effects of different grayscale conversion methods on roughness measurement method using binarization.

RESEARCH SIGNIFICANCE

Since RGB images contain three colors, there are many methos for converting them to grayscale images. Previous studies have only examined one grayscale conversion method (NTSC). By clarifying the impact on measurements, it is possible to find a more accurate method. In addition, the validity of selecting a certain grayscale conversion method can be indicated in this measurement.

MATERIALS AND METHOD

Concrete

Thirteen types of concrete with different roughness levels were used. The measurement area was set at 100 × 300 mm, and R_a was measured using a profile gauge. R_a is calculated using equation (2).

$$R_a = \frac{1}{l}\int_0^l |f(x)| \quad (2)$$

l: length of the profile gauge (mm), *f*(*x*): difference between the roughness curve and the linear approximation of the roughness curve. R_a was measured at eight points within the measurement area, and the average of these measurements is used as the representative value. The R_a values of the concrete are, in order, 0.04, 0.19, 0.31, 0.32, 0.41, 0.49, 0.49, 0.50, 0.52, 0.65, 0.72, 1.04, 1.11mm. Among these, the concrete with R_a = 0.04 mm has a smooth surface with almost no unevenness, while the other concrete has exposed aggregates and unevenness on the surface.

Methods For Obtaining Images

To create shadows on the concrete, a HOLOLIGHT (Pi PHOTONICS Inc.) was used to emit collimated light (Figure 1). The light source dimension is 100 × 100 mm, and it is a white LED surface light source. Unlike general lighting, this lighting does not spread light and can reproduce collimated light similar to sunlight. The images were taken in a dark room to eliminate the effects of artificial lighting and natural light other than the lighting used. The lighting was applied from the side of the concrete measurement area with a short side of 100 mm, and RGB images of the resulting shadows were acquired. Then, the lighting was applied again from the opposite short side, and RGB images were acquired. A total of two images were acquired for each concrete sample. In addition, considering the property of collimated light that does not spread, the angle of lighting was set at 1.0 to 3.0° in 1.0° increments to compare the effects of the angle. A digital camera (RICOH WG-80, RICOH IMAGING COMPANY, LTD.) was used to capture the images. The camera has approximately 16 million effective pixels and is equipped with a 1/2.3-inch CMOS sensor. From the image, a 100 x 300 mm measurement area was cut out at 1200 x 3650 px (4.3 million pixels) and used for binarization. A schematic of the experiment is shown in Figure 2.

Calculation of Shadow Area Using A New Grayscale Conversion

In the binarization used to calculate the shadow area, the RGB image is first converted to a grayscale image and then to a binary image. Until now, NTSC in equation (1) has been used to convert RGB to

Fig.1 Collimated light

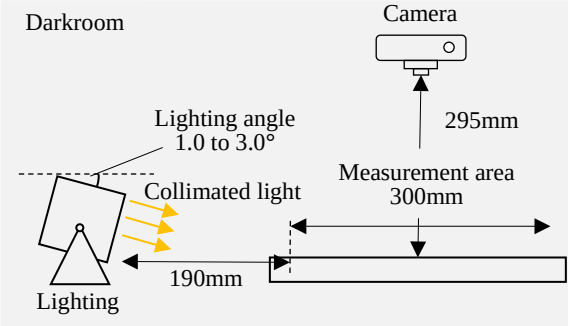

Fig.2 A schematic of the experiment
Note: Adapted from Urahata et al. [1]

grayscale images. In this study, we have used new methods: the average method, which simply Averages the RGB values; the Max method, which adopts the maximum value among RGB; the Min method, which adopts the minimum value among RGB; and the R method, G method, and B method, which adopt the RGB values as they are. The conversion equations for each method are shown in the following.

$$Y = \frac{R+G+B}{3} \quad (3)$$

$$Y = \max(R, G, B) \quad (4)$$

$$Y = \min(R, G, B) \quad (5)$$

$$Y = R \quad (6)$$

$$Y = G \quad (7)$$

$$Y = B \quad (8)$$

In the conversion from grayscale images to binary images, two types of thresholding methods were used: the Exhaustive method, which uses all thresholds from 0 to 255, and the Otsu method, which determines the optimal threshold for each image. Figure 3 shows the binarization used in this study. The grayscale conversions were compared and evaluated based on the shadow area values obtained.

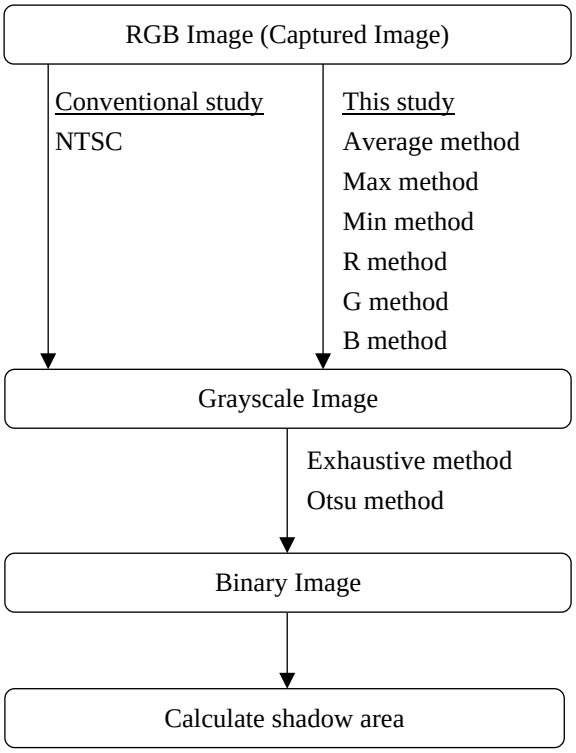

Fig.3 The binarization used in this study

RESULTS AND DISCUSSION

The relationship between the shadow area at a lighting angle of 2.0° and the arithmetic mean roughness R_a is shown in figures 4 to 9. In the Exhaustive method, analysis was performed for all thresholds from 0 to 255, and it was found that, regardless of the grayscale conversion method, a shadow area occurs even on smooth surfaces without unevenness at thresholds of approximately 50 to 100 or higher. In general, it is desired that the shadow area be 0% on smooth surfaces without unevenness. Therefore, in the Exhaustive method, comparisons were made between thresholds of 0 to 50.

The results of the Exhaustive method showing the highest coefficient of determination R^2 are shown in the figures 4 to 0. Additionally, the threshold for each methods are shown in Table 1 along with the NTSC results (from previous studies). Furthermore, the R^2 for each method are shown in Figure 10 and Table 2 for the Exhaustive method and Figure 11 and Table 3 for the Otsu method, along with the NTSC results. In addition, Figure 12 shows a captured image of concrete with R_a = 0.50 mm at a lighting angle of 2.0°, as well as grayscale and binary images obtained using the R method and B method.

Evaluation of The Coefficient Of Determination

Figures 10 and 11 show that all coefficient of determination R^2 were high, with values of 0.8 or higher. All conversion methods and threshold methods showed high R^2. In the exhaustive method shown in Figure 10, all conversion methods showed high R^2 values when the lighting angle was 2.0°. In addition, the R method showed higher R^2 values than the NTSC (conventional method) at all angles. Furthermore, the average method showed R^2 values similar to the conventional method. Other methods showed lower R^2 values than the NTSC.

In Figure 11, Otsu method showed almost the same R^2 for both 1.0° and 2.0°, with a tendency to decrease at 3.0°. The Min method and B method showed lower R^2 than NTSC at all angles.

In conclusion, the Exhaustive method showed higher R^2 in all cases and was found to be suitable for measurement. This trend was consistent with the results shown in previous studies [5].

About The Threshold of The Exhaustive Method

Table 1 shows that there was no difference in the threshold of the Exhaustive method depending on the angle, and the threshold values were almost constant for each conversion method. This trend is the same as the results shown in previous studies [5]. On the other hand, it became clear that the values tended to differ depending on the conversion method.

Differences Between Conventional Conversion Method (NTSC) And New Conversion Methods

We performed a paired t-test with a significance level of 5% for the R^2 values of NTSC in previous studies and the R^2 values of each conversion method used in this study. The results are shown in Table 4. As shown in Table 4, in the Exhaustive method, a

significant difference was observed only in the Min method. No significant differences were observed in other conversion methods, such as the R method, which showed an R^2 greater than NTSC, and the Average method, which showed almost the same value as NTSC. Therefore, although no significant difference was observed, it became clear that there is

a grayscale conversion that shows a larger R^2 than the conventional method. At the very least, it was found that the R method has an R^2 equal to or greater than NTSC, suggesting the possibility of improved measurement accuracy. In addition, it became clear that the average method has an equivalent R^2, suggesting that there is no difference in measurement accuracy. On the other hand, the Min method, which showed a significant difference and had a lower R^2.

In the Otsu method, significant differences were observed between the Max method, Min method, and B method. Therefore, it was suggested that the Max method and B method had lower measurement accuracy than NTSC. Although there was almost no difference in the R^2 value of the Min method compared to NTSC, a significant difference was observed, so it could not be evaluated this study.

Furthermore, considering the above results, it was suggested that NTSC, which has been used in previous studies, is a valid measurement method. When considering future measurements, NTSC, Average method, and R method are likely to be suitable for the Exhaustive method, which is a threshold setting method with a high R^2 value.

On the other hand, since the sample size in this study is only 3, the statistical robustness is low. Therefore, the optimal conversion method cannot be determined for measurement. In the future, it will be necessary to verify by increasing the sample size, such as acquiring data at a larger lighting angle (4.0° or more).

CONCLUSION

This study aimed to clarify the effects of different grayscale conversion methods on roughness measurement method using binarization, and the effects were verified. The findings of this study are summarized in the following.

- It was found that grayscale conversion methods affect measurements.
- It was suggested that some conversion methods improve measurement accuracy, while others reduce it.
- The validity of the conventional NTSC method was also indicated.
- As in previous studies, it was found that the exhaustive method is more suitable than the Otsu method for setting thresholds.

As mentioned in the Results and Discussion section, the challenge for the future is the need to use a large amount of data due to the small sample size. In addition, to establish this research, it is necessary to investigate the effects of different types of lighting and cameras on measurements. In particular, the lighting used in this study is collimated light, which has characteristics different from general lighting, so investigation is essential. Furthermore, although the experiments are conducted in a darkroom environment, it is also necessary to develop a method for conducting experiments in actual canals.

ABSTRACT

Bueng Kan, Thailand's newest province located in the northeast region, has experienced increasing tourism alongside rising road safety concerns. The province faces challenges with crash-prone roadways and a shortage of road safety engineering specialists. This research aims to identify high-risk road segments in Bueng Kan and develop targeted safety interventions that local authorities can readily implement. The methodology employed a three-phase approach: (1) statistical analysis of historical crash data; (2) identification of high-risk areas through agency data integration and comprehensive field investigations; and (3) development of evidence-based countermeasures using engineering solutions, behavioral interventions and monitoring systems. All proposed interventions were evaluated according to International Road Assessment Programme (iRAP) standards. Results identified six critical road segments scoring 1 star or lower on the iRAP star rating system within Bueng Kan Province. These segments fall under the jurisdiction of local administrative organizations and Bueng Kan Municipality. Following the implementation of the proposed safety improvements—including warning signage installation, road surface reinforcement, enhanced lighting and pavement markings—safety ratings improved to 3 stars or higher across all segments, demonstrating significant safety enhancements. Overall, the interventions are projected to reduce crashes by 41.9%, with the Ban Burapha-Ban Khok Krachae route demonstrating the highest economic benefit-cost ratio. This research provides local authorities with data-driven solutions to effectively improve road safety and a framework for optimizing budget allocation for long-term road safety improvement planning, ultimately reducing injuries and fatalities among road users in Bueng Kan Province.

Keywords: Road Safety, iRAP, Integration, Bueng Kan, Thailand

INTRODUCTION

Road traffic crashes remain a major public health and safety concern in Thailand, especially in rural provinces where infrastructure and traffic management systems are still underdeveloped. Bueng Kan, located in the upper northeastern region of Thailand, became a separate province from Nong Khai in 2011 [1] and is currently undergoing development efforts to enhance its overall capacity. Despite having a relatively small population compared to other provinces, Bueng Kan continues to face significant road safety challenges, particularly during major holidays such as Songkran, when crashes noticeably increase. According to crash statistics from 2023–2024, most crash victims were aged between 36 and 60 years and motorcycle-related incidents accounted for as much as 89% of total crashes [2] Although the number of fatalities and injuries has decreased compared to the previous year, hazardous road segments remain prevalent across the province—especially on roads under the responsibility of local administrative organizations.

To support sustainable development and enhance road safety, this research focuses on analyzing high-risk areas in Bueng Kan Province using traffic engineering principles combined with statistical data and field surveys. It aims to identify dangerous road segments and develop practical intervention measures that can be readily implemented. The ultimate goal is to provide local authorities with actionable insights for effective spatial planning and risk mitigation at the local level.

RESEARCH SIGNIFICANCE

This research is significant in analyzing and addressing road safety issues in Bueng Kan Province, with a focus on identifying high-risk locations and proposing intervention strategies to improve hazardous areas. The aim is to help reduce road crashes and associated injuries. The research findings will support the development of appropriate solutions for local authorities and promote long-term road safety improvements.

LITERATURE REVIEW

Statistical Model for Analyzing Crash Severity

Logistic regression is the primary statistical method commonly used to model crash severity, as it effectively handles categorical dependent variables and provides clear interpretations through odds ratios. This method has been widely applied to identify and quantify factors influencing crash severity outcomes. For instance, Wei et al. [3] employed both a Multinomial Logistic Regression Model (MN-logit) and a Random Parameter Logit Model (RP-logit) to explore the factors affecting injury severity. Ye and Lord [4] compared logistic regression with other statistical techniques, focusing on sample size and the efficiency of each method. Meanwhile, Abay [5] used a bivariate logistic regression model to analyze injury severity for both drivers and pedestrians in vehicle-pedestrian crashes, helping to better understand the complex relationship between injury outcomes for both involved parties.

Kernel Density Estimation (KDE)

Kernel Density Estimation **(** KDE) is a widely used non-parametric spatial analysis technique that serves as an effective tool for analyzing road crash data, particularly when location-specific crash information is available. This method enables the visualization and analysis of areas with frequent crash occurrences. By estimating the density of events within a given area using crash data distributed across various points in a continuous space—such as roads or urban zones—KDE helps to identify crash hotspots. [6-8] Furthermore, KDE has been proven to be well-suited for application in rural road networks and areas where GPS data is unavailable, demonstrating its flexibility and effectiveness in various geographic contexts. [9**,** 10]

iRAP Star Ratings

The International Road Assessment Programme (iRAP) provides a globally recognized method for assessing road infrastructure safety. Its Star Rating system evaluates roads from 1-star (least safe) to 5-star (most safe). Globally, only a small portion of travel occurs on 3-star or better roads, particularly for vulnerable road users. iRAP promotes a global target: ensuring that most road travel occurs on 3-star [11]

The iRAP (International Road Assessment Programme) methodology has been adopted in many countries to identify and rank risks across road networks, especially in areas where crash data is incomplete or inaccurate. For example, Algeria has implemented iRAP in combination with GIS systems to assess the safety levels of different segments of its road network [12-14] Additionally, the Star Rating for Schools (SR4S) program, developed by iRAP, has been used to evaluate road safety around school zones, enabling the design of appropriate and targeted intervention measures. [15**,** 16]

RESEARCH METHODOLOGY

The conceptual framework of this study represents a systematic process for enhancing road safety in Bueng Kan Province. It begins with the collection of historical crash data to understand the causes of road crashes and the factors contributing to crash severity within the study area. This information is then used to develop models identifying crash severity and high-risk locations. Subsequently, the data is utilized to conduct road safety assessments based on established criteria and checklists through Road Safety Audits (RSAs) [17], in parallel with an iRAP analysis—an internationally recognized methodology for evaluating road safety. These assessments lead to the development of conceptual solutions and intervention strategies proposed to local authorities. The final stage involves evaluating both the direct and indirect economic feasibility of the proposed measures prior to actual implementation, as illustrated in Fig. 1.

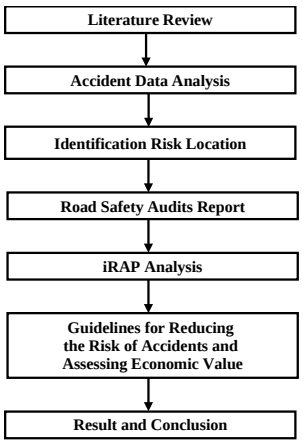

Fig.1 Research Framework

HISTORICAL CRASH DATA ANALYSIS

Historical crash data in Bueng Kan Province from 2019-2021 Data from the Bueng Kan Provincial Road Safety Operation Center, the Royal Thai Police and local hospitals will be used to create a Multinomial Logistic Regression model to analyze the factors affecting the severity of crashes. The dependent variable is the severity of the crash, which is divided into 3 levels: slightly injured, Serious injuries and deaths are caused by the model consisting of two models: a model that analyzes crashes where the victims are vulnerable road users and a model that analyzes crashes on roads that are intersections. The logit function of the covariates is defined as follows:

$$Y_k = \text{logit}(P_k) = \log\left(\frac{P_k}{1-P_k}\right) = \beta_0 + \beta_1 \cdot x_{i2} + \beta_2 \cdot x_{i2} + \ldots + \beta_i \cdot x_{in} \quad (1)$$

Hence, the probability of crash *i* resulting in injury severity *k* (k = 1 is a fatal crash and k = 0 is a non-fatal crash) can be written as:

$$P_k = \frac{EXP\left(\beta_0 + \beta_1 \cdot x_{i2} + \beta_2 \cdot x_{i2} + \ldots + \beta_i \cdot x_{in}\right)}{1 + EXP\left(\beta_0 + \beta_1 \cdot x_{i2} + \beta_2 \cdot x_{i2} + \ldots + \beta_i \cdot x_{in}\right)} \quad (2)$$

where β_i is a parameter estimate corresponding to the independent variable x_i. This paper uses *EXP(β)* (Odds Ratio) to interpret the influence of each independent variable.

Then, the Logistic Regression model was analyzed using the principle of selecting variables one at a time, based on the relationship between the independent and dependent variables. Out of a total of 16 variables, there was 1 dependent variable, FATALITY and 15 independent variables. Then, the Cox & Snell R Square and Nagelkerke R Square values were considered to indicate the efficiency of the model and its consistency with the empirical data.

The analysis of the accident model in the vulnerable group of accident victims found that driving faster than the legal limit is approximately 13.5 times more likely to cause death than other causes. The model that analyzes crashes at road intersections can be interpreted that if the victim wears a helmet at the time of the crash, the chance of death is only a 23.2 percent. Full regression tables and parameter values are provided in Tables 1-2.

Fig.2 shows the high-risk or hazardous locations using Kernel Density Estimation (KDE) within a GIS environment (ArcGIS Pro) using historical event data, using the 85th percentile density threshold. The analysis results revealed 6 areas with frequent and clustered accidents in Bueng Kan Province.

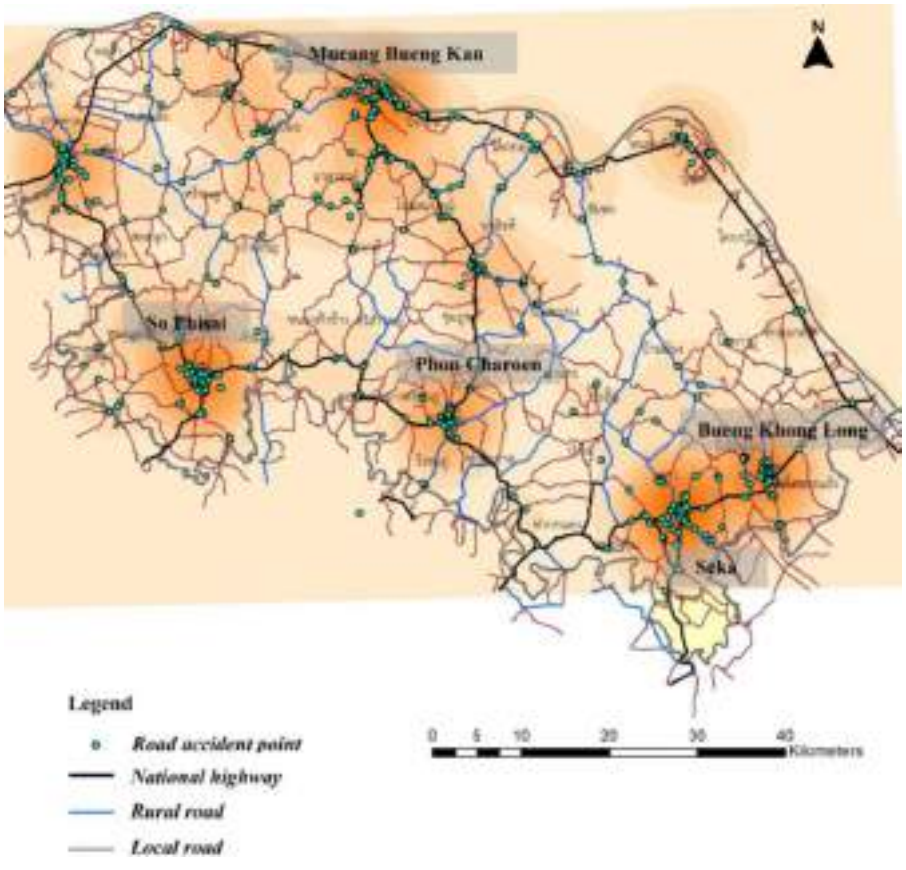

Fig.2 Results of crash cluster analysis in Bueng Kan province

ROAD SAFETY AUDIT (RSA) AND FIELD SURVEY

Selected high-risk locations undergo a thorough Road Safety Audit (RSA). The RSA process consists of:

1) Primary data collection: Collect existing road network maps, traffic volume data, historical crash details for specific areas and aerial photographs.

2) Preparing a checklist: Develop a standardized RSA checklist based on AUSTROADS, PIARC and Thai Highways Department guidelines, adapted to the local context.

3) Field inspection: Operated by a team of traffic engineering and road safety experts during different times (day/night, weekdays/weekends) and different weather conditions.

4) Data recording and analysis: Record observations, photographs and videos, as well as road user behavior.

Key issues examined include road courses and sections, intersection characteristics, drainage, road signs, traffic lights, road surface markings, roadside hazardous materials, road surface conditions and lighting.

From the KDE analysis, several crash clusters were identified. Based on crash frequency, severity, field surveys, RSA inspection results and consultation with local authorities, six high-risk road sections were prioritized for the design of remedial measures:

1) At the Bueng Kan Municipality roundabout: (3 points: roundabout, intersection of Bueng Kan Road and Phon Thuk Phai Road, intersection of Bueng Kan Road and Rak Song Road)

2) Roads under the responsibility of the Provincial Administrative Organization (PAO Roads): (3 points: Ban Saen Samran-Ban Huai Kong Road, Ban Burapha-Ban Khok Krachae Road, Ban Yang Rian Road)

IRAP STAR RATING ASSESSMENT

The International Road Assessment Programme (iRAP) methodology was used to assess the safety of selected road sections and the potential impacts of corrective measures. The assessment process and an example of software for iRAP assessment are shown in Fig.3-4 and is divided into three parts:

1) Road Coding: Road features were systematically encoded every 100 m using ViDA software. Over 50 roadway features related to design and traffic control features that influence crash probability and crash severity were recorded, using digital imagery and field data.

2) Star Rating Generation: From the encoded characteristics, a star rating (1 star to 5 stars) is generated for car users, motorcyclists, pedestrians and cyclists.

3) Selection of corrective measures and investment planning: Evidence-based corrective action measures, iRAP methodology, are proposed. It enables modeling of the impact of these measures on star ratings and assessment of reductions in fatalities and serious injuries (FSIs).

