GEOMATE Proceedings

THE 15th INTERNATIONAL CONFERENCE ON

Geotechnique, Construction Materials & Environment

11-13 November 2025, Kyoto Research Park

Kyoto, Japan

Edited By

Prof. Zakaria Hossain

Conference Chairman

PROCEEDINGS OF THE FIFTEENTH INTERNATIONAL CONFERENCE – GEOMATE 2025
GEOTECHNIQUE, CONSTRUCTION MATERIALS AND ENVIRONMENT, KYOTO, JAPAN
11-13 NOVEMBER, 2025

Geotechnique, Construction Materials and Environment

Edited by

Prof. Zakaria Hossain
Department of Environmental Science and Technology
Graduate School of Bioresources
Mie University, Japan

Table of Contents

	Preface	iv
	Organization	xix
ID	***Keynote Papers***	**1**
g15k1	BRITTLE BEHAVIOR IN SOIL, TAILINGS AND ROCK MASS: AN OVERVIEW John Victor Smith	**2**
g15k2	ADVANCED TECHNOLOGIES FOR EXISTING PILE EXTRACTION AND ASSOCIATED BOREHOLE BACKFILLING Shinya Inazumi	**10**
	Technical Papers	**17**
ID	***Geotechnique***	**18**
g15103	GEOTECHNICAL AND MICROSTRUCTURAL ASSESSMENT OF RIVER SLUDGE STABILIZED WITH SUSTAINABLE ADDITIVE SYNERGY Md Yachin Islam and Zakaria Hossain	**19**
g15111	RELIABILITY ANALYSIS OF DAMPALIT MEGA DIKE USING MONTE CARLO SIMULATION AGAINST SLIDING FAILURE Isaiah Sam Bartolome and Albert Griño Jr	**26**
g15122	DEBRIS FLOW CAUSED BY HEAVY RAINFALL IN NAGISO-TOWN IN NAGANO PREFECTURE IN JULY 2014 Naomasa Honda	**32**
g15127	EFFECT OF RICE HUSK ASH AS A PARTIAL CEMENT REPLACEMENT ON STRENGTH OF SUBBASE Chotikan Ratchakrom, Pisut Rodvinij, Sattaya Chaiwithee and Pitiwat Wattanachai	**38**
g15129	INVESTIGATING THE SOIL ARCHING PHENOMENON IN MICROPILES USING NUMERICAL ANALYSIS Muhammad Adeel Mazhar, Adnan Anwar Malik, Hung Manh Ho and Umair Ali	**44**
g15130	APPLICATION OF MULTI-CHANNEL ANALYSIS OF SURFACE WAVES IN PROBABILISTIC SEISMIC HAZARD ASSESSMENT: A CASE STUDY IN ISLAMABAD, NORTHERN PAKISTAN Muhammad Qasim Mirza, Ghulam Mohyuddin Sohail, Adnan Anwar Malik, Talha Qadri, Faiqa Shahid, Fatima Ijaz and Aneeza Munir	**49**
g15136	EVALUATION OF FLASH FLOOD SUSCEPTIBILITY IN RELATION TO LAND USE CHANGES IN CHIANG RAI, THAILAND Zhaolong Gu, Daisuke Komori and Thapthai Chaithong	**55**

g15138	THE STUDY OF HELICAL PILE BEHAVIOR UNDER COMPRESSION FORCE IN KHON KAEN LOESS Natchaphon Noiphang, Ratamanee Nuntasarn and Jitrakon Prasomsri	61
g15140	EFFECTS OF FREEZE-THAW HISTORY ON PILE PULL-OUT RESISTANCE Yusaku Fujita, Dai Nakamura, Kenta Nakai, Takanori Kadota and Yuki Minabe	67
g15143	SLOPE STABILITY OF SOIL-ROCK MIXTURE: A CASE STUDY ON LIMESTONE FORMATION AND HIGH RAINFALL AREA Arief Rachmansyah, Adefi Abioga Tiswa and Fajar Rahmanto	73
g15145	BACK-CALCULATED PARAMETERS AND THEIR ATTENUATION COEFFICIENTS FOR PILE DESIGN IN SEDIMENTARY ROCK Ketkaewngoen Mahakhotchasenichai, Kuo Chieh Chao and Shinya Inazumi	81
g15147	INTEGRATION OF SOIL RESISTIVITY AND BOREHOLE DATA TO EVALUATE GEOMATERIALS AND N_{60}-VALUE USING CLUSTERING ANALYSIS Ratchadakorn Chumkhiao, Sukit Yindeesuk, Kuo Chieh Chao and Shinya Inazumi	86
g15148	EVALUATION OF CHEMICAL GROUTING IN HETEROGENEOUS SOILS BY INTEGRATING FEM ANALYSIS AND AI MODELS Khin Nyein Chan Kyaw, Toshiyuki Motohashi, Shigeo Sasahara and Shinya Inazumi	92
g15150	MOVING PARTICLE SIMULATION VALIDATION AND APPLICATION TO CONCRETE FLOW IN CAST-IN-PLACE PILES Ayumi Morota and Shinya Inazumi	98
g15151	COMPARATIVE ANALYSIS OF SOIL RESISTIVITY PREDICTION USING REGRESSION MODELS AND POLYNOMIAL NEURAL NETWORK Kornkanok Sangprasat, Avirut Puttiwongrak and Shinya Inazumi	102
g15153	THE BEACHROCK DISTRIBUTION, CHARACTERISTICS AND FORMATION MECHANISMS IN TROPICAL ASIA: A SYSTEMATIC REVIEW Rahubadda Kankanamge Hiroshima Surangani, Anjula Buddhika Nayomi Dassanayake, Chulantha Lakmal Jayawardena, Niki Evelpidou and Satoru Kawasaki	108
g15154	BACTERIAL DYNAMICS BY MICROBIALLY INDUCED CALCIUM CARBONATE PRECIPITATION (MICP) UNDER MICROGRAVITY CONDITION FOR EXTRATERRESTRIAL BIOCEMENTATION ENGINEERING Yuru Chen, Tomoya Hamada, Chikara Takano, Kazunori Nakashima, Satoru Kawasaki	114
g15155	EVALUATION OF SHEAR PROPERTIES AT CONSTRUCTION BOUNDARIES FOR LATTICE-SHAPED GROUND IMPROVEMENT Miu Kanagawa, Kouta Kanno, Kenji Niwa and Shinya Inazumi	120
g15157	UNRAVELING THE MECHANISMS OF LIQUEFACTION-INDUCED SOIL EJECTA: A RULE-BASED APPROACH Emerzon S. Torres and Jonathan R. Dungca	126
g15159	SOME FEATURES OF EARTHQUAKES DISTRIBUTION IN TURKMENISTAN Valeriy Burmin and Goharik Petrosyan	132
g15163	CORRELATION BETWEEN STANDARD PENETRATION TEST AND CONE PENETRATION TEST FOR LIQUEFACTION ASSESSMENT Nami Nitta, Misko Cubrinovski and Shinya Inazumi	138
g15165	STRENGTH OF BAGASSE ASH GEOPOLYMER-STABILIZED RECYCLED MATERIALS FOR PAVEMENTS BASE: MLR AND PATH ANALYSIS Sattawat Chatchawan, Ratamanee Nuntasarn and Supakorn Tirapat	144
g15167	EFFECT OF SOIL CLODS INCLUSION ON THE END BEARING CAPACITY OF A PILE WITH AN ENLARGED BASE Asuka Takahashi, Naoaki Suemasa, Yoshiaki Tsukada, Tadashi Maejima and Jemy Chua	150
g15174	STUDY ON IMPACT FORCE OF GRANULAR FLOW ACTING ON RETAINING WALL Makoto Kobayashi, Akinobu Ogasawara, Naoto Naito and Tatsuya Matsuda	156

g15178	EXPERIMENTAL STUDY ON SWELLING CHARACTERISTICS OF BENTONITE BUFFER MATERIAL CONSIDERING VARIOUS INITIAL CONDITIONS Kira Iida, Shin-ichi Kanazawa, Masanori Kohno, Zihao Liu and Osamu Yoshino	161
g15181	EFFECT OF LONG-TIME SEEPAGE ON MULTI-LAYERED GROUND Yixuan Li, Yamato Kadoi and Mari Sato	167
g15182	POROSITY ASSESSMENT IN ONE-DIMENSIONAL PERMEATION GROUTING USING SUSPENSION-TYPE GROUT SOLUTION Jemy C. Chua, Naoaki Suemasa, Takamitsu Sasaki and Koichi Nagao	172
g15184	NUMERICAL SIMULATION OF SCOURING AROUND CYLINDRICAL BRIDGE PIERS UNDER STEADY FLOW USING REEF3D Shu Tsuyumine, Tatsuya Matsuda and Naoto Naito	178
g15185	PRECISION-CONTROLLED BACKFILLING METHODOLOGY FOR ENHANCING POSITIONAL ACCURACY IN FOUNDATION ELEMENT REPLACEMENT Haruka Kiyotomo, Yuji Taya, Masahiro Ueda, Tomio Tsuchiya and Shinya Inazumi	183
g15187	A STUDY ON THE EFFECT OF INJECTION FLOW RATE ON GELATION TIME IN CHEMICAL GROUTING METHOD Midori Suzuki, Jemy C. Chua, Naoaki Suemasa and Takamitsu Sasaki	187
g15188	INFLUENCE OF SEEPAGE AND SEISMIC DISASTERS ON THE FAILURE BEHAVIOR OF LARGE-SCALE EMBANKMENTS Satoko Io, Kazuya Itoh and Naoaki Suemasa	193
g15189	VISUALIZATION OF PORE WATER FLOW IN GRANULAR MEDIA USING CYLINDRICAL TRANSPARENT PARTICLES Shingo Hamano, Tatsuya Matsuda and Naoto Naito	199
g15190	GROUND IMPROVEMENT OPTIMIZATION USING DYNAMIC NUMERICAL ANALYSIS IN THE DEVELOPMENT OF THE BANYUWANGI AIRPORT IN INDONESIA Christopher Tanjung, Andhika Sahadewa, Pebri Herry, Reza Ismaniar and Aris Wibowo	204
g15195	EVALUATING THE VALIDITY OF MULTI-STAGE DIRECT SHEAR TESTING ACROSS DENSITY AND FINE CONTENT VARIATIONS IN SAND–CLAY MIXTURES María José Toledo Arcic and Jens Engel	210
g15200	UNCONFINED COMPRESSIVE STRENGTH OF RIVER-DREDGED SOIL STABILIZED WITH ZEOLITE-BASED GEOPOLYMER Jonathan R. Dungca, Roberto Gabriel A. Bas, Chris Anthony C. Elhig and Dana Isabelle P. Villano	216
g15203	A STUDY ON THE METHOD OF ESTIMATING THE BEARING CAPACITY OF TAPERED PILES Takaki Asano, Naoaki Suemasa, Tsuyoshi Tanaka, Satoshi Shingai and Yasutaka Sakamoto	222
g15205	STUDY ON INTERACTION OF PULL-OUT TESTING BETWEEN TIN TAILING AND REINFORCEMENT FOR GEOSYNTHETIC REINFORCED SOIL ABUTMENT Wijit Itthiwongkul, Peet Homchuen, Suphamat Chaichana, Tanapon Khunin and Zhen Zhang	228
g15209	SEISMIC BEHAVIOR OF STEEL STRIP REINFORCED SOIL WALLS WITH HIGH GROUNDWATER LEVEL Akinobu Ogasawara, Makoto Kobayashi and Kento Mori	234
g15210	THREE-DIMENSIONAL SIMULATION ANALYSIS OF OPEN-ENDED STEEL PIPE PILE BY USING FINITE ELEMENT METHOD Kiyoka Kono, Koji Watanabe, Shihchun Lin and Shuichi Kamei	239
g15212	DYNAMIC RESPONSE OF UNDISTURBED SOFT CLAY SOIL WITH SOIL DISTURBANCE EFFECT UNDER CYCLIC LOADING Angelo B. Edora, Taiju Ichizono and Kentaro Nakai	244
g15213	ALTERNATIVE APPROACH FOR SOIL IMPROVEMENT USING HYDRAULIC CEMENT COMBINATION WITH STEEL SLAG AND BIOCHAR Nattapas Khumsuprom, Supakij Nontananandh, Apiniti Jotisankasa, Susit Chaiprakaikeow and Shinya Inazumi	250

g15214	INVESTIGATION ON DISPERSIVE CHARACTERISTICS OF SOILS EXCAVATED FROM FLOOD RETENTION POND Supakij Nontananandh, Kittipong Tongphet, Susit Chaiprakaikeow, Patipan Thaimthong, Yuki Fuka and Shinya Inazumi	256
g15235	RESISTIVITY PATTERNS IN LOOSE BEDROCK USING DRONE-BASED ELECTROMAGNETIC EXPLORATION METHOD Hiroaki Hoshino, Atsuko Nonomura, Haruki Ojyuku, Shuichi Hasegawa and Akira Jomori	262
g15236	IMAGE-BASED ESTIMATION OF SOIL PARTICLE SIZE AS A SUPPLEMENT TO SIEVE ANALYSIS Jose Manuel U. Subido, Erica Elice S. Uy and Joenel G. Galupino	268
g15239	GEOTECHNICAL INVESTIGATION OF COMPACTION EFFORT, MOISTURE CONTENT, AND SOIL TYPE ON MAXIMUM DRY DENSITY IN PATHUM THANI, THAILAND Pattaraporn Nueasri and Rattanachot Thongpong	274
g15240	CENTRIFUGE MODEL TEST AND NUMERICAL ANALYSIS ON EVALUATION OF VERTICAL BEARING CHARACTERISTICS FOR SOIL-CEMENT COMPOSITE PILE Shohei Koga, Koji Watanabe and Nobuaki Tsuchiya	280
g15250	BEARING CAPACITY AND BEHAVIOUR OF SHALLOW FOUNDATIONS SUBJECTED TO CYCLIC LOADINGS: A STUDY IN 1G Fabien Szymkiewicz, Lamis Makki, Philippe Reiffsteck, Taisuke Sanagawa and Hidetoshi Nishioka	286
g15252	LANDFILL MINING IN BRAZIL: SOME CHALLENGING ASPECTS FOR APPLICATION Thiago Villas Bôas Zanon and Maria Eugênia Gimenez Boscov	292
g15256	IMPROVING THE PROPERTIES OF MATERIAL USED IN BUILDING CLAY HOUSES WITH CEMENT Nathiya Jaokaenkaew and Pongsakorn Punrattanasin	298
g15259	EFFECT OF ANTECEDENT RAINFALL ON POER WATER PRESSURE DISTRIBUTION CHARACTERISTICS IN RESIDUAL SOIL UNDER TROPICAL RAINFALL Mohamed Elbyhagi Elfadil	304
g15266	GEOTECHNICAL PROPERTIES OF RECYCLED GLASS STABILIZED WITH CEMENT Sereyroath Chea, Arul Arulrajah, Annan Zhou, Suksun Horpibulsuk and Kanagesperan Verumandy	312
g15270	PRACTICAL APPLICATION OF GEOLOGICAL STRENGTH INDEX FOR EXCAVATABILITY ASSESSMENT John Victor Smith	317
g15274	A CASE STUDY OF SLOPE FAILURE POTENTIAL MAPPING BASED ON WATERSHED UNIT IN THE NOTO PENINSULA DISTRICT Suguru Kaneko and Masanori Kohno	323
g15275	SSESSING LIQUEFACTION RISK AT LHOKSEUMAWE BEACH: IMPACT OF THE 2004 ANDAMAN AND 2016 PIDIE JAYA EARTHQUAKES Abdul Jalil, Lindung Zalbuin Mase and Yovi Chandra	329
g15286	NONLINEAR INERTIAL EFFECTS IN CAISSON FOUNDATIONS WITH SUPERSTRUCTURES: AN EXPERIMENTAL STUDY UNDER VARIABLE-AMPLITUDE SEISMIC LOADING Zain Bin Mazhar, Faruk Md Omar and Masato Saitoh	334
g15287	AN APPLICATION OF ELECTRICAL RESISTIVITY CONFIGURATION AS ELECTRO-OSMOSIS FOR PREFABRICATED VERTICAL DRAINAGE (PVD) ENHANCEMENT USING SANDBOX EXPERIMENT Khin Phyu Sin, Thanapong Lamphoei and Avirut Puttiwongrak	341
g15293	EVALUATION OF VISCOSITY REDUCTION USING ADVANCED AGENT IN HIGH-PRESSURED GROUT INJECTION FOR BANGKOK SOILS Sai Wunna Kyaw Khaung, Morris I-Min Wang, Ricky K. N. Wong, Yasuharu Nakanishi, Koike Shoko and Matsuda Takato	349
g15300	EXCAVATION TESTS ON ALUMINUM ROD MODEL GROUND TO SIMULATE GROUND HEAVE Moe Yagawa, Hidetoshi Nishioka, Shinji Konishi and Satoshi Sakata	357

g15302	TWO-DIMENSIONAL MODEL EXPERIMENTS ON THE SEISMIC BEHAVIOUR OF THE HEAD-FIXED DOUBLE SHEET PILE TEMPORARY EARTH RETAINING WALL METHOD Akihiro Kikuchi, Hidetoshi Nishioka, Ayaka Nasu, Michitaka Okamoto and Hideki Nagatani	363
g15305	TWO-DIMENSIONAL MODEL EXPERIMENTS ON SEISMIC RESISTANCE OF SPREAD FOUNDATION DAMAGED BY LOCAL SCOURING Yuki Yamakuri, Tomohito Ishii and Hidetoshi Nishioka	369
g15313	EROSION CONTROL EFFECT OF VEGETATION WORKS BY PHALARIS ARUNDINACEA L. AGAINST SURFACE RUNOFF Enkhzaya Batbayar, Dai Nakamura, Keishin Tsutsumi, Yuichiro Murakami, Eiji Tateyama, Yuki Minabe and Takayuki Kawaguchi	375
g15317	ENHANCING MITIGATION STRATEGIES FOR RAINFALL INDUCED ROADSIDE LANDSLIDES IN NEW ZEALAND Roohollah Kalatehjari, Lokesh Vemuri and Rajitha Sachinthaka	380
g15326	RELATIONSHIP BETWEEN PUBLIC SPACE AND PEDESTRIAN BRIDGES IN SUBURBAN RESIDENTIAL AREAS Ryunosuke Komatsu and Kazunari Tanaka	386
g15327	METHOD ON THE PREDICTION ABOUT FLOW LINES IN WALKING SPACES Ryuga Toda and Kazunari Tanaka	390
g15346	ARTIFICIAL INTELLIGENCE-BASED EARLY WARNING SYSTEMS FOR RIVERBANK EROSION IN THE MEKONG DELTA REGION Thang Ngoc Nguyen, Phong Vu Phuong Le and Tru Thi Tu	394
g15350	ECOFRIENDLY SLOPE STABILIZATION: FIELD APPLICATION OF BIOCEMENTATION WITH NATIVE BACTERIA AND LOW‐COST MATERIALS Azizul Moqsud	399
g15354	FINITE ELEMENT ANALYSES OF MEASURES TO MITIGATE ROCK SPALLING HAZARDS BY ASSESSING TUNNEL FACE DISPLACEMENT Rintarou Doi, Naotaka Kikkawa and Kazuya Itoh	404
g15358	THE DEVELOPMENT OF SUBSURFACE UTILITY ENGINEERING PRACTICES IN THAILAND Sitthiphat Eua-apiwatch, Rungroj Arjwech, Kanisorn Klamsuk, Anirut Nitas and Sirichai Pethrung	410
g15365	ANOMALY DETECTION FOR SLOPE EXCAVATION WORK USING BACKGROUND SUBTRACTION AND OPTICAL FLOW Masoho Ide, Nobutaka Hiraoka and Kazuya Itoh	418
g15369	SLOPE STABILITY STUDIES BASED ON DIFFERENT MATERIALS AND CONSTRUCTION METHODS Satoe Suzuki and Shin-ichi Kanazawa	424
g15371	EFFECT OF DEM PARAMETERS ON DEFORMATION BEHAVIOR OF ROCKFALL PROTECTION WALLS SUBJECTED TO ROCK SLOPE FAILURE Ayumu Takehara, Naoto Naito, Tatsuya Matsuda, Katsuhito Agui, Yuji Ushiwatari, Kazumichi Shimakura and Akinori Nakao	430
g15392	LABORATORY INVESTIGATION OF THE IMPACT OF RISING SOIL WATER CONTENT ON LIQUIDITY INDEX AND SLOPE INSTABILITY Nofrizal, Fauzan, Abdul Hakam, Bambang Istijono and Andriani	436
g15407	DESIGN AND CONSTRUCTION OF PRECAST BOX CULVERTS (DRAINAGE CHANNEL) IN AN URBAN ENVIRONMENT: A CASE STUDY OF KANIE TOWN IN JAPAN Md. Aminul Islam and Zakaria Hossain	442
ID	***Construction Materials***	456

g15101	GREENER OPPORTUNITIES: AN EXPERIMENTAL INVESTIGATION INTO TRANSFORMING BUILDING MATERIALS THROUGH WASTE-BASED TECHNOLOGIES Muhammad Ali Fardoush Siddquy and Zakaria Hossain	457
g15102	APPLICATION OF SEASHELL POWDER ISOLATELY AND COMBINED WITH RICE HUSK ASH IN CONCRETE AS CEMENT REPLACEMENT MATERIALS Md Soybur Rahman and Zakaria Hossain	463
g15104	SYNERGISTIC EFFECTS OF AMORPHOUS SILICA ON ADMIXTURE DEMAND, STRENGTH DEVELOPMENT, AND CO2 MITIGATION IN MODIFIED LOW-CARBON CONCRETE Alex Otieno Owino, Noma Tamaki and Zakaria Hossain	469
g15106	WATER ABSORPTION CHARACTERISTICS OF EPS-BASED LIGHTWEIGHT CONCRETE: EFFECTS OF FLY ASH COATING AND CEMENT REPLACEMENT Andi Prasetiyo Wibowo	481
g15114	USING NICKEL SLAG AND GOLD TAILINGS AS PARTIAL SUBSTITUTES IN CONCRETE FOR SUSTAINABLE CONSTRUCTION Lisa Oksri-Nelfia, Julien Meret, Ouali Amiri and Yohans Sunarno	487
g15215	HYDROGEOLOGICAL INTERPRETATION USING GEOELECTRICAL AND HYDROCHEMICAL DATA IN CIMANIS WATERSHED, KUNINGAN, WEST JAVA, INDONESIA Boy Yoseph CSS Syah Alam, Hadi Hidayat and Deden Zaenudin	494
g15131	WATER HYACINTH FIBER FOR LIMITED-LIFE GEOSYNTHETIC GEONET AS SUBGRADE REINFORCEMENT OF RURAL ROADS Mary Ann Adajar, Patricia Gwenn Ang, Judith Dungca, Julia Dominic Espinola and Nicole Gabrielle Tan	503
g15149	DEVELOPMENT OF SOLIDIFIED CULTIVATING SOIL BLENDED WITH WASTE WOODY BIOMASS PREPARED BY THE EICP METHOD Daiki Kawamura and Satoru Kawasaki	509
g15152	ANALYTICAL STUDY ON THE CONCRETE BREAKOUT STRENGTH OF HEADED REINFORCEMENT BAR EMBEDDED IN ROOF EXTERIOR BEAM-COLUMN JOINT Zev Al Jauhari and Tomoya Matsui	515
g15172	RECYCLING COAL BOTTOM ASH IN THE PRODUCTION OF FIRED CLAY BRICKS Nonthaphong Phonphuak, Anuwat Srisuwan, Anujit Phumiphan, Sarawut Dakaew and Siwat Lawanwadeekul	522
g15199	EXPERIMENTAL INVESTIGATION ON APPLICATION OF ALKALI-ACTIVATED MATERIAL WITH HIGH VISCOSITY TO HIGH FLUIDITY CONCRETE Kosuke Matsuoka, Yoichi Mimura and Itaru Horiguchi	528
g15245	INFLUENCE OF BIOCHAR WATER HYACINTH ON THE SHEAR STRENGTH OF ULTISOLS Erica Elice S. Uy, Jeann Patrick B. Barcelona, Juan Angelo V. Malaca, Lance Matthew R. Santiago, Jose Gabriel R. Zamora and Angelo B. Edora	534
g15260	SUSTAINABILITY ANALYSIS OF OPTIMIZED CONCRETE MIXES (PSC, PPC, HVFA) AGAINST STANDARD OPC MIXES FOR GRADES M15 TO M30 Pallavi Badry, Saikrishna Bondugula, Ravi Shankar Badry, N.Sudharsan, Srihari Saduwale and Ivaturi Sarma	541
g15279	INFLUENCE OF PRINTING ORIENTATION ON MECHANICAL BEHAVIOR OF MULTILAYER 3D-PRINTED CEMENT MORTAR Piti Sukontasukkul, Satharat Pianfuengfoo, Manote Sappakittipakorn, Sittisak Jamnam and Worathep Sae-Long	547
g15295	INVESTIGATION OF THE SHEAR STRENGTH OF STEEL BOLTED BAMBUSA BLUMEANA T-CONNECTION Bernardo A. Lejano, Richard Steven Lee and Carlo Cacanando	553
g15307	CORRELATION BETWEEN INFILL DENSITY AND MECHANICAL PROPERTIES IN 3D PRINTING Boonthum Wongchai	559
g15315	TWO-AXIS VIBRATION RESPONSE ATTENUATION OF BUILDING STRUCTURE USING ROLLING CYLINDER DYNAMIC VIBRATION ABSORBER Lovely Son, Mulyadi Bur, Bima Anugrah Saputra and Zeki Midi	565

g15319	CRITICAL ANALYSIS OF OLIVINE PERFORMANCE AND POTENTIAL FOR CARBON SEQUESTRATION IN SUSTAINABLE CONSTRUCTION Roohollah Kalatehjari, Sara Bayandor and Yousef Adeeb Chamachaei	572
g15329	A STUDY ON THE CORRELATION BETWEEN THE COEFFICIENT OF AIR PERMEABILITY AND AIR INFLOW AS AN INDEX OF PCM MATERIAL PERMEABILITY Arisa Nakamura, Barchinoyhon Sayfullaeva, Yuki Sakoda and Shushi Sato	578
g15337	EFFECT OF FLY ASH AND SILICA FUME AS PARTIAL REPLACEMENTS OF CEMENT ON THE MECHANICAL PROPERTIES OF SELF‐COMPACTING CONCRETE Fauzan, Suci Andini, Suci Meilita and Muhammad Johafis	583
g15338	ANALYTICAL STUDY ON THE SEISMIC BEHAVIOR OF NON‐STANDARD REINFORCED MASONRY HOUSES RETROFITTED WITH CROSSED FERROCEMENT LAYERS Fauzan, Abdul Hakam, Febrin Anas Ismail, Rio Yulanda and Muhammad Zulfian Saputra	589
g15339	SEISMIC ASSESSMENT AND RETROFITTING OF THE WEST SUMATRA BPBD OFFICE BUILDING USING SHEAR WALLS Fauzan, Abdul Hakam, Muhammad Ridho Zainadi, Arifin Shaleh and Muhamad Rezki	595
g15340	RETROFITTING OF ULAK KARANG SHELTER BUILDING IN PADANG CITY, INDONESIA, USING CONCRETE JACKETING Fauzan, Febrin Anas Ismail, Annisa El Husna, Muhammad Zulfian Saputra and Yozi Yuliardi	600
g15362	NUMERICAL ANALYSIS OF SMALL-SCALE EARTH RETAINING STRUCTURES DURING LIQUEFACTION Kakuta Fujiwara and Yan Boyu	606
g15368	DEVELOPMENT AND PERFORMANCE EVALUATION OF A UPV-BASED MODEL FOR EARLY FROST DAMAGE Sohee Moon, Youngwoong Jung, Seongpyo Kim, Jayeon Yun and Hyeonggil Choi	612
g15374	STUDY ON THE BEHAVIOR OF RECYCLED AGGREGATE CONCRETE UNDER HIGH TEMPERATURE EXPOSURE AND RECOVERY THROUGH RE-CURING Husnah, Herlien Dwiarti Setio, Ivan Sandi Darma and Patria Kusumaningrum	618
g15376	A NEW APPROACH TO PRELOAD CONTROL: DEVELOPMENT OF A FRACTURE-BASED HIGH-STRENGTH NUT FOR STEEL JOINTS Min-woo Choi and Yeol Choi	624
g15383	RSM OPTIMIZATION OF MECHANICAL AND DURABILITY PROPERTIES OF SELF-COMPACTING CONCRETE INCORPORATING ZINC ASH AND BLASTING GRIT NANOPARTICLES Rabeea W. Bazuhair, Ehab A. Mlybari and Wasayo Sanam Sahito	628
g15385	FOAM CONCRETE WITH UNIFORMLY GRADED AGGREGATES AND TAILINGS: STRENGTH AND MICROSTRUCTURE Kevin Chandra Nurwadji, Herlien Dwiarti Soemari and Ivan Sandi Darma	640
g15388	THE BEHAVIOR OF AN EXPERIMENTAL HOUSE IN RESPONSE TO SHRINKAGE Lamis Makki, Fabien Szymkiewicz, Céline Chesnais and Ning Sun	645
g15394	IMPROVING RUTTING RESISTANCE IN STONE MASTIC ASPHALT PAVEMENT USING FINE SEIZED WASTE TIRE RUBBER Enohmbey Chubisong Moses and Yoshitaka Kajita	651
g15400	PHYSICAL AND MECHANICAL PROPERTIES OF FLY ASH-BASED CELLULAR LIGHTWEIGHT CONCRETE Reni Suryanita, Yohannes Firzal, Harnedi Maizir and Raihan Arditama	657
g15401	EXPERIMENTAL INVESTIGATIONS ON SUSTAINABLE GROUND IMPROVEMENT USING SEASHELL POWDER AND RICE HUSK ASH Rufayda Jannat and Zakaria Hossain	663
g15404	INFLUENCES OF BASALT GEOSYNTHETICS ON SOIL SHEAR STRENGTH Mohamed Eltaher and Zakaria Hossain	669