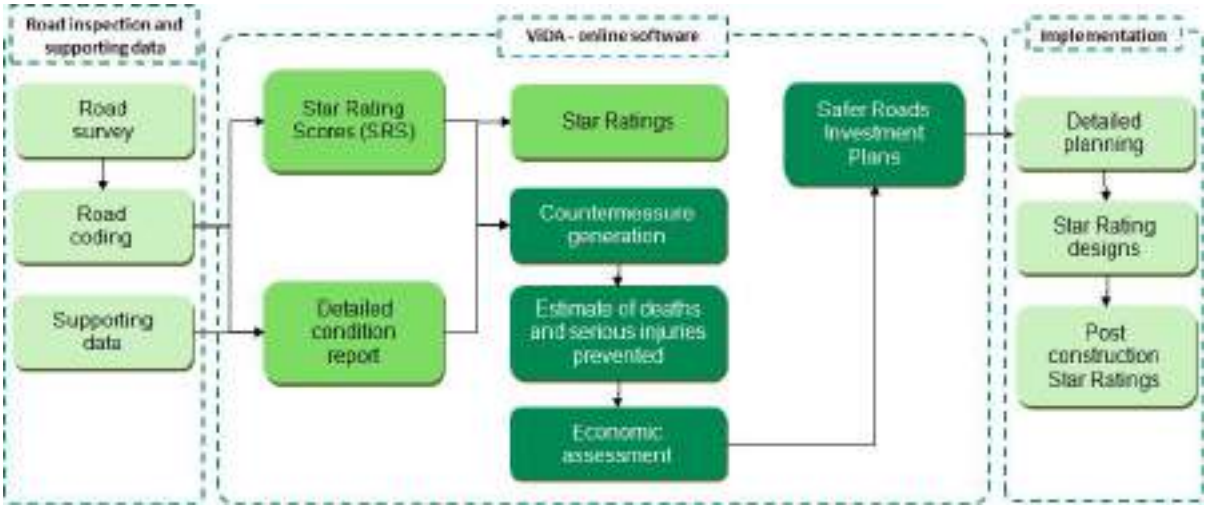

Fig.3 iRAP Assessment Process

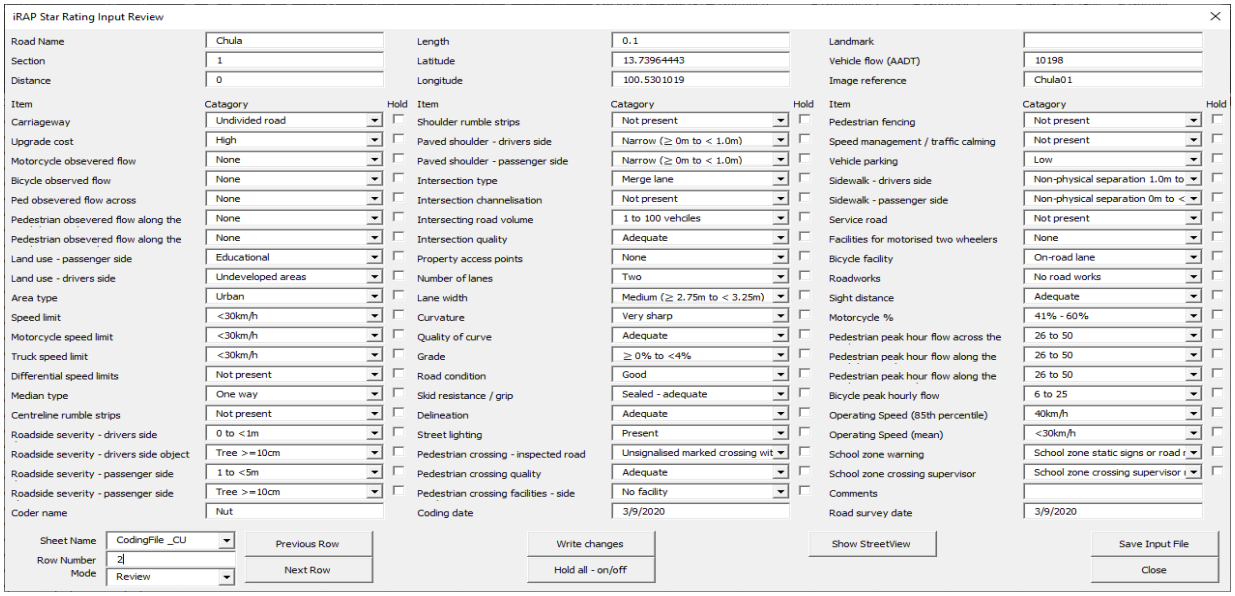

Fig.4 iRAP Assessment Process

The proposed remedial measures for the six high-risk road sections are expected to reduce crashes by an average of 41.9%, with all improved roads expected to receive an iRAP star rating. A rating of 3 stars or above for all road user groups, which is a significant safety improvement from the previous 1 or 2 stars, demonstrates that targeted, evidence-based engineering solutions can significantly improve road safety performance. The safety assessment results according to the iRAP criteria, conducted using the iRAP PreProcessor program, were based on analyzing images within a 100-meter radius and considering over 50 variables. The safety evaluation results according to the iRAP criteria after the improvement measures are shown in Table 3 and Fig. 5.

Table 3 The safety assessment results according to the iRAP criteria for the Ban Burapha - Ban Khok Krachae route Bok.3032 Road Mueang Bueng Kan District after the improvement measures.

Road User Group	Safety Rating (Stars)
Car Users	> 4 stars
Motorcycle Users	> 4 stars
Pedestrians	> 4 stars
Bicycle Users	> 4 stars
Car Users	> 4 stars
Motorcycle Users	> 4 stars

ECONOMIC COST ANALYSIS (CBA)

The economic value of the proposed remedial measures was assessed using (Cost-Benefit Analysis: CBA) using a project life expectancy of 10 years. Discount rate: 12% (based on the World Bank and National Economic and Social Development Board guidelines) Cost calculation includes initial construction and installation costs. Maintenance costs (regular and routine) and operating costs. Benefits will arise from reducing economic and social costs resulting from crashes, including reducing the cost of death.

Fig.5 Sample of iRAP's safety assessment results at the Ban Burapha - Ban Khok Krachae route Bok.3032 Road Mueang Bueng Kan District After the renovation

Estimated using the Value of Life Statistics (VSL) from the Office of Transport and Traffic Policy and Planning (OTP) (10.2 million baht per death, adjusted for 2021) Reducing the cost of injury: Serious injury (0.31 million baht/case), Minor injury (0.08 million baht/case) according to the NESDB and Reducing the cost of property damage: (0.05 million baht/case) in terms of indicators: Net Present Value (NPV), Benefit

Cost Ratio (BCR) and Internal Rate of Return (IRR).

Economic analysis showed different levels of cost-effectiveness. As seen in Table 4, while Bueng Kan Municipality Roundabout had the highest investment cost but a relatively low BCR (0.48), which may be due to the complexity of the area and the lower severity of previous crashes, Ban Burapha-Ban Khok Krachae Road showed the highest economic benefit-cost ratio (BCR = 1.55), indicating that investment in improving curves on high-crash rural roads could yield significant economic returns. Other areas showed BCR values between 0.69 and 0.91, even for areas with BCR < 1. Non-monetary benefits, such as improved quality of life, reduced suffering and improved community safety perception, were also significant and supported the implementation of these safety measures.

Table 4 Results of prioritization in resolving frequently problematic points/areas and economic analysis

Point/Area	Cost of troubleshooting (baht)	Reduced accident benefits (baht)	Benefit to Cost Ratio (B/C)	Ranking results
1. Bueng Kan Municipality roundabout area	2,266,532	331,977	0.48	6
2. Bueng Kan Road intersection, cutting across Phon Thuk Phai Road	1,563,762	342,331	0.71	4
3. Intersection of Bueng Kan Road and Raksong Road	1,319,999	331,977	0.82	3
4. Area along the route Baan Saen Samran - Baan Huai Kong, Road 3217, Mueang Bueng Kan District	850,735	238,575	0.91	2
5. Area along the Ban Burapha-Ban Khok	856,648	407,514	1.55	1
6. Area along the Ban Yang Rian route, Road 4015, Seka District	1,745,918	368,324	0.69	5

DISCUSSION

From the analysis of road crash data in Bueng Kan Province, it was found that crashes occurring on local roads are influenced by several factors that contribute to the severity of injuries and fatalities. In particular, vulnerable road users (VRUs) and crashes occurring at intersections are significant contributors. The findings are presented as follows:

Factors Affecting the Severity of Crashes

Using logistic regression to analyze the factors affecting the severity of crashes, several statistically significant factors were identified. These include exceeding the speed limit which increases the likelihood of death by up to 13.5 times, emphasizing the need for strict speed control. The gender of the driver shows that male drivers are 3.969 times more likely to die from a crash compared to female drivers. Crashes occurring at night without lighting increase the likelihood of death by 2.048 times. Wearing a helmet reduces the chance of death by 79.4% and driving under the influence may reduce the severity of the crash due to lower speed but it remains a significant risk factor.

Risk Areas and Solutions

Using Kernel Density Estimation (KDE) to analyze crash data, areas with high crash frequencies were identified. The areas with the highest crash density in Bueng Kan province include Muang Bueng Kan District (the municipal roundabout, which has traffic control and speed regulation issues), Bung Khong Long District (Highway 2026, a major road with high traffic volume), Se Ka District (Seka subdistrict, particularly at the intersection with the main highway) and Phon Charoen and So Phisai Districts (Highway 2095 and local roads).

Improvement Measures for Road Safety

The study suggests several measures to enhance road safety, including speed reduction measures (such as clear traffic signs, Optical Speed Bars and enforcement of speed limits), improvements in lighting systems (installing street lights at intersections and high-risk areas, especially rural roads), improving intersections (e.g., stop signs, yield signs, advance warning signs and considering roundabouts in high-traffic areas), road surface enhancements to increase friction (to reduce skidding, especially on wet roads, curves, intersections, or frequent braking zones), promoting helmet use (through law enforcement and public awareness campaigns) and upgrading road infrastructure (such as widening lanes, improving shoulders and drainage systems). The findings highlight factors affecting crash severity on local roads in Bueng Kan province, identifying six high-risk areas requiring infrastructure and policy improvements to enhance safety. Four main measures were emphasized: installing speed warning signs, reinforcing road surfaces, installing streetlights and placing road markings, which could reduce crashes by up to 41.9%. The cost-benefit analysis revealed that the Ban Burapa-Ban Khok Krachaeng route has the highest B/C ratio of 1.55, while the roundabout in the municipal area of Bueng Kan has the lowest B/C ratio of 0.48.

CONCLUSION

Crashes in Bueng Kan are chiefly linked to speeding, driver gender, night-time driving, helmet non-use, and drink-driving. Hot-spot districts—Muang Bueng Kan, Bung Khong Long, Se Ka, Phon Charoen, and So Phisai—need targeted upgrades: tighter speed control, better lighting, smoother intersections, stronger pavements, and campaigns to boost helmet use. Priority countermeasures—speed-warning signs, resurfacing, street lights, and clear road markings—could cut crashes by up to 42%. Cost-benefit analysis shows the Ban Burapa–Ban Khok Krachaeng corridor offers the best return (B/C = 1.55), while Bueng Kan's municipal roundabout

ranks lowest (B/C = 0.48).

INFLUENCE OF PORE SPATIAL DISTRIBUTION ON THE RELATIONSHIP BETWEEN MINOR LOSS AND FORCHHEIMER COEFFICIENTS

Junichiro Takeuchi[1] and Masayuki Fujihara[1]

[1]Graduate School of Agriculture, Kyoto University, Japan

ABSTRACT

Darcy's law states that there is a linear relationship between the flow velocity and the gradient of the piezoelectric head when the flow velocity in the porous media is sufficiently small. When the flow velocity increases to some extent, Forchheimer's law is applied by adding a squared term of the flow velocity to Darcy's law. Various equations have been proposed to estimate the coefficient of the squared term (Forchheimer coefficient) from the grain size and porosity. On the other hand, the Forchheimer coefficient is known to depend on the heterogeneity of the spatial distribution of the pores. The above equations do not consider the heterogeneity of the pore distribution. In this study, we investigate the relationship between the shape loss coefficient in the pores and the Forchheimer coefficient under laminar flow conditions using a pore network modeled as a network of interconnected pores in a porous medium. Specifically, a series of numerical experiments are conducted by changing the spatial distribution of the pores as well as the mean and variance of the shape loss coefficients. As a result, it is shown that there is a proportional relationship between the average of the shape loss coefficient in each pore and the Forchheimer coefficient. Furthermore, it is shown that the proportionality coefficient strongly depends on heterogeneity of porous media.

Keywords: Forchheimer coefficient, Minor loss coefficient, Pore network model, Network flow

INTRODUCTION

Generally, flow in groundwater is modeled by Darcy's law. However, even in laminar flow, when the flow velocity becomes sufficiently high, the pressure head loss due to the inertial effect can no longer be ignored, rendering Darcy law inapplicable. In such cases, Forchheimer's law, which adds a squared term of the flow velocity is added to Darcy's law, is used to describe the relationship between flow velocity and head loss.

Forchheimer's equation includes two coefficients related to the properties of the porous medium. One is related to the friction loss and corresponds to the permeability in Darcy's law, while the other, called the Forchheimer coefficient, is related to the inertial effect and is characteristic of Forchheimer's law. Many empirical formulas, such as Ergun's formula, have been proposed for these coefficients. In many cases, they are expressed using parameters such as the porosity and particle size of the porous medium [1,2]. However, the Forchheimer coefficient depends on the spatial heterogeneity of pores [3], which cannot be represented by macroscopic parameters like porosity and particle size.

On the other hand, the squared term of velocity in the Forchheimer equation is thought to originate from minor losses due to pore expansion, contraction, and/or bending [4]. By calculating flow within pores using methods such as the lattice Boltzmann method and the finite element method, loss coefficients for expansion/contraction regions or bending regions can be determined [5]. The Forchheimer coefficient for porous media can be calculated by computing flow in pores of a whole porous medium [6]. Additionally, by using a pore network model to calculate flow in a pipe channel that considers shape loss due to pore expansion and/or contraction, it is possible to evaluate flow within a porous medium. El-Zehairy et al. (2019) estimated shape loss coefficients from pore sizes obtained through micro-X-ray CT data and investigated the effects of porosity heterogeneity on non-Darcy flow [4].

The relationship between the minor loss coefficient and the Forchheimer coefficient has not been investigated. In direct methods that directly calculate flow within pores using LBM or FEM, it is difficult to predefine the desired minor loss coefficients. Therefore, the pore network approach is employed to prescribe arbitrary shape loss coefficients. This study aims to clarify the relationship between the minor loss coefficient and the Forchheimer coefficient, as well as the influence of porous media heterogeneity on them, through numerical experiments.

RESEARCH SIGNIFICANCE

This study quantitatively clarifies the link between the Forchheimer and minor loss coefficients

in porous media, emphasizing the critical role of pore-scale heterogeneity. The findings enhance the predictive accuracy of non-Darcy flow models, contributing to improved designs in groundwater management, civil engineering, and environmental protection where accurate flow prediction through porous media is essential.

MODEL DESCRIPTION

In this study, we investigate the relationship between Forchheimer coefficients at the macro scale and shape loss coefficients at the pore scale.

Darcy-Forchheimer Equation

Flow in porous media with relatively high Reynolds numbers is described not by Darcy's law but by Forchheimer's law, which considers the influence of the inertial term. Here, the following Forchheimer equation is used as an empirical formula representing the flow rate per unit area and the hydraulic gradient in a porous medium with a constant cross-section [4].

$$\frac{\Delta h}{L} = \alpha_F q + \beta_F |q| q \tag{1}$$

$$h = \frac{p}{\rho g} + z \tag{2}$$

$$q = \frac{Q}{A} \tag{3}$$

where Δh is the difference of the hydraulic head between the inlet and outlet of an objective porous medium, L is the length of the objective porous medium, q is the flow rate per unit cross-sectional area, p is the pressure, ρ is the fluid density, g is the gravitational acceleration, z is the height from a reference plane, Q is the total flow rate through the porous medium, A is the cross-sectional area of the porous medium, and α_F and β_F are the coefficients. The coefficient α_F is the inverse of the hydraulic conductivity K and is represented as follows.

$$\alpha_F = \frac{1}{K} \tag{4}$$

The quadratic term in q is due to inertial effects caused by pore expansion and/or contraction, etc.

Flow in Pore Network

The pores in a porous medium can be modeled as a network of repeatedly dividing and merging pores. Here, we use the SNOW algorithm to extract the pore network from the porous medium [7]. The extracted pore network consists of PBs (pore bodies) and PTs (pore throats). PBs constitute the bifurcation nodes, and PTs constitute the pipes between the bifurcation nodes in a pipe network. For a pipe network flow, the flow rate within each pipe (PT) and the piezometric head at the bifurcation nodes (PBs) are unknown variables. The solution can be obtained by simultaneously solving the following equations: the equations for head loss in each PT, the continuity equation at the PBs, and the equations for the hydraulic head at the inflow and outflow PBs.

$$h_j - h_k = f_i \frac{l_i}{d_i} \frac{q_i |q_i|}{2 g a_i^2} + \sum_m b_{i,m} \frac{q_i |q_i|}{2 g a_i^2} \tag{5}$$

$$d_i = \frac{4 a_i}{P_i} \tag{6}$$

where index i denotes the i-th PT and i is included in the set Λ^{PT} of PT indices, h_j and h_k are the hydraulic head at the both ends of PT i, and indices j and k are included in the set Λ_i^{PB} of PB indices at both ends of PT i. l_i, d_i, q_i, a_i and P_i are the length, hydraulic diameter, flow rate, cross-sectional area, and perimeter of PT i, respectively. f_i is the friction factor, and $b_{i,m}$ is the minor loss coefficient (e.g., for expansion and contraction), where multiple factors are assumed to exist within a single PT. When the flow in a PT is laminar, the friction factor f_i is represented as follows.

$$f_i = \frac{\gamma}{Re_i} \tag{7}$$

$$Re_i = \frac{d_i |q_i|}{v a_i} \tag{8}$$

where γ is a constant that depends on the shape of the cross-section. Typical values are 64, 56.908, or 53.333 when the cross section is a circle, square, or equilateral triangle, respectively. Re_i is the Reynolds number of the reach i, v the dynamic viscosity coefficient of water. Substituting Eqs. (7) and (8) into Eq. (5) yields Eq. (9), which describes head loss including the minor loss in laminar flow.

$$\frac{h_j - h_k}{l_i} = \alpha_i q_i + \beta_i q_i |q_i| \tag{9}$$

$$\alpha_i = \frac{\gamma v}{2 g a_i d_i^2} \tag{10}$$

$$\beta_i = \frac{\sum_m b_{i,m}}{2 g l_i a_i^2} \tag{11}$$

In this study, the head loss coefficients α_i and β_i are referred to as the friction loss coefficient and the shape loss coefficient, respectively.

The mass balance equations at each PB are represented as follows.

$$\sum_{i \in \Lambda_j^{\mathrm{PT}}} q_i = 0 \tag{12}$$

where Λ_j^{PT} is the set of PT indices connected to junction $j \in \Lambda^{\mathrm{PB}}$.

In addition to these equations, specified water heads are given at the upstream and downstream ends of the network.

$$h_j = h_{\mathrm{IN}} \qquad (j \in \Lambda_{\mathrm{IN}}^{\mathrm{PB}}) \qquad (13)$$

$$h_j = h_{\mathrm{OUT}} \qquad (j \in \Lambda_{\mathrm{OUT}}^{\mathrm{PB}}) \qquad (14)$$

where $\Lambda_{\mathrm{IN}}^{\mathrm{PB}}$ and $\Lambda_{\mathrm{OUT}}^{\mathrm{PB}}$ are the sets of PB indices of inlets and outlets, respectively.

The nonlinear equations system of Eqs. (9) through (14) is solved by the Newton-Raphson method.

Estimation Of Forchheimer Coefficients From Network Flow

From the total flow Q, which is obtained by summing all inflow or outflow rates, the apparent hydraulic conductivity K_{app} is calculated as follows.

$$K_{\mathrm{app}} = \frac{L}{h_{\mathrm{IN}} - h_{\mathrm{OUT}}} \frac{Q}{A} \qquad (15)$$

$$Q = \sum_{i \in \Lambda_{\mathrm{IN}}^{\mathrm{PT}}} q_i \left(\text{or } = \sum_{i \in \Lambda_{\mathrm{OUT}}^{\mathrm{PT}}} q_i \right) \qquad (16)$$

where $\Lambda_{\mathrm{IN}}^{\mathrm{PT}}$ and $\Lambda_{\mathrm{OUT}}^{\mathrm{PT}}$ are the sets of indices of PTs connected to the inlet and outlet, respectively.

On the other hand, the apparent hydraulic conductivity is represented by the following equation derived from Eq. (1).

$$K_{\mathrm{app}} = \frac{1}{\alpha_{\mathrm{F}} + \beta_{\mathrm{F}} |q|} \qquad (17)$$

By changing the head at the upstream end h_{IN}, apparent hydraulic conductivities for various flow rates can be obtained. From the relationship between the apparent hydraulic conductivities and flow rate (*i.e.*, Darcy velocity), the Forchheimer coefficients α_{F} and β_{F} are estimated using the least squares method.

Comparison Of Forchheimer Coefficients and Head Loss Coefficients

In this study, we derive the Forchheimer coefficients, which are characteristic of porous media, from the prescribed shape loss coefficients in a pore network. When comparing these coefficients, the flow rate per unit area q in Eq. (1) is the Darcy velocity, whereas the flow rate q_i in Eq. (9) is the flow rate within the pores, *i.e.*, the actual velocity. Therefore, Eq. (9) is converted to a Darcy velocity equivalent using the relationship between the Darcy and actual velocities.

$$q_i = \frac{q_i^{\mathrm{D}}}{\phi} \qquad (18)$$

where ϕ is the porosity of the porous medium. Then the Darcy velocity version of Eq. (9) becomes:

$$\frac{h_j - h_k}{l_i} = \frac{\alpha_i}{\phi} q_i^{\mathrm{D}} + \frac{\beta_i}{\phi^2} q_i^{\mathrm{D}} \left| q_i^{\mathrm{D}} \right| . \qquad (19)$$

$$\bar{\beta} = \frac{1}{\left| \Lambda^{\mathrm{PT}} \right|} \sum_{i=1}^{\left| \Lambda^{\mathrm{PT}} \right|} \beta_i \qquad (20)$$

where $|\Lambda|$ is the number of elements in a set Λ.

In the numerical experiments conducted in this study, the relationship between β_{F} and β_i (specifically, the average of β_i, *i.e.*, $\bar{\beta}$) is investigated. This is done by arbitrarily varying α_i in each reach while maintaining the connectivity of the pore network and the spatial positions of the junctions. Varying α_i implies changing γ and/or d_i.

NUMERICAL EXPERIMENTS

Virtual Porous Medium and Pore Network

A virtual porous medium is created using the discrete element method by randomly packing spherical particles and a pore network is extracted using SNOW algorithm [7]. When extracting a pore network, several PT features can be obtained, such as inscribed radius, equivalent radius, perimeter, and cross-sectional area. As with PTs, the inscribed radius, volume, and surface area of PBs can be obtained. Here, PTs of the pore network are assumed to be circular tubes, and their radius is defined as that of the inscribed circle.

Figures 1 and 2 show the created porous medium and its extracted pore network. The porous medium was created by randomly packing 5,747 spherical particles with a diameter of 2 mm into a container with a 3.6 cm square base side length.

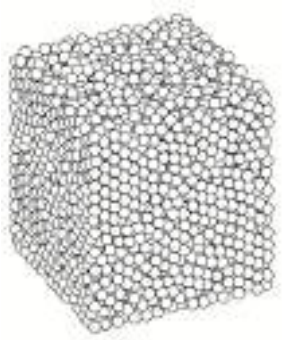

Fig.1 Virtual porous medium

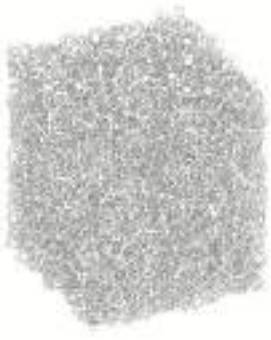

Fig.2 Extracted pore network

Head Loss Coefficients

To investigate the relationship between the shape loss and Forchheimer coefficients as the heterogeneity of the porous medium changes, four types of pore network are prepared here: Original, Homo, Hetero1, and Hetero2. Original refers to the original pore network extracted from the virtual porous medium. Homo refers to the one with all friction loss coefficients set to the average of Original's friction loss coefficients.

$$\alpha_i^{\mathrm{Homo}} = \bar{\alpha} \coloneqq \frac{1}{|\Lambda_{\mathrm{R}}|} \sum_{m \in \Lambda_{\mathrm{R}}} \alpha_m^{\mathrm{Original}} \tag{22}$$

where α_i^{Homo} and $\alpha_i^{\mathrm{Original}}$ are the friction loss coefficients for Homo and Original pore networks, respectively, and $\bar{\alpha}$ is the average of $\alpha_i^{\mathrm{Original}}$. Physically interpreted, this means that longer PTs are given a larger diameter.

Hetero1 and Hetero2 refer to the ones with friction loss coefficients following uniform random numbers as follows.

$$\alpha_i^{\mathrm{Hetero}} \sim U(\xi_\alpha, \eta_\alpha) \tag{23}$$

$$\frac{1}{2}(\xi_\alpha + \eta_\alpha) = \bar{\alpha} \tag{24}$$

$$r_\alpha \coloneqq \eta_\alpha - \xi_\alpha = \begin{cases} \bar{\alpha} & \text{for Hetero1} \\ 1.8\bar{\alpha} & \text{for Hetero2} \end{cases} \tag{25}$$

Where $U(\xi_\alpha, \eta_\alpha)$ is the random variable following a uniform distribution ranging from ξ_α to η_α. Here, ξ_α and η_α satisfy Eqs. (24) and (25). That is, the average of the random variable is $\bar{\alpha}$, and the width is $\bar{\alpha}$ for Hetero1 or $1.8\bar{\alpha}$ for Hetero2.

The shape loss coefficients are also given by a random variable following a uniform distribution ranging from ξ_b to η_b. Here, to clarify the physical meaning, the random number is assigned to the sum of $b_{i,m}$ instead of β_i.

$$\sum_m b_{i,m} \sim U(\xi_b, \eta_b) \tag{26}$$

Sixteen types of minor loss coefficients are generated by combinations of four types of averages and four types of widths.

$$\frac{1}{2}(\xi_b + \eta_b) = \bar{b} \in \{0.0, 0.1, 0.5, 1.0\} \tag{27}$$

$$r_b \coloneqq \eta_b - \xi_b \in \{0, 0.5\bar{b}, \bar{b}, 2\bar{b}\} \tag{28}$$

where $\bar{b}$ is the average minor loss coefficient in a single PT.

For numerical experiments, a total of 64 (=4×16) models with head loss coefficients are examined. Furthermore, to check the individual differences within each model, five samples were created using different random number seeds. The difference in piezometric heads between the inlet and outlet was set to 25 values ranging from 0.01 to 10 cm.

RESULTS

Typical flow distributions in the pore networks are shown in Figs. 3 to 5. Figure 3 shows the effect of the magnitude of $\bar{b}$, where the maximum flow velocity is suppressed as $\bar{b}$ increases. Figure 4 shows the flow velocity distribution for each model when the same spatial distribution of shape loss coefficients is applied. In the homogeneous medium Homo, the flow velocity distribution is nearly uniform in the vertical direction. In contrast, in the heterogeneous media Original and Hetero2, selective flow occurs. Hetero2, which is considered to have greater heterogeneity than Original, shows a stronger tendency. Figure 5 shows the effect of the variance of the shape loss coefficients in homogeneous media. It is shown that selective flow develops as the variance increases.

Table 1 Estimated Forchheimer coefficients ($r_b = 0.5\bar{b}$)

	Original		Homo		Hetero1		Hetero2	
$\bar{b}$	α_F	β_F	α_F	β_F	α_F	β_F	α_F	β_F
0.0	0.286	0.00	0.454	0.00	0.391	0.00	0.231	0.00
0.1	0.287	7.14×10^{-3}	0.454	7.97×10^{-3}	0.392	7.59×10^{-3}	0.232	6.11×10^{-3}
0.5	0.289	3.12×10^{-2}	0.455	3.79×10^{-2}	0.393	3.53×10^{-2}	0.235	2.64×10^{-2}
1.0	0.291	5.96×10^{-2}	0.456	7.43×10^{-2}	0.394	6.86×10^{-2}	0.237	4.99×10^{-2}

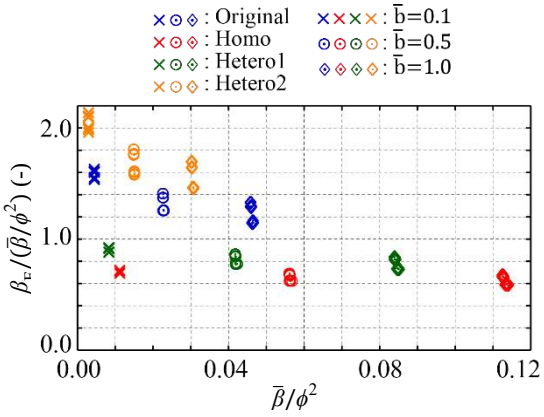

Fig. 7 Ratio of Forchheimer coef. to minor loss coef.

Figure 6 shows the changes in the computed apparent hydraulic conductivities and estimated regression curves for each porous medium model with $r_b = 0.5\bar{b}$. The horizontal axis shows the Darcy velocity (Q/A) when the difference in piezometric heads between the inlet and outlet varies from 0.01 to 10 cm, and the vertical axis shows the apparent hydraulic conductivity. These figures show that, even though the same spatial distribution of the minor loss coefficient is applied, the manner in which the apparent hydraulic conductivity emerges depends on the heterogeneity of the media. Table 1 shows the hydraulic conductivities and Forchheimer coefficients estimated from the computed results. The larger the degree of heterogeneity, the larger the Forchheimer coefficient.

Figure 7 shows the ratio of the Forchheimer coefficient to the corresponding minor loss coefficient. When the medium is homogeneous or has low heterogeneity, the ratio of the Forchheimer coefficient to the corresponding minor loss coefficient is less than 1, and the ratio increases as heterogeneity increases. These findings also demonstrate the dependence of the Forchheimer coefficient on the heterogeneity of porous media.

CONCLUSIONS

In this study, the relationship between the Forchheimer coefficient of a porous media and the shape loss coefficient in PTs was investigated through numerical experiments with pore network models. The results showed that the Forchheimer coefficient strongly depends on the heterogeneity of porous media. When a porous medium is homogeneous, the Forchheimer coefficient was slightly less than the average of corresponding minor loss coefficients. As the degree of heterogeneity became large, the ratio of the Forchhier coefficient to the corresponding minor loss coefficient also increased to about twice as much.

URBAN PUBLIC SPACE DESIGN AND UTILIZATION AS WELL AS THE DKI JAKARTA CITY GOVERNMENT'S EFFORTS TO EMPOWER STREET VENDORS

Elisabeth Ratu Rante Allo [1], Ruslan Prijadi [2] and Chotib [3]

[1,3] School of Strategic and Global Studies Universitas Indonesia; [2] Faculty of Economics and Business Universitas Indonesia

ABSTRACT

Problem Statement this research examines the utilization of public space by street vendors and its implications in Jakarta. The local government established a designated center for street vendors, known as the Binaan Location, equipped with essential facilities for electricity and water at reasonable costs. However, it has not attracted significant interest from street vendors, who tend to favor sporadic trading practices. Research Approach this research uses the Explanatory Sequential Mixed Method approach, where the quantitative phase is carried out first, and continued with the qualitative phase to enrich the quantitative findings. Field surveys and in-depth interviews were conducted utilizing a qualitative approach, complemented by ArcGIS mapping to analyze the spatial distribution of street vendor locations, the distance from the Binaan Location to these distributions, accessibility via public transportation networks, and spatial analysis through the overlay method of land use and resident density. Results the findings of this study are as follows: (1) The majority of Binaan locations experience low foot traffic and are distanced from populated areas; (2) Several structures within the Binaan location are inadequately maintained; (3) Street vendors are inclined to pay higher fees to thugs when operating outside the Binaan Location due to the influx of visitors.

Keywords: Urban Public Space Design, Street Vendors, Informal Economy, Spatial Analysis, Urban Planning

INTRODUCTION

Urban growth in developing countries like Indonesia has generated substantial informal sectors, with DKI Jakarta's informal economy employing over 193,000 individuals who make significant contributions to the local economy. Street vendors operating in public spaces such as sidewalks and parks create conflicts over urban space usage, reflecting the complex dynamics where informal economy needs clash with city modernization visions according to [1]. In a global context, similar issues are also experienced by various major cities in developing countries as noted [2].

Despite regulations like Governor Regulation No. 10/2015 intended to provide legal certainty and suitable locations for street vendors, implementation faces persistent challenges including vendor resistance and infrastructure limitations, leading to continued evictions that demonstrate policy-practice inconsistencies. The Jakarta government's Binaan Location program was designed as a win-win solution offering structured spaces with supporting facilities including drainage systems, waste management, public toilets, and electrical access, while maintaining urban order.

However, the program's underutilization reveals deeper structural issues in street vendor regulation approaches. The paradox remains that vendors continue to prefer sporadic selling using public facilities despite facing higher illegal levies, rather than utilizing well-organized designated locations with affordable cleanliness and security costs. This resistance indicates the need for comprehensive understanding of vendor preferences, consumer patterns, and informal economy dynamics to create effective and sustainable solutions that truly address the complex realities of urban informal commerce rather than imposing top-down spatial arrangements that fail to align with vendor economic logic..

RESEARCH SIGNIFICANCE

Street Vendor Concept In Jakarta

In Indonesia, street vendors are known as "kakilima" (five-foot), a term originating from the physical form of pushcart vendor [3]. The name represents five supporting points: two vendor legs, two cart wheels, and one additional cart support for balance when stationary.

According to DKI Jakarta Governor's Regulation No. 10/2015, street vendors are defined as "business actors who engage in trade using mobile or immobile business facilities, utilizing city infrastructure, social facilities, public facilities, land, and buildings owned by government and/or private entities on a temporary/non-permanent basis" (Peraturan Gubernur DKI Jakarta Nomor 10 Tahun 2015).

Figure 1. Illustration of a Street Vendor

Street Vendor as Urban Informal Sector

The term 'street vendor' generally refers to retail or wholesale trade of goods and services on the street and other related public thoroughfares such as alleys, roads, and boulevards. There are several other terms often used to describe 'street vendors,' such as Non-Permanent, street vendors, and small traders. The practice of street vendors can be observed in many countries; however, they are most prevalent in third-world countries, especially in urban areas as documented.

Street vendors are part of the informal sector. In fact, street vendors are the most visible manifestation of the informal economy. As an urban informal sector, street vendors have created job opportunities for the growing urban workforce, while also offering flexibility and innovation in the economy.

The term 'informal' indicates that street vendor activities are different from other 'formal' economic activities. The most important difference between the formal and informal sectors is the recognition by the relevant authorities. Street vendors have several weaknesses in terms of spatial planning provisions for their trading activities. The government's allocation of trade space is prioritized for formal economic activities, while the space available for street vendors is more limited as noted by [4].

Figure 2. Urban street vendors

Additionally, there is also a possibility of a connection between the formal and informal sectors. For example, street vendors might serve as an extension of formal economic activities, selling leftover goods or second-quality products from officially registered stores according to [5]. These examples show the unclear distinction between formal and informal activities as discussed [6].

Characteristics of Street Vendors in Jakarta City

Street vendors in Jakarta City vary greatly in scale, time, location, remuneration, labor, and the types of goods and services they offer, according to the opinions of [7] and [8]. One of the prominent characteristics of street vendors in Jakarta is their mobility and flexibility in daily operations.

Pachecho [9] describes two main types of street vendors based on their level of mobility, classifying them as permanent or non-permanent. Permanent types include vendors with kiosks or permanent stalls that remain in the same location all the time, even when there is no trading activity. Non-permanent types include vendors who are truly mobile or those who have structures that can be easily assembled and disassembled over time.

Also made another classification of street vendors, in terms of their operational methods. The first category is street vendors, who continuously move from one place to another to sell goods or offer their services. The second category is office supply traders who offer their goods and services at a fixed location. These traders are fixed in certain locations, and they can sell from permanent kiosks, trays, boxes and baskets, and carts. The nature of street vendors allows them to operate from one place to another. From here, they can establish markets that only operate on certain days, such as Sunday markets or during specific seasons according to [10].

Concept of Urban Public Space

This research argues for a fundamental shift in how urban planners approach street vendors - from viewing them as problems to recognizing them as valuable urban assets. The key findings emphasize that street vendors demonstrate remarkable resilience, can adapt to regulations, survive economic downturns, and potentially formalize their operations.

The study identifies critical flaws in current Binaan Location programs, particularly their failure to understand what vendors actually want, how consumers behave, and how informal economies function. Rather than simply allowing poor people to sell, policies should strategically integrate vendors into broader urban development frameworks.

The research outlines essential policy principles: adopting humane rather than punitive approaches, avoiding policies that inadvertently encourage rural-urban migration, rejecting one-size-fits-all solutions,

and accepting that integration will require substantial bureaucratic investment.

Success requires centralized, coherent policies that provide local governments with clear frameworks for community service. Most importantly, effective street vendor integration demands deep understanding of spatial relationships, vendor behaviors, and the complex dynamics between formal and informal urban economies. The emphasis is on strategic integration rather than elimination or mere tolerance.

RESEARCH METHODS

This study employs an Explanatory Sequential Mixed Method approach, combining quantitative and qualitative phases. The research utilized: (1) Field surveys and in-depth interviews; (2) ArcGIS mapping for spatial distribution analysis; (3) Statistical analysis of vendor willingness to relocate; and (4) Multistage random sampling with 1,400 respondents across Jakarta's administrative areas

Table 1. Number and Distribution of Samples Based on Location Typology

Criteria	Sample	Percentage	City	District	Village
Built Location	140	10%	28	14	7
Temporary Location	490	35%	98	49	35
Educated	70	5%	14	7	4
Not Set/Other	700	50%	140	70	35
Total	1400	100%	280	140	71

RESULTS

Statistical Analysis Results

The statistical analysis examined the supporting factors for the willingness of street vendors to move to the selling locations provided by the DKI Jakarta Provincial Government. The data analysis was processed by the author in 2025 and reveals several significant patterns.

Table 2. Distribution willing to move by Location of Street Vendors

Location	Willing to Move			
	0. No	1. Yes	Total	
	Row N %	Row N %	Count	Row N %
0 = Others	84.40%	15.60%	758	100.00%
1=Built Location	70.60%	29.40%	153	100.00%
2=Temporary Location	89.20%	10.80%	498	100.00%
Total	84.60%	15.40%	1409	100.00%

Source: processed by the author (2025)

Out of a total of 1409 respondents, the majority of traders representing 84.60% stated that they are not willing to relocate, while only 15.40% are willing to move. When the data is broken down by location category, traders located elsewhere show the highest unwillingness rate at 84.40%, followed by traders at construction sites at 70.60%, and traders at temporary locations at 89.20%. Interestingly, although traders at temporary locations have the highest percentage of unavailability, they also show the greatest variation in location distribution with 496 respondents.

Table 3. Distribution willing to move by Education of Street Vendors

Education	Willing to Move			
	0. No	1. Yes	Total	
	Row N %	Row N %	Count	Row N %
0= <= Junior High School	84.50%	15.50%	717	100.00%
1= >= Senior High School	84.70%	15.30%	692	100.00%
Total	84.60%	15.40%	1409	100.00%

Source: processed by the author (2025)

The education level analysis presented in Table 3 shows the distribution based on the education level of the traders. The data shows a pattern consistent with the previous findings, where the majority of traders at all education levels are unwilling to relocate. Merchants with education up to high school show a reluctance rate of 84.50%, while those with education above high school have a slightly higher reluctance rate of 84.70%. The distribution of respondents based on education shows that 717 traders with education below high school and 692 traders with education above high school, indicating a relatively even distribution in both education categories.

Table 4. Distribution willing to move by Owner of Street Vendors

Owner	Willing to Move			
	0. No	1. Yes	Total	
	Row N %	Row N %	Count	Row N %
0 = Others	84.70%	15.30%	98	100.00%
1 = Own his/herself	84.60%	15.40%	1311	100.00%
Total	84.60%	15.40%	1409	100.00%

Source: processed by the author (2025)

Table 4 categorizes respondents based on their business ownership status. The results show that both traders who own their own businesses and those who work for others have almost identical levels of unwillingness, namely 84.70% and 84.60%, respectively. The distribution of ownership shows a significant dominance of traders who own their own businesses, with 1311 respondents, compared to only 98 traders who work for others. This illustrates the dominant entrepreneurial character among street vendors.

Table 5. Statistic Summary of turnover by Willing to Move

Willing to Move	Mean	Median	Mode	Std	Minimum	Maximum	Count
0. No	6833032	4500000	3000000	11907328	70000	250000000	1192
1. Yes	8275942	5000000	4000000	10575638	200000	90000000	217
Total	7054278	4500000	3000000	11778552	70000	250000000	1409

Source: processed by the author (2025)

The statistical summary of turnover by willingness to move is presented in Table 5, showing comprehensive numerical distribution. For the group that is not willing to move, the average mean value recorded is 6,833,032, with a median value of 4,500,000, and the most frequently occurring mode value is 3,000,000. The very high standard deviation of 11,907,328 indicates a significant variation in the data, with a value range from a minimum of 70,000 to a maximum of 250,000,000 from a total of 1,192 respondents.

Meanwhile, the group willing to relocate shows a different pattern with an average of 8,275,942, a median of 5,000,000, a mode of 4,000,000, and a standard deviation of 10,575,638, with a range of values from 200,000 to 90,000,000 from 217 respondents. Overall, the combination of the two groups resulted in a total average of 7,054,278 with a median of 4,500,000 and a standard deviation of 11,778,552 from a total of 1,409 respondents.

Business Type Analysis

Table 6. Distribution willing to move by Type of Business

Type of business	Willing to Move			
	0. No	1. Yes	Total	
	Row N %	Row N %	Count	Row N %
0 = Others	90.90%	9.10%	164	100.00%
1 = Culinary	83.80%	16.20%	1245	100.00%
Total	84.68%	15.40%	1409	100.00%

Source: processed by the author (2025)

Table 6 analyzes the distribution of willingness to relocate based on the type of business run by street vendors. The data shows that traders with culinary businesses have a lower unwillingness rate compared to other traders, at 83.80%, while 16.20% are willing to relocate. On the other hand, traders with other types of businesses show a higher level of unwillingness at 90.90%, with only 9.10% willing to move. The distribution of respondents shows a significant dominance of culinary traders with 1,245 respondents compared to 164 traders from other types of businesses. These findings indicate that the type of business influences the flexibility of traders in considering relocation, with culinary traders being more open to the possibility of moving locations.

Hypothesis Testing Results

Table 7. Odd Ratio by Independent Variables determining willingness to move

Independent Variables	OR	Sig.
Location		0
Location(1) = Built Location	2.673	0
Location(2) = Temporary location	0.747	0.148
Educ(1) = High School++	1.072	0.663
Owner(1) = Owned by Me	1.069	0.825
Revenue	1	0.069
Type(1) = Culinary	1.856	0.031
Allocation(1) = proper allocation	0.709	0.066
Constant	0.094	0

Source: processed by the author (2025)

This odds ratio analysis identifies key factors influencing street vendors' willingness to relocate to designated areas (Binaan Locations). The study confirms five hypotheses through statistical analysis:

1 **Location and Accessibility (Hypothesis 1 - Proven)**: Vendors at construction sites show 2.67 times higher odds of relocating, while those at temporary locations are 25% less likely to move, demonstrating that physical location significantly affects relocation willingness.
2 **Education Level (Hypothesis 2 - Proven):** Higher education slightly increases relocation willingness (odds ratio 1.072), though the effect isn't statistically significant.
3 **Income Level (Hypothesis 3 - Proven):** Income shows statistical significance at the threshold level (p=0.069), with minimal impact per income unit increase, confirming income affects relocation decisions.
4 **Business Type (Hypothesis 4 - Proven):** This is the most significant factor - culinary vendors have 1.856 times greater odds of relocating compared to other business types (p=0.031).
5 **Location Suitability (Hypothesis 5 - Proven):** Vendors satisfied with their current location allocation are 30% less likely to relocate (odds ratio 0.700, p=0.066).

The analysis reveals that business type (particularly culinary) is the strongest predictor of relocation willingness, while location satisfaction creates resistance to moving. These findings suggest successful relocation programs must consider business categories and ensure adequate location allocation to maximize vendor participation.

Spatial Analysis of Street Vendors in DKI Jakarta

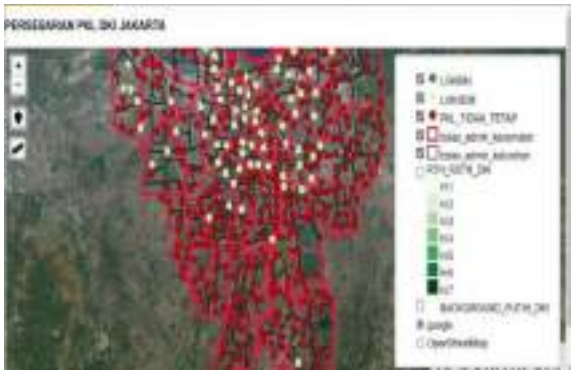

Figure 3. Distribution Map of Built Location, Temporary Location, and Non-Permanent Street Vendors in DKI Jakarta in 2021

The locations of non-permanent street vendors are evenly distributed throughout the DKI Jakarta area, while Built Locations are concentrated in the central and northern parts, and Temporary Locations are more sparsely distributed. The distribution of street vendor numbers in DKI Jakarta in 2021, based on the locations of Built Locations, Temporary Locations, and non-fixed street vendor locations, shows that the number of vendors at non-fixed street vendor locations is very high in all Administrative City areas.

The largest number is in the East Jakarta area with 6,777 traders, followed by North Jakarta, Central Jakarta, South Jakarta, and West Jakarta. The most Binaan traders are in West Jakarta, followed by East Jakarta and South Jakarta. Meanwhile, the largest number of traders in the Temporary Location is in South Jakarta, followed by West Jakarta and North Jakarta.

Figure 4 provides clearer visualization of the number of Built Location, Temporary Location, and Non-Permanent Street Vendors in DKI Jakarta in 2021.

Specifically, vendors at Non-Permanent street vendor locations are divided into three types: culinary vendors, non-culinary vendors, and service vendors. The locations of Non-Permanent street vendors in DKI Jakarta are dominated by culinary vendors, with the highest number in East Jakarta at 5,687 vendors, followed by North Jakarta and Central Jakarta. The highest number of non-food street vendors is also in East Jakarta, followed by North Jakarta and Central Jakarta.

The spatial analysis studies using Geographic Information System technology through several approaches including interpolation method with density estimation

method to analyze the spatial distribution of the locations of Built Location, Temporary Location, and Non-Permanent street vendors, range and road network analysis and its impact using buffer analysis, map overlay analysis between the locations of Built Location, Temporary Location, and Non-Permanent street vendors, land use, and population density, and spatial analysis for the capacity of temporary street vendor locations.