g15405	CHARACTERIZATION OF SOIL-RICE HUSK ASH-CEMENT MIXTURES FOR SUSTAINABLE GROUND IMPROVEMENT: MECHANICAL AND MICROSTRUCTURAL INSIGHTS Abdelmageed Atef and Zakaria Hossain	678
g15408	ENVIRONMENTAL AND MECHANICAL PROPERTIES OF CONCRETE PAVEMENTS INCORPORATING REFUSE-DERIVED FUEL FLY ASH Menglim Hoy, Suksun Horpibulsuk and Chutichai Tonueng	685
g15412	EFFECT OF SUPERPLASTICIZER ON WORKABILITY OF RICE HUSK ASH AND SEASHELL POWDER BLENDED CONCRETE Md Soybur Rahman and Zakaria Hossain	689
g15118	EFFECT OF CEMENTITIOUS MORTAR FOR REPAIRING REINFORCED CONCRETE (RC) BEAMS Leandro Madeira Branco, Abel Fernandes, Isamu Yoshitake	694
g15402	SUSTAINABLE SOIL IMPROVEMENT: THE SYNERGISTIC EFFECTS OF BASALT FIBER AND RICE HUSK ASH ON THE ONE-DIMENSIONAL CONSOLIDATION Nguyen Thi Hong Nhung* and Zakaria Hossain	703
ID	***Environment***	712
g15113	DATA-DRIVEN APPROACH TO GREENHOUSE GAS MITIGATION: SEM ANALYSIS OF SUCCESS FACTORS AMONG LOCAL GOVERNMENTS IN KHON KAEN, THAILAND Narongdet Mahasirikul, Narongwit Mahasirikul and Sirawit Rattasia	713
g15116	A STUDY OF TEMPERATURE REDUCTION METHODOLOGY IN URBAN HEAT ISLAND USING MICROCLIMATE TECHNIQUE Ekarin Sangthammarat and Chokchai Chutakositkanon	721
g15120	OPERATION PRINCIPLE OF ACTUATOR SYSTEM THAT COMBINES PHASE-CONTROLLED ACTUATOR WITH DIFFERENT DRIVE FREQUENCIES Hiroyuki Yaguchi and Sota Abe	726
g15144	A LIDAR-BASED DEEP LEARNING FRAMEWORK FOR DRIFTWOOD RECOGNITION AND QUANTIFICATION Shanpeng Liu, Koichi Isobe, Toshiki Iwasaki, Kensuke Shioda and Diyuan Li	735
g15146	APPLICATION OF LONG SHORT-TERM MEMORY MACHINE LEARNING NETWORKS FOR TEMPERATURE VARIATIONS PREDICTION OF ENERGY PILES Thiti Chanchayanon, Apiniti Jotisankasa, Susit Chaiprakaikeow and Shinya Inazumi	743
g15161	A PERFORMANCE STUDY OF DEHUMIDIFICATION IN AN EVAPORATIVE COOLING SYSTEM USING THERMOSYPHON HEAT PIPES Niran Watchrodom, Jeerattikul Kaharn, Aekchai Rattanabanlue, Luedate Phatedoung and Thana Ananacha	749
g15164	A STUDY ON FLOOD INUNDATION ANALYSES AND HAZARD MAPPING APPROACHES FOR SMALL-SIZED RIVERS Shengping Zhnag and Jie Qi	755
g15166	ENHANCING FLOOD RESILIENCE THROUGH UPDATED IDF CURVES: LESSONS LEARNED FROM RECENT EXTREME RAINFALL EVENTS IN THE UAE Khalid B. Almheiri and Rabee Rustum	761
g15169	HEAVY METAL CONCENTRATIONS OF CICADA SHELL AND CICADA ADULT IN JAPAN Hiroyuki Ii	770
g15170	STABILIZATION OF KHON KAEN LOESS FOR THE PAVEMENT STRUCTURE USING RICE HUSK ASH AND KAOLIN CLAY. Stanley Emeka Ovuta and Ratamanee Nuntasarn	776
g15173	OPTIMIZATION OF MICROORGANISM-ENRICHED BIO-COATED CLAY GRANULES FOR SUSTAINABLE PLANT GROWTH USING RESPONSE SURFACE METHODOLOGY Piyawadee Saraphirom, Orn-Anong Chaiyachet, Piyarat Namsena, Chakkrit Sreela-or, Nonthaphong Phonphuak and Mullika Teerakun	782

g15177	DEVELOPMENT OF NEW BASE MATERIALS FOR SEAWEED BEDS USING PROBLEMATIC SOILS, RECYCLED MATERIALS AND RICE BRAN AND ITS VERIFICATION MONITORING IN THE SEA Kentaro Yamamoto, Kazumasa Fukuda, Takehito Negami, Mizuki Hira and Yoshihisa Tsurunari	788
g15191	VIBRATION ANALYSIS OF AN AC MOTOR FOR PREDICTIVE MAINTENANCE AND ENVIRONMENTAL IMPACT ASSESSMENT Suphattharachai Chomphan	794
g15196	AI-BASED GEOTECHNICAL INFORMATION PREDICTION AND LIQUEFACTION HAZARD MAPPING FOR THE TOKYO METROPOLITAN AREA Arisa Katsuumi, Koutaro Takasuna and Shinya Inazumi	800
g15197	APPLICATION OF SROI FRAMEWORK IN COST-EFFECTIVENESS ANALYSIS FOR THE ENVIRONMENTAL PROTECTION INVESTMENTS OF QUARRY MINES. Ngwu Tochukwu, Somprasong Komsoon and Chanapol Charoentanaworakun	805
g15198	PERFORMANCE OF ENVIRONMENTALLY FRIENDLY SOLIDIFIERS UTILIZING WASTE GLASS AND BLAST FURNACE SLAG FOR LIQUEFIED STABILIZED SOIL Koki Shinohara, Kohei Maru and Shinya Inazumi	811
g15201	TROPICAL SOIL BEYOND THE TROPICS: THE INFLUENCE OF PALEOENVIRONMENTS ON ENGINEERING PROPERTIES John Victor Smith	817
g15202	WATER QUALITY CHARACTERISTICS OF THE TRADITIONAL WATER MANAGEMENT FACILITY "MANBO" IN HOKUSEI CHUO PARK, MIE PREFECTURE Maki Oyagi, Rion Ito and Toyokazu Hirozumi	823
g15208	EXTRACTION OF SLOPE VARIATION EXTENT USING OPTICAL SENSORS AND SAR FOR THE MANASLU CIRCUIT TRAIL, NEPAL Hijiri Shimojima	829
g15217	HEAVY METAL CONCENTRATIONS OF PLANTS GROWING AROUND MINES IN VICTORIA, AUSTRALIA Daiki Yamamoto	837
g15223	DEVELOPMENT OF A HAZARD ASSESSMENT APPROACH BASED ON AN INTEGRATED MODEL FOR LARGE WOODY DEBRIS DISCHARGE IN DAM WATERSHEDS Yunhao Liu, Daisuke Komori, Sartsin Phakdimek and Yuta Abe	842
g15225	ECOSYSTEM-LEVEL ASSESSMENT OF THE ADSORPTION AND REMOVAL CAPACITY OF CALCIA-IMPROVED SOILS USING MICROCOSM-WET TEST Sosuke Sato and Kazuhito Murakami	848
g15227	LABORATORY EXPERIMENTS OF ARSENIC ADSORPTION CHARACTERISTICS FOR LATERITE GRAINS BY USING FIXED-BED COLUMN STUDY Nayaka Bandaralage Indraji Madhushan Nayaka Bandara, Kengo Nakamura, Akihiro Matsuno and Ken Kawamoto	856
g15230	DEVELOPMENT OF ROOFTOP AREAS WITH THERMAL PERFORMANCE FOR REDUCING HEAT ACCUMULATION IN CONDOMINIUMS Anon Anan-archa and Thana Ananacha	863
g15234	THE ROLE OF ENVIRONMENTAL IMPACT ASSESSMENT AS AN EFFECTIVE TOOL FOR SUSTAINABLE DEVELOPMENT IN THAILAND Chutarat Chompumth	869
g15265	EFFECT EVALUATION OF TAILING SAND SOLIDIFICATION BY MICROBIALLY INDUCED CARBONATE PRECIPITATION Lai Yongming, Satoru Kawasaki and Liu Qian	875
g15269	DEVELOPMENT AND OPTIMIZATION OF MICROBIAL COMPOST POWDER FOR CLAY PELLETS: TOWARD A FUNCTIONAL AND MARKETABLE GROWING MEDIA Songklot Phonphuak, Wimolkarn Nithisiriwaritkun, Nonthaphong Phonphuak, Piyarat Namsena and Piyawadee Saraphirom	881
g15277	PLANT COLONIZATION AND WILDLIFE UTILIZATION ON A DISUSED ROAD IN WESTERN JAPAN Taizo Uchida, Takeya Matsumoto, Teruo Arase, Masaaki Furuno and Daisuke Hayasaka	887

g15278	RECHARGE ESTIMATION AND SITE IDENTIFICATION FOR MANAGED AQUIFER RECHARGE IN SUPHANBURI, THAILAND USING GIS AND MODFLOW Pinit Tanachaichoksirikun, Uba Sirikaew, Uma Seeboonruang and Jutamas Srisuk	897

Preface

On behalf of the GEOMATE 2025 Organizing Committee, we would like to welcome you to attend the Fifteenth International Conference on Geotechnique, Construction Materials and Environment held at Kyoto Research Park (KRP), Kyoto, Japan, in conjunction with The GEOMATE International Society, Mie University Research Center for Environmental Load Reduction, Glorious International, Japan.

On Friday, 11 March 2011, at 14:46 Japan Standard Time, the northeast of Japan was struck and severely damaged by a series of powerful earthquakes, which also caused a major tsunami. This conference was first dedicated to the tragic victims of the Tohoku-Kanto earthquake and tsunami disasters. The Geomate 2025 conference covers three major themes with 17 specific themes including:

- Advances in Composite Materials
- Computational Mechanics
- Foundation and Retaining Walls
- Slope Stability
- Soil Dynamics
- Soil-Structure Interaction
- Pavement Technology
- Tunnels and Anchors
- Site Investigation and Rehabilitation
- Ecology and Land Development
- Water Resources Planning
- Environmental Management
- Public Health and Rehabilitation
- Earthquake and Tsunami Issues
- Safety and Reliability
- Geo-Hazard Mitigation
- Case History and Practical Experience

This year, we have received many submissions from different countries. The participating countries are Australia, Azerbaijan, Bangladesh, Brazil, China, Czech Republic, Egypt, France, Ghana, India, Indonesia, Iraq, Japan, Malaysia, Morocco, New Zealand, Nigeria, Pakistan, Philippines, Poland, Saudi Arabia, Taiwan, Thailand, United Arab Emirates, United Kingdom and Vietnam. The technical papers were selected from the vast number of contributions submitted after a review of the abstracts. The final papers in the proceedings have been peer-reviewed rigorously and revised as necessary by the authors. It relies on the solid cooperation of numerous people to organize a conference of this size. Hence, we appreciate everyone who supports as well as participates in this joint conference.

Last but not least, we would like to express our gratitude to all the authors, session chairs, reviewers, participants, institutions, and companies for their contribution to GEOMATE 2025. We hope you enjoy the conference and find this experience inspiring and helpful in your professional field. We look forward to seeing you at our upcoming conference next year.

Best regards,

Prof. Zakaria Hossain,
Mie University, Japan,
Chairman (General)

Organization

Conference Honorary Chairmen:

Emeritus Professor Dr. Sohji Inoue, Mie University, Japan
Emeritus Professor Dr. Teruo Nakai, Nagoya Institute of Technology, Japan
Emeritus Professor Dr. Fusao Oka, Kyoto University, Japan
Prof. Dr. Bajang B.K. Huat, UPM, Malaysia

Scientific Committees:

Conference Chairmen:
Prof. Dr. Zakaria Hossain, Mie University, Japan

Conference Organizing Committee:

Prof. Dr. Zakaria Hossain, Prof. Mie University, Japan (Chair)
Prof. Dr. Satoshi Kaneco, Prof., Mie University, Japan (Co-Chair)
Prof. Dr. Sohji Inoue, E/Prof. Mie University, Japan (Co-Chair)
Prof. Dr. Toshinori Sakai, Prof. Mie University, Japan (Co-Chair)
Prof. Dr. Takamitsu Kajisa, E/Prof. Mie University, Japan (Co-Chair)
Prof. Dr. Kenji Okajima, Prof. Mie University, Japan (Co-Chair)
Prof. Dr. Masaaki Kondo, A/Prof. Mie University, Japan (Co-Chair)

National & International Advisory Committee:

Prof. Dr. Fumio Tatsuoka, E/Prof., Tokyo University of Science, Japan
Prof. Dr. Junichiro Takeuchi, Prof., Kyoto University, Japan

BRITTLE BEHAVIOR IN SOIL, TAILINGS AND ROCK MASS: AN OVERVIEW

John Victor Smith[1,2]

[1]School of Engineering, RMIT University, Australia; [2]CMW Geosciences, Australia

ABSTRACT

The understanding of the mechanisms of loss of strength responsible for many significant slope failures has developed over recent years. Unforeseen slope failures, including tailings dam collapses, have been one of the main catalysts for the improvements to geotechnical understanding. For example, in the case of earthquake design, international protocols no longer rely on pseudo-static seismic analysis where the focus is to emphasize the role of the transient change in loading. Rather the focus is on the loss of strength expected due to seismicity which can be assessed in order to establish adequate factors of safety. One driver for this has been an awareness that sudden loss of strength or brittleness can occur even without a trigger such as earthquake shaking. The extreme case of these processes is liquefaction which can cause very sudden loss of strength. The mechanism is typically understood to involve the rapid transition from drained to undrained behavior. Other slope failure mechanisms, including those that occur in rock masses, can be considered as examples of strength loss. One such mechanism is toppling. In toppling the layers or columnar blocks are initially in contact with each other and are in a configuration allowing down-slope rotation. The rate of movement is moderated by the frictional strength of the rock interfaces. Face-to-face contact between layers is lost as space opens up during rotation. This stage of failure can occur rapidly as the assemblage of layers loses its frictional strength and is effectively in a free-fall condition. The layers retain frictional strength once they have rotated into a condition of symmetry that restores the contact of rock interfaces. The new orientation of the toppled layers does not have the potential energy of the pre-toppling condition and the slope is locally self-stabilized.

Keywords: Brittleness, Strength loss, Soil, Tailings, Rock, Toppling

INTRODUCTION

It is understood that strength and strain are intimately related in geotechnics [1]. In particular, the strength of a material can change during strain. The reduction in strength, 'strength loss', being the most problematic for engineering purposes [1]. Loss of strength as a result of shearing has been described as brittleness since 1940s [1]. The strength of soil at large strain conditions can be referred to as the residual strength [2]. The brittleness index, a ratio of peak minus residual strength divided by peak strength has been attributed to Bishop in the 1960s [2]. The brittleness index defined this way only measures the magnitude of the strength loss but the rate of reduction should also be considered part of the concept [2]. Brittleness is sometimes considered to apply to the drained condition of soil and has been distinguished from 'sensitivity' which occurs in the undrained condition [2]. According to [2], brittleness is a function of fabric change during shear whereas sensitivity is a result of pore pressure increase. In this paper the term brittleness will be used broadly to refer to a wide range of strength loss conditions.

The history of the development of geotechnical knowledge has largely occurred when the strength of materials has been overestimated or the mechanisms of strength loss have not been fully appreciated and a catastrophic failure has unexpectedly occurred [3].

Some selected examples of 'unexpected' slope failures were presented in a previous GEOMATE conference and journal article [4]. Slope failures can be considered 'unexpected' if the strength has been under-estimated due to either inadequate investigation or incorrect assessment of material properties. The three examples cited in [4] were the Vajont dam in Italy, Guinsaugon landslide, Philippines and Yallourn coal mine, Australia.

The Vajont landslide occurred in 1963 during reservoir filling. The effect of reservoir filling on the groundwater and stress conditions in the surrounding hillside had not been adequately assessed and a large landslide occurred as a result and triggered failure of the dam due to the displaced water. Strength loss occurred due to hydrogeological processes which in hindsight could have been anticipated with a more comprehensive assessment of the risks.

The Guinsaugon landslide occurred in 2006. A later review [5] assessed that the natural slope's underlying rock mass had undergone strength deterioration. The transition from peak to residual strength during failure added to the large run-out of the failure debris. Earthquakes and rainfall were associated but the review [5] questioned the role of these as a trigger due to uncertain timing.

The Yallourn landslide, Victoria, Australia

occurred in 2007. This open cast coal mine is located near a river. As mining approached the river the buffer to encroaching groundwater was reduced. Relaxation of the rock mass during mining was inferred to have led to activating the inter-seam clay layers with low residual strength leading to slope failure [4].

These three examples show that rock mass, like soil, can undergo strength loss in an unexpected manner [4].

In the case of the Ontake landslide in Japan in 1984 an earthquake triggered a rock slide of over 30 million cubic meters with a run-out distance of over 5 km. The event was inferred to have been influenced by the preceding rainfall and movement focused on a weak pumice layer [6]. Studies of landslide prone areas after earthquakes show that landslides can continue to occur at an elevated rate for years after a major seismic event which is inferred to be a result of the progressive change from peak to residual strength [7].

RESEARCH SIGNIFICANCE

Brittleness, meaning rapid, significant strength loss can be considered a key concept across a wide range of geotechnical issues. Mechanisms of brittle strength loss are well known in soils and fine mine waste known as tailings. Understanding of brittle strength loss can be extended to rock mass conditions also. All these materials can have multiple strength conditions. If the conditions rapidly change from a stronger to a significantly weaker one then brittle strength loss has occurred. If an engineering design is based on a higher strength condition without regard to the potential transition to lower strength then serious consequences can occur. The overview of these concepts here is intended to draw attention to a range of brittle strength loss behaviors that can occur. All geotechnical engineers should consider whether the materials they are constructing on or with could undergo a rapid and significant reduction in strength and ensure that this risk is adequately covered in the design process.

CONCEPTS

The examples covered in this paper have been selected for illustration of general concepts. The overarching aim is to use ‘brittleness’ or ‘brittle strength loss’ as a conceptual lens to view a wide range of processes related to geomechanics. The aim is not to imply that all these processes are fundamentally related in terms of physics and mechanics. Rather, the aim is to make conceptual linkages that assist practitioners and researchers to work across areas of geotechnical application.

This way of thinking has developed from a career spanning multiple fields from structural geology, tectonics, volcanology, engineering geology and geotechnical engineering. In working across these fields the conventional boundaries of soil, rock and industrial materials such as tailings and also the boundary between natural processes of slope stability including volcanic activity versus engineered conditions are somewhat dissolved.

Two main areas emphasized are firstly the importance of the potential for brittle strength loss in assessing the safety of tailings dams. Assessing strength loss is seen by many as more significant than determining the likelihood of a triggering event such as an earthquake and assessing the pseudo-static force of the earthquake as will be outlined with relevant references below. Secondly, toppling kinematics in rock slopes is addressed to illustrate brittle strength loss in a rock mass.

In this broad coverage the references cited are inevitably highly selective and many important sources and authors have not been included. Citing a particular author in relation to a topic is only intended to indicate a source where a concept is well explained rather than to imply that the author cited is necessarily the originator of a concept.

General

The stability of a slope is typically described in terms of factor of safety or probability of failure [8]. In order to calculate such numbers the strength of the material must be understood in terms of its range of properties. Soil properties can be understood as drained versus undrained and as peak, fully softened and residual [8]. The terminology residual strength of soil needs to be differentiated from residual soil meaning a soil which has formed directly from the underlying rock without significant transportation [9]. These residual soils are typically quite dense as they are undisturbed by transportation [9]. Their behavior is typically comparable to over consolidated soils [9]. Experimental laboratory studies can be conducted to assess the peak and residual shear strength of various material compositions and moisture conditions [10].

The strength of cohesive and granular soils typically increases with depth [11]. Specifically, the strength of soils is influenced directly by the confinement condition [11]. Various studies have explored the relationships of plasticity via the 'velocity field' or kinematics of the deforming system in relation to the stress distribution. These models can be applied to common problems such as loading of soft soils by embankments or other earthworks [11].

Strain softening behavior of soil and rock can be observed in laboratory experiments and applied in geotechnical analysis [12]. It has been observed that at low confinement the rate and magnitude of the reduction in strength can be most pronounced [12]. A plastic shear strain threshold was applied to define the transition from a linearly decreasing strength with strain from a constant strength (residual) condition at greater strain [12]. The extent of strength loss has been described as the brittleness of the material [12].

Brittleness

The concept of brittleness and the brittleness index can express the sudden loss of strength of soils and other granular materials and has been used since the 1980s and earlier [13]. The original definition of brittleness was based solely on the magnitude of the strength reduction. However, the normal meaning of brittle includes a sense of rapid loss of strength. One approach to quantifying degrees of brittleness and the relationship to strain has been developed for tailings [14]. In this scheme, non-brittle or moderately brittle materials do not undergo any reduction in shear strength until 3% axial strain is developed (Fig.2).

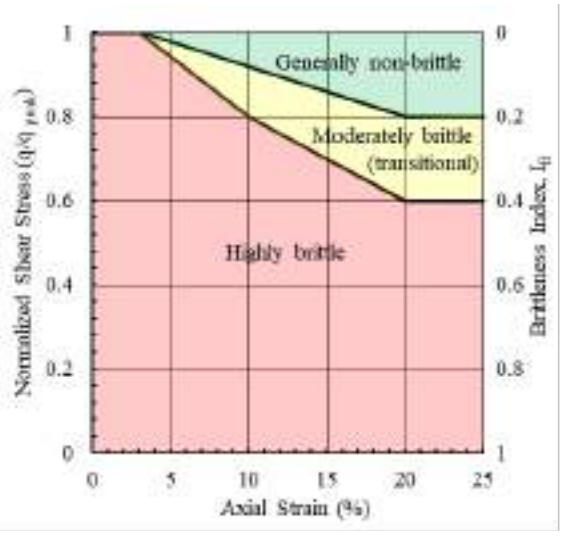

Fig.2 Definition of brittleness developed for tailings materials [14]

Non-brittle and moderately brittle materials can undergo 20% and 40% strength reduction, respectively. However, if these strength reductions occur prior to development of 20% axial strain then the materials may qualify for a higher degree of brittleness in this scheme (Fig.2).

Seismicity

Earthquakes stand out as a natural phenomenon that have the ability to cause destruction and damage through their effects on structures. A seminal work by the US Corps of Engineers (1980's) [15] outlined the pseudo-static method by stating "the seismic stability of embankment dams may be evaluated by a relatively simple method … in cases where there is no threat of liquefaction or severe loss of shear strength under seismic shaking.". That study emphasized that the pseudo-static approach to earthquake impact on dams is a 'screening tool' meaning it is not a sufficient check on stability itself but can be used to classify levels of concern that lead to applying appropriate acceptance criteria [15]. That work emphasized that dams with embankments or foundations that are susceptible to liquefaction or significant softening by cyclic loading require more specific stability assessments than can be achieved by pseudo-static approaches [15]. That work also refers to the "dynamic yield strength" of many earth materials being approximately 80% (i.e. 20% strength reduction) of the pre-seismic condition and that such strength reduction in analysis can be an appropriate way to assess seismic/cyclic conditions [15].

Further developments in seismic responses of dams in the 1990's [16] considered the strength of liquefied materials and noted they have a 'steady-state' or 'residual' (interchangeable terms) strength in the liquefied condition. Those studies found that triggering of failure in laboratory testing occurred at "the point at which control of the test is lost: if one were to stop the test in a load-controlled fashion after sufficient strain (with the stresses still applied) the sample would creep and ultimately flow in the steady-state mode" [16]. The residual strength of liquefied material is typically given as a strength to stress (i.e. depth) ratio [16].

Dilation and Contraction

The behavior of granular material is dependent on its density which is commonly measured as void ratio [16]. During shearing, granular materials will contract if they are loose or dilate if they are dense relative to a critical void ratio that represents a condition of shearing with constant volume. The critical void ratio varies with the degree of confining stress [16].

A mechanism called 'void redistribution' has been proposed as an explanation for the time delay that has been observed between possible triggers and actual slope failure [16-18]. The typical void redistribution scenario can occur where granular

material is below an impermeable layer. The trigger event causes some contraction of the granular material which expels excess water upward. However, the upward progress of water is prevented by the presence of the impermeable layer above [17,18]. In an extreme case, a film of water forms at the base of the impermeable layer with detrimental effects on stability of sloping ground. This mechanism is postulated in some rapid and significant loss of strength events [17]. It is understood that the void redistribution process takes time, leading to a delay between trigger and failure [17]. The process of void redistribution has been verified by centrifuge tests by various authors as reviewed by [17].

Strain Compatibility

Strain compatibility refers to the general concept that where different materials are in contact they may undergo different strains or strain rates in response to the stress conditions. Consequently, local stress variation or disturbances to the velocity field can cause strain incompatibility and can lead to discontinuity formation. Strain compatibility is also related to strain localization during shearing as the emerging shear zone must be oriented in a direction of zero longitudinal strain to maintain strain compatibility between the sheared and unsheared material [19]. These lines of no longitudinal strain are also known as the characteristic lines and are at less than 90^{o} to each other in conditions of dilatancy [19].

SOIL AND LANDSLIDES

Soils are typically derived from natural rock weathering either as a residuum or transported. Soil behavior is strongly influenced by the interaction of clay and water [8]. The ‘fully softened’ condition indicates that the shear strength of clay-dominated materials moves toward a low strength condition through the absorption of water over time, especially concurrent with strain [8].