Coverage and Transportation Network Analysis

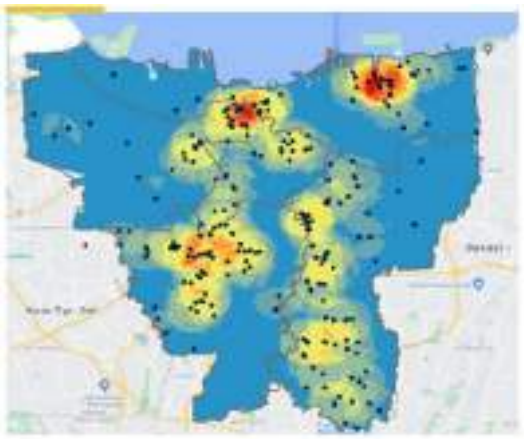

Figure 5. Map of Built Location and Temporary Location Distribution in DKI Jakarta in 2021.

The distribution of Built Location and Temporary Location points is concentrated around the areas of Kota Lama, Tanjung Priok, and Kebayoran Baru. They are also heavily distributed along Kampung Melayu-Dewi Sartika Main Road to Bogor Main Road. In other locations, they are still rare. The spatial distribution of street vendor locations is not evenly spread throughout the DKI Jakarta area along existing roads, except for the areas around Monas, TMII, and Halim PK Airport.

The analysis of the coverage and transportation network specifically MRT and Trans Jakarta with the locations of Built Location and Temporary Location points is shown in Figure 6. The concentration points of Built Location and Temporary Location locations appear to be quite appropriate, except in the Cilincing area, which is not accurate, as well as along the western and eastern routes. For the southern and southeastern routes, they are already appropriate.

Arguments For and Against Street Vendors

In the city of Jakarta, the presence of streetvendors can almost be seen in urban public places such as streets, parking lots, intersections, pedestrian sidewalks, parks, and other locations. In fact, it is impossible to avoid their presence in the cities as part of daily life, leading to both pros and cons regarding the existence of street vendors.

If linked to the consideration of both forms of arguments, it is possible to combine both arguments to a certain extent, raising the question of how far the presence of street vendors can be accepted in the city of Jakarta.

Further suggests that every argument, whether supporting or opposing street vendors, should consider

various aspects such as time, location, type of vendor activity, type and level of official control, as well as the background and aspirations of the individuals involved. This shows that the issue of street vendors in urban areas is fundamentally complex [11].

Spatial Justice and Right to the City

Emphasizing the political economy dimension of the right to the city, argues that the right to the city is not just about individual access to urban resources, but also about the collective right to change and control the process of urbanization. In the context of street vendors, this means not only providing physical space but also involving them in the planning and decision-making processes [12].

The concept of spatial justice becomes relevant in understanding why the Built Locations are often ineffective. Spatial justice is not only about equitable distribution but also about ensuring that all community groups have equal access to the economic and social opportunities provided by urban spaces. Provides a perspective on how informal cities contest public space. Donovan shows that street vendors not only use public space but are also active in creating new meanings and functions for that space. Donovan's approach emphasizes the importance of understanding street vendors as creative and adaptive urban agents [13[.

Sustainable Urban Planning Perspectives

Introduced the concept of ecocity, which emphasizes the importance of integrating ecological, economic, and social aspects in urban planning. Although the focus is on ecological sustainability, its principles can be applied in the context of street vendors where solutions must consider not only economic aspects but also social and environmental impacts.

In the context of Jakarta, the application of ecocity principles can mean creating Built Locations that are not only economically viable but also environmentally friendly and integrated with public transportation systems. This requires a holistic approach that considers various aspects of sustainability. Provides a perspective on how technology can be used to enhance the efficiency and effectiveness of urban services. In the context of street vendors, technology can be used to monitor the use of designated locations, analyze consumer movement patterns, and optimize the locations of supporting facilities [14].

DISCUSSION

This research reveals fundamental disconnects between urban planning policies and street vendor realities, where despite government provision of basic facilities and affordable fees at designated Binaan Locations, vendors overwhelmingly resist relocation, indicating deep policy-practice misalignments. The spatial analysis demonstrates a critical mismatch between successful vendor locations that feature high foot traffic, residential proximity, and commercial integration, versus many Binaan Locations that lack pedestrian flow and public transport connectivity, explaining why vendors pay premium informal fees for unauthorized but commercially viable spots.

Statistical analysis confirms that culinary vendors show greater relocation willingness than non-culinary vendors, suggesting policies need business-specific approaches rather than uniform solutions, while higher-income vendors

display slightly greater relocation willingness, indicating cost isn't the primary adoption barrier. The research fundamentally reframes street vendors from passive policy recipients to active economic agents making rational decisions based on sophisticated market knowledge and spatial understanding, where their preference for unauthorized locations reflects superior grasp of consumer patterns and urban economics rather than stubborn non-compliance.

The key implication is that vendors' resistance to relocation represents informed economic choice rather than obstacles to overcome, demonstrating that successful integration requires recognizing vendors as knowledgeable urban actors whose location expertise should inform policy design rather than viewing them as problems requiring correction.

CONCLUSION

The research demonstrates that the informal sector must be viewed as an asset for urban development rather than a problem to be eliminated. Street vendors can be regulated, can grow sustainably, withstand economic crises, and can potentially

transition to the formal sector. The failure of current Binaan Location programs stems from insufficient understanding of vendor preferences, consumer patterns, and informal economy dynamics.

The study reveals that street vendor policies should not only focus on allowing the poor to sell but also on integrating them strategically within urban development policies. This requires realizing policies that are humane and not repressive, ensuring that national development policies do not become a new magnet for rural-urban migration, recognizing that there is no single universal policy formula for street vendor arrangement, and understanding that the process of integrating the informal economy into urban development will incur significant bureaucratic costs.

The research emphasizes the need for reorganizing and providing orderly guidance and supervision to street vendors by creating centralized and clearly integrated policies that can serve as an umbrella for local government to perform its function of serving the community. The findings suggest that successful street vendor integration requires comprehensive understanding of spatial dynamics, vendor behavior patterns, and the complex interplay between formal and informal urban economies.

MODELING WELFARE-DRIVEN COMMUNITY TRANSFORMATION: AN INVESTIGATION IN REMOTE AREA, LABUAN BAJO, EAST NUSA TENGGARA, INDONESIA

Mohamad Axel Putra Hadiningrat [1], Beti Nurbaiti [2], and Chotib Hasan [3]

[1,3] Universitas Indonesia, Depok, Indonesia , [2] Universitas Bhayangkara Jakarta Raya, Jakarta, Indonesia

ABSTRACT

Problem Statement from this research is to analyze important factors in developing a welfare model that includes social capital, innovation, and motivation from the Labuan Bajo community, at East Nusa Tenggara, Indonesia. The research approach is a quantitative method where the existing findings are enriched with Focus Group Discussions (FGD), and in-depth interviews. This research uses field surveys by collecting data from 303 respondents with questionnaires, and 10 informants for FGD and in-depth interviews. The results of this research is that based on the Sobel Test, it is proven that the motivation variable is an intervening variable between the social capital and innovation variables on the welfare of the Labuan Bajo community. Additionally, social capital has been proven to have a direct positive impact on motivation and well-being, where the community helps each other materially and non-materially to meet daily needs. Moreover, community innovation is necessary because it has a direct positive impact on their motivation and well-being. The motivation of the local community has a direct positive impact on well-being. Another finding is that motivation has proven to be an intervening variable between social capital and innovation on welfare, as there is an indirect influence through the motivation variable. High-quality human resources can encourage the community to be absorbed into the labor market in the tourism industry sector as a super-priority destination area, which will impact their welfare. Traditional leaders, religious leaders, and local community leaders play a significant role in providing material and non-material assistance.

Keywords: Transformation; Welfare; Modeling; Social Capital; Innovation; Motivation

INTRODUCTION

Known for its stunning natural surroundings and rich cultural heritage, Labuan Bajo is situated in East Nusa Tenggara Province's West Manggarai Regency. The ethnic city of Labuan Bajo is encircled by hills and vast savannas, creating an extremely unusual sight, particularly after sunset. Labuan Bajo is also referred to as the city of a million sunsets because of its splendor (Hanita, 2023).

Although it already exists as community capital, this social capital has not been used to its full potential. In order to overcome obstacles in their daily lives, the Labuan Bajo population should make use of this capital.The community benefits from the presence of kinship, familial ties, and mutual trust through community approaches, particularly in trying times (Putnam and Robert, 2000). The Labuan Bajo community's social capital, which is bolstered by the environment and culture that now exist, inspires them to act to meet their everyday needs and innovate to produce innovations that result in economically useful services and goods. Social capital therefore helps them come up with new ideas to improve the welfare of the community, such as bringing people together for joint ventures, sharing ideas and talents, and cooperating to use solar power to create electricity, especially in rural locations.

The driving force behind the innovations that the Labuan Bajo community has been able to implement comes from social capital, driven by their motivation to complement each other's shortcomings. These innovations are still local in nature and have not yet been able to fully make the community prosperous; they require external support, particularly from regional and central governments. This inspiration serves as the catalyst for the community to turn its obstacles into opportunities for collective success (Hanita, 2023).

This study designed to address the following research questions :

1) Is there a direct effect of social capital on the welfare of the community in Labuan Bajo, East Nusa Tenggara?
2) Is there a direct effect of innovation on the welfare of the community in Labuan Bajo, East Nusa Tenggara?
3) Is there an indirect effect of social capital on the welfare of the community in Labuan Bajo, East Nusa Tenggara, through the intervening variable of motivation?
4) Is there an indirect effect of innovation on the welfare of the community in Labuan

Bajo, East Nusa Tenggara, through the intervening variable of motivation?
5) Is there a direct effect of social capital on the motivation of the community in Labuan Bajo, East Nusa Tenggara?
6) Is there a direct effect of innovation on the motivation of the community in Labuan Bajo, East Nusa Tenggara?
7) Is there a direct effect of motivation on the welfare of the community in Labuan Bajo, East Nusa Tenggara?

RESEARCH SIGNIFICANCE

Social Capital

Social capital can be explained by three different topologies: (1) bonding social capital; (2) bridging social capital; and (3) linking social capital. Social capital indicators, such as social cohesiveness and inclusion, are used to measure this. Social modalities help people in a community engage with one another and work together more successfully. For instance, the ability to link or promote interactions between individuals and groups with disparate identities is referred to as the usage of social modalities as social bridges (Narayan and Michael, 2016).
In Pierre Bourdieu's (1995) research, social capital is also incorporated into three key ideas: (1) Field, (2) Capital, and (3) Habitus. Finding important players with connections in the field is the following stage, which is based on these three ideas. According to Bourdieu, concentrating only on results is not enough; we also need to measure the variables that influence relationships, transactions, and important field occurrences. Powerful actors will control and possibly monopolize the industry. In the next phase, researchers examine the amount of money these individuals have contributed to the field in connection to their ties. Economic capital, social capital, cultural capital, and symbolic capital are all included in this capital.

Innovation

According to Nicholls et. al. (2019), innovation is defined as a novel concept that successfully solves issues by addressing unmet social demands. Rebalancing power disparities and economic disparities in society is a common emphasis of this innovation, which is related to shifts in social connections. This study makes use of social innovation, which is defined as the creation and implementation of novel concepts regarding how individuals ought to plan social interactions or interpersonal activities in order to accomplish one or more shared objectives.
According to Hussain et al. (2014), innovation is the capacity of commercial companies to comprehend, create, implement, and scale new goods, services, procedures, and business models for their clientele. In the meantime, innovation is a component that gives companies a competitive edge, claim Thiangtam et al. (2016). Company innovation can be divided into three categories: process, service, and product innovation.

Motivation

The Hygiene Factors hypothesis of Herzberg and Frederick (1968) and Adair (2006) is the motivation theory that is used. This theory emerged because, in work contexts, there are conditions that individuals within a community or organization perceive as "satisfying" and others as "dissatisfying." Findings related to individual achievement success are greatly influenced by their motivation, which is divided into two factors:
1) Extrinsic Motivation: encompasses material aspects such as salary, wages, incentives, bonuses, and allowances that can be measured in monetary terms.
2) Intrinsic Motivation: includes non-material aspects such as praise, recognition, career development opportunities, and self-actualization.

Therefore, to keep motivation burning within yourself, you must continuously seek the "fuel that ignites it." This type of motivation represents the strongest and most enduring form of motivation in humans. Intrinsic motivation is driven by personal interest or enjoyment in the activity, without external rewards or pressure. Intrinsic motivation drives individuals to share knowledge based on their own interest or pleasure in doing so, without expecting material rewards. Extrinsic motivation, on the other hand, is driven by action outcomes and focuses on goals such as monetary rewards or career advancement (Sudaryono et al., 2015).

Welfare

Alatartseva and Barysheva (2015) argue that welfare is measured from two perspectives: (1) the objective side, where welfare can be measured materially, and (2) the subjective side, where welfare represents each individual's inner experience rather than material possessions. Since both requirements must be met for someone to be deemed "wealthy," having a lot of material belongings does not ensure that someone will be deemed "wealthy" if they are unable to find inner peace, have little time for worship, feel inferior, oppressed, or repressed, or if they are denied the ability to express their thoughts, manifest themselves, and come together as social beings.

According to Abdullahi et al. (2021) and Ogwumike et al., (2018), welfare is a prerequisite for meeting citizens' material, spiritual, and social needs to live and develop adequately while fulfilling their social responsibilities. The objective aspect consists of wages/income, expenditure (consumption), wealth, living conditions, education, and health. The following are examples of objective aspects: (1) Having employment with sufficient income for basic needs including clothing, food, and housing;(2) The ability to meet nutritional needs such as healthy food; (3) Access to healthcare and education; and (4) Having a decent place to live.

The subjective aspect encompasses psychological, spiritual, and social welfare. This aspect typically refers to an individual's capacity regarding: (1) A lifestyle that maintains balance between work and family; (2) Interpersonal relationships, social networks, and community support; (3) A well-established relationship with the Creator through proper worship.

RESEARCH METHODS

The study employs a quantitative or deductive methodology, which is evaluated using observational data from surveys. Researchers use questionnaires as research tools, and collected data from 303 respondents. The researcher additionally does in-depth interviews to enhance and supplement the findings of the quantitative analysis (Creswell, 2016).

In Labuan Bajo, East Nusa Tenggara, 310 community members participated in a survey method used for primary data collecting. Of the 303 respondents' responses, 303 were deemed legitimate. The purposive sampling technique was used to determine the number. The Labuan Bajo area and its environs, which comprise other sub-districts in the West Manggarai Regency, served as the site for the data gathering.

There are 7 hypothesis in this research :

H1 : There is a direct effect of social capital on the welfare of the community in Labuan Bajo, East Nusa Tenggara.

H2 : There is a direct effect of innovation on the welfare of the community in Labuan Bajo, East Nusa Tenggara.

H3 : There is an indirect effect of social capital on the welfare of the community in Labuan Bajo, East Nusa Tenggara, through the intervening variable of motivation.

H4 : There is an indirect effect of innovation on the welfare of the community in Labuan Bajo, East Nusa Tenggara, through the intervening variable of motivation.

H5 : There is a direct effect of social capital on the motivation of the community in Labuan Bajo, East Nusa Tenggara.

H6 : There is a direct effect of innovation on the motivation of the community in Labuan Bajo, East Nusa Tenggara.

H7 : There is a direct effect of motivation on the welfare of the community in Labuan Bajo, East Nusa Tenggara.

RESULTS AND DISCUSSION

Descriptive Statistics Processing Results

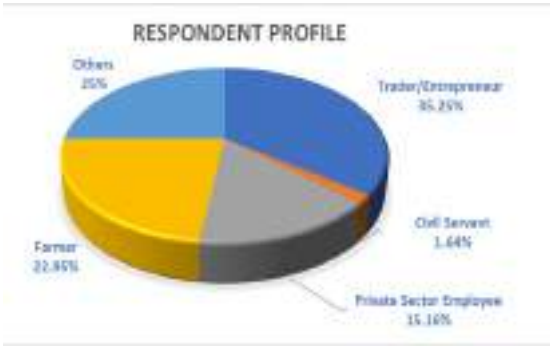

Figure 3. Respondent Profile

The majority of responders (35.25%) are traders or entrepreneurs, with other occupations, teachers, religious leaders, community leaders, and homemakers coming in second (25%). Next, the proportion of civil servants (1.64%), private workers (15.16%), and farmers (22.95%). The majority of survey participants were traders or entrepreneurs, including shop owners and MSME players, according to the profiles of the respondents.

This entrepreneurial career demonstrates that Labuan Bajo residents have a strong sense of entrepreneurship and are not dependent on office work. This further demonstrates the local community's strong desire to use its capital independently. Given the high cost of living, where the prices of daily essentials are high and not adequately offset by a Regional Minimum Wage (UMR), the local community must innovate to create new sources of revenue.

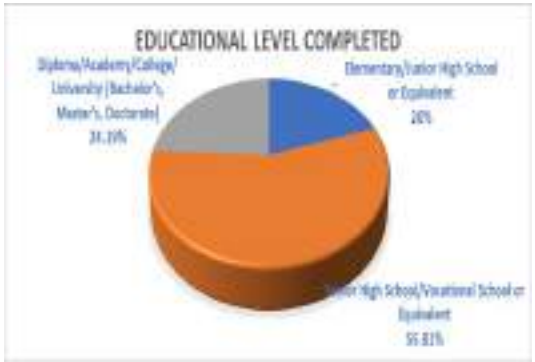

Figure 4. Education Level of Respondents Completed

High school/vocational school/equivalent accounts for 55.81 percent of respondents' education

levels, followed by diploma/academy/university (24.19%) and elementary/middle school/equivalent (20%). According to the aforementioned research findings, the majority of respondents have completed secondary education, such as high school, vocational school, or its equivalent, and the proportion of graduates with higher and lower education is about equal. This circumstance suggests that the local government must formally raise educational standards.

Programs for free school fees, building schools in outlying areas, enhancing the caliber of teaching staff's human resources (HR), donating school supplies like textbooks and stationery in accordance with the relevant curriculum, and supporting the infrastructure for road access from teachers' or students' homes to the school are all examples of how the government can help. Both the federal government and the municipal government, through the appropriate departments, are in charge of the educational component.

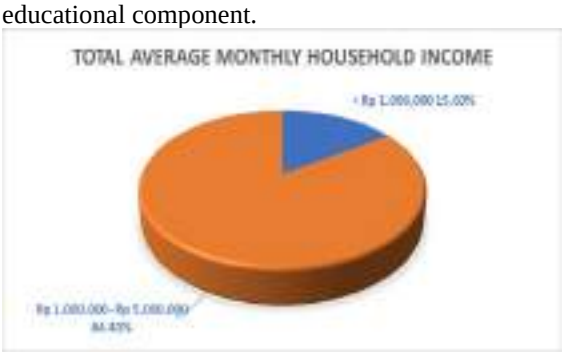

Figure 5. Average Monthly Household Income

Respondents' average monthly household income during the six months prior to the study was primarily between Rp 1 million and Rp 5 million. This scenario indicates that the growth in locals' income has not yet been affected by Labuan Bajo's designation as a Super Priority Destination (DSP). The cost of basic requirements is two to three times more than on the island of Java, so efforts to raise the community's income must be stepped up. Given that the majority of the community's resources are used to address comparatively high daily requirements, this conclusion is consistent with their capacity to seek higher education.

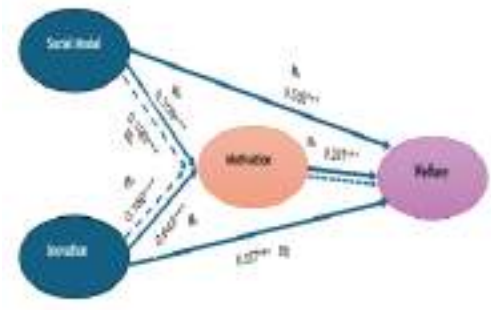

Figure 12. Conceptual Research Model

The respondents' average monthly household expenses for the previous six months were equal to their income, with the majority lying between Rp 1 million and Rp 5 million. Given that they are required to pay for high expenses, this scenario indicates that investments and savings are still not given priority. The community's income must at least double its expenses in order for them to have savings and investments.

Table 1. Estimation of Parameters for Path Analysis and Sobel Test

No	Route	Direct Effect Coeff. (Standardized)	Unstandardized Coeff.	Standard Error	Significance

Source: Data processed by the author (2024)

Based on the Sobel test above, it can be seen that all hypotheses (H1, H2, H3, H4, H5, H6, H7) are accepted, both direct and indirect effects through the intervening variable of motivation.

The Sobel Test results were confirmed by field findings through FGD and in-depth interviews. As a Remote Area town, Labuan Bajo's residents have not had the same access to high-quality education as those on Java Island. The primary barrier preventing the population from traveling great distances from their homes is geography, particularly in coastal regions and in communities of fishermen's villages. Furthermore, a large number of interprovincial routes remain without illumination. As a DSP area, Labuan Bajo has not yet been affected by the trickle-down effect. Their household incomes have increased, but the effect of tourism has not yet been consistent. The "sweetness of the development cake" from the explosion of five-star hotels, cafes, restaurants, and entertainment venues frequented by both domestic and foreign tourists is only enjoyed by a small percentage of the community. The quality of local human resources, which has not yet been able to be substantially absorbed by the labor market in the tourism sector, is the traditional issue that provides the explanation.

The supply chain and distribution channels of primary production elements, including fuel oil (BBM), are the cause of high costs for the community

as consumers and for small and medium-sized enterprises (SMEs). The "eternal" reason for high fuel costs outside of Java is the high cost of fuel, which is still mostly supplied by oil refineries on Java Island.

Because it has to do with distribution and transportation, fuel affects the cost of essentials. Government initiatives and laws aimed at eliminating fuel distribution inefficiencies have a major effect on lowering gasoline prices, which in turn lowers the cost of consumer goods. Ceteris paribus, revenue will not decline if costs are reduced and the society may set aside money for investments and savings.

When one individual/group in the community has difficulty marketing their goods, another group within the same community will help provide market access, free of charge. This is one example of the application of social capital, as there is a sense of mutual trust and assistance. When one group needs business capital and their application to the bank is rejected, another group can provide a free loan because of the mutual trust and support within that community. Another finding in the field encountered during the survey was that many novice individuals in the food and beverage business, who lacked the necessary skills, were taught for free by other groups within the community.

According to Qian and Yin, 2019, social cohesiveness and inclusiveness are equally significant sub-dimensions of social capital. This sub-dimension is a component of social capital that shows how closely people are bonded to one another in a community or society. When mutually beneficial contacts take place, networks—intangible resources that aid in resolving issues within particular societies—are created, and this is referred to as social cohesiveness. Beliefs and values, community organizations, laws, social ties and interactions, and social patterns all have an impact on social cohesiveness. The quality of family-based relationships can be enhanced by social capital, regardless of theoretical differences, where this finding is inline with the research conducted by Nurbaiti and Chotib (2020).

The innovations carried out by the community are largely generated from existing networks and supported by local traditional and religious leaders. For example, in terms of marketing innovation, when a group involved in fish floss production intends to market their product, local leaders assist in selling the product through bazaars during traditional ceremonies. The intricate process of community innovation involves introducing new plans, processes, or outcomes that fundamentally alter the underlying resource flows, authority structures, and trust systems of the community in which the innovation takes place. According to Suryana (2013), innovation can be interpreted in a number of significant ways, including as novelty, change, and advantage. In essence, innovation as novelty is a new value that people can obtain. A type of additional value in goods, services, or procedures is the subject of innovation. More socially acceptable technical solutions are always used to illustrate innovation. Innovation produces benefits in the form of managerial products, technology, methods, and process innovation.