The ability of pore water to migrate through a soil under stress defines the undrained and drained strength conditions. Undrained strength can exceed drained strength over parts of the confining stress range, particularly in over-consolidated conditions [20]. Pressure changes in the water within the pores of soils are intimately related to strain and control the drained strength via the effective stress principle. Negative pore pressures can develop in unsaturated soils and when lost by saturation can result in rapid loss of strength [8].

Non-Newtonian or thixotropic behavior can affect the stress-strain relationships as can creep in a wide range of materials [21-25]. Other processes that can influence soil behavior include progressive changes to grain-size through particle crushing and the discontinuous deformation of fissured clays [3].

Analysis of a faulted coarse gravel deposit in New Zealand showed a reduction from 78% clasts to 33% clasts. The process of faulting in this gravel deposit occurred by dilation of the clast-supported fabric to facilitate movement and concurrently for clay matrix material to migrate to the fault zone. This process is representative of inter-particle dilation to a critical state as is required for shearing of particulate systems generally. Due to the coarse grain-size of the gravel the changes caused by dilation can be observed directly in the field [25] (Fig.3).

Fig.3 Dilatation of a fault zone in a gravel deposit observed by reduced clast concentration [25]

TAILINGS

Tailings are the end product of rock and mineral grinding in mineral processing. Many mines place these tailings in impoundments by hydraulic methods [26]. A number of high profile tailings impoundment failures have occurred causing significant loss of life and environmental impact [27]. The comments made here are general in nature and original sources and guidelines should be referred to for all tailings impoundment works. Selected significant failure events are only briefly described here and readers should address the extensive literature for additional data and interpretation.

Various events and their analysis have been used in developing international [14] and National guidelines [28]. Limit-equilibrium analysis remains the main tool for assessment. Factor of safety of 1.5 has been used for static conditions and 1.1 or 1.0 for seismic conditions [28]. The seismic assessment must be based on cyclic and post-liquefaction parameter reduction rather than pseudo-static analysis [14, 28].

One of the well studied events was the of failure of the Mount Polley tailings storage facility in British Columbia, Canada in 2014. The failure mechanism was found to be complex and involved strain weakening in the foundation and its strain incompatibility relative to the rockfill embankment [29].

A significant development has been the recognition that critical state soil mechanics is fundamental to tailings behavior [30,31]. The

materials of the foundation, embankment and tailings can be defined relative to the critical state line in void ratio terms. This value is the state parameter and is positive for materials loose of critical state and negative for materials dense of the critical state [30,31]. The precision of void ratio measurement is approximately 0.05 due to variations in sample preparation [16]. The relationship between strength and confinement is related to important concepts of dilation and contraction [32]. The value used for boundary between dilative (non-liquefiable) and contractive (liquefiable) is -0.05 [33]. This value recognizes that materials just dense of the critical state can undergo liquefaction-like flow [33].

While limit-equilibrium is currently the prime method of analysis it has been recognized that limit-analysis applied in a finite element formulation can overcome some limitations of limit-equilibrium in the area of slip surface identification [32]. In limit-analysis the lower bound is based on an admissible stress field and the upper bound is based on a kinematically admissible velocity (plastic strain rate) field [32]. Limit-analysis and finite element analysis generally can also complement limit-equilibrium by responding to latent instability to undrained failure and stress rotation causing undrained failure [32]. A limit-analysis model of the 2015 Fundao tailings impoundment failure in Brazil was presented at a previous GEOMATE conference [34].

Another aspect of tailings impoundment failure that is not covered here is dam breach. Tailings dam breach outflow is a highly complex process and is critical to assessing potential impacts [35]. In dam breach events water ponded on the tailings surface erodes tailings and re-hydrates it to a more flowable form even beyond the effects of tailings liquefaction.

ROCK

Volcanic Processes

Many volcanic processes are driven by gravity and can provide insight into the behaviour of natural materials. For example, Bromhead [1] gives an example of his observation of a lava flow base directly over a mangrove swamp mud providing insight into the geomechanical processes in the location [1]. The flow of lavas and other volcanic products can inform understanding of viscous-granular flow, especially non-Newtonian effects [36,37].

Rock Mass

Rock material is typically brittle in nature and at high deviatoric stress can undergo microscopic damage (starting at about 40% of uniaxial compressive strength [38]. Rock mass refers to the rock material and the naturally occurring fractures that are typically present. These systems of fractures are the main control on how the rock mass behaves [38]. In order for a rock mass to deform, the confinement is typically low such that the blocks of rock can move relative to each other. The extreme example of low confinement is where fractures daylight in a face making the sliding or rotating motions of blocks feasible [38].

Toppling

Where rock mass deforms mainly by the rotation of elongate blocks, toppling is the failure mechanism [39]. Free fall toppling where columns or layers of rock at a face rotate under the influence of gravity is a very recognized type of toppling. Toppling also occurs where the adjacent blocks form a confining condition which can influence the rotation [40]. This type of toppling is similar to the processes observed in hillside creep of layered bedrock [40].

Toppling of columns or layers within a slope has a dilative and contractive phase (Fig.4). The dilative phase develops until the layers are perpendicular to the basal surface of rotation. The contractive phase then continues until the layers reach a mirror image configuration compared to their starting postion. At this point the toppling can self-stabilize. During the dilative phase the frictional contact between adjacent blocks decreases and the rock mass strength decreases.

Therefore, the toppling mechanism can be considered brittle in the sense that strength decreases as strain is accumulated in the early phase of deformation. Examples of toppled slopes in layered rocks are shown in Figure 5 and 6. The layers have buckled (Fig. 5B, Bk) where the layers have rotated to be perpendicular to the basal surface. Separation of layers in this zone also shows the occurrence of local dilation (Fig. 5B, D). Layers of different thickness can respond differently by having different angles of rotation compensated for by shearing in the same sense as the downslope movement (Fig. 5B, location 1 and 2 and shear arrows).

Figure 6 shows a location where layers have reached the self-stabilized configuration. The slip between layers with the opposite sense of movement to the downslope shearing is anotated by shear arrows with ‘s’. Local block rotation and other shears on joints with an opposite sense to the downslope shearing are also anotated on Fig.6. These mechanisms have been shown to be relevant to deep-seated (>100 m deep) toppling rock slides [41-43].

CONCLUSIONS

Geotechnical engineering for foundations, excavations and earthworks is fundamentally based on determining the strength of earth materials. These materials include soils and rock and also industrial waste products such as the finely ground rock residue

known as tailings. The strength of these materials can be determined by field and laboratory tests. However, the strength can change under a wide range of conditions including saturation by water, loading and strain. When strength changes to a lower value this can be considered to be a strength loss. If the strength loss is unexpected then failure may be the result.

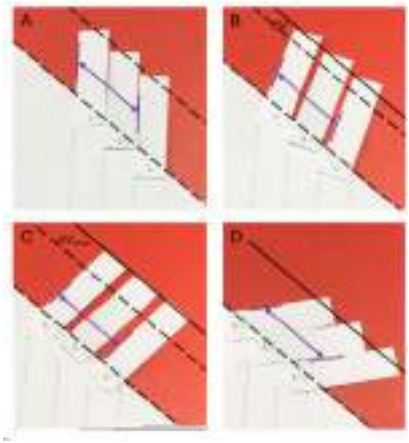

Fig.4 Toppling dilatancy in a paper model. A) Initial configuration. B) Opening phase. C) Maximum separation of blocks. D) Closure (self-stabilization)

The strength of geological materials including soils, tailings and rock masses is intimately associated with the amount, rate and type of strain that occurs. In particular 'loss of strength' that is sudden or unexpected reduction in strength of these materials should be considered along with the strain occurring.

The case of rock toppling can be included in brittle behavior in that the gravitational force induces shear strain in a downslope direction. If this shear strain induces rotation of elongate blocks of rock the kinematics of this proces can cause expansion of the deforming zone occuring in concert with separation of the side faces of the elongate blocks. If this toppling occurs within a confined condition such as hillslope creep or deep-seated toppling then complex internal kinematics can be observed or anticipated within the toppling rock mass. For example, 1) shear displacement of block faces with a sense of shear opposite (antithetic) to the overall downslope shear strain, 2) shearing of block faces sub-parallel to the overall shear strain with the same sense of shear (synthetic), 3) delamination of layers, 4) buckling of layers and 5) local deformation of weak layers. These processes introduce mechanisms of deformation which would not occur without the dilation of the rock mass driven by the rotation of elongate blocks. Therefore, this pattern of strain (kinematics) leads to a reduction in strength. The rotation of the elongate blocks eventually leads to a more stable configuration as the blocks attain an orientation equal and opposite to the original configuartion relative to the basal plane of the toppling. This stabilising configuration has been referred to as the mirror image configuration that leads to self-stabilization of toppling.

Fig.5 Constrained toppling showing the complex shearing and rotation accommodated in the dilating zone (Melbourne Formation, Plenty Gorge, Victoria Australia). A) Large arrows show the gravity-driven shear sense. B) Detail with features described in the text

This overview encourages geotechnical engineers and related professionals to ensure that foundations, excavations and earthworks are designed with a full understanding of the potential of the materials to reduce in strength under a range of conditions. Importantly, a safe design is one which can maintain stability even when the strength of the material decreases to a lower level – especially if the change in strength is rapid.

ADVANCED TECHNOLOGIES FOR EXISTING PILE EXTRACTION AND ASSOCIATED BOREHOLE BACKFILLING

Shinya Inazumi

College of Engineering, Shibaura Institute of Technology, Japan

ABSTRACT

This keynote addresses the critical challenges facing modern urban redevelopment through innovative approaches to existing pile extraction and borehole backfilling. As aging infrastructure worldwide requires comprehensive renewal, the development of safe and efficient methodologies for existing pile removal has become paramount for sustainable land use and environmental stewardship. This presentation introduces groundbreaking technologies developed within Japan's unique geological and urban context, including the pile tip gripping and lifting method and advanced cement-based backfill materials enhanced with sodium carbonate and thickening agents. These innovations demonstrate significant improvements in safety, operational efficiency, and environmental sustainability compared to conventional extraction methodologies.

Keywords: Pile extraction, Borehole backfilling, Infrastructure aging, Urban redevelopment

INTRODUCTION

The Global Infrastructure Aging Crisis

The rapid economic growth experienced globally during the post-war period has resulted in extensive infrastructure networks that are now approaching end-of-life conditions, necessitating comprehensive renewal strategies [1,2]. Japan exemplifies this challenge with iconic structures constructed around the 1964 Tokyo Olympics, including Tokyo International Airport, the Metropolitan Expressway, and the Tokaido Shinkansen bullet train line, all of which now require systematic renewal and reconstruction [3]. This infrastructure aging phenomenon extends beyond Japan, creating urgent global needs for innovative demolition and reconstruction methodologies that prioritize safety, efficiency, and environmental sustainability.

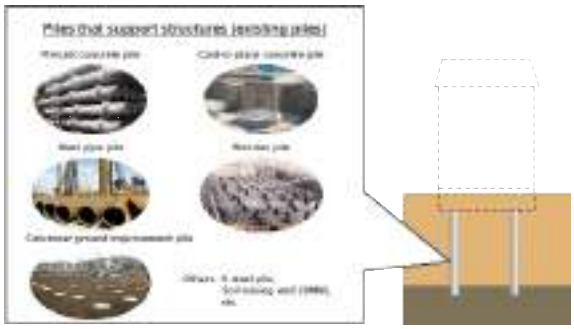

Fig. 1 Overview of various types of pile foundations

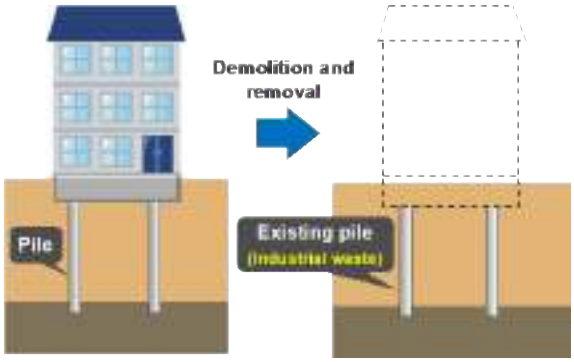

Fig. 2 Definition of piles and existing piles designated as industrial waste

The demographic shifts associated with declining birth rates and aging populations have fundamentally altered infrastructure utilization patterns, leading to decreased demand for certain public facilities while simultaneously increasing the need for disaster-resilient reconstruction following major seismic events such as the 1995 Kobe Earthquake, 2011 Great East Japan Earthquake, and 2016 Kumamoto Earthquakes [4,5]. These natural disasters have heightened awareness of disaster prevention requirements, driving comprehensive infrastructure renewal initiatives that extend far beyond simple replacement strategies [6,7].

The widespread utilization of pile foundations in urban environments, particularly in soft soil conditions prevalent in many global cities, presents unique challenges following structural demolition. As demonstrated in Fig. 1, various pile foundation types support existing infrastructure systems, including precast concrete piles, cast-in-place concrete piles, steel pipe piles, wooden piles, and specialized ground improvement systems. Upon demolition, these foundations become "existing piles in the ground," as illustrated in Fig. 2, often classified as industrial waste requiring specialized removal techniques [8,9].

Consequences Of Inadequate Pile Management

The improper management of existing piles

following structural demolition creates substantial geotechnical and environmental challenges that extend beyond immediate construction sites. Fig. 3 demonstrates the local subsidence caused by incomplete backfilling of boreholes with sand, illustrating the critical importance of proper soil stabilization following pile extraction. Such differential settlement can lead to significant land degradation, affecting not only the immediate construction site but also adjacent structures and infrastructure systems [10,11].

The presence of remnant piles in the ground creates complications in land transaction processes, as these underground obstructions are often perceived as defects that can significantly impact property values and future development potential [12]. Fig. 4 illustrates the common problems associated with partial pile remnants remaining in the ground and poor backfilling practices following pile removal, highlighting the dual challenges that must be addressed through integrated technical solutions.

Current practices in Japan for pile removal remain outdated and rely heavily on empirical field experience without comprehensive standardized guidelines, leading to persistent unresolved issues in process improvement and quality assurance [13,14]. This lack of systematic approaches has resulted in various technical uncertainties and safety concerns that require immediate attention through innovative technological development and implementation.

CRITICAL ANALYSIS OF CONVENTIONAL WIRE ROPE METHODS

The wire rope method, illustrated in Figs. 5 and 6, represents the conventional technique widely employed in the construction industry for existing pile extraction and removal [15,16]. This method involves a sequential process beginning with borehole drilling around the pile circumference using protective casing to maintain structural integrity and minimize ground disturbance. Following casing installation, wire rope attachment to the existing pile enables upward force application through heavy equipment for pile extraction.

The wire rope extraction process presents significant technical challenges and safety risks that have persisted throughout decades of implementation. Fig. 7 demonstrates the critical accidents encountered with wire rope methods, including wire rope breakage due to underestimated loads and pile structural failure during extraction processes. These failures often result from increased frictional forces around pile circumferences caused by borehole wall collapse and soil backfill into extraction cavities [17,18].

The mechanical failure modes associated with wire rope methods create substantial safety hazards in dense urban environments. Wire rope breakage, as shown in Fig. 7a, frequently occurs at the initiation of

Fig. 3 Example of local subsidence due to poor backfilling of boreholes with sand

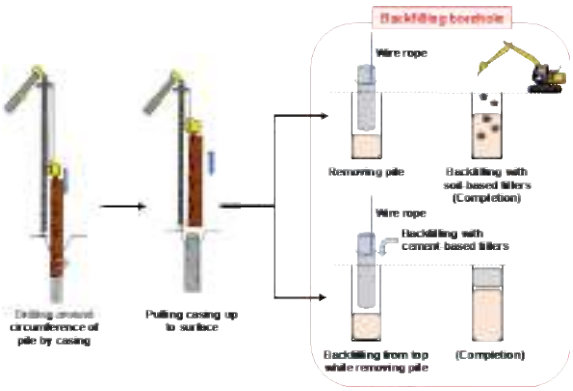

Fig. 5 Methods of borehole backfilling that can be employed in wire rope method

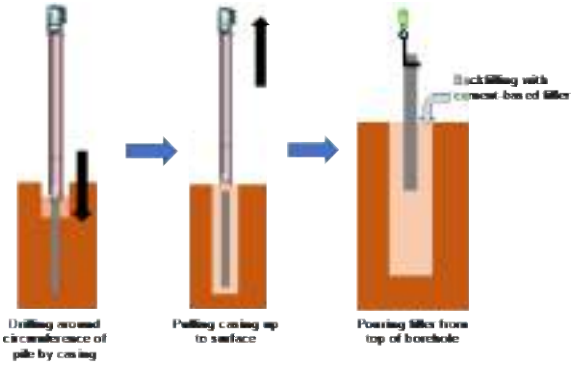

Fig. 6 Schematic of wire rope method (conventional technique)

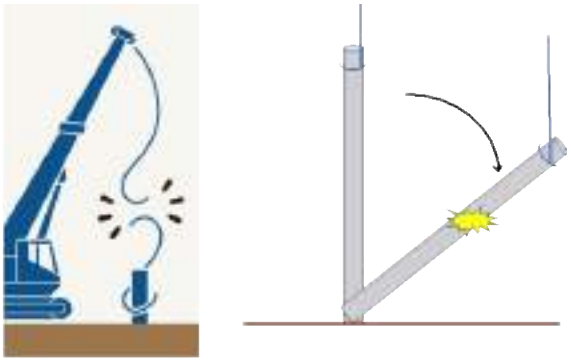
extraction operations due to inadequate load estimation during design and operational phases. Additionally, pile breakage during extraction,



(a) Breaking of wire rope (b) Breaking of pile

Fig. 7 Accidents encountered with wire rope method

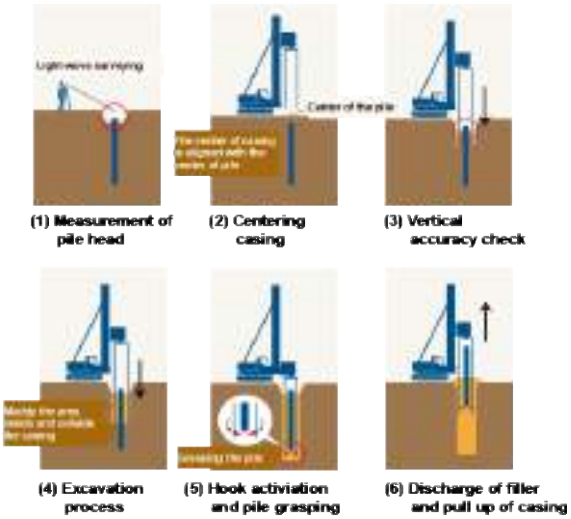


Fig. 8 Schematic of pile tip gripping and lifting method (commonly referred to as PG method)

illustrated in Fig. 7b, can lead to severe secondary disasters, particularly when extracted pile segments fall unexpectedly or when sudden tension release causes equipment instability [19].

The incomplete removal of existing piles through conventional methods creates long-term geotechnical challenges that affect subsequent construction activities. Remnant pile segments buried in the ground can impede new foundation installation, causing alignment problems and compromising the structural integrity of newly constructed foundations. Even when remnant piles do not directly interfere with new pile installation, their presence affects foundation design and performance evaluation, particularly under seismic loading conditions [20].

INNOVATIVE PILE TIP GRIPPING AND LIFTING TECHNOLOGY

The development of the pile tip gripping and lifting method, commonly referred to as the PG method, represents a significant advancement in pile extraction technology specifically designed to address the quality and safety limitations of conventional extraction techniques [15,19,21,22]. This innovative approach fundamentally differs from traditional wire rope methods through its unique pile gripping mechanism and integrated backfilling capabilities.

Fig. 8 illustrates the comprehensive operational sequence of the PG method, demonstrating the systematic approach to pile extraction that ensures precision and safety throughout the process. The method employs specialized hooks located at the casing tip to securely grasp existing piles while simultaneously discharging filler material to backfill the extraction cavity. This integrated approach not only streamlines the extraction process but also enhances safety by eliminating wire rope failure risks and providing immediate ground stabilization.

The operational sequence begins with precise pile head measurement to ensure accurate extraction planning, followed by careful casing alignment with the existing pile centerline to minimize potential ground disturbance and structural damage. Vertical accuracy verification ensures proper casing orientation before commencing excavation activities. During the excavation process, water or cement slurry discharge from the casing tip creates muddy conditions that reduce ground resistance while preventing borehole wall collapse and existing pile damage from soil movement.

The hook activation and pile grasping phase represents the critical technical innovation of the PG method. Once casing excavation reaches completion, specialized hooks engage to securely grip the existing pile structure. The subsequent filler discharge and casing extraction phase enables simultaneous pile removal and backfill placement while maintaining continuous monitoring of injected filler volumes through precision flow measurement systems.

The PG method offers substantial advantages over conventional extraction techniques through elimination of wire rope failure risks, reduced frictional resistance around pile circumferences, and integrated backfilling capabilities that ensure immediate ground stabilization [27]. Additionally, the method addresses pile damage concerns by safely containing damaged pile segments within the protective casing throughout the extraction process.

ADVANCED BACKFILL TREATMENT TECHNOLOGIES

The critical importance of backfill treatment in pile extraction processes cannot be understated, as proper soil stabilization directly affects long-term site performance and construction quality. Fig. 9 demonstrates the adverse effects of poor backfilling practices on surrounding soil conditions, illustrating various failure modes including subsidence occurrence, structural tilting and collapse, retaining wall deformation, heavy machinery instability, new

pile installation complications, and negative impacts on cast-in-place concrete pile construction.

Conventional backfilling methods present significant technical limitations that compromise treatment effectiveness. Fig. 10 illustrates the traditional top-pouring approach employed in wire rope methods, highlighting the formation of stratified structures within boreholes due to sediment attached to existing piles and drilling mud accumulation based on specific gravity differences [15,21]. This stratification creates uneven filler distribution throughout borehole depths, leading to weak zones and potential long-term stability problems.

The performance requirements for effective backfill materials encompass multiple technical specifications that must be simultaneously satisfied to ensure adequate ground stabilization. Fillers must provide uniform strength characteristics regardless of depth, prevent material segregation during placement and curing, develop adequate strength rapidly to accommodate construction scheduling requirements, and resist groundwater infiltration effects that can compromise material properties [23-26].

Soil-based fillers such as sand and gravel offer economic advantages but present significant challenges in achieving uniform fill characteristics and stable strength development throughout borehole volumes. Cases have been documented where loose soil-based backfilling resulted in settlement of backfilled areas compared to original soil conditions, particularly during the first month following installation or during heavy rainfall events [11,12,17].

CEMENT-BASED FILLER DEVELOPMENT AND ENHANCEMENT

The development of advanced cement-based fillers represents a critical advancement in borehole backfilling technology, addressing the fundamental limitations of conventional soil-based approaches. Cement slurry formulations consisting of water, cement, and bentonite provide high fluidity characteristics and self-setting properties that enable effective filling of irregular cavities where mechanical compaction is not feasible [23,26].

However, traditional cement slurries face significant technical challenges including material segregation due to constituent density differences and susceptibility to groundwater infiltration effects that can compromise design strength achievement. The incorporation of sodium carbonate (Na_2CO_3) into cement slurry formulations addresses these limitations through multiple enhancement mechanisms [27,28].

Fig. 11 illustrates the comprehensive mechanism of property enhancement achieved through sodium carbonate addition to cement slurries. The process involves ion exchange reactions that promote bentonite swelling characteristics while accelerating

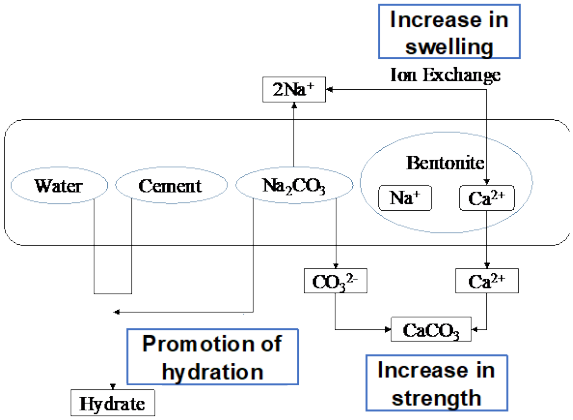

Fig. 11 Mechanism of various properties in cement slurry mixed with sodium carbonate

cement hydration processes. The formation of calcium carbonate ($CaCO_3$) as a reaction product contributes to long-term strength development and improved material durability.

Extensive laboratory investigations have demonstrated that sodium carbonate addition

significantly reduces cement slurry bleeding to less than 1% within one hour of mixing, compared to substantially higher bleeding rates in conventional formulations [28,29]. This bleeding reduction ensures improved material homogeneity and prevents strength reduction associated with water segregation and surface concentration.

The strength development characteristics of sodium carbonate-enhanced cement slurries demonstrate accelerated early strength gain compared to conventional formulations. Fig. 12 illustrates the enhanced bentonite swelling mechanism achieved through sodium carbonate treatment, showing the transformation from calcium-type bentonite with limited swelling capacity to sodium-type bentonite with significantly improved swelling characteristics that enhance void-filling capabilities and reduce material segregation potential.

THICKENER TECHNOLOGY INTEGRATION

The integration of thickening agents into cement slurry formulations provides additional performance enhancements that address specific challenges associated with borehole backfilling applications. Thickeners modify rheological properties including flowability and viscosity characteristics, enabling improved material placement control while maintaining workability for extended periods [30-32].

Fig. 13 demonstrates the comparative material segregation characteristics between standard cement slurry and thickener-enhanced formulations when exposed to aqueous environments. The thickener-enhanced cement slurry maintains structural integrity and prevents constituent separation, ensuring uniform material properties throughout the backfilled volume.

Research investigations have demonstrated that thickener incorporation enables effective blowout prevention even in dilute cement slurries with water-cement ratios exceeding 400%, while maintaining rheological properties for up to two hours following mixing [30-32]. The prevention of cement slurry dissolution in drilling mud represents a critical advantage for borehole operations, contributing to more reliable and consistent construction practices.

COMPREHENSIVE SOLUTION INTEGRATION AND QUALITY ASSURANCE

The integration of PG method extraction technology with advanced cement-based backfill materials creates a comprehensive solution that addresses the full spectrum of technical challenges associated with existing pile removal and site stabilization. This integrated approach provides complete pile extraction assurance while ensuring immediate ground stabilization through high-performance backfill material placement.

The quality assurance framework for integrated

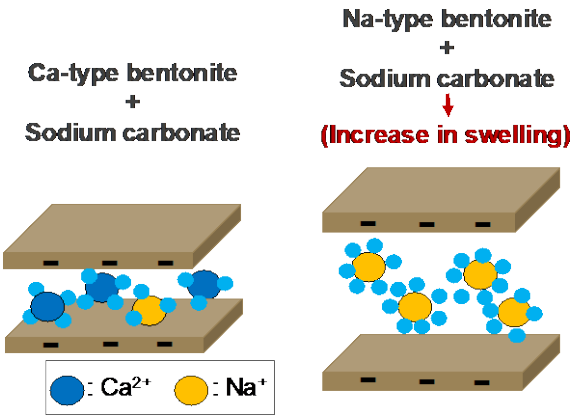

Fig. 12 Effect of mixing sodium carbonate on swelling of bentonite

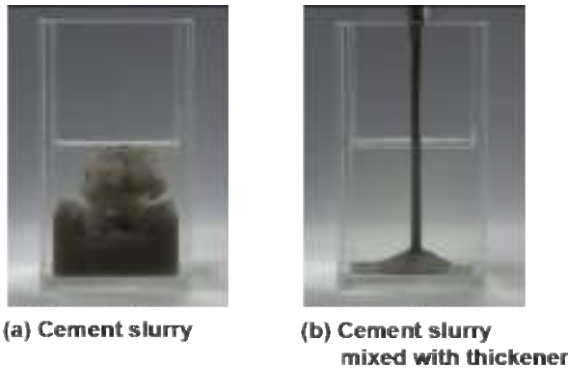

Fig. 13 Comparison of material segregation characteristics in water for cement slurry alone and cement slurry mixed with thickener

pile extraction and backfilling operations requires comprehensive monitoring protocols including boring tests, standard penetration testing, and screw weight sounding assessments to verify treatment effectiveness [17,18]. Continuous quality control throughout extraction and backfilling processes ensures that performance specifications are consistently achieved across project sites.