Motivation needs to be encouraged at the community level with support from local community leaders. Although the local government has provided assistance, the community is more motivated in their daily lives by local figures. Motivation that originates from outside sources is known as external motivation, and it runs out fast. Fundamentally, everyone's motivation originates from within themselves; motivation is like a stove that continuously burns and must be constantly fueled to keep burning—without fuel, motivation will gradually die until it is completely extinguished. According to Tamara et al. (2020) , Lapsomboonkamol et al. (2020), the act of motivating or persuading someone to accomplish their desires.

Although the people of Labuan Bajo are far from the national capital, with an average income below the national average, and the prices of goods being relatively high because they have to be brought in from outside the region, they are able to overcome these limitations by utilizing social capital, doing innovation and motivation in the spirit of community. Society assesses well-being not only by the material possessions one has but also by non-material aspects such as time spent with family members, the ability to worship peacefully, participating well in traditional events, thereby fostering good relationships and networks. This finding is in line with Alatartseva and Barysheva (2015) that well-being consists of two types, namely subjective (material) and objective (non-material).

CONCLUSION

The transformation has occurred in the community of Labuan Bajo City, Komodo District, West Manggarai Regency, both in terms of economic, social, and spatial transformation. Remote location of Labuan Bajo contributes to the high cost of living, which is not covered by local population income. Stated differently, Labuan Bajo's status as a DSP has not yet resulted in the trickle-down effect. With all the existing limitations, it turns out that social capital has a significant impact on the transformation of the Labuan Bajo community in achieving its prosperity, where the most influential aspects of social capital are Trust and Solidarity and Information and Communication.

The innovation of the Labuan Bajo community is currently not optimal in the process of transforming Labuan Bajo into a more prosperous society. The Labuan Bajo community still needs to be encouraged from outside the community, by the local government and related parties. The role of traditional leaders, religious figures, and the community is very important in motivating the society to reach welfare.

A PILE DOWNDRAG STUDY FOR LNG PROJECTS

Anil Bhandari [1], and Jianchun Cao [1]

[1] Bechtel Corporation, Houston, Texas, USA

ABSTRACT

With the projected increase in global energy demand from approximately 580 quadrillion Btu in 2024 to 650 quadrillion Btu in 2050, Liquefied Natural Gas (LNG) is poised to play a significant role in the transition towards a carbon-neutral energy landscape. In the United States, natural gas accounts for about one-third of primary energy consumption, primarily for heating and electricity generation. The LNG export capacity from North America is anticipated to more than double by 2027. Many LNG projects are situated in near-shore areas, where thick layers of very soft and highly compressible fine-grained soils are prevalent. These soils undergo substantial settlement under site-grading fill applied during site development, necessitating consideration of drag load in pile foundation design. Drag load imposes an additional compressive axial load on the pile, potentially altering geotechnical resistance during operational conditions. This paper presents a pile-soil interaction model developed using t-z and Q-W curves, calibrated with measured skin friction and end bearing resistances from a pile load test. The investigation into drag load on a pile designed for an LNG project revealed a decrease in drag load as the load applied to the pile head increased. The drag load determined with consideration of operational load on the pile head was employed for the final pile design. The paper discusses several pile design strategies to mitigate or accommodate drag load, including: Reducing soil settlement potential through pre-loading techniques to consolidate soils prior to construction. Controlling pile settlement by reducing the utilization factor of pile capacity, ensuring compliance with stringent settlement requirements for supported structures. Decreasing drag load by increasing the utilization factor of pile capacity, applying a lower factor of safety. Enhancing pile end bearing, such as using expanded bottom piles, to counteract the effects of drag load.

Keywords: Liquefied natural gas (LNG); dredged material; soil settlement; drilled soil displacement concrete pile (DD pile); drag load; neutral plane; pile capacity; pile skin friction; pile end bearing

INTRODUCTION

An LNG project typically comprises various structures such as process trains, flares, spill impoundment basins for process areas and transfer lines, heavy haul roads, piperacks, and associated structures. Most LNG projects are developed in near-shore areas characterized by the presence of very soft, fine-grained deposits, necessitating the use of deep foundations to support major structures. The phenomenon of drag load, caused by the long-term excessive settlement of these subsurface soils, particularly in thick and soft fine-grained deposits, is a significant concern in deep foundation design.

Various studies have explored the impact of downdrag and estimation of drag load (Fellenius, 1998; Lee and Ng, 2004). However, there is a lack of literature that specifically addresses LNG projects.

To investigate the impact of downdrag on pile design for LNG projects, a TZPILE model was developed utilizing a typical generalized soil profile and the estimated long-term soil settlement. Drilled soil displacement concrete piles (DD piles) were the focus of this study, although the findings are also applicable to other types of deep foundations used to support structures for LNG projects.

The drag load was calculated for the operational scenario, with an applied load of 778 kN on the pile head. The paper outlines several strategies to mitigate the impact of downdrag on pile design, including reducing potential soil settlement, optimizing the utilization factor of pile capacity, and enhancing the pile's end bearing capacity (e.g., using expanded bottom piles) to counteract the effects of drag load.

This study focuses on a single pile size (diameter and length) and one soil profile. Pile drag load is related not only to the total pile capacity, but also to the ratio of friction to end bearing (assuming the same soil settlement profile). Parametric studies—including various pile sizes and different soil profiles—can help deepen our understanding of this topic and extend the study results to different conditions. We plan to expand this research into a future journal paper, in which a parametric study will be included. When an LNG project presents a different soil profile or alternative pile sizes are selected, the pile drag load should be estimated using the methodology presented in this paper.

GENERALIZED SUBSURFACE PROFILE AND SOIL SETTLEMENT

Generalized Subsurface Profile

Geotechnical investigations for the case study LNG project have revealed that the dredged fill,

which comprises alternating layers of very loose to loose sands and very soft to firm clayey material, extended from the existing grade to depths ranging from 3 meters to 10 meters, with an average thickness of approximately 6 meters.

Underlying the dredged fill was bauxite residue, characterized by very loose to loose clayey sand and soft clay, with thickness varying from 2.5 meters to 7.5 meters and an average thickness of about 3.5 meters.

Beneath the bauxite residue, alternating layers of competent stiff to hard clays and medium dense to dense sands were typically encountered to the maximum explored depths of approximately 100 meters below the existing grade.

Based on the characteristics of these soil conditions, a generalized subsurface profile for this study consists of 10 sub-layers of soils from the grade to a depth of about 45m below. They are Fill/Stabilized Soil, Dredged Material (Clay), Very Soft Bauxite Residue, Stiff Clay, Medium Dense to Dense Silty Sand, Very Stiff Clay, Dense Silty Sand and Clayey Sand, Very Stiff to Hard Clay, Very Dense Silty Sand, and Hard Clay. The thickness of each sub-layer and the design soil parameters are presented in Table 1. Pre-loading technique (surcharge) was used to reduce the soils' settlement of the site.

Soil Preloading and Soil Stabilization

The substantial layer of very soft and highly compressible fine-grained soils encountered at the case study LNG project site necessitated a significant settlement mitigation. To address this issue, site development processes included the implementation of wick drains and preloading with a surcharge of 2-5 meters of fill. The upper 1.5 meters of existing soft clay was stabilized using a combination of lime and cement. This approach ensured a stable working platform, provided support for construction equipment, and enhanced the lateral capacity of pile foundations.

To monitor the soil settlement and ensure that 90% of the consolidation settlement was achieved before removing the surcharge fill, a field monitoring system, including settlement plates and vibration wire piezometers, was installed. Weekly settlement readings were taken during fill placement and for the first two months afterward, followed by bi-weekly readings. The measured settlement data was analyzed using Asaoka's (1978) observational procedure to estimate the final settlement. Approximately four months later, the measured settlement exceeded 90% of the estimated total settlement.

Table 1: Generalized Subsurface Profile and Design Soil Parameters

Layer No.	Soil Type	Layer Thickness (m)	Total Unit Weight (kN/m^3)	Su (kPa) or Friction Angle (°)
1	Fill/Stabilized Soil	1.8	17.0	85
2	Dredged Material (Clay)	1.8	16.0	5
3	Very Soft Bauxite Residue (Clay)	4.0	16.0	10
4	Stiff Clay	3.4	18.5	70
5	Medium Dense to Dense Silty Sand	3.1	19.5	40
6	Very Stiff Clay	5.5	19.0	165
7	Dense Silty Sand and Clayey Sand	3.1	20.0	38
8	Very Stiff to Hard Clay	3.6	20.5	200
9	Very Dense Silty Sand	8.7	20.5	40
10	Hard Clay	9.5	19.5	200

Long-term Settlement of Subsurface Soils

Although the primary consolidation of the subsurface soils was completed prior to the construction of the structures and buildings, the secondary consolidation settlement will take a considerable amount of time to achieve. Based on the field geotechnical investigations for the project, a perched water condition existed near the surface, with the groundwater table located approximately 1 to 2 meters below ground surface (BGS). It is anticipated that the groundwater level will drop by 3 meters over the long term, to approximately 4.5 meters BGS after 25 years of design life. This potential decline in the initial groundwater table will induce additional ground settlement. The long-term settlement of the subsurface soils, including both secondary consolidation settlement and settlement due to groundwater reduction, will create a drag load on the pile foundations. It should be noted that a small relative movement between pile and soil is sufficient to mobilize the shaft resistance, and the drag load can be induced by a small amount of secondary consolidation itself.

The estimated long-term settlement of the subsurface soils within the design pile penetration depth for this study is presented in Figure 1 and has been used to estimate the drag load.

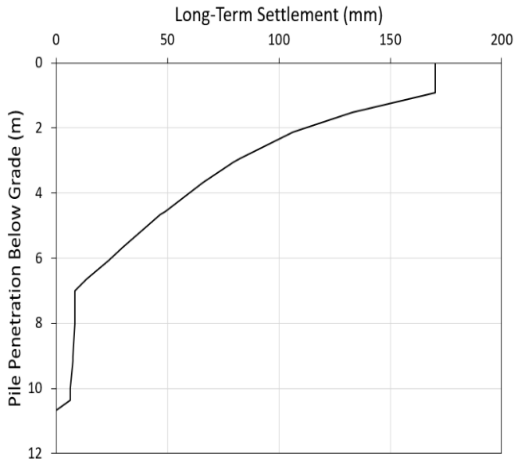

Figure 1: Estimated Long-term Settlement of Subsurface Soils

DESIGN PILE AND PILE LOAD TESTING

Based on the bearing pressures of the LNG facilities and the subsurface soil conditions outlined in Table 1, 0.46m-diameter DD piles were selected to support the buildings and structures. All piles were designed to a length of 12.2m, with the pile tips embedded approximately 0.6m into the Medium Dense to Dense Silty Sand layer.

The axial pile capacity was estimated using the API method and the soil design parameters provided in Table 1. Each 0.46m-diameter pile was calculated to have an ultimate capacity of approximately 1,606 kN, including a skin friction of 552 kN and an end bearing of 1,054 kN.

A static load testing program was conducted, which included tension load testing and compression load testing. Davisson's method (Davisson, 1972) was utilized to determine the pile's ultimate capacity for the static load tests. The measured total pile compression capacity was 2,140 kN, including skin friction of approximately 534 kN and end bearing of about 1,606 kN.

Comparing to the estimated pile capacity, the measured pile total capacity (i.e., 2,140 kN) is about 1.33 times the estimated total capacity (i.e., 1,606 kN). The measured pile skin friction (i.e., 534 kN) is close to the estimated (i.e., 552 kN). The measured pile end bearing (i.e., 1,606 kN) is about 1.52 times the estimate end bearing (i.e., 1,054 kN). A few factors may have contributed to the measured pile capacities being larger than the estimated values. Firstly, the actual diameter of the test pile was larger than the design pile diameter (i.e., 0.46 m). According to the Thermal Integrity Profiling (TIP) test results, the actual diameter of the test pile varied between 0.46 to 0.64 m along the depth, with an average value of 0.56 m. Secondly, the soil design parameters selected in Table 1 did not consider the densification of the sandy formation (Layer 5) on which the piles were terminated. Installation of the drilled displacement piles laterally pushed the soil and densified the sandy formation; thereby, increased the pile capacity (mostly end bearing component in this case).

The load testing results aligned closely with the API method, showing that a settlement of approximately 1%D (where D is the pile diameter) is required to fully mobilize the pile's ultimate friction, and a settlement of about 5–10%D is needed to mobilize the pile's end bearing capacity. These test results validated the applicability of the API method (t-z and Q-w curves) for pile drag load analysis. Furthermore, the load-settlement curve measured during pile load testing reflects the pile's short-term behavior, whereas pile drag load develops over the long term. Considering that only relative movement between the pile and soil can generate drag load, and that the development of drag load does not affect the performance of the pile foundation provided the maximum drag load is accounted for in the design, it is reasonable to use the pile load test results for calibrating the TZPILE model. This approach is both appropriate and reliable.

PILE DRAG LOAD ESTIMATION

Pile downdrag refers to the ground settlement or downward soil movements relative to a pile. Typically, downdrag results in two primary effects on piles: 1) an additional compressive axial load, known as drag load, and 2) a reduction in geotechnical resistance. Downdrag often occurs due to the placement of construction fill near the pile group and should be considered in the design of deep foundations across all limit states.

The Neutral Plane method is commonly utilized to calculate the pile's drag load, as illustrated in Figure 2. A central concept in the Neutral Plane method is the relative movement between the soil and the deep foundation after installation, indicating a dynamic system. The neutral plane is the depth along a deep foundation element where soil and pile settlements are equal, resulting in zero mobilized side resistance at that specific location. Below the neutral plane, the settlement of the pile, due to loading, exceeds the settlement of the adjacent soil, leading to load transfer from the pile to the soil through side shear and end bearing. Above the neutral plane, the surrounding soil settles more than the pile, causing negative side resistance and axial compression load transfer from the soil to the pile through side shear, also known as drag load. The maximum drag load is calculated based on the nominal geotechnical side resistances of the soil layers located above the neutral plane depth.

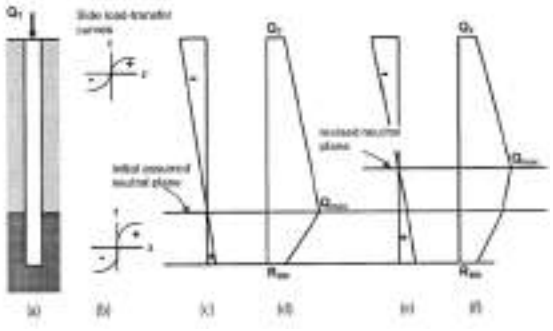

Figure 2: Mechanics of Downdrag Development and Possible Location of the Neutral Plane (Ensoft Inc., 2021)

Development of TZPILE Model

To estimate the drag load on a pile, the commercial software TZPILE was employed. TZPILE incorporates the well-established method of soil-structure interaction, commonly known as the t-z method, where t-z and Q-w curves are utilized respectively for load transfer in side resistance and end bearing. The t-z and Q-w curves can be internally generated for piles (or drilled shafts) with the provision of information regarding the supporting soil and the pile's geometry. This software is capable of calculating the drag load on a pile (Ensoft, 2021).

A TZPILE model was developed for a 0.46-meter diameter pile with a penetration depth of 12.2 meters, using the soil design parameters detailed in Table 1 and the API method. The model inputs included soil design parameters (i.e., undrained shear strength (s_u) and unit weight (γ) for clay, and internal friction angle (φ) and unit weight (γ) for sand), pile design parameters (i.e., ultimate unit skin friction and ultimate end bearing), and pile diameter and pile section modulus (i.e., AE - cross-sectional area multiplied by the pile's elastic modulus). The load versus deflection curves derived from the developed TZPILE model are presented in Figure 3.

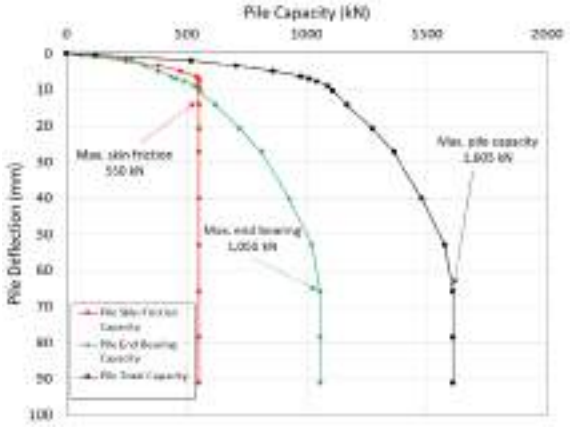

Figure 3: Load vs. Pile Deflection Curves – TZPILE Model

Figure 3 demonstrates that the pile's skin friction capacity, end bearing capacity, and total capacity obtained from the TZPILE model are 550 kN, 1,055 kN, and 1,605 kN, respectively. These figures closely correspond to those estimated using the API method, thereby validating the precision and reliability of the TZPILE model.

To align with the pile load test results, a load factor of 1.52 was applied to the end bearing in the developed TZPILE model. The load versus pile deflection curves from the matched TZPILE model are illustrated in Figure 4.

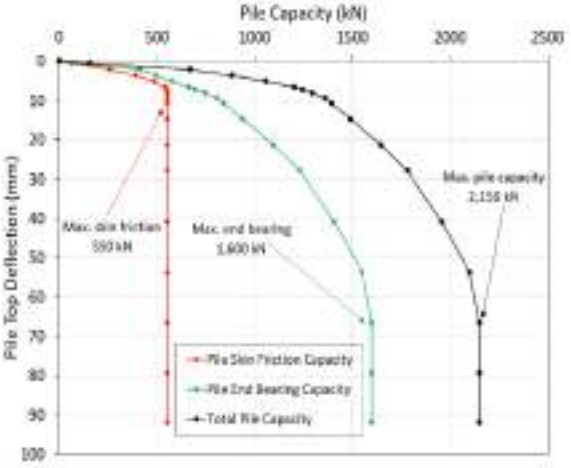

Figure 4: Load vs. Pile Deflection Curves – Matched TZPILE Model

Figure 4 illustrates that the matched TZPILE model exhibits a skin friction capacity of 550 kN, an end bearing capacity of approximately 1,600 kN, and a total pile capacity of about 2,150 kN. These values closely align with the results obtained from pile load tests, thus confirming the suitability of the matched TZPILE model for accurately estimating the drag load on the pile.

Estimated Drag Load

Utilizing the matched TZPILE model and considering the estimated long-term soil settlement presented in Figure 1, the downdrag analysis results are detailed in Table 2 and Figures 5 through 7. The axial load distributions versus pile head loads are illustrated in Figure 5, which also indicates the locations of the neutral plane. In each scenario, the drag load is determined by subtracting the pile head load from the load at the neutral plane depth. Figures 6 and 7 provide further insights, showing the neutral plane location versus pile head load and drag load versus pile head load, respectively.

Table 2: Downdrag Analysis Results vs. Pile Head Loads

Load on Pile Head (kN)	Total Capacity at Neutral Plane (kN)	Drag Load (kN)	Neutral Plane Location Below Pile Head (m)	Pile Top Movement (mm)
107	476	369	10.6	1.8
249	605	356	10.5	3.3
778	956	178	10.3	8.1
1,192	1,334	142	6.6	14.5
1,512	1,641	129	5.9	27.7
1,882	1,988	107	4.3	53.6
2,242	2,309	67	1.5	130.3

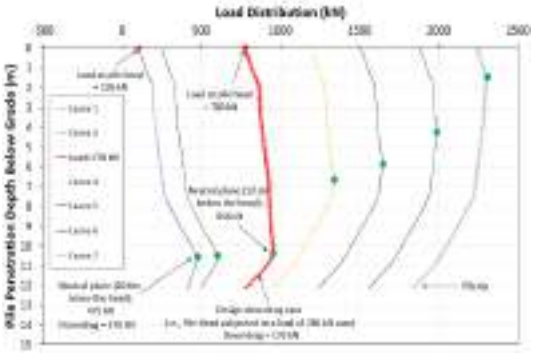

Figure 5: Load Distribution vs. Pile Head Load

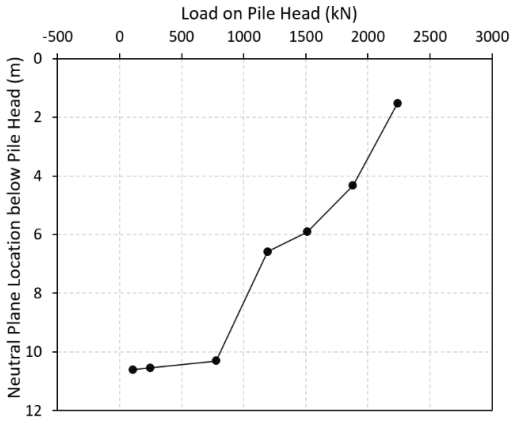

Figure 6: Neutral Plane Location vs. Pile Head Load

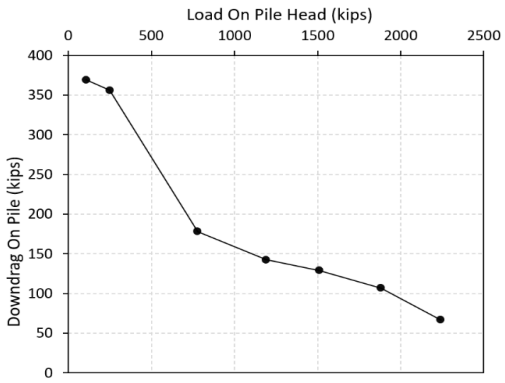

Figure 7: Drag Load vs. Pile Head Load

It can be observed from Table 2 and Figure 5 through Figure 7 that:

- Neutral plane moves upward with increase in pile head load (Table 2, Figure 5 and Figure 6). For example, if the pile head load increases from 249 to 1,192 or 249 to 1,882 kN, the neutral plane moves up to from 10.5 to 6.6 and 4.3m respectively (Curve 2, Curve 4 and Curve 6).
- Drag load decreases with increase in pile head load (Table 2 and Figure 7). For example, the drag load decreases from 369 kN to 178 kN with pile head load increasing from 107 kN (Curve 1) to 778 kN (Curve 3).
- Curve 1 presents the maximum drag load case (an extreme case). The maximum drag load is about 369 kN which corresponds to the case that the pile has negligible or no movement (i.e., the case with largest relative movement between pile and soil).
- The estimated drag load during operating (i.e., pile head is subjected to the design load of 778 kN) is about 178 kN.

STRATEGIES TO REDUCE THE INFLUENCE OF DOWNDRAG

Various pile design strategies can be employed to mitigate the effects of downdrag, including selecting an appropriate utilization factor for pile capacity, reducing long-term settlement of subsurface soils, and increasing pile end bearing capacity.

Utilization Factor of Pile Capacity

Increasing Utilization Factor of Pile Capacity: For a design pile (with a defined diameter and penetration) and a specified long-term soil settlement profile, the drag load decreases as the pile head load increases (Figure 7). Therefore, enhancing the utilization factor of pile capacity is an effective strategy to mitigate the impact of downdrag. This approach can be applied under the following conditions: 1) high confidence in the design loads and soil parameters, 2) tolerance for relatively large settlement and differential settlement in the structure/building, and 3) insignificant consequences in the event of structural failure. Using a lower factor of safety in these scenarios can result in a cost-effective design.

Decreasing Utilization Factor of Pile Capacity: While increasing pile head load can reduce drag load, it also leads to increased pile displacement, as illustrated in Figures 8 and 9. For instance, pile head displacement rises from 3.3 mm to 53.6 mm when the

pile head load increases from 249 kN to 1,882 kN. Therefore, for structures/buildings with stringent settlement requirements, decreasing the utilization factor of pile capacity (applying a higher factor of safety) can help to minimize the effects of downdrag. However, this strategy typically results in a more cost-intensive design.

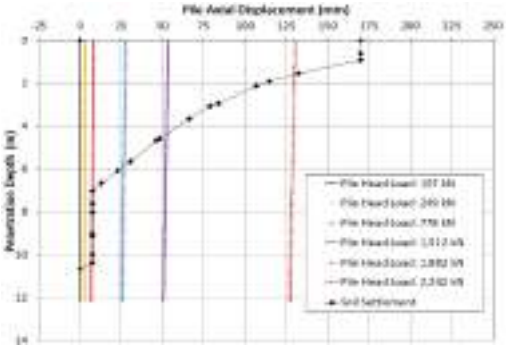

Figure 8: Pile Axial Displacement vs. Pile Head Load

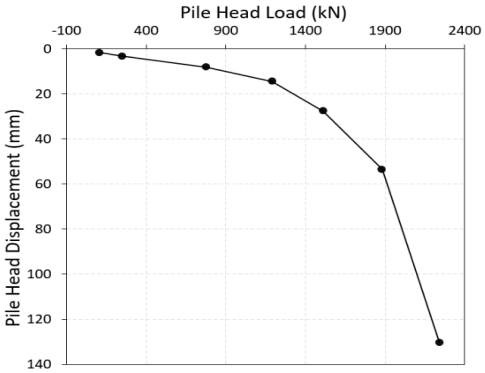

Figure 9: Pile Head Displacement vs. Pile Head Load

Reducing Settlement of Subsurface Soils

Theoretically, reducing the long-term settlement of subsurface soils can effectively decrease the drag load on the pile. Utilizing the matched TZPILE model, a series of analyses were conducted for various settlement scenarios while maintaining a constant pile head load of 780 kN. The findings of these analyses are presented in Table 3, Figure 10, and Figure 11.

Table 3: Downdrag Analysis Results Considering Reducing Settlement of Subsurface Soils

Settlement (mm)	Relative Settlement (%)	Load at Pile Head (kN)	N.P. Depth BGS (m)	Capacity at Neutral Plane Level (kN)	Drag Load (kN)	Relative Drag Load (%)
170.2	100	778	10.3	956	178	100
127.6	75	778	8.2	930	151	85
85.1	50	778	6.8	921	142	80
42.5	25	778	6.4	912	133	75
21.3	12.5	778	5.4	890	111	63

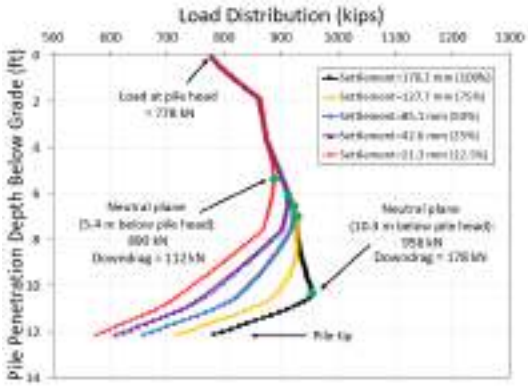

Figure 10: Load Distribution vs. Settlement

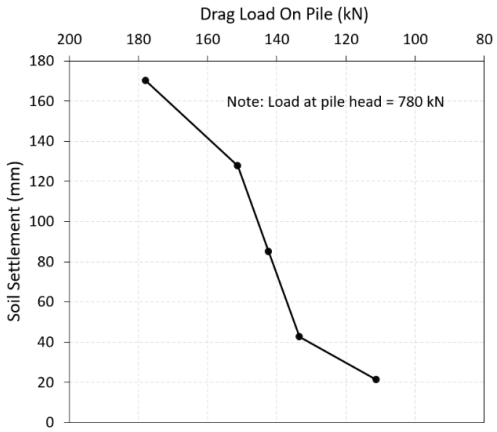

Figure 11: Soil Settlement vs. Drag Load

It can be seen from Table 3, Figure 10, and Figure 11 that for a given pile head load (i.e., 778 kN):

- The drag load decreased with the reduction in the settlement of soils. For example, the drag load decreases from 178 kN when soil settlement is 170.2 mm to 142 kN when soil settlement is reduced to 85.1 mm and further reduces to 111 kN when soil settlement is reduced to 21.3 mm.
- The rate of decrease in drag load is smaller than the rate of decrease in soil settlement. For example, when the soil settlement decreased from 170.2 mm to 85.1 mm (50%) or 170.2 mm to 21.3 mm (12.5%), the drag load decreases from 142 kN to 142 kN (80%) and 111 kN (63%) respectively.

The strategy of reducing long-term settlement of subsurface soils prior to pile installation has potential to mitigate the drag load (downdrag) on piles. However, the effectiveness of this method is often limited by significant settlement in thick layers of highly compressible, fine-grained soils. Additionally, secondary consolidation can further contribute to the drag load. From a practical perspective, this approach may be seen as laborious and time-intensive.

Increasing Pile End Bearing Using Expanded Bottom Pile

Another method to mitigate the effects of downdrag is by enhancing the pile's end bearing capacity using an expanded bottom pile. As illustrated in Figure 12, a conventional expanded bottom pile was employed in this study. To streamline the analysis, the physical expansion of the pile bottom was not simulated. Instead, the end bearing capacity in the TZPILE model was artificially augmented by applying a larger load factor. To assess the impact of the expanded bottom pile on downdrag, a series of TZPILE analyses were conducted considering various pile end bearings, while maintaining a constant pile head load of 778 kN. The findings are detailed in Table 4, Figure 13, and Figure 14.

Table 4: Downdrag Analysis Results Considering Increasing Pile End Bearing

Pile Dia. (m)	Relative Increase of Pile Dia. (%)	End Bearing (KN)	Total Capacity (kN)	Increase of Total Capacity (kN)	Load at Pile Head (kN)	Drag Load (kN)	Increase of Drag Load (kN)	Net Increase of Capacity (1) (kN)
0.46	0.0	1,600	2,139	0	778	178	0	0
0.51	11.8	2,000	2,540	400	778	258	80	320
0.56	22.5	2,400	2,940	801	778	298	120	681
0.60	32.3	2,800	3,340	1,201	778	329	151	1,050
0.65	41.4	3,200	3,741	1,601	778	347	169	1,432

Note: (1) Net Capacity = Total Capacity - Downdrag

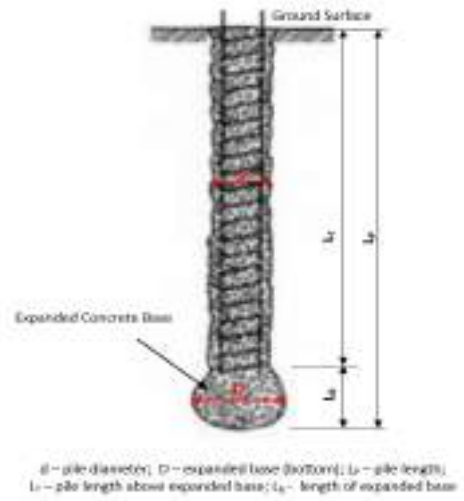

Figure 12: An example of Expanded Bottom Pile

It can be observed from Table 4 and Figure 13 that for a given pile head load of 778 kN, the drag load experiences an increase with an enhancement in the pile's end bearing. For instance, if the pile's end bearing augments from 1,600 kN to 2,400 kN or 1,600 kN to 3,200 kN, the drag load increases from 178 kN to 298 kN and 347 kN, respectively.

Additionally, as illustrated in Table 4 and Figure 14, both the drag load and pile capacity exhibit an

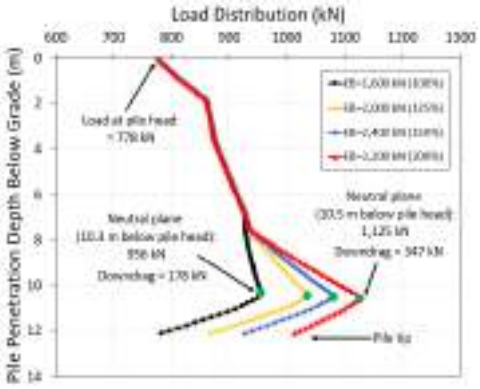

Figure 13: Load Distribution vs. End Bearing

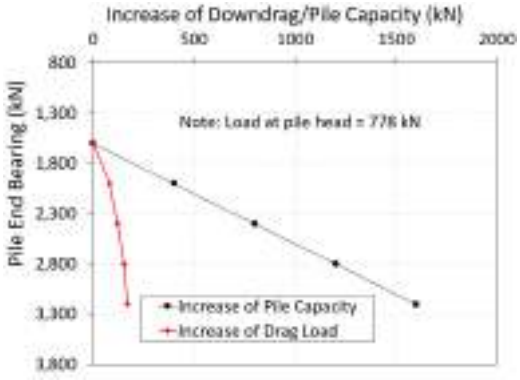

Figure 14: Increase of Drag Load/Pile Capacity vs. Pile End Bearing

upward trend with an increase in the pile's end bearing. Notably, the increment in the pile capacity surpasses the increment in the drag load, resulting in a higher net capacity of the pile. For example, when the pile's end bearing increases from 1,600 kN to 2,400 kN, the drag load increases by 120 kN (from 178 kN to 298 kN), while the pile's capacity increases by 801 kN (from 2,139 kN to 2,940 kN). Consequently, the net capacity of the pile increases by 681 kN (801 kN - 120 kN). This suggests that enhancing the pile's end bearing serves as an effective strategy to mitigate the impact of downdrag.

To increase the pile's end bearing, expanding the pile's bottom proves to be an efficient solution, particularly when the pile bottom is embedded in sandy soils. As depicted in Figure 15, when the pile's bottom diameter increases from 0.46 meters to 0.56 meters (a 22.5% increase) or from 0.46 meters to 0.65 meters (a 41.4% increase), the end bearing rises from 1,600 kN to 2,400 kN (a 50% increase) and to 3,200 kN (a 100% increase), respectively. It should be noted that the results above are based on a simplified model—specifically, the physical expansion of the pile bottom was not directly simulated. Modeling the actual pile geometry, soil–pile interaction, stress distribution, and soil failure mechanisms around the expanded base with the finite element method may yield more realistic and accurate results.

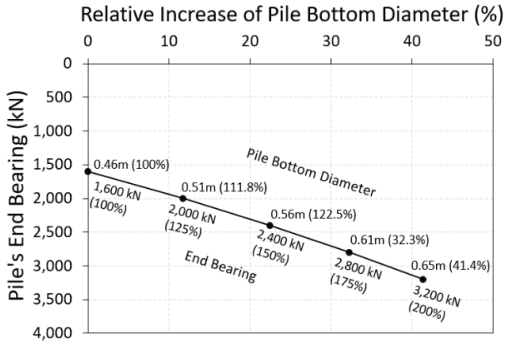

Figure 15: Pile Bottom Diameter Vs. Pile End Bearing

These aspects will be addressed in future extensions of this study for journal publication. Furthermore, additional research is needed on strategies for mitigating drag load, so that quantitative design guidance and cost–benefit analyses can be developed. This includes the creation of specific design charts or equations relating pile capacity utilization to expected settlements, cost comparisons among various mitigation methods, recommendations for when to consider each strategy, and construction feasibility and quality control requirements for each approach.

CONCLUSIONS

This paper has presented the development of the TZPILE model for a 0.46-meter diameter downdrag (DD) pile to investigate the impact of downdrag, using a generalized soil profile derived from LNG projects and accounting for excessive long-term settlement, primarily caused by a relatively thick layer of very soft and highly compressible fine-grained soils. The following conclusions can be drawn:

- For the design pile (i.e., 0.46-meter diameter pile with 12.2-meter penetration depth), the drag load decreases with the pile head load. A more realistic drag load would be achieved when the operating load is considered in the downdrag analysis.
- To mobilize the pile ultimate capacity, relatively large pile movement will occur to overcome the downdrag effect. For structures with stringent settlement requirements, reducing the utilization factor of pile capacity (i.e., using a larger factor of safety) is an effective approach to control the pile's settlement.
- For structures that represent a low hazard to human life in the event of failure, increasing the utilization factor of pile capacity (i.e., using a relatively smaller factor of safety) is an effective approach to reduce the impact of downdrag.
- Reducing long-term settlement before pile installation is another solution to mitigate the impact of downdrag. However, this is time-consuming and the effectiveness of this approach is limited.
- Increasing the pile's end bearing will increase the drag load; the impact of downdrag (drag load) can be effectively managed by increasing the pile's end bearing, as the pile's capacity increases more than the drag load.
- The pile's end bearing can be enhanced by expanding its bottom. Using an expanded bottom pile is an effective solution for projects with a sandy soil bearing stratum underlying a thick layer of very soft and highly compressible fine-grained soils.

DESERTIFICATION IN SAUDI ARABIA: IMPACTS OF EXCESSIVE IRRIGATION AND CLIMATE CHANGE ON VEGETATION LOSS THROUGH MATHEMATICAL MODELING

Dalal Adnan Maturi [1]

[1]Departement of Mathematics, Faculty of Science, King Abdulaziz University, Jeddah, Saudi Arabia

ABSTRACT

In Saudi Arabia, as defined by the United Nations Convention to Combat Desertification (UNCCD) as "land degradation in arid, semi-arid, and dry sub-humid areas resulting from various factors, including climatic variations and human activities" desertification is becoming a more serious environmental issue, particularly in regions like Al-Qassim While climate change makes water scarcity and vegetation degradation worse, over-irrigation speeds up soil degradation The purpose of this study is to determine how vegetation dynamics are impacted by dust pollution, over-irrigation, and climate change Three differential equations representing dust pollution (D), vegetation density (P), and climatic change intensity (G) were used to create a nonlinear mathematical model. The model captures essential environmental dynamics, emphasizing how vegetation helps mitigate climate change, the challenges posed by limited water availability, and the impact of dust on plant life. Using MATLAB, numerical simulations were performed to explore different environmental scenarios and evaluate their effects. Results showed that excessive irrigation and high dust pollution lead to soil salinization and weaken plant resilience, accelerating vegetation decline. In contrast, reforestation and sustainable irrigation play a crucial role in stabilizing plant ecosystems and slowing desertification. Maintaining ecological balance requires a well-planned combination of afforestation, dust control, and responsible water management. If left unchecked, uncontrolled irrigation and rising dust levels speed up land degradation, highlighting the urgent need for climate adaptation measures and sustainable water policies. By leveraging mathematical modeling and numerical simulations, engineers and ecologists can gain valuable insights into managing agriculture and environmental sustainability in arid regions like Saudi Arabia. These tools help develop data-driven strategies that improve long-term land use and conservation efforts.

Keywords: Desertification, Irrigation, Climate Change, Vegetation Loss, Mathematical Modeling.

INTRODUCTION

The Climate change scenarios predict shifts in aridity across the Middle East and North Africa (MENA) region, including Saudi Arabia. Under the Paris Agreement scenarios, Saudi Arabia is expected to experience increased rainfall, which may transition some areas from hyper-arid to arid conditions. However, the increase in potential evapotranspiration (PET) could offset these benefits, leading to a drier climate overall [1]. The increase in temperature and decrease in precipitation exacerbate water scarcity, impacting agricultural productivity and leading to desertification [2]. Excessive irrigation in Saudi Arabia has led to increased evaporation and altered local climates. The Saudi Green Initiative, which involves large-scale forestation, requires significant irrigation, further straining water resources and potentially increasing local temperatures due to lower albedo and higher evaporation rates [3]. The use of irrigation in agriculture has been shown to increase latent heat flux, which can affect local climate conditions and contribute to desertification if not managed sustainably [4]. Mathematical models, such as the FAO-CROPWAT and SALTMED, have been used to estimate crop water requirements and assess the impacts of climate change on irrigation needs. These models indicate that irrigation water requirements will increase significantly under high emission scenarios, leading to higher deficits in water availability for major crops [5]. Optimizing water use through improved irrigation planning and crop pattern selection can mitigate some adverse effects. For instance, reallocating water resources among competitive crops like date palms can enhance water use efficiency and reduce overall water demand [6]. Soil erosion, driven by high rainfall intensity and lack of vegetation cover, is a critical factor in land degradation and desertification. The Revised Universal Soil Loss Equation (RUSLE) model, coupled with GIS, has been used to assess soil erosion risk in Saudi Arabia, highlighting areas with high erosion potential due to steep slopes and sparse vegetation [7].The study investigates the regional climate impact of irrigated forested areas on temperature and precipitation in the Arabian Peninsula, particularly focusing on the effects of Saudi Arabia's "Saudi Green Initiative," which aims to plant ten billion trees despite challenges such as insufficient rainfall and the need for irrigation, which

increases evaporation and alters local climate conditions [8]. The study focuses on estimating crop water requirements (CWR) in Saudi Arabia, where agriculture heavily depends on limited water resources such as groundwater and desalinated water. It utilizes high-resolution satellite data and environmental variables to improve the accuracy of CWR estimations, addressing the challenges posed by a lack of micro-level data in agricultural systems [9]. The study investigates the impact of climate change on soil salinity and pomegranate productivity in the Al-Baha region of Saudi Arabia, where groundwater depletion, rising temperatures, and decreasing precipitation have led to deteriorating groundwater quality and reduced agricultural productivity. Over a 24-year period, average temperatures increased by 1.1 °C–1.6 °C, while rainfall decreased by 24–41%, prompting the use of the SALTMED model to analyze future scenarios [10]. The study estimates the greening effect over the desert in Saudi Arabia using a meteorological numerical model (MM5) combined with a sophisticated land surface model (LSM), revealing that greening by grassland vegetation can increase regional rainfall by +65% [11]. In recent years, mathematical modeling techniques have played a pivotal role in understanding environmental challenges such as desertification, particularly in arid regions like Saudi Arabia. The phenomenon of vegetation loss due to excessive irrigation and climate-induced heat stress requires robust models that simulate soil heat dynamics and water transfer processes. Finite Difference Methods (FDM), as demonstrated by Maturi and colleagues in modeling heat conduction in granite and brick materials [12-13], provide a foundational approach for approximating thermal changes in semi-arid soil environments.

Moreover, analytical and semi-analytical methods such as the Adomian Decomposition Method and Variational Iteration Method, used by Maturi in solving singular integral and Laplace equations related to heat and groundwater flow [14-15],[18] 2024), can be extended to simulate evapotranspiration, root-zone temperature profiles, and subsurface hydrologically critical to vegetation sustainability in desert-prone regions. Notably, recent work on heat transfer modeling in biological materials, such as apple refrigeration and heat flow in metallic electric cables [16-17], illustrates the potential to apply these methods to plant physiology under stress conditions caused by irrigation mismanagement or high ambient temperatures. These mathematical tools not only enhance our predictive understanding of desertification dynamics but also aid in designing mitigation strategies by quantifying soil-water-heat interactions in deteriorating ecosystems.

RESEARCH SIGNIFICANCE

This study addresses the escalating challenge of desertification in Saudi Arabia by quantitatively analyzing the synergistic impacts of excessive irrigation and climate change on vegetation loss. By integrating variables such as soil moisture, groundwater dynamics, and irrigation policies into a mathematical framework, the research offers a novel predictive tool to assess ecosystem vulnerability. The findings provide critical insights for sustainable water management, enabling policymakers to balance agricultural demands with groundwater preservation. This model not only deepens our theoretical understanding of how desertification happens in dry regions, but it also offers a practical framework that other countries facing water shortages can adapt. It contributes to global sustainability efforts, such as the United Nations' Sustainable Development Goals (SDGs), and fits perfectly within the framework of Saudi Arabia's Vision 2030.

GENERAL FORM OF THE DPG MODEL

The DPG system is given by:

$$\begin{cases} \frac{dD}{dt} = A - \mu_0 D - \alpha DP = F_1(D,P), \\ \frac{dP}{dt} = rP\left(1 - \frac{P}{K-cG}\right) - \beta DP = F_2(D,P,G), \\ \frac{dG}{dt} = Q - \gamma_1 DG - \gamma_2 PG - \mu_1 G = F_3(D,P,G). \end{cases} \quad (1)$$

The Jacobian matrix for the system is:

$$J = \begin{bmatrix} \frac{\partial F_1}{\partial D} & \frac{\partial F_1}{\partial P} & \frac{\partial F_1}{\partial G} \\ \frac{\partial F_2}{\partial D} & \frac{\partial F_2}{\partial P} & \frac{\partial F_2}{\partial G} \\ \frac{\partial F_3}{\partial D} & \frac{\partial F_3}{\partial P} & \frac{\partial F_3}{\partial G} \end{bmatrix} \quad (2)$$

Substituting the partial derivatives:

$$J = \begin{bmatrix} -\mu_0 - \alpha P & -\alpha D & 0 \\ -\beta P & r - \frac{2rP}{K-cG} - \beta D & -\frac{rcP^2}{(K-cG)^2} \\ -\gamma_1 G & -\gamma_2 G & -\gamma_1 D - \gamma_2 P - \mu_1 \end{bmatrix} \quad (3)$$

Local stability analysis of $Z_1 = (D_1, 0, G_1)$:

Equilibrium point :

$$D_1 = \frac{A}{\mu_0}, \quad P_1 = 0, \quad G_1 = \frac{Q\mu_0}{A\gamma_1 + \mu_0\mu_1} \quad (4)$$

Jacobian at point Z_1:

$$J(Z_1) = \begin{bmatrix} -\mu_0 & -\alpha D_1 & 0 \\ 0 & r - \beta D_1 & 0 \\ -\gamma_1 G_1 & -\gamma_2 G_1 & -\gamma_1 D_1 - \mu_1 \end{bmatrix} \quad (5)$$

Eigenvalues of $J(Z_1)$:The eigenvalues (λ) are obtained by solving:

$$\det(J(Z_1) - \lambda I) = 0 \quad (6)$$

This simplifies to:

$$\begin{vmatrix} -\mu_0 - \lambda & -\alpha D_1 & 0 \\ 0 & r - \beta D_1 - \lambda & 0 \\ -\gamma_1 G_1 & -\gamma_2 G_1 & -\gamma_1 D_1 - \mu_1 - \lambda \end{vmatrix} = 0 \quad (7)$$

Since the matrix is lower triangular, the eigenvalues are the diagonal elements:

$$\lambda_1 = -\mu_0, \quad \lambda_2 = r - \beta D_1, \quad \lambda_3 = -\gamma_1 D_1 - \mu_1 \quad (8)$$

Stability Conditions for Z_1:

- All eigenvalues must be negative for stability.
- $\lambda_1 = -\mu_0 < 0$ (always true since $\mu_0 > 0$).
- $\lambda_3 = -\gamma_1 D_1 - \mu_1 < 0$ (always true).
- $\lambda_2 = r - \beta D_1 = r - \frac{\beta A}{\mu_0}$.

Thus, Z_1 is locally stable if: $r < \frac{\beta A}{\mu_0}$

Bifurcation at Z_1:

- If $r = \frac{\beta A}{\mu_0}$, $\lambda_2 = 0 \rightarrow$ Transcritical bifurcation occurs.
- If $r > \frac{\beta A}{\mu_0}$, Z_1 becomes unstable, and Z_2 emerges as stable.