The sustainability considerations associated with integrated pile extraction and backfilling technologies extend beyond immediate construction benefits to encompass long-term environmental stewardship and resource efficiency optimization. The enhanced land reuse potential achieved through complete pile removal and proper ground stabilization contributes to more sustainable urban development practices while minimizing environmental disruption during construction activities.

CONCLUSIONS AND FUTURE DIRECTIONS

The innovative technologies presented in this keynote demonstrate transformative approaches to existing pile extraction and borehole backfilling that address critical challenges in modern urban redevelopment. The pile tip gripping and lifting

method represents a paradigm shift in extraction technology that enhances safety through elimination of wire rope failure risks while improving operational efficiency through integrated backfilling capabilities.

The development of advanced cement-based backfill materials enhanced with sodium carbonate and thickening agents provides superior performance characteristics compared to conventional soil-based approaches, ensuring long-term ground stability and construction quality. These material innovations demonstrate the potential for chemical enhancement strategies to address fundamental limitations in geotechnical applications.

The integration of extraction and backfilling technologies creates comprehensive solutions that support sustainable urban redevelopment through improved safety, enhanced efficiency, and environmental stewardship. The continued development of these technologies, coupled with comprehensive guideline establishment and international technology transfer initiatives, will be essential for addressing the worldwide infrastructure renewal challenge while maintaining public safety and environmental protection standards.

Future research directions should focus on advanced material formulation optimization, automated system development, real-time monitoring technology integration, and sustainable material sourcing strategies that support global implementation across diverse geological and urban contexts. The establishment of standardized testing protocols and performance evaluation criteria will facilitate international adoption of these innovative technologies for sustainable infrastructure renewal worldwide.

GEOTECHNICAL AND MICROSTRUCTURAL ASSESSMENT OF RIVER SLUDGE STABILIZED WITH SUSTAINABLE ADDITIVE SYNERGY

Md Yachin Islam[1] and Zakaria Hossain[1]

[1]Graduate School of Bioresources, Mie University, Japan

ABSTRACT

The utilization of river sludge (RS) in geotechnical engineering offers an environmentally sustainable solution; however, its practical application is hindered by high compressibility and low strength, primarily due to its organic content. This study explores the potential of enhancing RS through stabilization using rice husk ash (RHA) and cement, with a focus on sustainable additive synergy. A series of oedometer tests were conducted on RS blends incorporating varying proportions of RHA and cement to assess key consolidation characteristics-the coefficient of consolidation (cv), coefficient of volume change (mv), and permeability (k). Microstructural analyses using scanning electron microscopy (SEM) and energy-dispersive X-ray spectroscopy (EDS) were conducted to investigate changes in the internal structure and to identify pozzolanic interactions. Among the tested mixtures, the combination of 10% RHA and 6% cement demonstrated optimal performance, significantly reducing compressibility and permeability. These results highlight the effectiveness of RHA in combination with minimal cement content in improving the geotechnical behavior of river sludge. The study contributes to the development of sustainable soil stabilization techniques, offering practical applications in embankment construction, subgrades, and other foundational works.

Keywords: River sludge, Rice husk ash, Geotechnical properties, Pre and post consolidation, Microstructural analysis

INTRODUCTION

Construction on problematic soils often faces challenges such as differential settlement, which can lead to costly structural damage [1]. To address these issues, soil stabilization using cementitious materials is a common and practical approach. River sludge, a typical soft soil, is known for its low strength, high compressibility, and elevated water content, making stabilization essential to achieve acceptable engineering properties [2].

Traditional binders, such as cement and lime, have been widely used to enhance soil strength and reduce compressibility and porosity. Among them, Ordinary Portland Cement (OPC) is the most prevalent stabilizer [3,4]. However, OPC production is highly energy-intensive and contributes significantly to global CO_2 emissions, with approximately 0.95 tons of CO_2 emitted per ton of cement produced. This environmental impact drives the need for more sustainable and energy-efficient alternatives that still provide effective soil improvement [5].

Rice husk ash (RHA), a by-product of agricultural waste combustion, has attracted attention as a sustainable stabilizer due to its high silica content and pozzolanic properties [6-8]. Its unique microporous structure and large specific surface area help reduce moisture in river sludge, improving compaction and stability. RHA's chemical composition primarily consists of amorphous silica (SiO_2), along with various oxides depending on combustion conditions. When produced at optimal temperatures (600-700°C), RHA exhibits high pozzolanic activity, reacting with calcium compounds to form cementitious phases such as calcium silicate hydrates, thereby enhancing the strength and durability of stabilized soils [9].

Recent research has increasingly focused on stabilizing river sludge using various innovative additives [10-12]. For example, Jaditager and Sivakugan [13] examined sedimentation improvements in dredged mud slurry from Townsville, Australia, using a fly ash-based geopolymer binder. Their settling tests showed enhanced sedimentation with higher geopolymer content, despite limited chemical interaction between the binder and soil particles [13]. Similarly, Peng, L. & Chen, B [14] evaluated the influence of polyacrylamide (PAM) on the compressibility of river sludge from Tianjin, China. They found that the coefficient of consolidation (cv) generally increased with PAM concentration in normally consolidated samples, while over-consolidated samples showed more complex behavior depending on PAM dosage [14]. Further, Jaditager and Sivakugan [13] reported that increasing fly ash-based geopolymer content effectively reduced the coefficient of volume compressibility (mv) in dredged soils. These studies demonstrate diverse methods of enhancing river sludge properties through novel stabilization

techniques [15].

Addressing gaps in sustainable stabilizer combinations, this study investigates river sludge stabilization with varying proportions of rice husk ash (RHA) at 5%, 10%, and 15%, alongside cement at 2%, 4%, and 6%. The key objectives include:

- Determining optimal RHA-cement ratios to improve compressibility and consolidation behavior of river sludge composites.
- Evaluating the effects of these additives on consolidation parameters such as coefficient of consolidation (cv), coefficient of volume change (mv), and permeability (k) under different conditions.
- Characterizing microstructural changes in stabilized samples through advanced techniques including scanning electron microscopy (SEM), energy-dispersive X-ray spectroscopy (EDS), and X-ray diffraction (XRD).

RESEARCH SIGNIFICANCE

This study provides a systematic evaluation of the compressibility and consolidation behavior of river sludge stabilized with rice husk ash (RHA) and cement, focusing on critical geotechnical parameters such as the coefficient of consolidation, coefficient of volume change, and permeability through oedometer testing. By integrating advanced microstructural and chemical analyses, including energy-dispersive X-ray spectroscopy (EDS) and X-ray diffraction (XRD), the research offers valuable insights into the interaction mechanisms between RHA and cement within the composite material. Although RHA has demonstrated potential in enhancing soil properties, the combined effects of varying RHA proportions with cement on consolidation characteristics remain underexplored. This investigation addresses this gap, contributing to the advancement of sustainable, low-carbon soil stabilization methods suitable for geotechnical applications, thereby promoting eco-friendly construction practices.

MATERIALS AND METHODOLOGY

Materials

River sludge

The river sludge samples were sourced from Saga Prefecture, Japan. After collection, the sludge was air-dried for three weeks and passed through a 200 µm sieve to prepare it for laboratory testing. Soil classification was performed using sieve and hydrometer analyses, along with liquid and plastic limit tests. The sludge exhibited liquid and plastic limits of 62.31% and 52.27%, respectively. According to the AASHTO classification system, the material was classified as A-2-5(0), indicating a silty and clayey gravelly sand. All procedures adhered to the Japan Industrial Standards (JIS), specifically JIS A 1204 for particle size distribution and JIS A 1205 for Atterberg limits [16].

Binder materials

Two additives-rice husk ash (RHA) and ordinary Portland cement (OPC)-were employed to stabilize the river sludge. The RHA, containing 93.30% silica, was sourced from Make Integrated Technology Co., Ltd., Osaka, Japan. It was produced by incinerating rice husks for 27 hours in a computer-controlled furnace at temperatures ranging from 650 to 700°C, resulting in a high silica content. The RHA particle sizes ranged from 0.07 to 0.3 mm.

OPC was added in small amounts to act as a supplementary binder by providing calcium oxide ions that promote pozzolanic reactions. Its physical and chemical properties are also detailed in Table 1. The combined use of these additives was intended to improve both the geotechnical performance and microstructural integrity of the stabilized river sludge composites.

Methodology

Consolidation behavior testing

River sludge (200 g) was mixed with rice husk ash (5%, 10%, 15%) and cement (2%, 4%, 6%) by dry weight. Water content was adjusted to just below the liquid limit (50.5%–58%) to optimize handling and mimic natural conditions. The mixtures were blended, shaped into 30 mm thick cylinders, and equilibrated for 24 hours before trimming to 60 mm diameter and 20 mm height.

Figure 1 illustrates a step-by-step outline of specimen preparation for all 16 combinations, following the Japan Industrial Standards (JIS). Filter papers were placed to prevent clogging during consolidation testing. Samples underwent incremental loading from 9.8 to 1256 kPa and stepwise unloading, each stage lasting 24 hours to ensure complete consolidation. Settlement was monitored continuously using an LVDT system over 16 days. After testing, specimens were dried for final moisture content, and samples were taken for SEM analysis.

Microstructural analysis

A detailed microstructural and mineralogical investigation of the RS-RHA-C composites was performed using Scanning Electron Microscopy (SEM), Energy-Dispersive X-ray Spectroscopy (EDS), and X-ray Diffraction (XRD). SEM provided high-resolution images of particle arrangement, pore structure, and cementitious bonding by examining polished, gold-coated specimens. EDS analysis identified elemental compositions, revealing the

formation of key hydration products like calcium silicate hydrate (C-S-H) and calcium aluminosilicate hydrate (C-A-S-H), which enhance soil stabilization. XRD was used to detect mineralogical changes and crystalline phases induced by the additives. Together, these techniques offered comprehensive insights into the microstructural evolution and chemical interactions within the composites, supporting improved consolidation and durability in geotechnical applications.

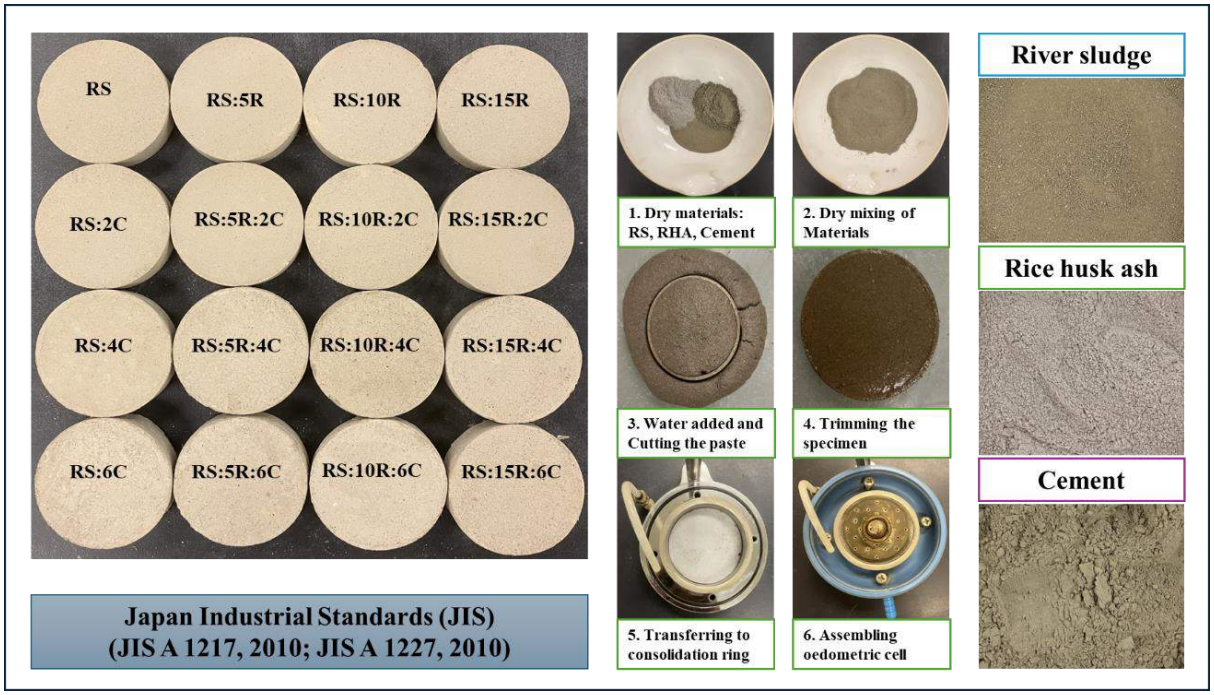

Fig.1 Comprehensive specimen preparation procedure with constituent materials and oedometer cell configuration

RESULTS AND DISCUSSIONS

Geotechnical Analysis

The conditions of the specimens before and after consolidation are presented in Table 1, along with their corresponding statistical descriptions.

The stabilized specimens showed an average saturation of 94.54%, with mean void ratio and wet density values of 1.21 and 1.51 g/cm³, respectively. Low standard deviations confirmed uniform specimen preparation and test consistency. Interestingly, saturation exceeded 100% in some mixes (RS:4C, RS:5R:2C, RS:10R:2C), likely due to the influence of RHA and cement on pore structure and water retention. This behavior may enhance microstructural bonding but also suggests the need to consider specific gravity changes, hydration effects, and possible air entrapment when interpreting consolidation results.

In one-dimensional consolidation, soil undergoes time-dependent deformation under an applied load, leading to the gradual dissipation of excess pore water pressure. According to consolidation theory, key assumptions include soil linear elasticity, incompressibility of soil grains and water, vertical loading, one-dimensional drainage, and constant consolidation parameters.

The time-displacement trends revealed that at low pressures, the transition between primary and secondary consolidation was subtle, but became more distinct as pressure increased. Using the log-time method [17], T50 − the time for 50% primary consolidation- was determined. An increase in RHA content from 5% to 15% resulted in a noticeable reduction in T50, indicating faster consolidation under constant stress, consistent with previous studies. Additionally, RHA-cement-stabilized specimens showed shorter T50 durations at higher pressures, reflecting improved consolidation behavior and reduced settlement delays. These results highlight the effectiveness of RHA and cement in accelerating the consolidation process and enhancing soil stability.

The permeability coefficient (k) of the stabilized specimens ranged between 10^{-10} and 10^{-9} m/s and was strongly influenced by consolidation pressure. An initial rise in k was observed during the pre-yield stage, followed by a marked reduction in the post-yield phase across all samples. Permeability tended to increase with higher RHA content, likely due to the porous nature of RHA introducing more voids into the soil structure. In contrast, specimens with moderate RHA and cement content showed lower permeability, as pozzolanic reactions promoted

effective bonding and reduced pore spaces. The 10% RHA with 6% cement mix demonstrated particularly efficient permeability control, aligning with trends reported in earlier studies.

With increased consolidation pressure, the permeability coefficient gradually decreased and stabilized around 10^{-10} m/s for all specimens. This reduction reflects the densification of the soil-RHA-cement matrix due to void elimination and improved particle arrangement. The strong correlation between void ratio and permeability confirms that voids are the primary factor influencing water flow, consistent with previous findings by Cheng, X., Huang, H., Li, R., Pu, X., Huang, W., & Yuan, X. [18]. Additionally, the influence of RHA content on permeability diminished beyond a certain threshold, indicating that high RHA percentages may stabilize the permeability response under varying pressures. This understanding is useful for predicting field performance of stabilized soils.

Table 1 Statistical summary of the specimen conditions during consolidation

Description (Unit)	Specimen number	Mean	Standard deviation	Coefficient of variation	Mean absolute deviation	Maximum	Minimum
Initial moisture content (%)	16	53.18	3.87	0.07287	3.24578	59.84	48.67
Final moisture content (%)	16	51.84	4.01	0.0775	3.42818	58.01	45.83
Void ratio	16	1.21	0.12	0.10295	0.09535	1.43	0.97
Wet density (g/cm^3)	16	1.51	0.06	0.03996	0.04462	1.64	1.40
Saturation (%)	16	94.54	6.19	0.06551	5.17194	105.82	84.91

Microstructural Analysis

Figure 2 presents SEM images showing significant microstructural improvements in the stabilized specimens. The RS:10RHA:6C composite exhibited a dense, well-bonded matrix with reduced pore spaces and strong interparticle bonding, suggesting active pozzolanic reactions. In contrast, other combinations exhibited a more porous structure due to the presence of unreacted RHA, resulting in weaker bonding and higher compressibility. EDS analysis confirmed the presence of key elements such as Ca, Si, and Al, indicating the formation of cementitious compounds like C-S-H and C-A-S-H.

XRD results (Figure 3) further supported these findings, identifying mineral phases associated with hydration, including portlandite and other reaction products. These results align with the consolidation behavior observed, confirming that moderate RHA-cement ratios enhance structural integrity, while excessive RHA reduces pozzolanic efficiency.

CONCLUSIONS

This study investigated the consolidation behavior of river sludge stabilized with varying ratios of rice husk ash (RHA) and cement through oedometer testing and microstructural analysis. The results showed that the inclusion of RHA and cement significantly influenced consolidation parameters, with the RS:10RHA:6C mix offering the most favorable performance. This composition exhibited the lowest coefficient of consolidation and permeability due to the formation of a dense, well-bonded matrix, attributed to pozzolanic reactions between RHA and cement.

While the coefficient of volume change was more dependent on applied pressure than composition, stabilized specimens consistently demonstrated reduced compressibility compared to untreated sludge. SEM, EDS, and XRD analyses supported these findings by revealing the development of compact cementitious networks in optimized mixes, while excess RHA led to unreacted particles and increased porosity. Empirical equations were developed to predict key consolidation parameters, offering a useful reference for similar stabilization efforts, though further validation is needed.

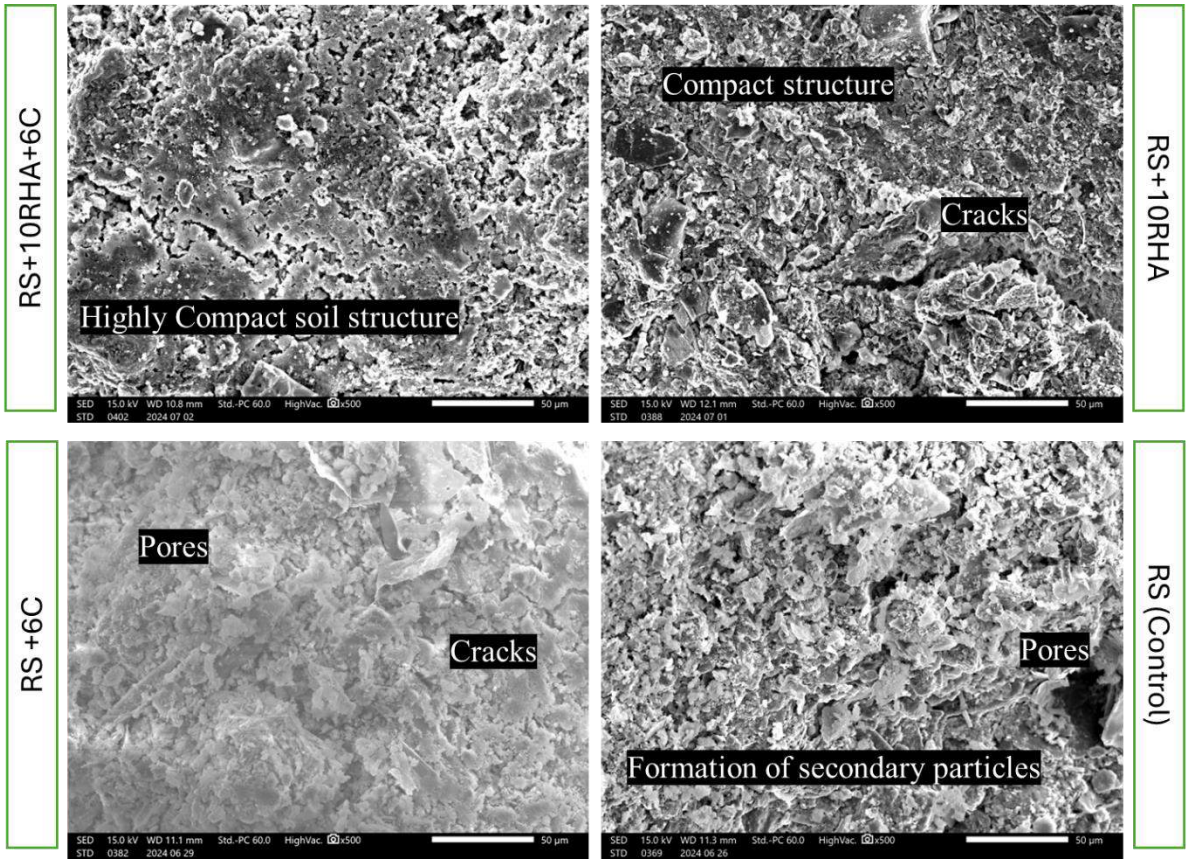

Fig.2 SEM images of RS and stabilized composites with varying RHA and cement content

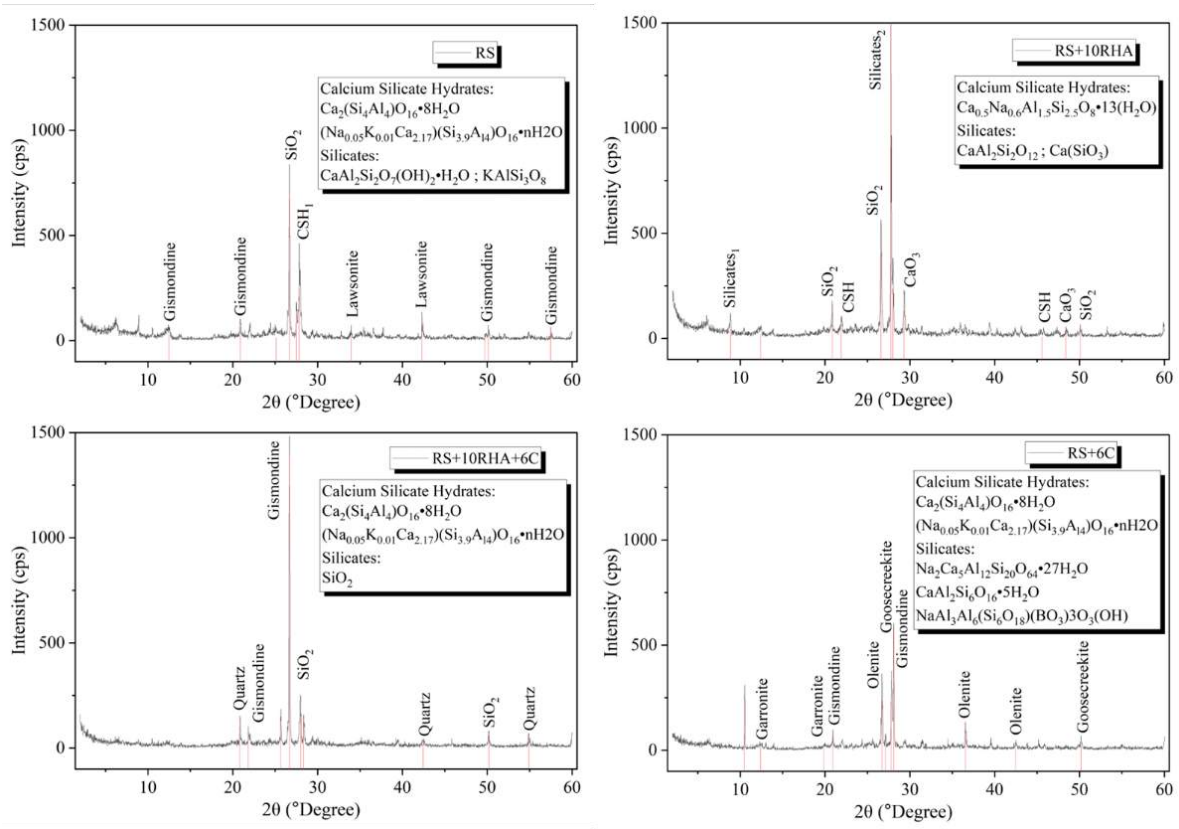

Fig.3 XRD patterns of RS and stabilized composites with varying RHA and cement content

Although commercial RHA was used in this study, the findings underscore the potential of using natural RHA as a low-carbon stabilizer, promoting sustainable practices in geotechnical engineering. Further research is encouraged to evaluate long-term durability, field-scale application, and the efficiency of natural RHA in diverse soil conditions.

ACKNOWLEDGMENTS

The authors extend their sincere appreciation to the Japan Ministry of Education, Culture, Sports, Science, and Technology (MEXT) for awarding the MEXT scholarship, which facilitated the completion of this research at Mie University.

RELIABILITY ANALYSIS OF DAMPALIT MEGA DIKE USING MONTE CARLO SIMULATION AGAINST SLIDING FAILURE

Isaiah Sam Bartolome[1] and Albert Griño, Jr [1]

[1]Faculty, Adamson University, Philippines

ABSTRACT

The main purpose of coastal defenses is to mitigate the effects of an increased rise in sea levels and the abrupt changes in storm surges brought about by various uncertainties. Evaluation of the Dampalit Mega Dike's resistance against sliding failure using Reliability Analysis provides an avenue for considering these uncertainties that would affect the structural safety of the dike. In this study, random variables, including the angle of friction, water level, and wind speed, were considered as the parameters in determining the dikes' probability of failure. Wave action and storm surges were considered, which were vital since these would greatly affect the resistance of the dike. A deterministic approach was initially performed using PLAXIS 2D to compare the conventional design and analysis with a probabilistic approach. For the probabilistic method, both serviceability (SLS) and ultimate limit states (ULS) were evaluated with 100,000 iterations using Monte Carlo Simulation, wherein results show a probability of failure of 0.54 for SLS and 0.86 for ULS. The significant deviation from the acceptable value of x 10^{-3} to the computed values highlights a potentially critical issue in the structural system or the underlying assumptions used in the analysis. A high risk of failure in terms of sliding was concluded; however, biases were observed in the data since no correlations were found between the variables. Moreover, to increase the soil stability of the dike, an additional embankment on the seaward side was recommended to improve the resistance against sliding failure of the dike.

Keywords: Reliability analysis, Storm Surge, Monte Carlo Simulation, Probability of failure, Dike

INTRODUCTION

The rise of sea levels contributes to the increase in flooding, especially in Asian deltaic cities, which include Ho Chih Minh City, Jakarta, Tokyo, and Manila. Exposure to tropical cyclones, excessive groundwater extraction, and rapid urbanization leads to elevated flood levels, affecting the city's socioeconomic development. By 2100, the global mean sea level will rise to 2.92 m. This will affect about 150 – 250 million people, especially those living near coastal areas and low-elevation areas [1]. According to the National Integrated Climate Change Database and Information Exchange System, or NCCDIES (2024), the Philippines is experiencing an exceptionally high rate of sea level rise of 60 centimeters, which is roughly three times faster than the global average of 19 centimeters, which puts 13.6 million Filipinos at risk. Climate models provide a range of predictions for future sea level rise, reflecting different greenhouse gas emission trajectories.

The city of Manila in the Philippines is considered one of the most vulnerable megacities in Southeast Asia in terms of the rapid rise in sea levels. The Dampalit Mega Dike, which is located in Barangay Dampalit, Malabon City, is an 8.6-kilometer mega dike that was constructed for the protection against flooding of the surrounding areas [2]. The Dampalit Mega Dike is important for Malabon's safety and economy. Failure could lead to widespread flooding, endangering lives and disrupting the economy.

Uncertainties are dominantly present in every structure constructed, and these affect its overall function. In the Philippines, the design of numerous structures, including flood defenses, was mainly based on a deterministic approach, which only considers normal ranges based on structural codes. The problem with a purely deterministic designed structure is that the data is gathered under various environmental and material conditions, including imposed loads and material properties. The utilization of statistics and probability in the design of the structure is beneficial in considering the uncertainties that are present in the location [3].

RESEARCH SIGNIFICANCE

The relevant information of this study would help benefit local government authorities and community stakeholders as they contribute to informed decision-making, policy formulation, and the overall resilience of Manila Bay Coastal Defenses. The present study's outcomes would assist LGUs in identifying gaps and challenges inherent in their existing risk management practices. It provides insights into how risk management strategies in Manila City and neighboring areas can be effective. This study can serve as a valuable reference for establishing performance functions that address serviceability and ultimate limit states for sliding of sea dikes.

LITERATURE REVIEW

Probabilistic structural analysis is defined as the art of formulating mathematical models wherein one can acquire results concerning the probability of a structure behaving in a definite manner through calculations. It involves analyzing the behavior of a structure using random material properties and the effect of an external factor on the stability of a structure with random or incomplete known properties [4]. Reliability analysis provides an advanced and more accurate calculation of structures since safety factors from the deterministic method more often than not offer a safety margin that is relatively not 100% safe due to the effects of uncertainties [5].

Random Variables

The presence of uncertainties in various parameters used in the conventional design and analysis contributes to the difficulty in providing a safe and resilient structure through a deterministic approach [6]. This is why establishing a reasonable basis is beneficial, as it provides a means of assessment that can be fulfilled through the evaluation of its reliability and probability of failure. Failure does not always mean losing the function of a structure; rather, it signifies that the structure does not meet the expectations based on its design.

For this study, the random variables considered were based on the primary phenomenon of sliding failure and the effects of storm surges on the dike. The random variables chosen for this study include the sea level h, angle of friction ϕ, and wind speed V_s. These random variables were evaluated since these are where uncertainties can be readily observed, and abrupt changes in these factors can contribute to the overall safety of the dike [7]. Furthermore, since the location of the structure under consideration is near a flood-risk area, the sudden changes in sea levels will affect its stability to some extent. Since the main concern of this study is the strength, it is best to provide an assessment of the present situation of the Dampalit Mega Dike using reliability analysis.

Loads and Forces

According to the National Structural Code of the Philippines (2015), the dead load includes the permanent self-weight of a structure and its installed utilities, such as in the case of a mega dike, while live loads account for temporary loads like human occupancy and vehicles. Dikes are subject to various lateral and vertical forces such as earth pressure—governed by Rankine's and Coulomb's theories—hydrostatic pressure, wave forces [9,10], and storm surge [11,12] loads, all of which require careful consideration in structural design. These forces, which include dynamic factors like wave impact and storm surge elevation, must be properly accounted for to ensure the stability and effectiveness of the dike structure.

Performance Function

The performance function or limit state function $g(X)$ is an expression used to identify the safe and unsafe zones for R (resistance of the structure) and S (load on the structure). Structural conditions are set to provide a depth analysis of the performance function based on the established random variables. Two structural conditions will be considered for this study, namely the Serviceability Limit State (SLS) and the Ultimate Limit State (ULS). SLS describes that the failure of the structure is based on the serviceability loss, which doesn't imply a valuable impact on the overall safety of the structure. On the other hand, the ULS dwells more on the structural integrity and safety of the structure, which may eventually lead to complete failure [13].

Monte Carlo Simulation

Simulations governing both systems of physical and mathematical relations are the main objective of Monte Carlo Simulation. The Monte Carlo Simulation or Monte Carlo Method involves the generation of random events through a computer model wherein the procedure is done multiple times. The occurrence number for a specific condition set by the researcher is then counted and recorded.

The probability of failure of the system can be calculated through the integration of the random variables in a performance function. In some instances, it would be hard to determine the probability of failure through analytical methods since some boundaries of the integral are not known. The use of reliability methods, specifically Monte Carlo Simulation, is more applicable for data sets that are relatively small [14].

The Monte Carlo Simulation is a highly regarded statistical technique that assists organizations in effectively managing risk and making informed decisions when faced with uncertain situations. This powerful tool can be utilized in disaster risk management by simulating a significant number of random variables to analyze the potential outcomes of a complex system. By generating a comprehensive set of individual realizations of sea level time series, decision-makers can leverage descriptive statistics to understand the probability and consequences of disasters. As a result, they can implement more effective risk management strategies [15].

METHODOLOGY

This study utilizes various uncertainties that can

affect the structural integrity of the dike. This includes the effects of storm surges, which are not common in the design of the dike. The occurrence of uncertainties, which are determined through various historical data and reports, is used to determine the probability of failure due to sliding phenomena through the evaluation of the limit state equations using Monte Carlo Simulation.

Moreover, the evaluation of the Dampalit Mega Dike considers the effect of storm surge as the ultimate load that would affect the structure. The random variables that were considered are the angle of friction, sea level, and wind speed, and these are incorporated in the resistance and loads of each limit state equation. The values for these parameters were set based on the simulations performed on the data collected, and the results are used to calculate the probability of failure of the dike.

Data Gathering

The main sources of data for this study came from the geotechnical investigation report which was obtained from the Department of Public Works and Highways (DPWH), the sea level data which was requested from the local government of Dampalit, and the wind speed data were obtained from Philippine Atmospheric, Geophysical and Astronomical Services Administration (PAG-ASA).

Deterministic Method

In the Philippine setting, the common method used in the design of most buildings and infrastructures is governed by the use of a deterministic approach. This is through the use of various codes for design and analysis, which includes the NSCP and other codes vital in providing a safe and resilient structure. These codes were mostly based on theoretical analysis and experimental models in which several assumptions are made [16]. According to Skrzypezak, Slowik, and Buda-Ozog (2017), a purely deterministic approach cannot completely define the reliability and safety of a structure since it is mostly based on a single globally used factor and does not take into consideration the effects of uncertainties with regards to the load and strength assessments provided by the structure.

This study employed deterministic and probabilistic approaches to accurately represent the failure due to the sliding of the Dampalit Mega Dike. The study utilized PLAXIS 2D software for the structural analysis of the dike.

Probabilistic Method

Several parameters were not considered in the deterministic method; thus, it was difficult to provide an overall assessment of the safety of the dike. Therefore, reliability analysis must be done to assess the structure thoroughly. Random variables were viewed as the governing parameters in quantifying uncertainties and risks that a system would experience. The first step in determining the structure's probability of failure and reliability index was to identify the possible variables that would affect the overall safety [17].

In this study, pre-existing mathematical models were considered for the selected random variables wherein the angle of internal friction followed a log-normal distribution while both sea level and wind speed followed a Weibull distribution as presented in Table 1. The mean and coefficient of variation were derived from the data acquired, which were then used to determine the distributions by performing simulations using MATLAB.

Table 1 Distribution of random variables

Random Variable	Distribution	Mean, μ	Coefficient of Variation, *COV*
Angle of internal friction, ϕ	Log-normal	27.19°	0.001°
Sea level, h	Weibull	10.07 m	0.002 m
Wind speed, V_s	Weibull	2.87 m/s	0.198 m/s

Calculation of the probability of failure

This study considers the sliding failure mechanism's effect on the dike's safety with the impending rise of sea levels. The SLS and ULS equations for the sliding failure mechanism is defined in Eq. (8) and Eq. (9), respectively.

$$g(X) = F_k - (P_h + W_A + P) \quad (8)$$

$$g(x) = F_k - (P_h + W_A + P + S_L) \quad (9)$$

Where F_k is the sliding force or Law of Kinetic Friction derived from Amonton's and Coulomb's Law of Friction. The sliding force acted as the resistance of the dike; it was used for both the serviceability and ultimate limit state equations. The load for SLS was based on the summation of the applied loads on the structure which includes lateral earth pressure P_h, wave action W_A, and hydrostatic force P while for that of the ULS.

In relation to the factor of safety, the probability of failure can be defined as the probability where the factor of safety falls below 1.0 if there are adverse effects of certain variables present in the calculations [18] which is shown in Eq. (10).

$$Pf = P(S > R) \quad (10)$$

This study utilized 100,000 simulations for both the random variables and performance functions to be able to generate several data points. This would provide a good balance between obtaining increased

accuracy and calculation duration for the equations. Moreover, it has been a common practice to use 100,000 simulations in performing the Monte Carlo Simulation wherein larger numbers lean to a more statistically reliable result [19].

The results for both the deterministic and probabilistic methods would provide reliable results that would support the occurrence of failure on the dike. Determining the failure points of the dike using PLAXIS would provide the necessary results to attest to the decrease in safety in terms of sliding. Moreover, probabilistic methods using reliability analysis would present the probability of failure due to the presence of uncertainties in the environment.

RESULTS AND DISCUSSION

The initial results of the deterministic method using PLAXIS 2D, as seen in Fig. 1, show a significant displacement, mostly due to hydrostatic forces and lateral earth pressure applied on the dike. The red regions represent the failure points where increased values of hydrostatic forces can cause the displacement of the soil beneath the dike, leading to failure.

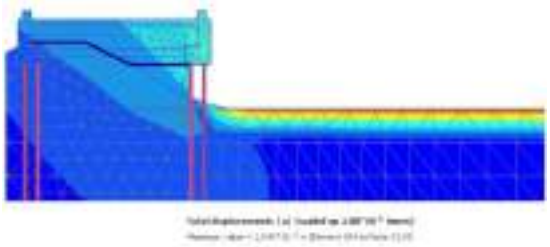

Fig. 1 Result of PLAXIS 2D analysis (total displacement of Dampalit Mega Dike)

Based on the results, there is an evident failure on the seaside of the dike where possible sliding is due to increased pressure brought by both hydrostatic and lateral earth forces on the structure. Lack of sufficient support or increased soil stability caused the structure to fail at that specific point, especially with the effects of storm surges, which can cause higher wave impact, which weakens the soil [20].

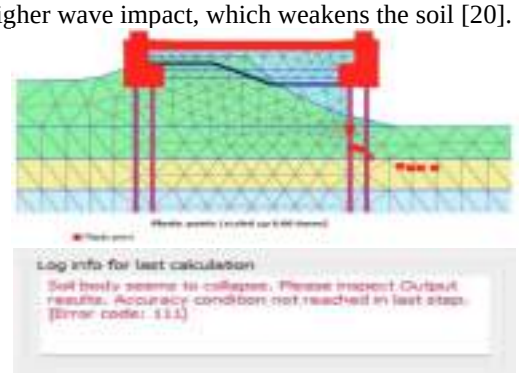

Fig. 2 Results of PLAXIS 2D (failure points)

Based on the results of PLAXIS 2D, the software indicates that the dike would slide by about 0.002045 meters or 2.045 mm. towards the seaside. PLAXIS 2D also indicated that the “soil body seems to collapse” as presented in Figure 10 which is due to the uplift pressure caused by the sea water causing instability in the bottom-right part of the dike. The steepness of the topography of the soil where station C0+040.00 is situated, the soil could not handle the weight and forces applied on the dike, which resulted in its sliding.

The gathered data for the angle of friction, wind speed, and water level were simulated 100,000 times to properly provide a reliable distribution which was utilized for the calculation of the probability of failure. It was important to identify the distribution of these random variables through their mean and coefficient of variance to be able to appropriately apply the right method of estimate for the performance functions.

The statistical parameters derived from the analysis were implemented in MATLAB, where custom-developed code facilitated simulations and probabilistic assessments. The methodology relied on the Monte Carlo Simulations, enabling a comprehensive evaluation of system performance by quantifying the effects of variability and uncertainty in the input parameters. This approach allowed for robust predictions of system behavior under diverse conditions and informed decision-making regarding soil-structure interaction and environmental considerations.

The probability of failure was calculated for each limit state equation and its corresponding resistance and loads. To provide an accurate result of the probability of failure in multiple occurrences presented by each simulated value of the random variables, 100,000 simulations were also done using Monte Carlo Simulation for both SLS and ULS. It must also be taken into account that the computation of the load combinations followed a modified loading combination since the National Structural Code of the Philippines does not have a specific section for dike structures.

Based on the results, it is evident that there is no direct correlation between resistance and the load. However, the probability of failure for both performance functions shows a significant value. Moreover, a change in the load would not affect the resistance of the dike since both acts independently of each other.

The probability of failure of the dike against sliding failure was calculated using 100,000 simulations with the equation $Pf = P(S > R)$ which is determined by a normal cumulative distribution that resulted in $Pf = 0.54$ for SLS and $Pf = 0.86$ for ULS. Based on the graph, the failure point for the resistance is determined to be at around 3.1 x

10^{-3} for both SLS and ULS, while that of the load is estimated to be around 1,300 kN of force.

Based on the results of both deterministic and probabilistic methods, it is evident that the water level, wind speed, and angle of friction would affect the dike's sliding resistance. These uncertainties would affect the overall stability of the Dampalit Mega Dike, especially with the capacity of the soil to prevent the sliding of the dike. Varying degrees of pressure brought by the hydrostatic force on the dike induce displacement of the soil where the dike is constructed.

According to Zhang, et al (2017), a great factor that affects the destabilization of a dike is the combined effects of normal hydrostatic force exerted by seawater and the increased shearing effect from overtopping flows. The abrupt increase and decrease in wave pressure affect the resistance of the dike, resulting in sliding and eventually failure. Coastal dikes are most vulnerable to drastic changes in hydrostatic and hydrodynamic loads.

The knowledge and understanding of wave loads and storm surges are typically not common [21]. Furthermore, overtopping waves in dikes are considered a detrimental threat to both properties and lives in coastal areas. The inclusion of a probabilistic method in the analysis of structures, especially with dikes, can provide a more conservative and resilient design.

The results for the probability of failure for SLS shows a value of 0.54 while that of the ULS shows a value of 0.86. Such a result suggests that the structure under consideration is highly unreliable and fails to meet the minimum safety requirements. Moreover, a result that shows an almost 100% failure is very unlikely, and certain parameters must be checked to ensure the viability of the results

According to Li and Yang (2023), the significant deviation from the acceptable value of $x10^{-3}$ to the computed value of 1.000000 highlights a potentially critical issue in the structural system or the underlying assumptions used in the analysis. This discrepancy may arise from inadequacies in design parameters, improper material properties, or unforeseen environmental loads. It underscores the necessity for an immediate reassessment of the design, including a comprehensive review of the input parameters, modeling assumptions, and boundary conditions.

These findings emphasize the critical importance of accurate reliability analysis in engineering design. The ability to detect such high probabilities of failure ensures that corrective measures can be implemented to prevent catastrophic outcomes. Future work should focus on refining the computational framework, validating input data, and exploring alternative design solutions to align with acceptable safety margins.

CONCLUSIONS

Based on the analysis conducted on the Dampalit Mega Dike, this study assessed the likelihood of failure due to sliding using both deterministic and probabilistic methods. The deterministic analysis carried out using PLAXIS 2D revealed that the dike would experience sliding with a minimal displacement of 0.002 meters under current conditions. The displacement was so minimal that it was nearly unnoticeable, suggesting that the structure remains functional under serviceability loads.

This indicates that, based on static loading conditions, the dike is still operational and capable of performing its intended function. However, the results of the probabilistic analysis, which included random variables such as angle of friction, water level, and wind speed, showed that the dike falls into a "failure zone" due to the combined effects of these uncertainties. Specifically, the probabilistic approach highlighted that the variability in environmental forces (wind speed and wave action) and soil properties can lead to an increased likelihood of failure.

In line with the study, the geotechnical report clearly shows pre-determined values and lacks actual results since there are few boreholes used for the geotechnical analysis of the soil where the dike was constructed. Although evidence of failure is prominent in the results of the study, further investigations should be made, especially with the soil parameters concerning the stability of the dike. Issues regarding the actual reports must be investigated to prevent loss of structural integrity on the part of the construction of dikes near bodies of water, since an increase in water pore pressure due to elevated water levels can affect the sliding failure, which in turn affects the dike [22].

DEBRIS FLOW CAUSED BY HEAVY RAINFALL IN NAGISO-TOWN IN NAGANO PREFECTURE IN JULY 2014

Naomasa Honda[1]

[1] Faculty of Regional Environment Science, Tokyo University of Agriculture, Japan

ABSTRACT

In 2014 in the Nashizawa basin in Nagiso-Town in Nagano Prefecture, a huge, devasting debris flow was caused by a heavy rainfall due to typhoon No.8. Based on effective rainfalls and rainfall index *R'*, we discuss the relationship between the rainfall characteristics and the debris flow occurrence. Judging from the results, the rain's influence before the debris flow occurrence remained as *R'* = around 50mm until just before the occurrence. A heavy amount of rain fell (70mm/h) and a debris flow occurred. Based on our debris flow runoff analysis, two check dams provided a debris flow control function. The debris flow might continue at slightly less than 20% of the sediment flux concentration at the valley's exit with earth flow characteristics. The flow directly continued in the curved section of the channel works and arrived at the Kizu River junction.

Keywords: Previous Prolonged Rainfall, Last Short Strong Rainfall, Effective Rainfall, Rainfall Index R', Debris Flow Runoff Analysis

INTRODUCTION

In Nagiso-Town in Nagano Prefecture, typhoon No. 8 caused heavy rainfall in July 2014, followed by a huge debris flow through the Nashizawa Valley. Concerning the characteristics of this debris flow occurrence, the hourly precipitation just before was smaller than the past maximum amount. On the other hand, the previous prolonged rainfall, which continued for 72hours before the event occurrence, was considerably large.

Generally, debris flow occurrences are affected by both the previous prolonged rainfalls and the most recent brief, strong one [1][2]. Clarifying such relations is critical for practically predicting debris flow occurrences and examining the timing of evaluation warnings and announcements by local governments.

For the debris flow generated in Nagiso-Town, in this paper, we discussed the relationship between the rainfall characteristics and debris flow occurrences, based on effective rainfalls and rainfall index *R'*. We also analyzed the debris flow runoff to specify such debris flow characteristics as flow depth, flow velocity, sediment flux concentration, and flow discharge along the river's path.

METHOD AND PROCEDURE FOR STUDY

Outline of debris flow disaster

In the Nashizawa Valley in Nagiso-Town (Fig. 1), a huge debris flow occurred at about 17:40 on July 9, 2014 due to heavy rainfall from typhoon No. 8 (Fig. 2(a)). During this debris flow, one person died, and many houses, buildings, and roads were damaged or destroyed. Railroad tracks also deluged [3].

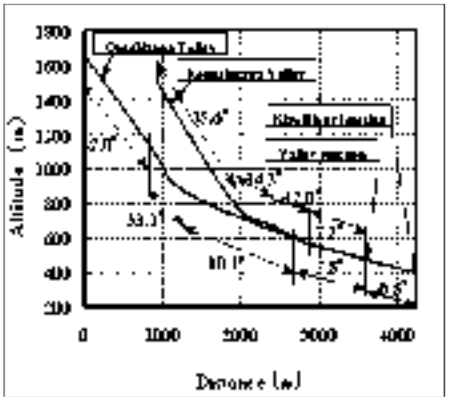
(a) Rainfall data: Nagiso rainfall gauging station



(b) Bed profile: Nashizawa Valley [3]

Fig.2 Rainfall data and bed profile: Nashizawa basin in July 2014

Figure 2(a) shows the observed rainfall data and the debris flow occurrence times at the nearest rainfall gauging station. Fig. 2(b) shows the river-bed profile in the Nashizawa Valley.

As shown in Fig.2(a), the hourly precipitation just before the debris flow occurrence was 70mm. A localized, heavy amount rain fell near Mt. Nagiso, but it didn't exceed 89mm/h, which was the previous maximum amount recorded at the Nagiso rainfall gauging station.

On the other hand, 111.5mm of precipitation continued for 72hours before the event occurrence. This amount is considerably larger than any previous prolonged rainfall; since the mountain slope held too much water, it was susceptible to a sediment-related disaster. The debris flow occurred approximately two hours after the strong rainfall's start (88.5mm per 2 hours, Fig. 2(a)).

As shown in Fig. 2(b), the Nashizawa basin, which is on the side of the Kiso River basin, is comprised of the Ohnashizawa and Konashizawa Valleys that merge downstream and join the Kiso River. In the upper basin, which is the debris flow occurrence zone, the river-bed slope exceeds 30 degrees, and the surface geology is weak granite [4]. We assume unstable sediment deposits on the river-bed. In the Nashizawa basin, debris flows often occurred in the past and formed an alluvial fan downstream. The houses and buildings that were destroyed by this debris flow were also built on this alluvial fan.

The above inherent factors are characterized by the unstable bed sediment on the river-bed runoff with excessive water from the heavy rainfall and formed a debris flow. It flowed down while entraining the bed sediment in a flow process, and its size greatly increased. The debris flow traveled on the curved section of the channel works downstream and overflowed onto residential areas. The incline of the channel works downstream from the flooding's start spot ranged from about 7 to 8 degrees, and the flood area's gradient ranged from about 5 to 6 degrees. Since both values are relatively large, the debris flow arrived at the Kizu River which was approximately more than 300m downstream from the spot of the flooding's start.

Effective rainfall

Effective rainfall R_t is a standard value of debris flow occurrences that investigates the influence of previous rainfall. It is calculated by Eqs. (1) and (2) [1]:

$$R_t = r_t + \sum a_n r_{t-n} = r_t + a_1 r_{t-1} + \cdots + a_n r_{t-n} \quad (1)$$

$$a_n = 0.5^{n/T} \quad (2)$$

where t is time, r_t is its precipitation, a_n is the decrease coefficient, and T is the half-life. In this study, short-term effective rainfall is denoted by r_w, and long-term effective rainfall is denoted by R_w.

Rainfall index *R'*

Rainfall index R' is calculated by Eqs. (3) and (4) [5]:

$$R_{fw} = \sqrt{(R_1 - R_w)^2 + a^2 (r_1 - r_w)^2} \quad (3)$$

$$R' = R_{fw0} - R_{fw} \quad (4)$$

where R_{fw} is the long diameter of the oval, R_1 and r_1 are its central coordinates ($R_1 = ar_1$), R_{fw0} is a value for $R_w = r_w = 0$, and a is a coefficient that replaces an oval with a circle (Fig. 3).

r_w and R_w are calculated based on the observed rainfall data (Fig. 2). For T, 1.5 hours are generally applied for short-term effective rainfall, and 72 hours are applied for long-term effective rainfall. Therefore, we used them.

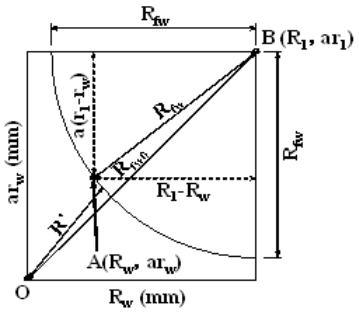


Fig.3 Diagram of rainfall index *R'*

R_1, r_1, and a (R_1=ar_1) are required for calculating *R'*. R_1 is given by the value of R_w (graph's cross axis) that can clearly express all the calculation results by a quadrant, and a is decided by the test calculations that produced R_1 and assumed a. In this study, R_1 is given by 600mm, and a is assumed to be 3, 4, and 5. Since a=3 most closely matches all the examples, we adopted the following values: a=3, R_1=600mm, and r_1=200mm.

Debris flow runoff analysis

Governing equations for debris flow

The following are the mass conservation equations for the flow mixture and for sediment alone:

$$\frac{\partial h}{\partial t}+\frac{1}{B}\frac{\partial Bvh}{\partial x}=\frac{E}{c_*} \tag{5}$$

$$\frac{\partial \varepsilon ch}{\partial t}+\frac{1}{B}\frac{\partial \varepsilon cBvh}{\partial x}=E \tag{6}$$

where t is the time, x is the coordinate axis along the flow, h is the flow depth, B is the flow width, v is the flow velocity, E is the erosion velocity (its negative value designates the deposition), c is the sediment concentration by volume, ε is the correction factor (see Egashira et al. [6], where $\varepsilon c = c_t$, c_t is the sediment flux concentration), and c_* is the sediment concentration of the river-bed layer.

The following is the momentum conservation equation:

$$\frac{\partial v}{\partial t}+v\frac{\partial v}{\partial x}=g\sin\theta-\frac{1}{\rho_m h}\frac{\partial P}{\partial x}-\frac{vE}{c_* h}-\frac{\tau_b}{\rho_m h} \tag{7}$$

$$\rho_m=(\sigma-\rho)c+\rho \tag{8}$$

The second term on the right-hand side in Eq. (7) is the pressure gradient and the third term is the resistance due to the sediment erosion. g is the gravity acceleration, θ is the river-bed slope, P is the pressure, τ_b is the river-bed shear stress, ρ_m is the mass density of the flow mixture defined by Eq. (4), σ is the mass density of the gravel, and ρ is the mass density of the water.

The following is the mass conservation equation of the river-bed sediment:

$$\frac{\partial Z_b}{\partial t}=-\frac{E}{c_*\cos\theta} \tag{9}$$

$$\theta=\sin^{-1}\left(-\frac{\partial Z_b}{\partial x}\right) \tag{10}$$

where Z_b is the river-bed elevation, and θ is expressed by Eq. (10).

Even though E and τ_b play critical roles in the above governing equations, no general formulas have been developed for them. We used the formulas for E and τ_b developed by Egashira [7], [8]. The following is erosion velocity E:

$$\frac{E}{v}=c_*\tan(\theta-\theta_e) \tag{11}$$

$$\theta_e=\tan^{-1}\left\{\frac{(\sigma/\rho-1)c}{(\sigma/\rho-1)c+1}\tan\phi_s\right\} \tag{12}$$

where θ_e is the equilibrium river-bed slope corresponding to the sediment concentration defined by Eq. (12) and ϕ_s is the internal friction angle of the sediment.

The following is the formula for τ_b, developed by Egashira et al. [9]:

$$\tau_b=\tau_y+\rho f v^2 \tag{13}$$

$$\tau_y=\left(\frac{c}{c_*}\right)^{1/5}\rho(\sigma/\rho-1)cgh\cos\theta\tan\phi_s \tag{14}$$

$$f=\frac{25}{4}\left\{k_f\frac{(1-c)^{5/3}}{c^{2/3}}+k_g\frac{\sigma}{\rho}(1-e^2)c^{2/3}\right\}\left(\frac{h}{d}\right)^{-2} \tag{15}$$

In Eq. (13), τ_y is the yield stress caused by the particle-to-particle contacts defined by Eq. (14), and f is the friction factor defined by Eq. (15), where e is the restitution coefficient, d is the reference grain size, and k_f and k_g are the following coefficients: k_f =0.16, k_g =0.0828.

River conditions

We analyzed the 4,240m long river reach of the Ohnashizawa Valley that ranges from 400 to 1660m above sea level (from its upper spot to the Kizu River junction, Fig. 2(b)). The river-bed and river-width profiles are shown in Fig. 4. In this reach, two check dams are located downstream [3].

Based on the analytical result of the vibration wave pattern of the debris flow provided by a seismic observation meter installed at the Kizu River junction, we assumed that the peak flow discharge occurrence time of the Konashizawa Valley was different from that of the Ohnashizawa Valley [3]. Therefore, in this paper, we ignored the inflow of the debris flow from the Konashizawa Valley to the Ohnashizawa Valley.

Bed material entrainment conditions

We have no hillside landslide data at the upstream reach or any river-bed erosion data throughout it. So we assume that the sediment is mainly supplied by river-bed erosion and estimate that the critical erosion depth of the bed material equaled 2.0m based on the previous field survey results [3].

Water supply conditions

We also have no runoff data upstream. But if a little water is supplied and the bed sediment (which is basically in saturated soil state) begins to move, it is sufficient for a numerical simulation. We constantly supplied 0.10m^3/sec as the inflow water discharge at the upstream boundary and assumed for convenience that sediment concentration c_{in} is 5 % by volume.