The SECOND- LOCAL STABILITY ANALYSIS OF Z_2

Equilibrium point $\boldsymbol{Z_2}$:

$$\boldsymbol{D_2 = \frac{A}{\mu_0 + \alpha P_2}}, \quad \boldsymbol{G_2 = \frac{Q(\mu_0 + \alpha P_2)}{\alpha\gamma_2 P_2^2 + (\mu_0\gamma_2 + \mu_1\alpha)P_2 + (A\gamma_1 + \mu_0\mu_1)}} \quad (9)$$

where $\boldsymbol{P_2}$ is a root of

$$f(P) = e_1 P^4 + e_2 P^3 + e_3 P^2 + e_4 P + e_5 = 0. \quad (10)$$

Jacobian at point $\boldsymbol{Z_2}$:

$$J(Z_2) = \begin{bmatrix} -(\mu_0 + \alpha P_2) & -\alpha D_2 & 0 \\ -\beta P_2 & r - \frac{2rP_2}{K - cG_2} - \beta D_2 & -\frac{rcP_2^2}{(K - cG_2)^2} \\ -\gamma_1 G_2 & -\gamma_2 G_2 & -(\gamma_1 D_2 + \gamma_2 P_2 + \mu_1) \end{bmatrix} \quad (11)$$

LOCAL STABILITY ANALYSIS OF

Characteristic Equation:

The eigenvalues are solutions of:

$$\lambda^3 + S_1\lambda^2 + S_2\lambda + S_3 = 0 \quad (12)$$

where:

$$\boldsymbol{S_1 = \mathrm{tr}(J) = -(J_{11} + J_{22} + J_{33})},$$
$$\boldsymbol{S_{12} = \text{sum of principal minors}}$$
$$\boldsymbol{S_3 = -\det(J)},$$

Routh-Hurwitz Stability Criterion. For stability, the following must hold:

1. $S_1 > 0$,
2. $S_3 > 0$,
3. $S_1 S_2 > S_3$.

If these conditions are met, Z_2 is locally asymptotically stable.

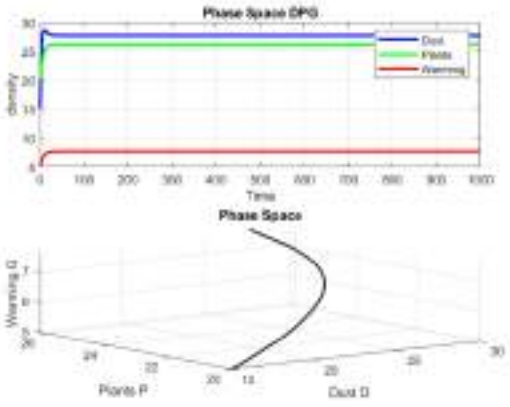

Fig.1 Dynamic simulation of DPG model for Scenario Value1, Dust concentration D(t) in mg/m³, vegetation biomass P(t) in kg/ha, and temperature anomaly G(t) in °C. This scenario represents moderate dust emissions and plant growth rates.

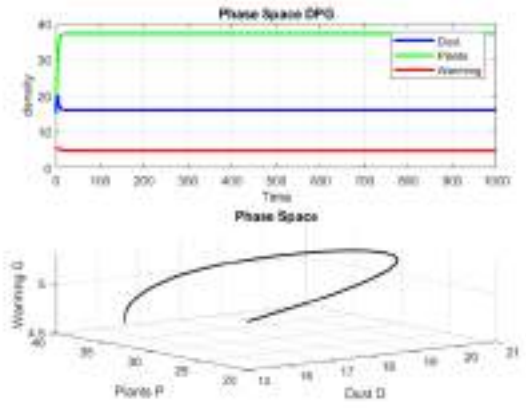

Fig.2 Dynamic simulation of DPG model for Scenario Value2 — Same variables and units as Fig. 1, but with higher dust emission and reduced plant growth resilience.

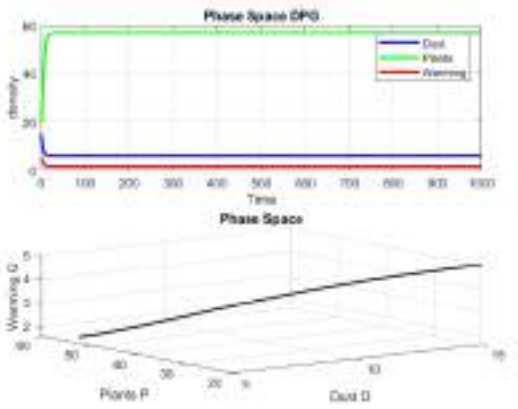

Fig.3 Dynamic simulation of DPG model for Scenario Value3. Represents high carrying capacity with moderate warming sensitivity.

Table 1 Description of DPG System Parameters with Value

Items	Description	Units	Value1	Value2	Value3
A	Dust emission rate	mg/m³/day	10	15	13
μ_0	Natural dust depletion rate	day⁻¹	0.1	0.2	0.5
α	Plant-induced dust removal coefficient	m³/(kg·day)	0.01	0.02	0.03
r	Plant intrinsic growth rate	day⁻¹	0.22	0.44	0.33
K	Plant carrying capacity	kg/ha	30	40	60
c	Warming-induced desertification coefficient	ha/(kg·°C·day)	0.01	0.02	0.03
β	Dust-induced plant degradation rate	m³/(mg·day)	0.001	0.002	0.003
Q	Global warming increase rate	C/year°	0.821	0.841	0.861
γ_1	Dust cooling effect on warming	C·m³/(mg·day)°	0.001	0.002	0.003
γ_2	Plant cooling effect on warming	C·ha/(kg·day)°	0.003	0.004	0.009
μ_1	Human mitigation of warming	year⁻¹	0.001	0.002	0.003

APPLICATIONS

We model the interaction between plant biomass and dust pollutants using two ODEs:

$$\begin{cases} \frac{dP}{dt} = rP\left(1-\frac{P}{K}\right) - aPD & \text{(Plant growth)} \\ \frac{dD}{dt} = Q - bD - cPD & \text{(Pollutant dynamics)} \end{cases}$$

$P(t)$: Plant biomass
$D(t)$: Dust pollutant concentration
r: Intrinsic growth rate of plants
K: Carrying capacity of plants
a: Pollution stress coefficient
Q: External pollutant input rate
b: Natural removal rate of pollutants
c: Interaction rate (plants removing pollutants)

At equilibrium, $\frac{dP}{dt} = \frac{dD}{dt} = 0$: Non-Desertification Equilibrium ($P^* > 0, D^* > 0$):

We solve: $\begin{cases} rP^*\left(1-\frac{P^*}{K}\right) = aP^*D^* \\ Q = bD^* + cP^*D^* \end{cases}$

1. From Plant Equilibrium:
$$r\left(1-\frac{P^*}{K}\right) = aD^* \Longrightarrow D^* = \frac{r}{a}\left(1-\frac{P^*}{K}\right)$$
2. From Pollutant Equilibrium:
$$Q = bD^* + cP^*D^* \Longrightarrow P^* = \frac{Q - bD^*}{cD^*}$$
3. Substitute D^* into P^*:
$$P^* = \frac{Q - b\left(\frac{r}{a}\left(1-\frac{P^*}{K}\right)\right)}{c\left(\frac{r}{a}\left(1-\frac{P^*}{K}\right)\right)}$$

This is a nonlinear equation in P^* and must be solved numerically.

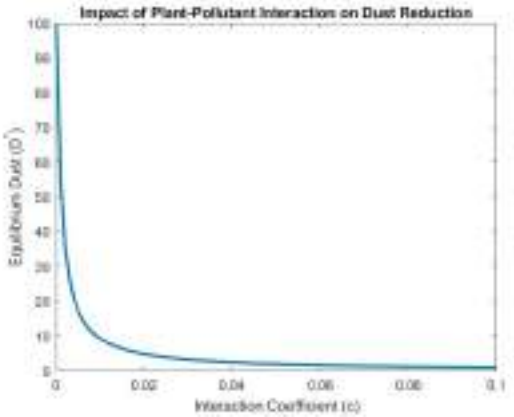

Fig.4 Impact of plant-pollutant interaction on dust reduction . D(t) in mg/m³ decreases as interaction rate c increases.

We study how D^* changes as c varies using implicit differentiation.

1. Differentiate Pollutant Equilibrium w.r.t. c:

$$0 = b\frac{dD^*}{dc} + P^*D^* + cD^*\frac{dP^*}{dc} + cP^*\frac{dD^*}{dc}$$

2. From Plant Equilibrium, express $\frac{dP^*}{dc}$ in terms of $\frac{dD^*}{dc}$:

$$\frac{dD^*}{dc} = -\frac{r}{aK}\frac{dP^*}{dc}$$

3. Substitute and solve for $\frac{dD^*}{dc}$:

$$\frac{dD^*}{dc} = \frac{-P^*D^*}{b + cP^* + \frac{aKcD^*}{r}}$$

Since all terms in the denominator are positive, $\frac{dD^*}{dc} < 0$, meaning increasing c decreases D^*.

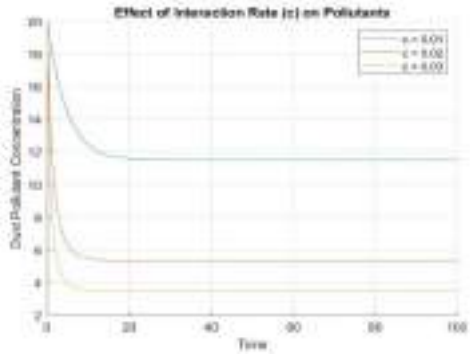

Fig.5 Effect of interaction rate c on pollutants. Detailed sensitivity curves showing negative slope, confirming that increased plant-dust interaction reduces dust concentration.

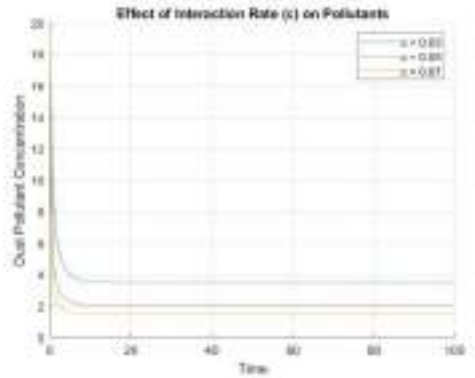

Fig.6 Effect of interaction rate c on pollutants . Detailed sensitivity curves showing negative slope, confirming that increased plant-dust interaction reduces dust concentration.

Equilibrium Analysis: If c increases → D^* decreases (more pollutant removal by plants).

If Q increases → D^* increases (more external pollution).

Sensitivity: $\frac{dD^*}{dc} < 0$ confirms that higher plant-pollutant interaction reduces dust concentration.

CONCLUSIONS

Dust pollutants, in conjunction with global warming, pose a significant threat to the ecological environment. This phenomenon may lead to the gradual conversion of verdant areas into ecologically unsustainable zones. The present study introduces and critically assesses a mathematical model designed to explore the effects of global warming and dust contaminants on the growth of plant biomass. The analytical framework employs the stability theory of differential equations to facilitate a comprehensive evaluation of the model. The analysis reveals that the system is characterized by two equilibrium states: the non-desertification equilibrium and the desertification equilibrium. The model analysis presents several compelling insights regarding the stability of these equilibrium states. Furthermore, the analysis uncovers noteworthy findings pertaining to various bifurcation types, including transcortical and Hopf bifurcations surrounding the equilibrium points. Additionally, the following results were discerned through numerical simulations. The atmospheric concentration of dust pollutants diminishes as the interaction rate between dust contaminants and plant biomass escalates. The plant biomass is threatened with the transition of green spaces into desertified areas if the intrinsic growth rate of plant biomass, the dust pollutants-induced depletion coefficient of plant biomass, and the natural depletion coefficient for dust pollutants remain uncontrolled. The potential for averting desertification exists if the conditions delineated in Theorem 1 ensure that plant biomass can persist alongside global warming and dust pollutants in a stable equilibrium. From the sensitivity analysis of the non-desertification equilibrium point, the findings indicate that the carrying capacity of plant biomass is a pivotal parameter that significantly mitigates the adverse effects of dust pollutants and global warming. Consequently, enhancing vegetation via reforestation initiatives is imperative for preventing desertification and fostering stability at the non-desertification equilibrium. In future research endeavors, we will explore the extension of the model to encompass interactions with additional ecological factors, such as animal populations, with a particular emphasis on herbivorous species.

AUTOMATION AND INNOVATION IN PRECAST CONCRETE MANUFACTURING: A STRATEGIC APPROACH

*Amalia Rizka Sugiarto[1,2], Yusuf Latief [1]

[1] Faculty of Engineering, University of Indonesia, Indonesia
[2] Faculty of Engineering, University of Singaperbangsa Karawang, Indonesia

ABSTRACT

The precast concrete manufacturing industry is undergoing a transformation toward digitalization and automation, driven by the need for improved efficiency, precision, and integration across production stages. However, the adoption of automation technologies remains fragmented, with most implementations focusing only on isolated processes. This study aims to develop a strategic framework that maps digital and automation technologies systematically across the full cycle of precast concrete production. Using a conceptual and literature-based approach, the research identifies key production stages—from design and material preparation to casting, curing, quality control, and on-site installation—and aligns them with relevant technologies such as Building Information Modeling (BIM), Enterprise Resource Planning (ERP), RFID, IoT, robotics, Digital Twin, and 3D printing. The study results in a comprehensive visual framework that integrates these technologies with stakeholder roles (designer, factory, contractor) and system layers (physical, control, data, decision). In addition to the framework, this paper presents a technology matrix, system architecture model, and stepwise adoption roadmap to guide gradual implementation. The framework offers strategic value by enabling closed-loop control, predictive monitoring, and real-time decision-making. It also addresses the research gap regarding holistic technology mapping in precast production and supports the construction industry's transition toward Industry 4.0. Future research is recommended to validate the proposed framework through industrial case studies and practical application.

Keywords: Precast concrete, Industry 4.0, Visual framework, Automation technologies

INTRODUCTION

The construction industry has undergone significant transformation along with advances in automation and digitalization technology in recent decades [1][2]. One construction sub-sector that has received special attention is precast concrete manufacturing [3]. Precast products have been proven to increase construction time efficiency, reduce waste at project sites, and provide more consistent quality [4][5]. However, the conventional precast production process still faces various challenges, such as dependence on manual labor, inefficiency of production flows, human error, and limitations in real-time quality control systems [6].

In the Industry 4.0 era, various technologies such as Building Information Modeling (BIM), Enterprise Resource Planning (ERP), robotics, intelligent sensors (IoT), and Digital Twin have developed rapidly and offer the potential to be integrated into the precast production process [7] [8]. The integration of these technologies allows companies to build smarter, more adaptive, and high-precision production systems [9][10][11]. For example, the use of automated cutting and curing robots can replace manual activities with higher accuracy; RFID and IoT sensors can improve supply chain visibility; and the application of Digital Twin allows digital product simulation and monitoring to improve quality [12][13].

Although various studies have discussed digital technology in construction, there is still a gap in the literature regarding a strategic approach that systematically maps the implementation of automation technology based on the entire precast production cycle. This study aims to develop a strategic framework that integrates automation technology into every stage of the precast concrete production process. By developing this framework, it is expected to contribute to more efficient, measurable, and high-quality construction manufacturing practices.

RESEARCH SIGNIFICANCE

This research has significance in supporting digital transformation in the precast concrete manufacturing sector through a strategic approach based on automation technology. By compiling a technological framework according to the stages of precast production, this research provides an application guide for the industry in integrating systems such as BIM, ERP, robotics, and smart sensors. The results of this research are expected to improve operational efficiency, product quality, and the readiness of the construction industry to face the

challenges of Industry 4.0.

MATERIAL AND METHODS

This study adopts a conceptual and descriptive approach to develop a strategic framework for automation integration in precast concrete manufacturing. The objective is to systematically map digital and automated technologies into each stage of the precast production cycle [14] [15].

Literature Review

A comprehensive review was conducted on current technologies in digital construction and industrial automation, including Building Information Modeling (BIM), Enterprise Resource Planning (ERP), Internet of Things (IoT), Digital Twin, and robotics in precast production systems [16][17].

Identification of Production Stages

The typical precast production cycle was analyzed and classified into key stages: design and modeling, material supply, mold setup, casting and curing, quality control, and distribution [18]. These stages formed the basis for mapping relevant technologies [19][20].

Technology Mapping

A dataset of technologies applicable to precast production was compiled from industrial sources and previous studies [21][22]. Each technology was matched to the most appropriate stage in the production cycle based on its function, capability, and integration potential [23][24][25].

Framework Construction

Using the mapped data, a visual framework was constructed to illustrate how automation systems interact with each phase of the precast process [26][27]. The diagram reflects data flows, system integration points, and the role of each actor involved (designer, factory, specialty contractor, and general contractor) [28][29][30].

No physical experiments were conducted; instead, this research is based on a conceptual system design using validated data and technologies already applied in real-world precast contexts.

RESULT AND DISCUSSION

General Stages of Precast Concrete Production

The production of precast concrete involves a series of structured and sequential stages that must be carefully managed to ensure quality, efficiency, and consistency. The process begins with the design and modeling phase, where structural and reinforcement drawings are prepared using digital tools to define the dimensions, geometry, and specifications of the precast components. This stage plays a crucial role in determining the accuracy of downstream activities and is often supported by Building Information Modeling (BIM) to enhance coordination across disciplines.

Following the design phase, the next stage is the preparation of materials and logistics, which includes procurement, inventory management, and the scheduling of deliveries. Efficient material handling is essential to avoid delays and reduce waste. The process continues with the setup of formwork and reinforcement, where molds are prepared and rebar or other reinforcement components are placed based on production drawings.

Once formwork is completed, the casting and curing stage begins. In this phase, concrete is poured into molds under controlled conditions, followed by curing to achieve the desired strength and durability. After the curing process, the elements undergo demoulding and finishing, where the products are removed from the molds, cleaned, and surface-treated as needed.

The final phases include quality control, which ensures the components meet design specifications and tolerances, and storage and delivery, where precast elements are organized, tracked, and prepared for transportation to the construction site. These stages are increasingly supported by digital and automated systems, enabling more precise, traceable, and scalable production workflows.

Integration of Automation Technology Based on Production Stages

Through literature studies and analysis of technology data available in the industry, this study develops a mapping of automation technology based on the stages of the precast concrete production process. This mapping includes not only the name of the technology, but also the main functions, types of systems used, and examples of commercially available applications. The results of the mapping are presented in Table 1.

Tabel 1. Automation and Digital Technologies in Precast Concrete Manufacturing

Business Process Stage	Technology	Software	Function
Design	Building Information Modeling (BIM)	Autodesk Revit, Tekla Structures, ArchiCAD	Creating 3D digital models of precast components; real-time multidisciplinary collaboration
Design & Simulation	Digital Twin	Siemens NX, ANSYS TwinBuilder, Dassault 3DEXPERIENCE	Digital representation of physical components for simulation and precision analysis
Production Planning	ERP System	SAP ERP, Oracle NetSuite, Microsoft Dynamics	Integration of planning, material management, and precast production scheduling
Supply Chain & Inventory	RFID (Radio Frequency ID)	RFID management software such as Zebra RFID Software	Real-time material tracking, loss prevention, inventory optimization
Production – Cutting	Cutting Robot	Robotic software (FANUC, ABB, KUKA Sim)	Cutting steel bars and molds with high accuracy based on BIM model
Production – Printing	3D Printing (non-mass production)	Rhino & Grasshopper, Autodesk Fusion, 3D Slice Software	Fabrication of unique/custom components such as architectural façades, non-standard panels
Production – Assembly	Robotic Assembly Line	PLC-based Control System, SCADA	Automated assembly of rebar, formwork, and material setup before curing
Production – Curing	Curing Robot	Automated temperature & humidity control (custom SCADA)	Precision control of curing environment to ensure optimal concrete quality
Production Monitoring	ERP (integrated with MES)	SAP Manufacturing Execution System, Oracle MES	Real-time monitoring of production status, daily output, and technical issues
Quality Control	Digital Twin & Computer Vision	AI QC software, Digital Twin Analyzer	Comparing physical results with digital models, defect detection, deviation tolerance
Internal Logistics	Autonomous Crane Navigation	Crane Pathing Software, AI	Automatically lifting and transferring precast elements to shipping area
Delivery to Site	RFID & ERP Integration	Fleet Tracking System, ERP Logistics Module	Ensuring real-time scheduling and logistics status, improving delivery efficiency
On-Site Installation	BIM & AR / MR Viewer	Trimble XR10, Microsoft HoloLens, Fuzor	Precise component positioning on-site using digital guidance
Feedback Loop	IoT Monitoring & AI Analytics	Power BI, Grafana, custom AI dashboard	Collecting post-installation performance data to improve future design and production

Strategic Discussion

The results of automation technology mapping in Table 1 show that a strategic approach to automation in the precast concrete industry cannot be done partially. An integrative framework is needed that unites the digitalization process from upstream to downstream. The use of BIM at the design stage, for example, not only functions as a visualization tool, but also as the main data source that flows into the ERP system and Digital Twin platform for product validation.

Tabel 2. Strategic Benefits of Key Technologies in Precast Concrete Manufacturing.

Technology	Primary Function	Strategic Benefit
Building Information Modeling (BIM)	Design coordination and data integration	Enhances design accuracy and reduces rework
ERP System	Production planning and resource control	Improves efficiency, material flow, and project cost control
RFID	Inventory and logistics tracking	Enables real-time visibility and minimizes material loss
Robotics	Automation of physical tasks (cutting, handling)	Increases precision, speed, and labor efficiency
Digital Twin	Simulation and virtual inspection	Enables predictive quality control and scenario planning
3D Printing	Customized element production	Allows design flexibility and fast prototyping
IoT Sensors	Monitoring temperature, humidity, or equipment	Supports real-time condition tracking and maintenance
Autonomous	Automatic lifting	Reduces manual labor

Technology	Primary Function	Strategic Benefit
Crane	and positioning	and improves safety in handling operations
AI Analytics	Post-process evaluation and optimization	Enables continuous improvement through performance insights

Table 2 summarizes key technologies and their corresponding benefits in improving operational and decision-making efficiency**.** Furthermore, the ERP system plays a role in integrating cross-functional data—from supply chain, production monitoring, to quality management. This system enables real-time data-based decision making, while minimizing process inefficiencies.

Robotic and sensory technologies such as robotic arms, curing robots, and autonomous cranes increase precision and speed in the physical production stage. Meanwhile, the use of Digital Twin and laser scanners in quality control allows early detection of product non-conformities before being sent to field projects.

The use of 3D concrete printing offers great opportunities in producing non-standard or complex components that are uneconomical when done conventionally. This opens up new potential in modular design, time efficiency, and reduction of production waste.

Fig. 1 Strategic Framework Precast Production

From a strategic perspective, the adoption of this technology still faces several challenges, starting from High initial investment, especially for robots and advanced ERP systems. Limited human resources who understand cross-digital system integration and Readiness of data and network infrastructure, especially in the application of sensors and real-time communication.

However, with gradual planning and a clear implementation roadmap, the transformation towards automation-based precast manufacturing can be a long-term solution in increasing the competitiveness of the construction industry, both in terms of cost efficiency, product quality, and operational sustainability.

Strategic Discussion and Research Gap

Although automation has been increasingly adopted in precast concrete manufacturing, its implementation remains largely fragmented. Many companies integrate specific technologies such as Building Information Modeling (BIM), Enterprise Resource Planning (ERP), or Internet of Things (IoT) in isolated processes, without a unified data architecture or workflow. This disconnection reduces the potential efficiency and visibility that a fully integrated automation system can offer.

One of the most significant innovation opportunities lies in establishing end-to-end digital connectivity across systems. The integration of BIM with ERP allows design data to be seamlessly linked to procurement and scheduling. When coupled with IoT-based monitoring and Digital Twin simulations, the entire production process—from design to quality control—can be tracked, validated, and optimized in real-time. This creates a closed-loop control environment, where feedback from the field or production floor informs upstream decisions on design and planning.

In contrast, traditional precast production workflows rely heavily on manual labor, paper-based documentation, and visual inspections, making them

vulnerable to human error, inefficiency, and lack of traceability. Without digital tools, design revisions are slow to propagate, inventory and logistics are difficult to monitor, and quality assurance often lacks objective verification.