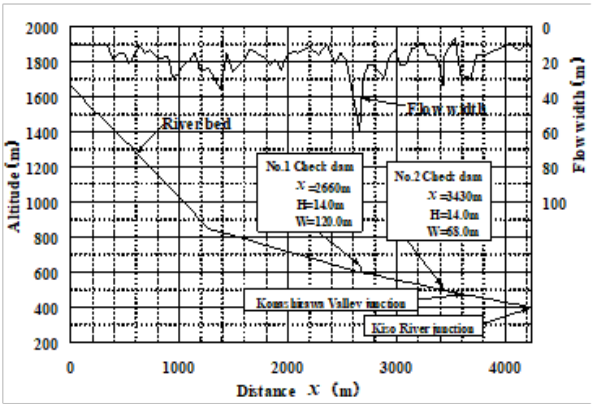

Fig.4 Bed profile and flow width of Onashizawa Valley

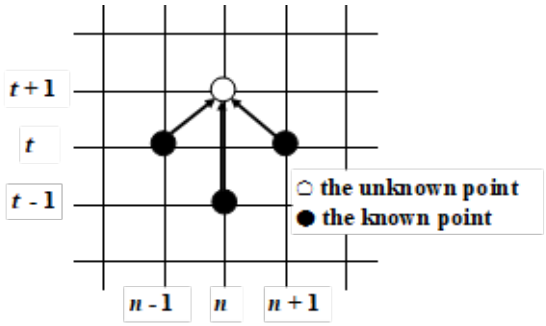

Fig. 5 Schematic diagram of leap-frog scheme

Physical conditions of sediment

The following parameters are required for computation: σ= 2.70g/cm^3, ϕ_s = 39.0degrees, d= 5.0cm, and c_*= 0.50.

Relationship between water density and fine sand concentration in water

The fine sand concentration in water, c_s, is closely related to a rise in the water's density (muddy water). Because such a rise increases buoyancy, our analysis cannot ignore its influence [10]. When we assume that c_s equals 10%, ρ is calculated by Eq. (8) as follows: ρ =1.17g/cm^3 (c_s = 10%)

Numerical analytical conditions

We used the finite difference method (leap-frog scheme in Fig. 5). The time and distance are discriminated as Δt=0.025 seconds and Δx=5.0m, respectively.

RESULTS AND DISCUSSIONS

Relationship between rainfall characteristics and debris flow occurrence

Figure 2(a) shows the calculation results of R_w, r_w, and R' that were determined by precipitation per hour r. The precipitation, which was the previous continued rainfall, began to fall at 18:00 on July 6 and stopped at 20:00 on the next day. A rainless state continued for 26 hours until 22:00 on July 8, though a mere 0.5mm did fall at 18:00.

When we focused on R_w in Fig. 2(a), we confirmed that the influence of the previous prolonged rainfall remained as of 22:00 on July 8. When we looked at R', which included the influences of r_w and R_w, we also confirmed that it equaled around 40mm. It began to rain again at 22:00 on July 8 and stopped at 3:00 on the next morning; a rainless state continued for 12 hours until 15:00 on July 9.

But as shown by R' in Fig. 2(a), the influence of the previous prolonged rainfall remained as R' = around 50mm as of 15:00 on July 9, which was 69hours after the rainfall began at 18:00 on July 6 and just before the debris flow occurrence at 17:40 on July 9. Consequently, the huge debris flow occurred approximately two hours after the final, short strong rainfall's start, which was 88.5mm per 2hours, and although it was smaller than the previous maximum rate.

Debris flow runoff characteristics

Figure 6 shows the temporal changes of the bed elevation near two check dams after 600 seconds with

the water supply. Two check dams deposited sediment at their storage areas, softened the river-bed slopes, and controlled the debris flow's power. The river-bed erosion immediately downstream of the check dam was caused by overflow from the dam.

Figures 7(a), (b), (c), and (d) show the temporal changes of such debris flow characteristics as flow, depth, flow velocity, sediment flux concentration by volume, and flow discharge.

As shown in Figs. 7(a) and (d), the debris flow traveled down and increased its scale with entrainment of the river-bed material, and the flow depth and discharge became maximum near x=2,000m. In addition, the flow discharge decreased downstream of the dams (x= 2,700m and 3,500m) and we confirmed that the check dams controlled the debris flow's power.

As shown in Fig. 7(c), the sediment flux concentration was high from around 20 to nearly 50 % upstream and midstream from x= 1,000 to 2,000m. But it fell as the incline softened downstream.

The sediment flux concentration was around 14% at the Konashigawa Valley junction (x= 3,600m), and the sediment transport mode changed from a debris flow to an earth flow.

The x= 3,900m spot was equivalent to the curved section of the channel works (the flooding's start spot). As shown in Fig. 7(c), its sediment flux concentration was maintained by around 13% after 600 seconds with water supply.

At the x= 3,900m in Figs. 7(a), (b), and (d), the maximum flow depth was 3.3m, the maximum flow velocity was 4.5m/sec, and the maximum flow discharge was 176m^3/sec. Based on previous field survey results [3], the mean flow depth was 3.4m, the mean flow velocity was 6.5m/sec, and the mean flow discharge was 196m^3/sec. Thus, a comparison of our numerical results with field survey results showed relatively good agreement.

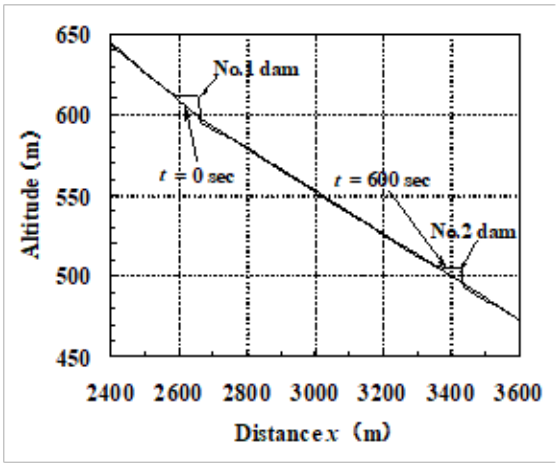

Fig.6 Temporal changes of bed elevation: Onashizawa Valley

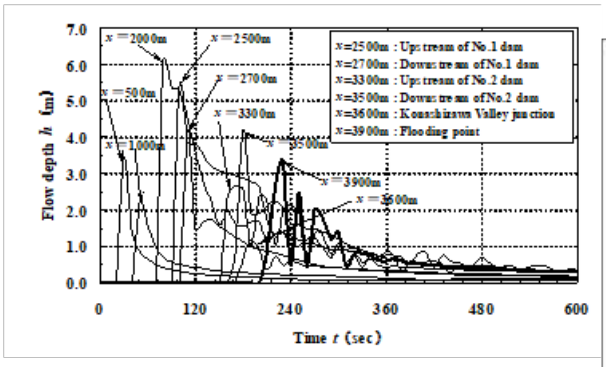
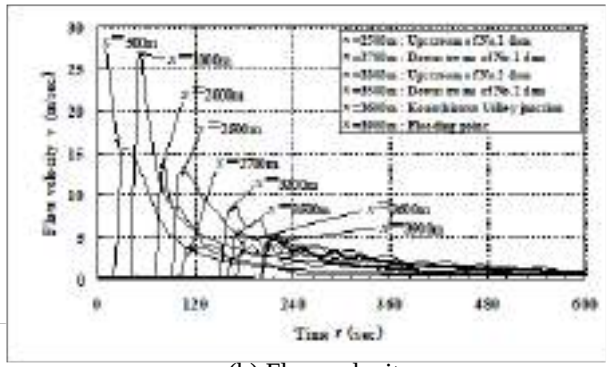
CONCLUSION

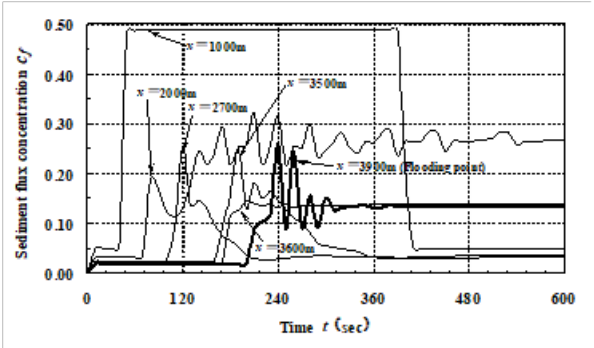
We discussed the relationship between the rainfall characteristics and a debris flow occurrence, based on effective rainfalls and the rainfall index R'. In addition,



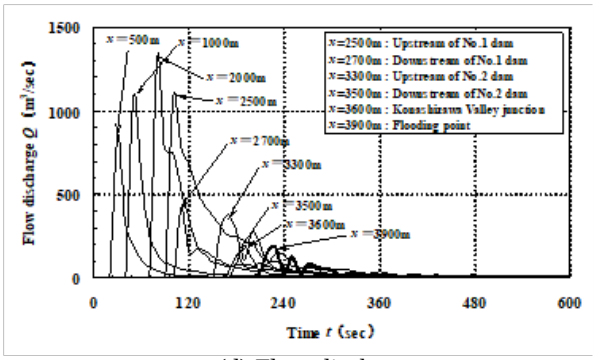
(a) Flow depth



(b) Flow velocity



(c) Sediment flux concentration



(d) Flow discharge

Fig. 7 Temporal changes of debris flow characteristics value: Onashizawa Valley

we analyzed a debris flow runoff to identify the debris flow characteristics along the river's path and obtained the following interesting results.

(1) The influence of the previous prolonged rainfall remained as *R'* = around 50mm just before the debris flow occurrence. Consequently, a huge debris flow occurred approximately two hours after a final, short strong rainfall's start, although it was smaller than the previous maximum scale.

(2) Two check dams deposited sediment in their storage areas and softened the river-bed slopes. The flow discharge decreased downstream of the dams, and we confirmed that the check dams controlled the debris flow's power.

(3) The sediment flux concentration was high from around 20 to nearly 50% upstream and midstream, but it fell downstream as the incline became softer. The sediment flux concentration was around 14% at the Konashigawa Valley junction, and the sediment transport mode changed from a debris flow to an earth flow.

(4) Rainfall index *R'* is very useful for judging the risk of debris flow occurrences and examining the timing of such emergency warnings as evaluation announcements from local governments.

(5) Our proposed numerical simulation of debris flow can reproduce the actual sediment runoff processes in a mountain torrent where such sabo facilities as check dams and channel works are constructed. Predicting sediment runoff characteristics yields valuable results for the evaluation of debris flow control with sabo facilities.

EFFECT OF RICE HUSK ASH AS A PARTIAL CEMENT REPLACEMENT ON STRENGTH OF SUBBASE

Chotikan Ratchakrom[1], Pisut Rodvinij[1], Sattaya Chaiwithee[2] and Pitiwat Wattanachai[2]

[1]Faculty of Engineering, Rajamangala University of Technology Lanna, Thailand; [2]Faculty of Engineering, Chiang Mai University, Thailand

ABSTRACT

Lateritic soil is used as a construction material for road subbase in Thailand. However, lateritic soil obtained from some areas still does not meet the required standards. Therefore, soil stabilization techniques are considered suitable for being economical and sustainable. This study focused on the utilization of rice husk ash (RHA) to improve the strength of subbase. Rice husk is one of the most abundant agricultural wastes and a major cause of air pollution problems in northern Thailand. Therefore, the utilization of rice husk ash can relieve waste management and air pollution. Rice husk ash in this study was burned in an oven at 600 °C for 3 hours and then mashed by ball mill grinding machine. Soil samples were mixed with cement at 3% by weight, and then RHA was used to replace cement in the mixture at 10%, 30%, 50% and 70% by weight. The samples were conducted on unconfined compressive strength tests and capillary rise tests to investigate the strength and water absorption of the improved soil. The results demonstrated that replacing cement with 10% RHA can enhance the strength of soil more than using cement alone at 28, and 56 days. However, when RHA was used to replace more than 10% of cement, the results showed that the strength tended to decrease as the proportion of RHA in the mixture increased. Moreover, soil mixed with 10% RHA as a replacement for cement showed a water absorption similar to soil mixed with 3% cement.

Keywords: Rice husk ash, Unconfined compressive strength, Cement replacement, Soil improvement, Subbase

INTRODUCTION

In Thailand, lateritic soil is widely used for building subbase in road construction. This is due to lateritic soil is abundant in Thailand and the price is low. However, it has become a realized problem because of poor-quality lateritic soil which has low compressive strength and durability. Lateritic soil obtained from some areas still does not meet the required standards. Moreover, rain infiltration or the water inundates of the subbase can cause road damage [1,2]. Therefore, soil stabilization techniques are considered suitable due to their economic and sustainable benefits. Soil stabilization refers to the treatment of soils to improve their strength and durability [3]. The most commonly used additive for soil stabilization is ordinary Portland cement. However, soil stabilization by using cement alone resulted in high construction costs. Therefore, the use of cement with by-product materials from industry or agriculture can be an alternative for soil stabilization at present. Therefore, replacing cement with high volumes of pozzolanic materials can improve the cost efficiency of subbase construction. Additionally, Portland cement's production is inherently carbon-intensive, generating substantial CO_2 per ton manufactured. Thus, replacing portions of the Portland cement with secondary cementitious materials in soil stabilization can reduce the overall environmental impact of the stabilization process [3]. This established method confirms that pozzolanic materials can effectively improve soil bearing capacity through stabilization [1,2,4]. However, the engineering properties of subbases improved with pozzolanic materials should be evaluated according to the requirements of Thailand's Department of Highways.

This study focused on replacing cement with rice husk ash to improve the strength of subbase materials. Rice husk is one of the most abundant agricultural wastes in Thailand [5], where approximately 21-26 million tons of rice are produced annually. Most rice husks are burned in the open air unless utilized otherwise. Such wasteful practice provides no benefits and instead causes significant environmental problems [6]. This contributes to increased PM2.5 levels, which is a major air pollution issue in northern of Thailand. However, utilizing biomass for power generation presents a viable solution. Using rice husks for power generation is a sensible strategy to reduce environmental damage and air pollution caused by open burning. Additionally, rice husk ash is produced as a by-product and can be repurposed for various applications. Due to its high silica content, rice husk ash can be used as an ingredient in industrial materials such as cement, and more [6].

When rice husk is properly burned at a temperature below 800 °C, rice husk ash (RHA) with a cellular microstructure and a high percentage of amorphous SiO_2 is produced [5]. The resulting RHA

is highly suitable for use as a pozzolanic material to enhance the compressive strength and durability of cement-based materials [7]. RHA can act as a source of excess SiO_2 to chemically reacting with $Ca(OH)_2$ to form additional calcium silicate hydrate (C-S-H), the primary strength-contributing compound in cement-based materials [5]. Additionally, a literature review demonstrated the potential of RHA as soil stabilization materials. The optimal amount of RHA in soil can enhance long-term strength [3]. The increase in the RHA content at specified cement content also improved UCS values with curing age [8]. Therefore, this study focused on replacing cement with RHA to improve subbase strength.

RESEARCH SIGNIFICANCE

This study examines the utilization of rice husk ash (RHA) to enhance soil strength for subbase construction while reducing the cement content. This approach leads to reduce environmental impact from the stabilization process. The research investigates the effects replacing 10-70% of cement with RHA on soil strength and water absorption properties. Rice husk ash in this study was burned in an oven at 600 °C. The strength of soil mixed with RHA was evaluated using unconfined compressive strength tests, while water absorption was measured through capillary rise tests. The finding demonstrated the optimal RHA replacement ratio for cement and RHA's effectiveness in developing soil strength.

MATERIALS AND METHODOLOGY

Lateritic Soil

The soil used in this study is lateritic soil from local areas in Chiang Mai, Thailand. The properties of the soil samples, including a particle size distribution, specific gravity, liquid limit, plastic limit, optimum moisture content and maximum dry density were investigated. The engineering properties of the soils were measured in accordance with the standard set by the Department of Highway (DOH), Thailand, for use as soil-cement subbase material [9].

The specific gravity of the soil samples was determined in accordance with ASTM D854 [10]. To analyze the particle size distribution, wet sieving tests and hydrometer tests were conducted following ASTM D422 [11]. Liquid limit and plastic limit tests were performed on soil samples passing through a 0.425 mm sieve, following ASTM D4318-00 [12]. Additionally, the optimum moisture content and maximum dry density of the soil were determined using modified Proctor compaction tests in accordance with ASTM 1557 [13].

Rice Husk Ash

The rice husk used in this study was collected from the Lanna Rice Research Center at Chiang Mai University. The rice husk was golden to light brown, with a curved and rigid shape and a rough surface. Its bulk density ranged between 100-150 kg/m^3. In this study, RHA was used as cement replacement material. A commercial type of Portland Cement (Type 1) was used as the base material.

To prepare the rice husk ash (RHA), rice husk was burned in an oven at 600 °c for 3 hours. Color of burning RHA illustrated blackish grey and whitish grey. The whitish grey color shows higher content of silica. However, blackish grey color shows high content of unburnt carbon. Subsequently, the RHA was mashed using a ball mill grinding machine for 90 minutes to achieve a particle size finer than 0.075 mm, as shown in Fig.1.

Fig.1 Burning rice husk ash and rice husk ash mashed ball mill grinding machine

Sample Preparation and Testing

Unconfined compressive strength (UCS) testing

The UCS tests were conducted in accordance with ASTM D1633 (Method A) [14] using cylindrical specimens measuring 101.6 mm in diameter and 116.4 mm in height. The soil samples were mixed with a binder at 3% by weight of soil in different ratio, as shown in Table 1. Ordinary Portland cement was partially replaced with RHA at 10%, 30%, 50%, and 70% by weight. The water content for each mixture was set at the soil's optimum moisture content.

The samples were compacted in five layers, with each layer compacted 25 blows from a 10 lb hammer to achieve modified compaction energy. After compaction, each sample was extruded from the mold and cured in a seal plastic bag to prevent moisture loss during the curing period of 7, 28 and 56 days. Prior to testing, the cured samples were soaked in the water for 2 hours and air-dried for 15 minutes. The samples were then subjected to compression testing to evaluate the strength improvement of the soil. The compressive strength values for each mixture represent the average of three specimens. The results demonstrate the potential of using agricultural wastes materials (RHA) as a partial cement replacement to enhance the strength of subbase materials.

Table 1 Mixture proportion of soil-cement-RHA

Mixture	Cement replacement by RHA (%)	Raw materials (g)		
		Soil	Cement	RHA
C3%	0	2700	81	0
RHA10	10	2700	72.9	8.1
RHA30	30	2700	56.7	24.3
RHA50	50	2700	40.5	40.5
RHA70	70	2700	24.3	56.7

Capillary Rise Testing

Capillary rise tests were conducted on the stabilized specimens to evaluate water absorption in the improved soil. The tests followed the Australian Standard AS1141.53 [15]. The specimen dimensions were identical to those used in the UCS tests.

The specimens were prepared using the modified compaction method and cured in seal plastic bag for 7 days, following the same procedure as the UCS sample preparation. Prior to testing, the specimens were oven- dried at 60 °C for 72 hours and air-cooled for 2 hours. Subsequently, the samples were partially submerged in a water container, maintaining a 10 mm water height for 72 hours. The capillary rise (increase in water height) was measured as shown in Figure 2. The reported water height for each mixture represents the average of three specimens. Height (h) of water rise from base of specimen was measured using a ruler and was recorded at various times. The capillary rise (CR) as a percentage of the specimen height (H) were determined as follows Eq. (1). The complete testing scheme for this study is presented in Table 2.

Fig.2 Capillary rise test conducted on specimens

$$CR = \frac{h \times 100}{H} \quad (1)$$

Table 2 Testing scheme

Properties	Tests	Moisture	Curing Time (days)
Compressive Strength	Unconfined compressive strength	OMC of soil	7, 28 and 56
Water absorption	Capillary rise test		7

RESULTS AND DISCUSSION

Engineering Properties of Lateritic Soil

Soil samples were tested for Atterberg limits test (liquid limit and plastic limit), particle size distribution (sieve analysis and hydrometer tests), and compaction characteristics (modified compaction test) to determine their engineering properties. The test results showed liquid limit, plastic limit, and plastic index values of 20%, 17%, and 3%, respectively. The particle size distribution of the soil samples is presented in Fig 3.

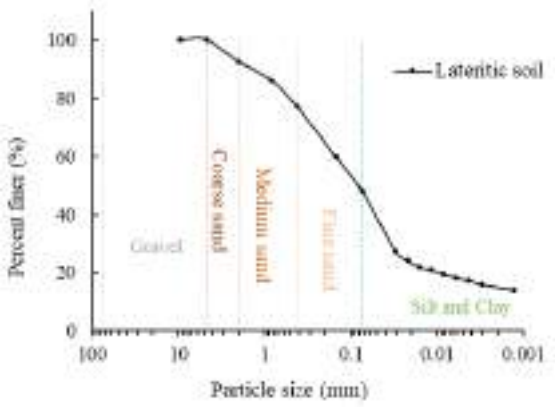

Fig.3 The particle size distribution of soil sample

The results indicated that 48% of the soil particles were finer than 0.075 mm. Based on these characteristics, the soil was classified as silty sand (SM) according to the Unified Soil Classification System (USCS). All tests were conducted in accordance with the standards specified by the Department of Highways (DOH), Thailand, for soil-cement subbase materials [9]. The complete test results are summarized in Table 3.

Table 3 The engineering properties of lateritic soils

Properties	Lateritic Soils	DOH Standard (Subbase Materials)
Specific gravity, G_s	2.65	Not specified
Liquid Limit, LL (%)	20	≤35
Plastic Limit, PL (%)	17	Not specified
Plastic Index, PI (%)	3	≤11
Passing No. 200 (%)	48	≤40

The results of modified compaction tests are shown in Fig 4. The compaction curve represents the relationship between dry density and moisture

contents of the soil samples in this study. The results demonstrated maximum dry density and optimum moisture content (OMC) of soil samples was 2,035 kg/m^3 and 10.2%, respectively. Consequently, the optimum moisture content of 10.2% was used for sample preparation in both unconfined compressive strength tests and capillary rise tests.

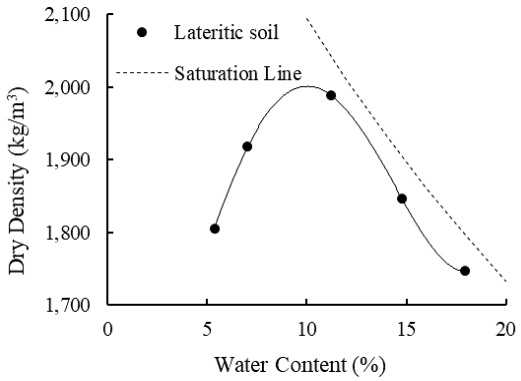

Fig.4 Compaction test results of soil sample

Unconfined Compressive Strength of Stabilized Soil

The UCS test results for stabilized soil are summarized in Table 4 and illustrated in Fig 5. The unconfined compressive strength of untreated soil was 427 kPa. The results demonstrated the soil strength increase with binder addition. Specimens with 10% RHA replacement demonstrated the highest strength at 28 days and 56 days curing periods, while 3% cement mixtures showed the highest strength at 7 days. According to DOH standards [9], the minimum required 7 days UCS for subbase applications is 689 kPa. The tested mixtures (C3%, RHA10, RHA30, and RHA50) all exceeded this requirement, with C3% showing particular effectiveness for early strength development.

The effect of RHA as a partial cement replacement on the strength development of the stabilized soil was considered, as shown in Fig. 6. The results demonstrated that the strength of the samples tended to decrease as the proportion of RHA in the mixture increased after 7 days of curing. This is due to the early strength of the soil mixed with cement results from the formation of primary cementitious compounds, such as C-S-H, which are generated by the hydration reaction between cement and water [16].

Additionally, Fig. 6 shows that replacing cement with 10% RHA can enhance long-term strength more effectively than using cement alone, as observed after 28, and 56 days of curing. The strength of the RHA10 mixture was approximately 19-22% higher than that of the C3% mixture. When RHA is incorporated into the mix, a pozzolanic reaction occurs, producing calcium silicate hydrates (CSH) and calcium aluminate hydrates (CAH), which results in increased soil strength [17]. However, when RHA was used to replace more than 10% of cement, the strength tended to decrease as the RHA proportion increased.

Table 4 Results of unconfined compressive strength test

Specimen symbol	Cement replacement by RHA (%)	UCS (kPa)			
		0 day	7 days	28 days	56 days
Soil	-	427	-	-	-
C3%	0		1,484	1,698	1,874
RHA10	10		1,398	2,078	2,238
RHA30	30	-	1,097	1,276	1,621
RHA50	50		1,033	1,212	1,446
RHA70	70		613	736	882

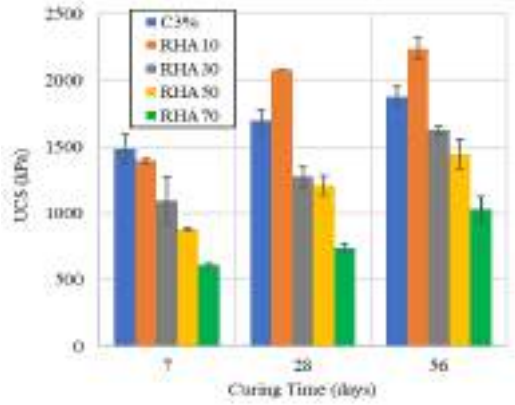

Fig.5 Unconfined compressive strength of stabilized soil

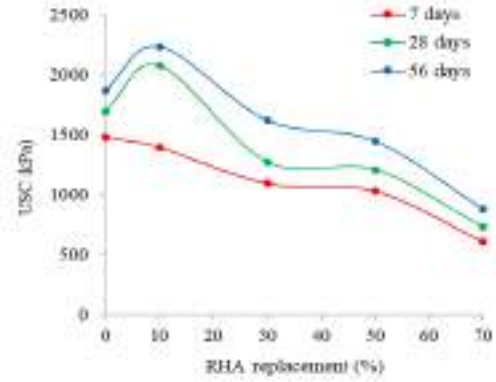

Fig.6 Effect of RHA as a partial cement replacement on unconfined compressive strength

Fig. 7 shows the strength increase rate of all the samples. The results demonstrated that RHA10 was the most effective in developing strength between 7 and 28 days, with an increase of approximately 49%. The strength increase rate of RHA10 was about 35%

higher than that of C3%. Thus, the results indicate that RHA is effective in enhancing the strength of stabilized soil after 7 days.

When considering the strength increase rate between 28 and 56 days, the results showed that replacing cement with 30% RHA (RHA30) was the most effective, achieving a strength increase of approximately 27%. Moreover, cement replacement with 30-70% RHA was more effective in developing long-term strength compared to RHA10. This suggests that RHA in the mixture triggers a pozzolanic reaction, leading to an increased long-term strength gain.

Overall, replacing cement with 10% RHA (RHA10) was the most effective for strength development, as evidenced by 60% strength increase rate observed over 7-56 days. In contrast, C3% showed only a 26% increase. Additionally, RHA30, RHA50, and RHA70 exhibited higher strength increase rates than C3%, further confirming the effectiveness of RHA in improving the long-term strength of stabilized soil.

	C3%	RHA10	RHA30	RHA50	RHA70
(7-28 days)	14	49	16	17	20
(28-56 days)	10	8	27	19	20
(7-56 days)	26	60	48	40	44

Fig.7 Strength increase rate of stabilized soil

Capillary Rise of Stabilized Soil

Fig. 8 shows the capillary rise of the sample after 7 days of curing. The results are presented in terms of the capillary rise as a percentage versus time. The capillary rise percentages of soil, RHA50, and RHA70 were similar, all reaching 100% capillary rise at 480 minutes. In contrast, RHA30 and RHA10 showed lower capillary rise percentages at the same time: 86% and 71%, respectively.

The results indicate that capillary rise tends to increase with higher proportions of RHA in the mixture. Additionally, the data clearly demonstrate that RHA10 had a lower capillary rise than C3% by approximately 5-10% after being submerged in water for 60 minutes.

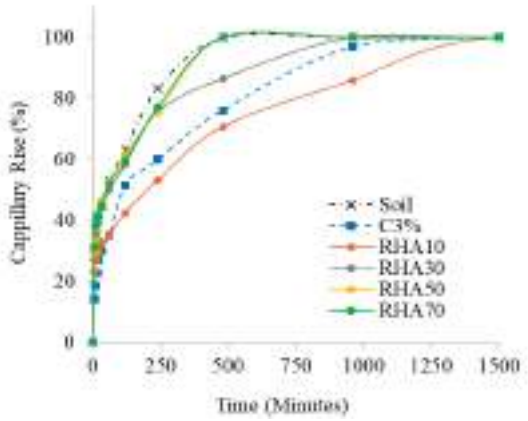

Fig.8 Capillary rise percentage versus time of stabilized soil after 7 days of curing

CONCLUSION

Based on the investigation into the use of rice husk ash (RHA) as a partial cement replacement to enhance the strength of lateritic soil for subbase construction, the key finding of this study are summarized as follows:

1. Soil mixed with 3% cement or soil mixed with RHA replacing 10-50% of cement achieved strength values exceeding the Department of Highway (Thailand) requirement of 689 kPa after 7 days of curing.

2. Replacing 10% of cement with RHA enhanced soil strength more than using cement alone at 28, and 56 days. Specially, 10% RHA replacement increased strength by approximately 19-22% compared to soil stabilized with 3% ordinary Portland cement (OPC). However, at 7 days of curing, the strength of stabilized soil decreased as the RHA proportion increased.

3. RHA demonstrated long-term strength development in stabilized soil. A 10% RHA replacement was the most effective for strength gain between 7-28 days, showing 35% higher strength increase rate than cement alone. However, higher RHA replacements (30-70%) resulted in greater strength development at 28-56 days.

4. A 10% replacement of cement with rice husk ash (RHA) represents the optimal ratio for balancing cement reduction and RHA's effectiveness in enhancing soil strength. However, RHA replacements of up to 50% still maintain compressive strength exceeding the Department of Highways' requirements.

5. Replacing 10% of cement with RHA reduces water absorption in stabilized soil to levels comparable to soil mixed with cement alone. However, higher replacement ratios (50-70%) exhibit

water absorption similar to non-stabilized soil.

6. The use of RHA increases subbase soil strength while decreasing cement usage, consequently reducing the environmental impact associated with soil stabilization.

INVESTIGATING THE SOIL ARCHING PHENOMENON IN MICROPILES USING NUMERICAL ANALYSIS

Muhammad Adeel Mazhar[1], Adnan Anwar Malik[2], Hung Manh Ho[3] and Umair Ali[4]

[1]Equipment Consulting Service Department (ECSD), Saudi Aramco, Dhahran, Saudi Arabia; [2]School of Engineering, The University of Newcastle Australia; [3]Bentley Systems, Singapore; [4]Department of Civil and Environmental Engineering, King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia

ABSTRACT

The application of micropiles is increasing as more and more research outcomes highlight their advantages in various ground conditions. Additionally, its sustainability aspects, including minimal site impact, adaptability, and efficient material use, further enhance its applicability. These piles can be used under embankments to reduce stress on weaker soils, resulting in reduced localized and differential settlements. Under embankments, the number of piles is high; therefore, the group effect of piles has a more significant influence on the overall performance of the pile-supported improvement system. Soil arching is a critical factor in group piles that needs to be precisely investigated for an economical design that increases the service life of the structure. To further explore this, experimental trapdoor experiments were conducted to establish the arching effect in the sand, which was subsequently simulated using the hardening soil model with small-strain stiffness with PLAXIS 2D (FEM code). A parametric study was conducted to investigate the effect of the arching phenomenon on stress concentration and load in micro piles with varying interface conditions that reflect the roughness of the pile associated with micro pile shaft threading. Results showed that due to the arching phenomenon, stresses were transferred to the pile, and this transfer of stresses increases with the increase in interface stiffness in the axial direction.

Keywords: Soil arching, Micro piles, Sand, Shaft roughness effect, Numerical analysis

INTRODUCTION

Soil arching is defined as the increase or decrease of vertical stress on the buried structure due to the relative movement of the soil [1]. Stress reduction occurred in the yielding zone due to the redistribution of stress resulting from soil arching [2]. The soil arching mechanism can be studied for various geotechnical applications, such as underground cavities, tunnels, pile embankments, underground pipelines, culverts, retaining structures, and excavation support structures [2-9]. George and Dasaka [2] proved numerically that the equilibrium of stress transfer exists in the trapdoor experiment, i.e., an increase or decrease in pressure at the trapdoor is similar to the increase or decrease at the rigid portion. A very small movement in the trapdoor setup can generate load transfer due to soil arching [10]. Iglesia [11] stated that during the initial movement of the trapdoor, the load decreased considerably to reach its minimum value, indicating a fully developed arch. However, further movement gradually increases the load on the trapdoor. Another study indicated that an increase in soil density has no considerable effect on soil arching [12].

According to Ali [3], the height of the model and the particle shape affect the arching behaviour. Moreover, arching development is related to the height-to-width ratio of the buried structure. Many studies have been conducted to develop an expression to estimate the pressure reduction on the trapdoor. According to George and Dasaka [2], the cubic polynomial profile represents soil arching over the trapdoor in the yielding area.

Pile embankments are used in highway and railway construction as a ground improvement technique in areas with problematic soils [13]. Zhuang [14] stated that in areas of soft soils, embankments on floating piles are a cost-effective choice. In addition, the study indicated that soil arching began to develop when the embankment height to clear spacing ratio is greater than or equal to 1.6. The study also highlighted that the internal friction angle and cohesion of embankment fill improve the soil arching phenomenon. The use of micro piles has seen a notable rise in recent years across different geotechnical applications. Their performance mainly relies on skin friction, which is the friction developed at the contact surface between the surrounding soil and the micro-pile or grout. Despite their growing use, limited research has been conducted on how the arching phenomenon affects micro piles. This study aims to address this gap by employing numerical analysis to investigate how arching affects stress concentration and load transfer in micro piles, with special emphasis on the role of the soil–pile interface.

RESEARCH OBJECTIVE AND METHODOLOGY

The objective of this study is to investigate the arching phenomenon in terms of stress concentration and load on the pile in micro piles with varying interface conditions that reflect the roughness of the pile associated with micro pile shaft threading. To achieve the set objectives, the following methodology is adopted.

- Trapdoor experimental results are modelled in the PLAXIS 2D software using the Hardening Soil Model with Small Strain Stiffness (HSS).
- Validating the stress concentration ratio between the experimental and numerical analysis at the height of the soil (H) to fixed section (B) ratios (H/B) of 4.0 and 4.5.
- Including micro pile(s) in the model using embedded beam elements.
- Parametric study by increasing the interface stiffness in the axial direction (R_s) to reflect the increase in roughness between the soil and the pile section of micro piles.

EXPERIMENTAL AND NUMERICAL MODEL

Experimental Model

The experimental model consisted of a rectangular container whose floor was divided into seven sections (100 mm each), which could move upward and downward at a selected movement rate [3, 15]. The container was 700 mm long, 555 mm high, and 294 mm deep, as shown in Fig.1. Load cells that can measure both vertical and horizontal loads were mounted on all seven plates. Toyoura sand was used to prepare the model ground at a relative density of approximately 95 %. The dry pluviation method was used to achieve the desired relative density. The used sand material properties are D_{50} = 0.203 mm, C_u = 1.61, G_s = 2.64, e_{min} = 0.637, and e_{max} = 0.946. Ali's [3] paper contains more details on the experimental model.

Numerical Model

The numerical model was created in PLAXIS 2D, a FEM code, [16] with plane strain conditions. The model's width was 300 mm, representing three floor sections (each 100 mm) as shown in Fig.1. The middle section had fixed boundary conditions, whereas the other two sections were movable through a prescribed downward displacement of 0.25 mm (similar to the experiment), as shown in Fig.2. The soil is modelled as a Hardening Soil (HS) Model [17] with small-strain stiffness [18]. The material properties of Toyoura sand with a relative density of 95 % are shown in Table 1.

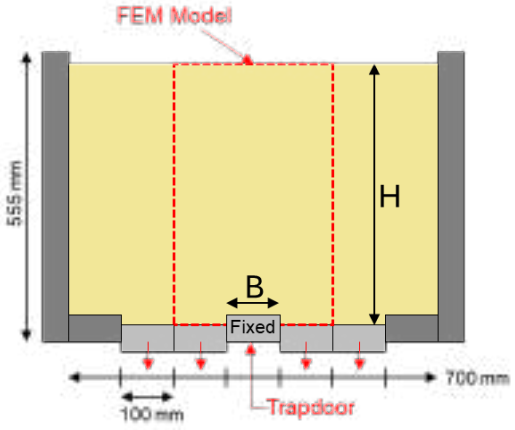

Fig.1 Schematic illustration of the trapdoor experiment setup

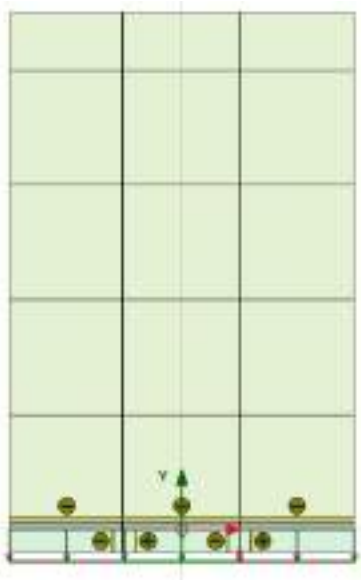

Fig.2 PLAXIS 2D FEM model to represent trapdoor experimental model

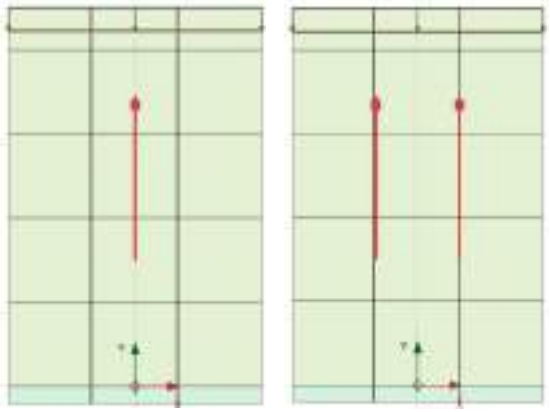
Table 1: Toyoura sand properties with relative density of 95 % considered in the numerical model

Description	Values
E_{50} in kPa	29,000
E_{oed} in kPa	30,000
E_{ur} in kPa	85,000
ν_{ur}	0.2
G_0^{ref} in kPa	300,000
c´ in kPa	1
ϕ´ in degrees	41
Ψ in degrees	16

After validating the arching phenomenon using experimental data, a parametric study was conducted, where micro piles were modeled as embedded beam elements with single and two-pile arrangements in the

PLAXIS model, as shown in Fig. 3. The considered length of the micro pile was 195 mm, and its diameter was 75 mm. The spacing between the piles was considered to be 150 mm. The distance of the pile head from the ground surface was considered to be 105 mm. In the parametric study, the interface axial stiffness (R_s), which reflects soil-pile interaction, varied from 2 to 4 times its default value to investigate its effect on the stress concentration and load on the pile due to the arching phenomenon. A prescribed displacement of 0.25 mm (reflecting ground settlement due to embankment load) was applied at the ground surface to see the stress concentration and load on the pile. The bottom of the model was kept in a fixed boundary condition.



(a) (b)

Fig.3 PLAXIS 2D FEM models including micro piles as embedded beam element (a) 1-pile (b) 2-piles

The parametric study details are shown in Table 2. According to PLAXIS 2D 2024.3 reference manual [16], the default value of ISF is calculated as,

$$ISF_{RS,\ RN,\ KF} = 2.5\left(\frac{Lspacing}{D}\right)^{-0.75} \quad (1)$$

The interface stiffness in PLAXIS is calculated as follows [16].

$$R_S = ISF_{RS}\frac{G_{Soil}}{L_{spacing}} \quad (2)$$

$$R_N = ISF_N\frac{G_{Soil}}{L_{spacing}} \quad (3)$$

$$K_F = ISF_{KF}\frac{G_{Soil}R_{eq}}{L_{spacing}} \quad (4)$$

$$R_{eq} = \frac{D_{eq}}{2} = \sqrt{\frac{12EI}{EA}} \quad (5)$$

Where ISF stands for Interface Stiffness Factor, R_N stands for stiffness in lateral direction, Rs stands for stiffness in axial direction, K_F stands for base stiffness, $L_{spacing}$ represents spacing between the piles, G_{soil} represents surrounding soil shear stiffness, and R_{eq} represents equivalent radius.

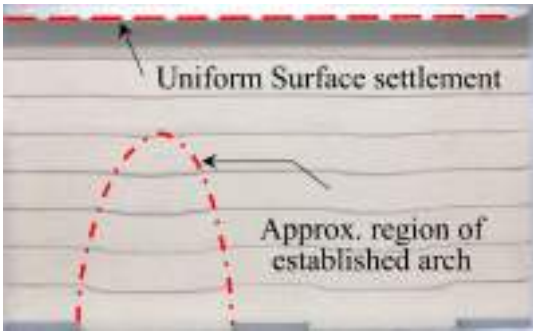
Table 2 Parametric study details

Case No.	Interface Axial Stiffness Factors (ISF_{RS})	Increase in RS
1	1.844	-
2	3.68	2 x Case 1
3	7.37	4 x Case 1

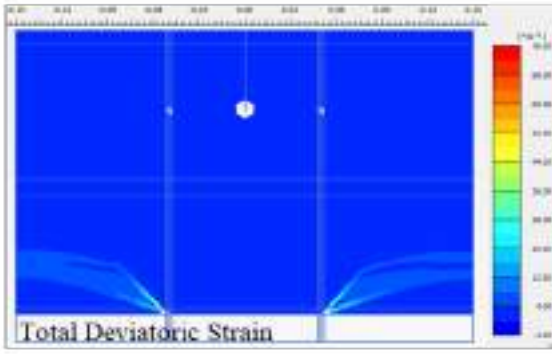
RESULTS AND DISCUSSIONS

Validation of the Arching Phenomenon

The trapdoor experiment was conducted with soil heights (H) of 400 mm and 450 mm, with the central section (B) having a width of 100 mm of the container floor (trapdoor) fixed. The H/B ratios were 4.0 and 4.5. The floor sections around the central fixed section were lowered at a constant rate of 0.0012 mm/sec until the downward displacement reached 10 mm. Figure 4(a) shows the arch formation in the experiment. In the case of the PLAXIS 2D model, the movable sections surrounding the central fixed section were displaced downward by 0.25 mm to achieve the arching effect in the model, as shown in Fig.4(b). Ali's [3] paper contains more details on the experimental model.



(a)



(b)

Fig.4 Arch formation for H/B = 4.0 (a) Experiment [3] (b) PLAXIS 2D model using HSS

The normalized stress concentration, measured using load cells mounted on the floor during the experiment, is compared with the stress concentration extracted from the PLAXIS model, as shown in Fig.5, and shows good agreement, reflecting the validity of the created 2D FEM model.

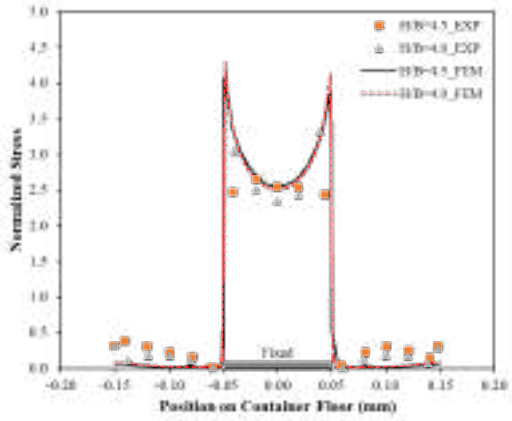


Fig.5 Comparison of normalized stress concentration on the floor between experimental and FEM model for H/B = 4.0 and H/B = 4.5

Effect of Arching on Micro Piles

To investigate the effect of arching on micro piles, a parametric study was conducted using the validated FEM model in PLAXIS 2D. As micro piles contain threading along their shafts, frictional resistance depends on the spacing and depth of the threading. In this parametric study, the interface stiffness in axial direction (R_s), which reflects soil-pile interaction, varied from 2 to 4 times its initial value to investigate its effect on stress concentration and load on the pile due to the arching phenomenon. Figure 6 illustrates the arching phenomenon observed between the two piles when a prescribed displacement of 0.25 mm is applied to the model ground surface, reflecting ground settlement due to the embankment load.

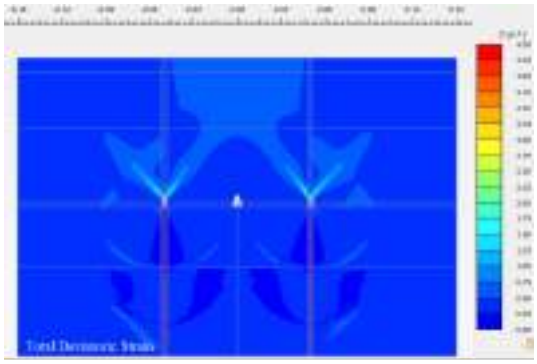

Fig.6 Development of arching in micro piles, 2-pile case

After observing the arching phenomenon in micro piles, the interface stiffness in axial direction (R_s) is increased by 2 to 4 times the initial value (using Eq. 2) in PLAXIS FEM model and its effect on the increase in load and stress concentration on the pile is recorded under prescribed downward displacement of 0.25 mm (represents ground settlements due to embankment load). The results showed that with an increase in R_s, the load on the pile also increases, as shown in Fig.7. Stress concentration on the pile (stress on pile/stress on soil) also increases with the increase in R_s, but in a non-linear way, as shown in Fig.8. These results indicate that due to arching the stresses are transferred to the pile and this transfer of stresses increases with the increase in the pile soil interface axial stiffness (R_s).

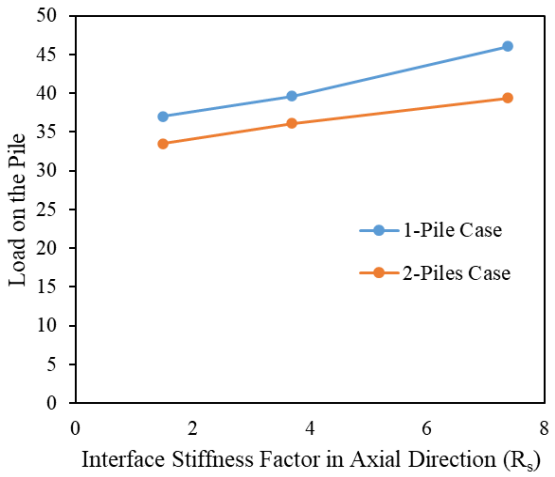

Fig.7 Relationship between interface stiffness factor in axial direction and load on the pile due to arching

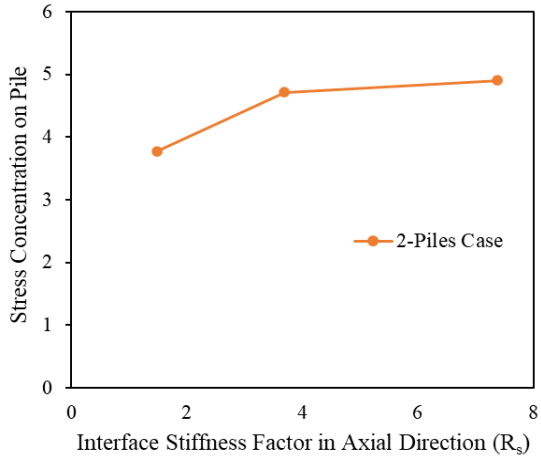

Fig. 8 Relationship between interface stiffness factor in axial direction and stress concentration on the pile due to arching

CONCLUSIONS

This paper investigated the effect of the arching phenomenon in terms of stress concentration and load on the micro piles with varying interface conditions, which reflect the roughness of the pile associated with micro pile shaft threading. The trapdoor experiment is modelled in PLAXIS 2D, and the arching phenomenon is validated. After validation, a parametric study was conducted, in which interface stiffness in the axial direction was increased from 2 to 4 times the initial value to examine the increase in stress concentration and load on the pile due to the arching phenomenon produced by ground settlement. The following are the primary outcomes of this study.

- The Hardening Soil Model with Small-Strain Stiffness can accurately reflect arching in soils, yielding a good agreement with the normalized stress concentration from the trapdoor experiment.
- Transfer of load on the pile due to arching increased linearly with the increase in interface axial stiffness.
- Transfer of stress concentration on the pile due to arching increased non-linearly with the increase in axial stiffness.
- These results indicate that due to arching, the stresses are transferred to the pile, and this transfer of stresses increases with the increase in the pile soil interface axial stiffness (R_s).

APPLICATION OF MULTI-CHANNEL ANALYSIS OF SURFACE WAVES IN PROBABILISTIC SEISMIC HAZARD ASSESSMENT: A CASE STUDY IN ISLAMABAD, NORTHERN PAKISTAN

ABSTRACT

The Multi-channel Analysis of Surface Waves (MASW) technique is a modern geophysical method for measuring shear wave velocity (Vs_{30}), a critical parameter in Seismic Hazard Assessment (SHA) for determining seismic design parameters. While MASW is widely used globally, its application in Pakistan remains very limited and in the initial phase, where traditional methods like downhole or cross-hole surveys, often impractical due to cost, time, and accessibility constraints, are still dominant. As a result, researchers and engineers frequently rely on generalized literature-based Vs_{30} values, which may not accurately represent site-specific conditions. To address this, greater adoption of MASW in Pakistan is essential, particularly for preliminary infrastructure design and research, as it offers a faster and more cost-effective solution. This paper presents novel research on MASW adoption in SHA for Islamabad to evaluate seismic design parameters, aiming to encourage its broader use in Pakistan for more accurate and efficient hazard assessments.

Keywords: Multichannel Analysis of Surface Waves, Seismic Hazard Assessment, Probabilistic Seismic Hazard Analysis, Shear Wave Velocity, Vs30, Peak Ground Acceleration, Non-Destructive Testing

INTRODUCTION

Non-destructive geophysical methods, especially when combined with artificial intelligence (AI) and machine learning, have become highly useful in engineering and environmental studies due to their cost and time efficiency. One such technique, Multi-channel Analysis of Surface Waves (MASW), measures shear wave velocity (Vs_{30}), the average speed of seismic waves down to 30 meters, which is crucial for assessing soil types, earthquake risks, liquefaction potential, and foundation strength. While MASW is gaining global popularity, its use in Pakistan remains limited, despite its potential to improve geotechnical and seismic studies.

The estimation of seismic parameters is critical not only for ensuring stable and safe design but also for achieving an economically sound design of civil infrastructures. The financial constraint is one of the hurdles in attaining accurate parameters as it requires extracting high-quality, undisturbed samples and conducting direct laboratory tests that reflect site conditions in terms of stress path or loading sequence, in-situ stress state, drainage, and other relevant factors at the site [1]. Non-destructive testing (NDT) is one of the ways to overcome this constraint, as it does not disturb the in-situ conditions [2]. Additionally, non-destructive testing (NDT) is a safe, environmentally friendly, and cost-effective method when compared to other options [3,4]. According to Park [5], the estimation of soil stiffness from shear wave velocity obtained from Multichannel Analysis of Surface Waves (MASW) has increased worldwide. The soil stiffness parameter is critical in evaluating site stability.

The purpose of this study is to showcase the application of Multichannel Analysis of Surface Waves and its benefits in achieving safe and economical design. This study represents a significant step forward in utilizing MASW for earthquake risk assessment. This method is executed in Islamabad's northern region, and its results are analyzed to determine key earthquake safety factors. The findings of this study help demonstrate how MASW can be effectively applied in earthquake engineering across Pakistan.

RESEARCH SIGNIFICANCE

This research offers a crucial first application of the Multichannel Analysis of Surface Waves (MASW) method for site-specific seismic hazard assessment in Pakistan. It directly addresses a significant gap in local practice, where reliance on imprecise literature-based values or costly traditional methods continues. By demonstrating MASW's efficiency and cost-effectiveness, this study creates a practical framework for obtaining accurate shear wave velocity (Vs_{30}) profiles. The results provide a reproducible model for improving seismic safety in

infrastructure design, promising more economical and reliable hazard assessments across Pakistan and other developing regions with similar geological conditions and constraints.

APPLICATION OF MASW IN SEISMIC HAZARD

The Multichannel Analysis of Surface Waves (MASW) is a common geophysical method that measures shear-wave velocity (V_s) to study the properties of soil and rock [6,7]

MASW is useful for seismic hazard studies, as shear-wave velocity helps assess ground shaking risks [6,8]. It calculates Vs_{30} (average V_s in the top 30 meters), which is vital for seismic site classification (NEHRP, Eurocode 8). MASW also detects liquefaction risks and soft soils that worsen earthquakes [9,10]. It identifies faults, supports seismic zoning, and enhances earthquake predictions with detailed V_s data [11,12]. In the Pakistani context, this study will provide a guide in using MASW for seismic hazard studies.

DATA COLLECTION AND RESEARCH PROGRAM

Given MASW's growing role in earthquake risk studies and geotechnical engineering, a well-planned research effort is needed to enhance its application, especially in high-risk areas such as Pakistan, where these methods are still relatively new. This study will focus on determining local shear-wave velocity (Vs_{30}), a key factor in seismic analysis. Working with geotechnical, geophysical, and earthquake experts will help apply MASW in real projects. The goal is to make MASW a standard, affordable tool for seismic safety, supporting safer urban development in earthquake-prone areas. Unlike costly methods like Downhole or Crosshole tests (which require drilling and additional steps), MASW is faster and more cost-effective, making it ideal for feasibility studies, design, and research.

The MASW method measures subsurface shear-wave velocity (Vs) by analyzing surface waves. It starts with field tests using geophones placed in a line and a seismic source (like a hammer strike), as shown in Fig.1. The geophones record surface waves (mainly Rayleigh waves), which are then processed to study how wave speeds change with frequency (dispersion curve). This data is converted into a velocity profile using computer models, sometimes with the aid of known geology. The final Vs profile reveals soil stiffness, layers, and earthquake response, making MASW useful for geotechnical and seismic safety studies.

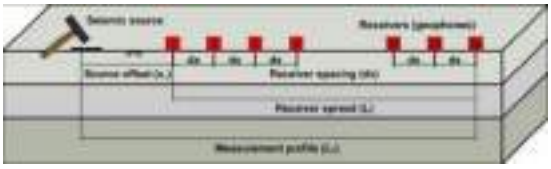

Fig.1 Field setting of MASW survey

To measure shear-wave velocity down to 30 meters (Vs_{30}), MASW surveys were conducted in Islamabad and nearby areas in northern Pakistan. The study examined the surface geology that consists of silty clay, clayey silt, gravel, boulders, loose soil, and soft to moderately weak rock beneath the sites. The region has sedimentary rock layers. The MASW surveys adhered to the [13], utilizing various tools, hammers, ropes, and operating methods.

CALCULATION OF SHEAR WAVE VELOCITY (V_S AND V_{S30})

MASW data processed using Seismic Pro 9.3, a specialized software from Geogiga Technology Inc. First, we examined the color-coded images showing how wave speeds change with frequency for each test location. We focused on the clearest wave patterns (fundamental mode) for our analysis. The software calculated wave speeds multiple times using different settings until we got the cleanest results (highest signal-to-noise ratio). For each test site, we converted these wave speed measurements into a depth-based velocity profile. The software automatically compared calculated and measured wave patterns, selecting the most accurate match (lowest RMSE error) to create the final Vs_{30} profile. The average Vs_{30} of six profiles is interpreted as 745 meters/second. The inverted S-wave Velocity Models of MASW are shown in Figures 2 and 3.