Despite the growing body of research on digital construction technologies, there is a noticeable lack of studies that provide a comprehensive and structured framework mapping these technologies across the full precast production cycle. This gap highlights the need for strategic guidance to help stakeholders understand where and how automation technologies can be adopted incrementally. The framework developed in this study seeks to fill that void by offering a practical, stage-based roadmap for automation integration that aligns with both operational requirements and the broader goals of Industry 4.0 transformation in construction.

CONCLUSIONS

This research has produced a strategic framework for the integration of automation technology in the precast concrete production process. The framework systematically maps the stages of precast production from design to installation in the field, and links them to key technologies such as BIM, ERP, IoT, RFID, robotics, Digital Twin, and 3D Printing.

Through this approach, the precast production process can be transformed to be more efficient, precise, and digitally documented. This framework also shows the importance of connectivity between digital systems and integrated data management to support decision making based on real-time information.

The main contribution of this research lies in the preparation of a comprehensive precast production cycle-based technology mapping, which until now has rarely been discussed in full in the literature. This framework can be used as a basis for developing an automation roadmap by precast construction companies that are transforming towards industry 4.0.

Further research can be directed at validating this framework in a real industrial context, including case studies of the implementation of part or all of the system in a real precast production environment.

ABSTRACT

Arsenic contamination in groundwater has been reported in lowland areas such as Red River Delta and Mekong River Delta in Vietnam, and it is required to apply a low-cost and feasible arsenic-contaminated groundwater treatment technology by using local available materials. In this study, we focused on Vietnam laterite that is rich in metal oxides/hydroxides as an easy available adsorbent for developing the low-cost groundwater treatment system. The surface of metal oxides/hydroxides can be expected to form surface complexes with arsenic ion in water and to promote the arsenic removal from arsenic-contaminated groundwater. Several studies have examined the arsenic adsorption characteristics of Vietnam laterite, on the other hand, the combined studies of arsenic adsorption and desorption are limited. In this study, therefore, we evaluated the effect of pH on the arsenic adsorption and desorption characteristics for raw laterite grains (RL) and thermal-treated laterite grains (TTL) using a series of batch experiments in the laboratory. Results showed that the maximum arsenic adsorption capacities became 3.65 mg/g for RL and 6.28 mg/g for TTL at initial solution pH=2.0. The maximum desorption efficiencies became 16.4% for RL and 26.6% for TTL at pH=8.0. Based on the analysis of adsorption isotherms, it was implied that the adsorption process was mainly controlled by the multilayer adsorption for both RL and TTL. In addition, the adsorbed arsenic was hardly desorbed at low pH condition but was desorbed to a certain extent at high pH condition.

Keywords: Laterite, Arsenic, Adsorption, Desorption, Batch test, Vietnam

INTRODUCTION

Solid arsenic is widely distributed in nature and can leach into groundwater through natural processes and anthropogenic activities [1]. For example, the risk of drinking groundwater with arsenic concentrations of 10 μg/L is considerable, with approximately 45 million people in Bangladesh at high risk, with arsenic-related mortality reported to be 1 in 18 adult deaths [2].That is why achieving compliance with the maximum permissible limit of 10 μg/L requires implementing measures to limit the sources of arsenic contamination and utilizing highly efficient purification technologies.

There is a river called Red River from the fact that the water is red due to the iron oxide contained in it. In the Red River Delta, the presence of arsenic in groundwater was first discovered in Hanoi in 1998, with a maximum concentration of 3050 μg/L (average of 127 μg/L) [3]. Other locations in the Red River Delta provinces of Hanoi, Ha Nam, Ha Tay, and Hung Yen were observed as areas of high arsenic contamination, close to 890 μg/L [4]. The arsenic concentration in some areas of both deltas exceeds the permissible limit of 10 μg/L. In these areas, arsenic-contaminated groundwater is used as a freshwater source for domestic water and agricultural activities, so arsenic contamination in groundwater is a serious problem [5].

Currently, methods used to treat arsenic include ion exchange, adsorption, phytoremediation, chemical precipitation, electrokinetic, and electrocoagulation. Although these methods help remove arsenic from soil and water, each has drawbacks in terms of cost and efficiency. The selection of an appropriate arsenic treatment method is determined by various factors, including limitations on soil and water treatment technologies, requirements of local and national authorities, the country's stage of development, and regional strategies regarding arsenic levels in industrial and water systems [6].

Among the techniques for treating arsenic in water, adsorption is efficient and cost-effective, depending on the adsorbent used. It also does not require advanced technology or large amounts of electricity, making it suitable for practical use in developing countries. Adsorption has shown a high quantitative efficiency of over 95% in the removal of both As(III) and As(V) [7]. The effectiveness of this technique relies on a separation process based on van der Waals forces and electrostatic attraction between adsorbed molecules [8]. Adsorbents used for arsenic include kaolinite [9], zeolite [10], iron oxide [11], iron oxide-coated cement [12], activated carbon [13], lightweight cellular concrete [10]. The efficiency of arsenic adsorption is influenced by various factors, such as exposure period, pH conditions, presence of

other elements, adsorbent dosage, initial arsenic concentration, and temperature [14]. Among them, pH is considered a very influential parameter in the arsenic removal process since it determines the predominant chemical species in the water.

In this study, we focused on soil called laterite as an arsenic adsorbent. Soil composed of iron and aluminum oxides, kaolin, etc. is generally called laterite [15]. Laterite is also used in Southeast Asian architecture and is widely used as a building stone. Laterite is rich in active charge carriers on the surface, which are expected to promote anionic metal adsorption by forming surface complexes. Arsenic adsorption is a chemical and physical adsorption phenomenon that occurs on the hydroxyl and acid groups on the surface of iron and aluminum, the main components of laterite [16,17].

The treated laterite that had been chemically treated with hydrochloric acid and sodium hydroxide was used as an arsenic adsorbent [16]. The maximum Langmuir adsorption capacity of the treated laterite for As (V) and As (III) was 24.1±4.0 and 8.0±1.4 mg/g, respectively, which was approximately 30 − 40 times higher than the arsenic adsorption capacity of raw laterite. Other studies have also shown that the adsorption capacity of laterite increases when it is subjected to thermal or chemical treatment [18,19,20].

As mentioned in the previous section, numerous studies have focused on laterite and treated laterite as arsenic adsorbents, with many publications on the adsorption process. However, there are few studies on the adsorption and desorption processes of arsenic adsorbed on laterite, which is an essential characteristic of the water treatment process. Therefore, it is necessary to evaluate its characteristics. Since previous studies have found that the adsorption process is affected by pH, likely, the desorption process is also affected by pH at the same time.

MATERIALS AND METHODS

Granular laterite was used as the sample in this study. Laterite, an industrial by-product from Vietnam, was crushed and sieved to obtain samples with particle sizes of 0.25-0.60 mm. Previous study has shown that heat treatment of laterite increases its arsenic adsorption capacity (Sanou et al., 2020). Laterite was heated in a muffle furnace at 500°C for 1 hour to obtain thermal-treated laterite (TTL), which was used as the adsorbent. In this study, the laterite that was not thermal-treated is referred to as raw laterite (RL) to distinguish it from TTL.

Table 1 shows the measured values of each physical property. No significant difference was observed between RL and TTL in specific gravity and SSA. Table 2 shows the metal oxide ratios measured by wavelength dispersive XRF and the element ratio measured by SEM-EDS.

Arsenic solutions for adsorption tests were prepared by dissolving disodium hydrogen arsenate heptahydrate ($Na_2HAsO_4 \cdot 7H_2O$: Fujifilm Wako Pure Chemical Industries, Ltd.) in deionized water.

Table 1 Physical properties of RL and TTL

Items	Particle size (mm)	Specific Gravity (g/cm^3)	AD (%)	pH	SSA (m^2/g)
RL	0.25-0.6	2.90	2.0	4.3	53.2
TTL	0.25-0.6	2.96	2.6	5.4	52.1

Note: AD is water content of Air dry, SSA is Specific Surface Area.

Table 2 Chemical properties of RL and TTL

Items	Metal oxide (%)			Element ratio (%)		
	SiO_2	Fe_2O_3	Al_2O_3	Si	Fe	Al
RL	33.2	22.2	28.1	12.9	9.9	16.0
TTL	38.8	20.7	29.7	17.1	4.9	20.4

The mass of disodium hydrogen arsenate heptahydrate was adjusted so that the arsenic concentrations were 50, 100, 250, 500, 750, and 1000 mg/L. After that, the pH was adjusted by mixing the arsenic solution with nitric acid or sodium hydroxide solution, resulting in a pH of 2.0, 5.0, or 8.0 for each concentration. In addition, for the liquid to be used in the desorption test, deionized water containing no arsenic was mixed with nitric acid or sodium hydroxide solution to adjust the pH to 2.0, 5.0, or 8.0.

The adsorption test was carried out according to the standard batch method of the Organization for Economic Co-operation and Development [21]. In the adsorption test, 30 mL of arsenic solution and 3 g of adsorbent (liquid-solid ratio 10) were placed in the same centrifuge tube and shaken horizontally at 20°C and 100 rpm for 24 hours using a shaker (MMS-310 Multishaker, EYELA Tokyo Rikakikai Co., Ltd., Japan). Three centrifuge tubes were prepared for each condition. The solution was then centrifuged at 8000 rpm for 15 minutes (LCX-100, TOMY, Japan) and filtered through the 0.22 μm membrane filter to prepare the test solution. In the desorption test, the adsorbent from the adsorption test and deionized water with the same pH as the arsenic solution used in the adsorption test were placed in the same centrifuge tube and shaken horizontally at 20°C and 100 rpm for 24 hours, with a liquid-solid ratio of 10. The solution was then centrifuged and filtered to prepare the test solution. The pH and EC were measured before, after, and after the adsorption test. The test liquid was also analyzed with an atomic absorption spectrophotometer (AA-6200, Shimadzu Corporation, Japan) to measure the concentrations of iron, aluminum, and calcium along with arsenic. The atomic absorption spectrophotometer atomizes the

test liquid at high temperature, irradiates it with light, and measures the absorption spectrum to quantify the elements in the test liquid. The concentration range of the standard solution in the atomic absorption spectrophotometer is 0-20 mg/L.

RESULTS AND DISCUSSION

The Freundlich equation shown in Equation (1) and the Langmuir equation shown in Equation (2) were used to prepare the adsorption isotherm.

$$\text{Log } Q_e = \text{Log } K_f + (1/n)\text{Log } C_e \quad (1)$$

where Q_e is the amount of arsenic adsorbed per adsorbent at equilibrium (mg/g), K_f is the Freundlich adsorption capacity (L/g), $1/n$ is the adsorption strength and C_e is the equilibrium concentration of arsenic (mg/L).

$$C_e/Q_e = 1/bQ_m + C_e/Q_m \quad (2)$$

where C_e is the equilibrium concentration of arsenic (mg/L), Q_e is the amount of adsorption per adsorbent at equilibrium (mg/g), b is the Langmuir constant (g/L) representing the binding strength, and Q_m is the maximum adsorption capacity (mg/g).

These equations are initially suitable for adsorption by homogeneous chemicals. Since soils such as laterite exist in the natural environment and are not homogeneous, neither equation is entirely suitable. However, it is important to determine which adsorption isotherm is suitable for the adsorption in this study in order to clarify the adsorption mechanism. In addition, the adsorption isotherm enables a quantitative evaluation of the adsorption capacity, which facilitates comparison with adsorbents used in other studies. The adsorption isotherm curves for each adsorbent are shown in Figs. 1. The amount of adsorption was calculated using Eq. (3).

$$M_a = (C_i - C_e) \times (V/M) \quad (3)$$

where M_a is the amount of arsenic adsorption (mg/g), V is absorbent volume and M is Absorbent amount. Tables 3 and 4 show the parameters of the Freundlich and Langmuir equations obtained from each adsorption isotherm. From Fig. 1 and Tables 3 and 4, it can be seen that the arsenic adsorption capacity of heat-treated laterite was greater than that of natural laterite when compared under the same pH conditions. In Table 3, for example, the values of $1/n$ for RL was 0.296 at pH 2.0 and that was 0.485 for TTL, indicating the improvement of adsorption capacity by heat treatment. Comparing the determination coefficients of the Freundlich equation and the Langmuir equation (R^2 in Tables 3 and 4), it was found that the Freundlich equation was larger overall. Comparing the average value of the actual adsorption amount and its error bars plotted in Fig. 1, it can be seen that the Freundlich model fits better. From this, the Freundlich equation is more suitable for expressing adsorption in this study.

Table 3 Parameters of Freundlich equation

	RL			TTL		
pH	2.0	5.0	8.0	2.0	5.0	8.0
$1/n$	0.296	0.298	0.268	0.485	0.109	0.365
R^2	0.876	0.741	0.838	0.883	0.181	0.948

Table 4 Parameters of Langmuir equation

	RL			TTL		
pH	2.0	5.0	8.0	2.0	5.0	8.0
Q_m	3.65	3.61	2.31	6.28	4.14	2.34
R^2	0.834	0.808	0.450	0.975	0.380	0.837

On the other hand, the parameters of the Langmuir equation obtained in this study were compared with those of previous studies, and it was found that the Q_m of TTL at pH 2.0 is larger than those of other studies that used kaolinite [9], zeolite [10], activated carbon [13], and iron oxide-coated cement [12] to adsorb As, making it a superior adsorbent.

In this study, desorption tests were conducted three times in total, and the formulas [22] for calculating the arsenic desorption rate on a weight basis from the arsenic concentration after the desorption tests are given by Eqs. (4) and (5).

$$M_d = C_d \times (V/M) \quad (4)$$

where M_d is the amount of arsenic desorbed (mg), Arsenic equilibrium concentration C_d (mg/L) after desorption test.

$$R_d = M_d/M_a \times 100 \quad (5)$$

where R_d is the arsenic desorption rate (%). In this research, if arsenic is completely desorbed after three times desorption tests, the sum of the three R_d will be 100%.

Figures 2 (a) and (b) showed the stacked results of the three R_d for each sample. These results show that the arsenic concentration is highest after the first desorption test, and that, although there is some variation, the arsenic concentration was the highest at pH=8.0, followed by pH 5.0 and 2.0. The maximum desorption efficiencies became 16.4% for RL and 26.6% for TTL at pH 8.0. Also, looking at each sample, it can be seen that the R_d is high for the first time, and the R_d for the second and third times are much lower than that for the first time. This indicated that desorption caused by shaking is almost complete within the first 24 hours and that little desorption occurs with subsequent shaking.

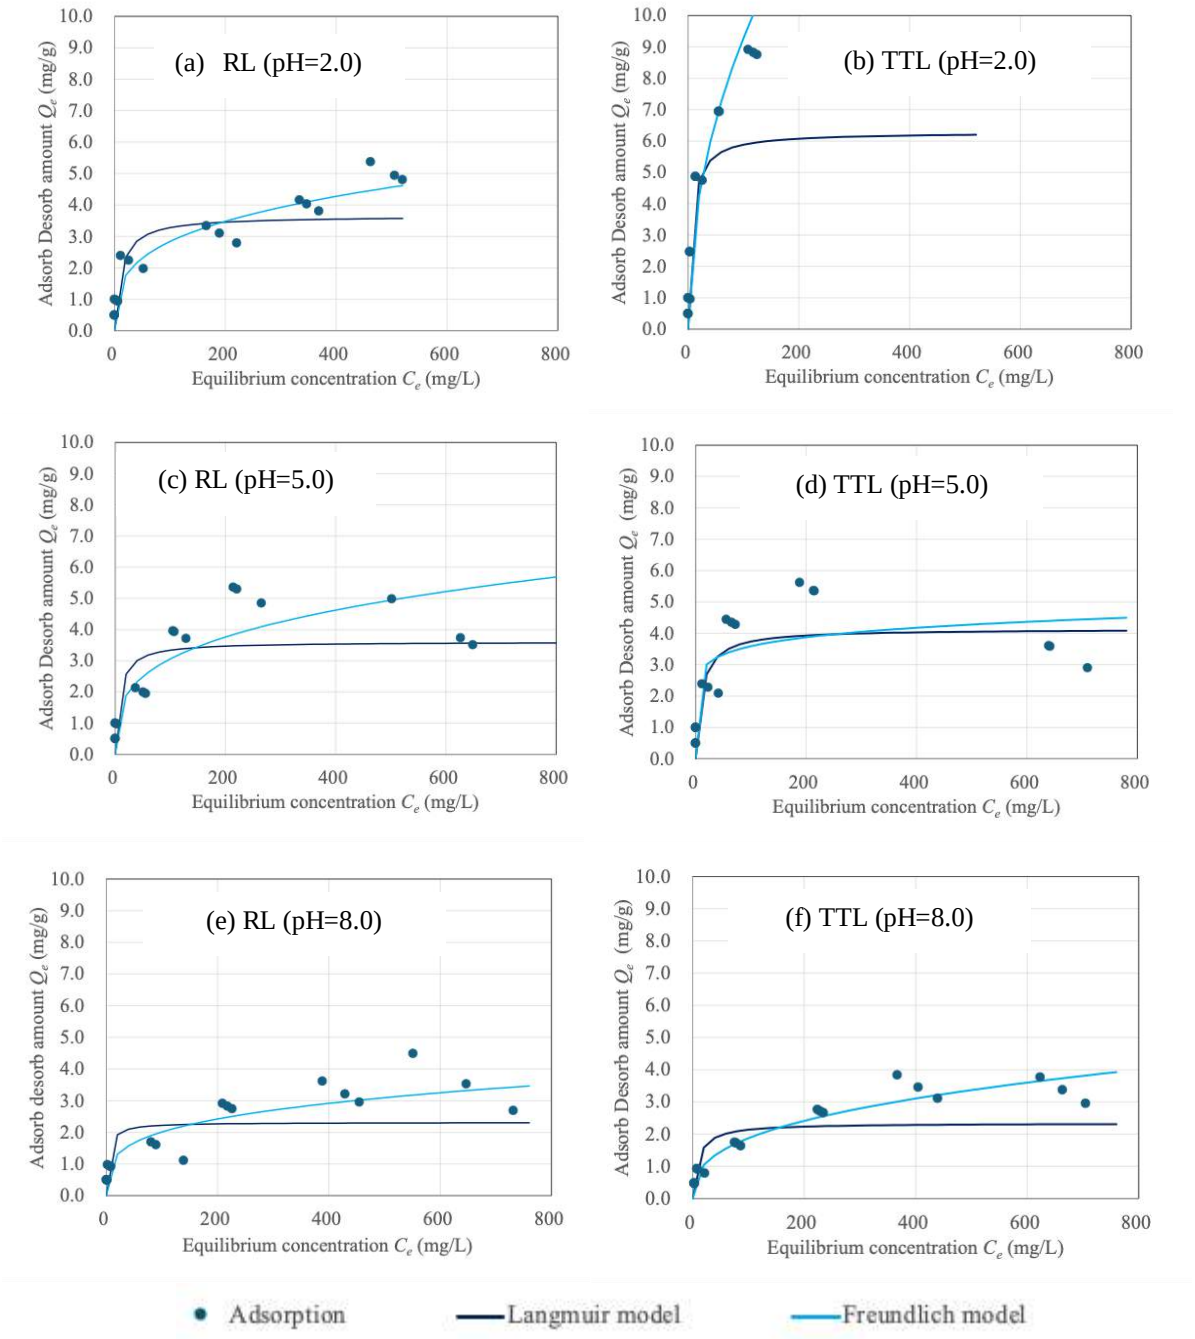

Fig.1 Adsorption isotherm curves for RL: (a) pH=2.0 (c) pH=5.0 (e) pH=8.0 and TTL: (b) pH=2.0 (d) pH=5.0 (f) pH=8.0).

In addition, when comparing the results for different initial pH values under the same initial arsenic concentration, the order of R_d was pH=8.0, pH=5.0, and pH=2.0. This is the opposite of the adsorption results (Fig.1). It was shown that adsorption on laterite occurs more easily in an acidic environment. While desorption occurred more easily in an alkaline environment, implying that more negatively charged surface areas appeared on the laterite at higher pH. The results of the desorption test also showed the larger variation in arsenic concentration at initial pH 5.0 than those at initial pH 2.0 or 8.0. This resulted in the maximum R_d was about 25% under the conditions of the desorption test in this study. Therefore, arsenic could not be completely desorbed. This shows that even when arsenic is used as an adsorbent, it can continue to be used as an adsorbent while retaining a certain amount of arsenic.

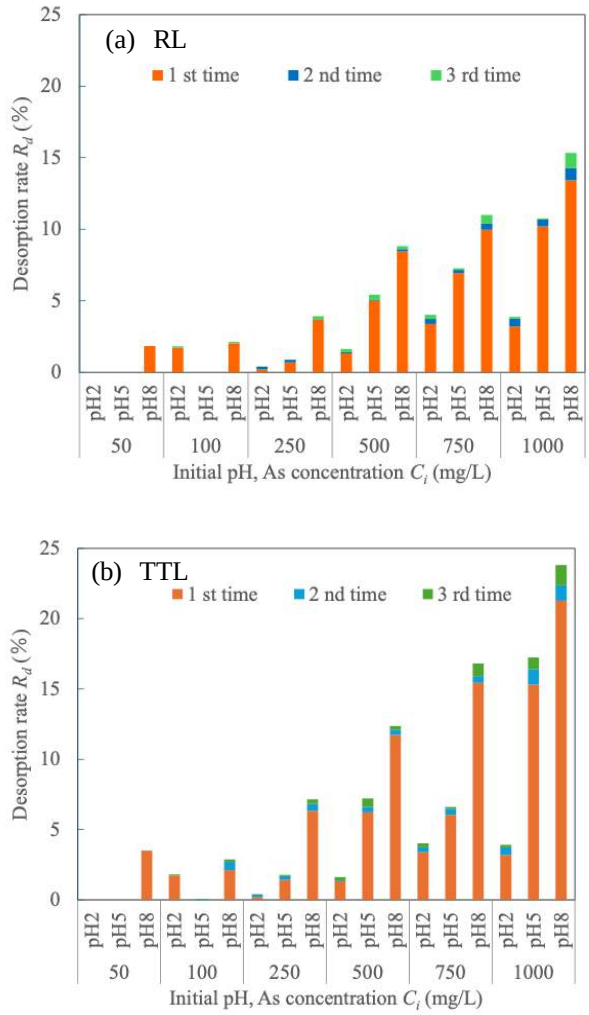

Fig.2 Adsorption isotherm curves for (a) RL and (b) TTL (pH=2.0, 5.0, 8.0)

CONCLUSIONS

In the batch test, the arsenic adsorption and desorption characteristics of RL and TTL were evaluated. The adsorption test showed that the laterite had more adsorption sites and stronger arsenic adsorption capacity due to heat treatment. RL and TTL are excellent arsenic adsorbents, and TTL in particular had a higher maximum adsorption amount than other adsorbents. The tested results showed that the maximum arsenic adsorption capacities became 3.65 mg/g for RL and 6.28 mg/g for TTL at initial solution of pH 2.0. The adsorption amount increased in the order of initial pH 2.0, 5.0, and 8.0. This is thought to be because laterite has a positive surface charge in an acidic environment, which attracts arsenic anions, but in an alkaline environment, a negative surface charge appears and repels arsenic anions. OH- in the solution may inhibit arsenic adsorption. The desorption test showed that the desorption rate was particularly low when the initial arsenic concentration was low, and that laterite had strong arsenic adsorption. The desorption amount increased in the order of initial pH 8.0, 5.0, and 2.0. This is thought to be because the negative surface charge of laterite in an alkaline environment repels the adsorbed arsenic.

ACKNOWLEDGMENTS

This research was supported by the project of Japan Science and Technology Agency (JST) – Japan International Cooperation Agency (JICA) on Science and Technology Research Partnership for Sustainable Development (SATREPS) (No. JPMJSA1701) and the research grant from Saitama University Strategic Research Center.