USE OF V_{S30} IN SEISMIC DESIGN PARAMETERS

The study area is in the close vicinity of the tectonic boundary between the Indian and Eurasian tectonic plates, thus lying within a seismically active zone. Several moderate to large earthquakes have been recorded in northern Pakistan over the last 100 years. The study area lies in a region dominated by thrust-type faults, which also exhibit some strike-slip components in certain places. These faults are considered active due to the association of observed seismicity with them. As per available published literature/geological maps of regional extent, the Main Boundary Thrust (MBT) is the major Fault of the study region/surrounding, as shown in Fig.4.

The Probabilistic Seismic Hazard Analysis (PSHA) for the current study is conducted using the methodology developed by [14]**.** For PSHA, the Next Generation Attenuation (NGA) West2 equations developed under Pacific Earthquake Engineering Research (PEER) Centre by [15-17] were used as these equations are valid for tectonically active regions of shallow crustal faulting worldwide. The site foundation condition with Vs_{30}=745 m/sec (adopted on the basis of results of site-specific determination of shear wave velocity- Vs_{30} by Multichannel Analysis of Surface Waves. The probabilistic hazard analysis was carried out by using EZ-FRISK software developed by FUGRO Consultants, USA. The results of the probabilistic seismic hazard analysis are presented in Fig. 5 for a very dense soil/soft rock site foundation condition with Vs_{30} =745 m/sec, showing the annual frequency of exceedance of horizontal peak ground acceleration (PGA) at the study area. Peak Ground Acceleration (PGA) value against very dense soil/soft rock foundation conditions with V_{s30} = 745 m/sec. (Soil Profile Type SC) has been calculated as 0.24g for 10% probability of exceedance in 50 years, i.e. 475 return period (Fig. 5).

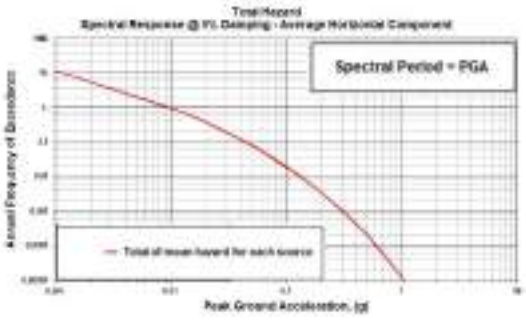

Fig.5 Total hazard curve for site foundation condition with V_{s30} = 745 m/sec

The uniform hazard response spectra obtained by probabilistic seismic hazard analysis are shown in Fig. 6.

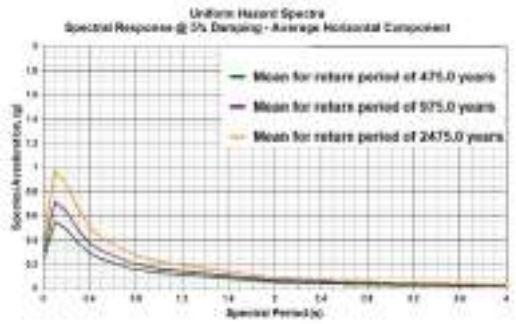

Fig.6 Uniform hazard spectra for site foundation condition with V_{s30} = 745 m/sec

RESULTS/CONCLUSIONS

The current local practice in Pakistan for obtaining Vs_{30}, a critical seismic design parameter, is hampered by significant limitations. Engineers often have to rely on generalized values from literature that may not reflect site-specific conditions or on traditional methods like Downhole or Crosshole tests, which are prohibitively expensive, time-consuming, and often impractical for preliminary studies. This paper demonstrates how applying the MASW method directly addresses these constraints by offering a standardized, non-destructive, and highly efficient alternative. By providing accurate, measured Vs_{30} profiles cost-effectively, this study establishes a reproducible framework that enhances local seismic hazard assessment practices, leading to safer and more economically optimized infrastructure design in Pakistan and similar settings.

The Multi-channel Analysis of Surface Waves (MASW) is a modern method for measuring shear wave speed (Vs_{30}, the average speed down to a 30m depth). It is becoming increasingly crucial in earthquake and soil engineering to study ground layers, calculate earthquake risks, assess liquefaction danger, and evaluate soil strength. While MASW is growing globally, Pakistan is just starting to use it.

This paper shows how MASW can improve earthquake safety practices in Pakistan. It is expected that this study will start a new approach by combining MASW results with earthquake risk studies. As Pakistan's major MASW research for seismic hazard assessment, it aims to guide future earthquake safety planning using this advanced technique.

The key conclusions and recommendations of this current research are as follows.

- Peak Ground Acceleration (PGA) value against very dense soil/soft rock foundation conditions with Vs_{30} = 745 m/sec. (Soil Profile Type S_C), has been calculated as 0.24g for 10% probability of exceedance in 50 years, i.e. 475 return period.
- Pakistan urgently needs to use MASW more for Vs_{30} measurements. This faster, cheaper method is especially useful for early-stage projects and research work.

ABSTRACT

Flash floods are among the most destructive hazards, threatening lives and infrastructure in steep, rapidly changing landscapes. This study assessed flash flood susceptibility in Chiang Rai, Thailand, by integrating remote sensing, GIS, and hydrological modeling. Land use maps from 2007, 2012, and 2018—classified as agriculture, grassland, urban, woodland, water, and bare soil—revealed shifting surface characteristics. Terrain slope was extracted from the Copernicus GLO-30 DEM, and soil types were identified using the HYSOGs-250 m dataset, highlighting high-runoff group C and D soils. Curve Number analysis yielded values above 70, indicating elevated runoff risk. A multi-criteria weighted overlay combined slope, land use, soil, and CN to compute the Flash Flood Potential Index (FFPI), which was then divided into five risk classes. Results showed that in Chiang Rai no areas are at Low risk; the regions are ranged from Moderate to High risk. Conversion of woodland to agriculture (2007–2012) and agriculture to urban (2012–2018) notably increased flood vulnerability.

Keywords: Flash Flood, Urbanization, Land Use Change, GIS, Flash Flood Potential Index

INTRODUCTION

Flash floods are sudden inundations triggered by short duration, high intensity rainfall events and, because of their rapid onset and unpredictability, are considered among the most destructive hydrological hazards worldwide [1]. They typically occur within minutes to a few hours after rainfall cessation, inundating normally dry areas and posing severe threats to life and property. In recent years, climate change has intensified both the frequency and magnitude of extreme precipitation, while urbanization and deforestation have diminished natural water-retention capacity and increased surface runoff, further amplifying flash flood risk [2]. Northern Thailand exemplifies these challenges: Chiang Rai Province, situated in the mountainous, monsoonal upper Mekong basin, experiences intense rainfall from May to October that frequently produces riverine flooding and flash floods with very limited warning time [3]. Conventional reliance on river gauges and rain-gauge networks is inadequate in such sparsely instrumented mountainous terrain, often leaving authorities unprepared for upstream flood peaks. To enable spatially explicit flash flood risk assessment, Smith (2003) developed the Flash Flood Potential Index (FFPI), which standardizes and weights physio-graphic factors-slope, soil type, land cover, topographic curvature, and others-within a GIS framework to generate grid-based susceptibility scores [4]. This approach has been widely applied in ungauged catchments to identify potential flash flood source areas. Numerous global and regional studies demonstrate the efficacy of integrating FFPI with remote sensing and GIS data: Lazar (2020) compared FFPI maps for 1989 and 2019 in Romania's Zabala catchment, revealing that deforestation markedly elevated FFPI values [5]; Shehata (2018) evaluated the risk in the Kyushu Island and confirmed that steep, sparsely vegetated subcatchments exhibit high FFPI scores [6]. These studies underscore that multi source data such as DEMs, land-cover maps, and vegetation indices can effectively delineate flash flood hotspots. Globally, as urbanization accelerates and ecosystems fragment, dynamically assessing how specific land use transitions (e.g., forest to agriculture, agriculture to urban) drive flash flood susceptibility has become a critical challenge in hydrology and disaster management. While Lazar (2020) employed bi-temporal FFPI comparisons to highlight the impact of singular land use changes on runoff and flood potential, their work was limited to static two date analyses and did not directly couple multi temporal land-use changes with quantitative FFPI variation [5]. Meanwhile, Chiang Rai Province with its complex terrain, monsoonal rainfall regime, and recurring extreme floods remains without high resolution FFPI based susceptibility mapping. To address these gaps, the present study uses 2007, 2012, and 2018 satellite-derived land use data to construct corresponding FFPI raster models, performs detailed susceptibility analyses in representative Chiang Rai catchments, and introduces a dynamic "risk transition" metric-calculating the proportion of area shifting among FFPI risk categories to quantify the spatiotemporal

evolution of flash flood susceptibility and inform regional flood mitigation planning and land-use management.

STUDY AREA

Chiang Rai province occupies the northernmost tip of Thailand, sharing borders with Myanmar to the north and Laos to the east. Encompassing approximately 11,460 km², the province forms part of the upper Mekong River Basin. Its terrain is dominated by rugged mountain ranges, deeply incised river valleys, and undulating hills, with elevations rising from about 400 m in the lowlands to over 2,000 m in the highest peaks. Two principal river systems-the Nam Kok and Nam Mae-drain much of the province, flowing southeastward toward the Mekong main stem [3]. Annual precipitation in the highlands commonly exceeds 2,000 mm, with individual storms sometimes delivering more than 100 mm of rain within 24 hours. However, the Thai government's current hydrological monitoring framework is confined to lowland flood events and lacks any systematic observation of flash floods in highland regions [7]. Land cover in Chiang Rai is a mosaic of tropical evergreen and deciduous forests in the upper catchments, interspersed with shifting-cultivation zones and terraced agriculture on mid-slope benches. In the lower valleys, paddy fields, small-holder orchards, and expanding peri-urban developments dominate. This heterogeneous landscape, combined with steep slopes and narrow floodplains, creates highly variable surface runoff responses. As agricultural frontiers and urban fringe areas encroach upon formerly forested hill slopes and valley bottoms, the natural infiltration capacity diminishes, exacerbating flood peaks and reducing lead times for warnings [2]. Given this complex physiography, climate regime, and land-use pattern, Chiang Rai provides an ideal setting for applying the Flash Flood Potential Index (FFPI) to identify spatial flash-flood hot spots and to assess how evolving land-use dynamics influence susceptibility across multiple time points.

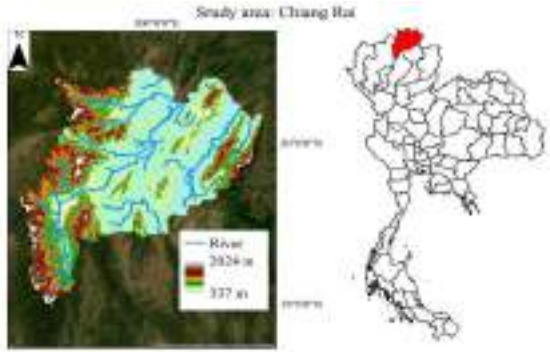

Fig.1 Study area design

METHODOLOGY

This study adopts an integrated geospatial approach to evaluate flash flood susceptibility under changing land use conditions. The overall methodology consists of five main steps described as follow. First, Land use/land cover (LULC) data of 2007, 2012, and 2018 were obtained and classified to map the spatial distribution of land use categories across Chiang Rai. Next, a high-resolution Digital Elevation Model (DEM) was analyzed to extract slope gradients, representing the terrain's influence on runoff generation. Soil data for the region were then processed to determine Hydrologic Soil Groups (HSGs), which indicate the infiltration capacity of different soil types. Using the land cover and HSG information, Curve Number (CN) values were assigned to quantify runoff potential for each land use‐soil combination. Finally, a Flash Flood Potential Index (FFPI) model was implemented by integrating the slope, land use, and soil (CN) datasets to produce a composite flash flood susceptibility map. The following subsections describe each step in detail.

The Land Use Classification

The Land use data for 2007, 2012, and 2018 were obtained from official Thai government sources. The datasets were classified into agriculture, grassland, road, built-up areas, woodland, water, and bare soil. The land use map for 2007, 2012, and 2018 is presented in Figure 2, illustrating the distribution of major land cover types across Chiang Rai. This land use information provides the basis for analyzing how changes in land cover (e.g. deforestation or urban expansion) might affect runoff and flash flood susceptibility.

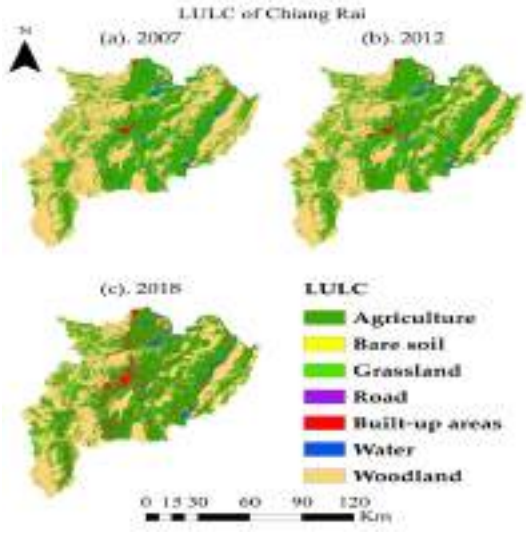

Fig.2 LULC in Chiang Rai (2007, 2012, and 2018)

Slope Extraction

Topographic slope is a critical factor influencing surface runoff velocity and concentration. In this study, slope values were derived from a DEM of the Chiang Rai region [6]. The Copernicus GLO-30 Digital Elevation Model (DEM) was used to extract slope data across Chiang Rai. Slope plays a critical role in determining runoff accumulation, flow velocity, and erosion potential. The DEM data were processed in a GIS environment to generate a slope map, which was later incorporated into the flash flood potential analysis. Fig 3.(a) showed the distribution of slope in Chiang Rai. This categorized slope layer was then prepared for input into the flash flood susceptibility analysis.

Hydrologic Soil Groups Determination

Soil characteristics were incorporated via the Hydrologic Soil Group classification, which distinguishes soils by their infiltration capacity [6]. To determine the hydrologic soil types in Chiang Rai, this study utilized the Global Hydrologic Soil Groups (HYSOGs-250m) for Curve Number-Based Runoff Modeling data set [8]. The dominant soil types in the study area were identified and each was assigned to an HSG category (A, B, C, or D) according to its texture and permeability. In general, Group A soils have high infiltration rates and low runoff potential (e.g., sandy or well-drained loams), whereas Group D soils have very low infiltration (high runoff potential, often clayey or shallow soils). Intermediate groups B and C represent moderate and low infiltration capacities, respectively. Figure 3(b) displays the spatial distribution of these HSGs across the study area. Notably, Chiang Rai's soil (Fig 3.(b)) is consist of soil group C and D, indicating a high runoff potential. This HSG layer serves as a crucial input for assessing runoff generation, as it provides a spatial representation of soil-driven infiltration variability.

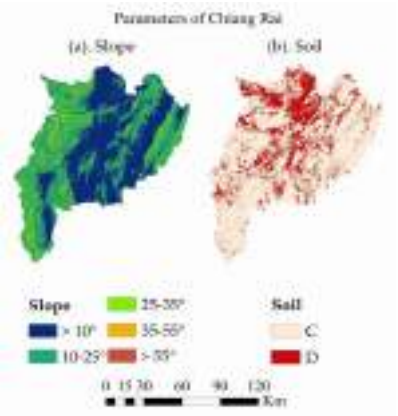

Fig.3 (a).Slope and (b). Hydrologic Soil groups of Chiang Rai

Curve Number (CN) Assignment and Analysis

The NRCS Curve Number method was employed to quantify the runoff generation potential based on combined land use and soil conditions [6]. Using the land use classification (Fig.2) and the HSG map (Fig.3 (a)), a CN value was assigned to each unique land use – soil group combination in the study area. Standard Curve Number lookup tables developed by the USDA Soil Conservation Service for Antecedent Moisture Condition II guided the assignment [9]. For example, forested areas on well-drained Group A soils typically receive a low CN (indicating high infiltration and low runoff potential), whereas urban or paved areas on Group D soils are given a high CN (indicating very high runoff potential). The output of this step was a spatial CN map representing the runoff coefficient across Chiang Rai for 2007, 2012, and 2018, showed in Fig.4. This CN map was examined to understand how land use changes have altered runoff potential over time. Specifically, by comparing CN distributions between the historical and recent land use scenarios, we could identify areas where urban expansion or deforestation has significantly increased runoff susceptibility. The CN analysis thus provides a quantitative link between land cover change and hydrologic response, serving as a foundation for the subsequent flash flood risk modeling.

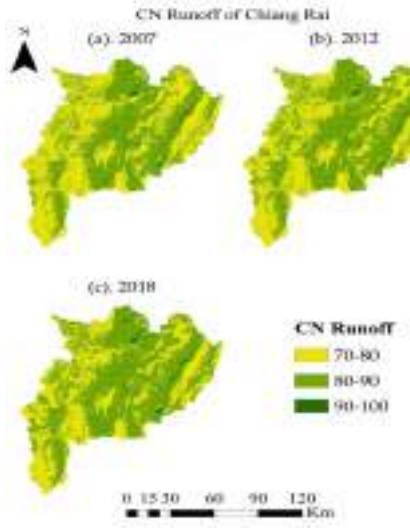

Fig.4 CN runoff in Chiang Rai (2007, 2012, and 2018)

Hydrologic Soil Groups Determination

The final step involved modeling the Flash Flood Potential Index to delineate areas with high Flash flood susceptibility [6]. The FFPI is a dimensionless index that integrates the key contributory factors-topography, land cover, and soil/infiltration

characteristics-into a single susceptibility score for each location. In this study, the FFPI was computed by combining the LULC (Fig.2), slope (Fig.3 (a)), and soil/infiltration information (Fig.3 (b)). Each input parameter was first standardized to an appropriate scale so that higher values correspond to higher flash flood risk. Land use categories were likewise assigned risk scores reflecting their imperviousness or vegetation cover (for instance, urban areas and bare land were given high risk scores, while forested areas were given low scores due to better rainfall absorption). Slope classes and HSGs were converted to rank scores (1 to 10) based on their tendency to generate runoff (with steep slopes and low-infiltration soils receiving higher scores). The CN runoff values were also utilized to inform the weighting of land use and soil contributions, ensuring that areas with high CN (indicative of high runoff potential) are represented as high-risk in the FFPI computation. The integrated FFPI was then calculated on a cell-by-cell basis by combining the factor scores referred to Table 1 [6], effectively averaging or summing the contributions of slope, land cover, and soil.

The final FFPI values were classified into five risk categories:

1.Low (1–3): Low flash flood risk.

2.Moderate (3–5): Potential flash flood risk.

3.Medium (5–6): Increased flash flood likelihood.

4.Elevated (6–8): Significantly prone to flash floods.

5.High (8–10): Frequent flash floods expected.

Table 1. The weighted contribution of each parameters and the ranks of each parameters category [6]

Layer	Weight	Category	Rank
Slope	40	< 10°	1
		10°-25°	3

		80-90	9
		90-100	10

RESULTS

FFPI Distribution in Chiang Rai (2007, 2012, and 2018)

Fig.5 illustrates the spatial distribution of the Flash Flood Potential Index (FFPI) across Chiang Rai for 2007, 2012, and 2018. Notably, no areas in the province fell into the “Low” FFPI category during this period. Instead, the entire landscape was classified within the Moderate, Medium, Elevated, or High risk classes, indicating a generally elevated baseline of flash flood susceptibility throughout Chiang Rai. The Medium FFPI category covered the majority of the area in all three years, followed by the Moderate category, whereas Elevated-risk zones constituted a much smaller fraction of the area, and High-risk zones were extremely limited (consistently <0.1% of the province’s area in each year). This absence of Low-risk areas and dominance of at least Moderate FFPI values suggest that most of Chiang Rai had non-trivial flash flood susceptibility.

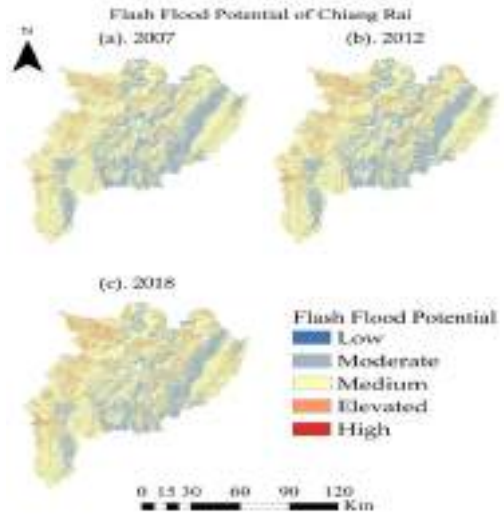

Fig.5 The FFPI results in Chiang Rai (2007, 2012, and 2018)

Relationship between FFPI and flash flood records

To validate the ability of the FFPI distributions to reflect local flash flood conditions in Chiang Rai, recorded flash flood events from 2019 to 2023 were compared with the 2018 FFPI map at the sub-district level. In the absence of detailed inundation extents or depth measurements, the analysis employed the count of severe flash flood occurrences per sub-district. Fig.6 illustrates the spatial correspondence between event frequency and 2018 FFPI values, revealing a concentration of higher flash flood frequency in the regions where elevated and medium FFPI values are more concentrated. The higher number of events within a given period indicates the elevated flood risk [2], this spatial clustering

supports the predictive capability of FFPI. Collectively, this comparison indicated that the FFPI can meaningfully approximate the temporal and spatial patterns of flash floods in Chiang Rai.

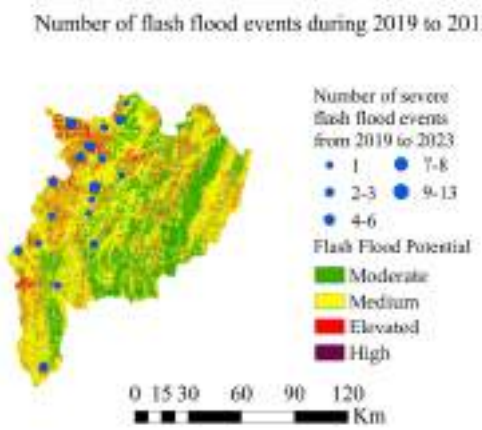

Fig.6 Number of flash flood events during 2019 to 2023 in Chiang Rai

Relationship between FFPI Distribution Changes and Land Use/Land Cover Changes

Overall FFPI trends

The region's FFPI distribution shifted toward higher risk categories over time, as showed in Fig.7. Across the entire province, the area classified as High FFPI increased substantially, while Elevated-risk areas also expanded, especially by 2018. In contrast, Moderate-risk zones shrank continuously, and Medium-risk areas fluctuated (slightly decreasing from 2007 to 2012, then increasing by 2018).

Fig.7 The FFPI distributions in Chiang Rai (2007, 2012, and 2018)

According to Table 2, during the initial 2007-2012 period, changes were modest. For example, the total area under High FFPI rose by only about 55.5% relative to 2007, and Elevated by 28.3%, whereas Medium and Moderate categories saw small declines (around -2.5% each). However, in the subsequent 2012 – 2018 interval a more pronounced escalation in risk occurred: High FFPI area grew by an additional 17.8%, and Elevated by 10.0% (relative to 2012 values), while Medium-risk area rebounded by 3.9% and Moderate continued to decline by -9.3%. The net result by 2018 was a greater proportion of the landscape in the High and Elevated categories than in 2007. These trends underscore an overall increase in flash flood susceptibility in Chiang Rai between 2007 and 2018, pointing to underlying drivers that intensified flood potential over time.

Table 2. Changes in FFPI category coverage across Chiang Rai

FFPI Category	Change in Area (2007–2012)	Change in Area (2012–2018)
High	+55.45%	+17.83%
Elevated	+28.29%	+10.01%
Medium	-2.53%	+3.87%
Moderate	-2.86%	-9.25%

FFPI changes in urban areas

When focusing on urbanized areas (built-up land and roads), the FFPI shifts were even more concentrated and extreme. Table 3 shows that in areas of urban growth, higher-risk FFPI classes expanded dramatically, especially during 2012 – 2018. In that period, the area classified as High FFPI in urban regions increased fivefold (approx. +500%), while Elevated-risk urban areas tripled (+208%), and Medium-risk urban areas nearly quadrupled (+296%). By contrast, from 2007 to 2012 the urban FFPI changes were minimal – High-risk urban area remained effectively unchanged (0% increase), and only modest growth occurred in the Elevated (+26%) and Medium (+21%) categories. The sharp rise in High and Elevated FFPI within urban and peri-urban zones after 2012 indicates that rapid urban expansion considerably intensified local flash flood potential. In other words, new development has been occurring in, or contributing to, areas of higher inherent flood risk, raising concern for those urbanizing locales.

Table 3. Changes in FFPI category coverage in Urban areas of Chiang Rai

FFPI Category	Change in Area (2007–2012)	Change in Area (2012–2018)
High	0.00%	+500.00%
Elevated	+26.23%	+207.82%
Medium	+21.18%	+295.61%

Land use/Land cover (LULC) change linkages

The observed FFPI increases are closely linked to major land use transitions in Chiang Rai over the study period. The extensive LULC changes by area are showed in Fig.8. Between 2007 and 2012, the largest transition was the conversion of

approximately 754.58 km^2 of woodland to agricultural land. Replacing forest cover with agriculture tends to increase runoff and flash flood potential. This woodland-to-agriculture conversion corresponds with the moderate rise in Elevated FFPI areas observed in 2007-2012. In the 2012-2018 period, the dominant change was urban expansion: about 437.87 km^2 of agricultural land was transformed into urban/built-up use (including road networks). This extensive agriculture-to-urban conversion greatly reduced infiltration and further increases runoff, aligning with the marked surge in High and Elevated FFPI areas after 2012. Another major change was an additional 407.01 km^2 of woodlands (intact through 2012) being converted to agriculture by 2018, reinforcing the pattern of deforestation contributing to flood hazard. Overall, these land use changes explain the FFPI distribution shifts: early-stage deforestation for agriculture created conditions for higher runoff (elevating flood risk), and subsequent urbanization of farmland amplified that effect, leading to a notable increase in high flash-flood-susceptibility zones across Chiang Rai by 2018.

Fig.8 Proportions of the major LULC in Chiang Rai (2007, 2012, and 2018)

CONCLUSIONS

The results indicated that sub-districts in western Chiang Rai with steeper slopes exhibit higher FFPI values compared to lower-gradient eastern lowlands, particularly where urban expansion has occurred on steep terrain. This observation suggests that high-slope areas accelerate surface runoff and reduce infiltration time, thereby amplifying the intensity and sudden onset of flash floods. From an exposure standpoint, human activities in these high-slope zones are inherently more susceptible to flash flood impacts than those in gentler areas. Moreover, ongoing urbanization and deforestation further exacerbates the surface runoff formation in rainfall events, increasing community vulnerability. Consequently, land use in high-slope regions must be rigorously regulated, and targeted flood-control infrastructure, such as check dams designed to retard runoff velocity, should be implemented to mitigate flash flood hazards and protect at-risk populations.

THE STUDY OF HELICAL PILE BEHAVIOR UNDER COMPRESSION FORCE IN KHON KAEN LOESS

Natchaphon Noiphang, Ratamanee Nuntasarn and Jitrakon Prasomsri

Faculty of Engineering, Khon Kaen University, Thailand

ABSTRACT

Khon Kaen loess soil is classified as collapsible and poses a serious challenge to foundation design, particularly under varying moisture conditions. While it exhibits high strength in dry conditions, moisture infiltration can cause significant settlement and structural damage over time. This study compares the design of a 6.5-meter-long triple helix helical pile with a helix spacing-to-diameter ratio (S/D) = 3 in Khon Kaen loess, using parameters obtained from Consolidated Drained (CD) triaxial tests on undisturbed and unsaturated soil. Theoretical predictions of ultimate bearing capacity were calculated using the individual bearing method. This study focuses on soil strength parameters from the Saturation, Transition and Residual Regime of the Soil-Water Characteristic Curve (SWCC) for the Khon Kaen loess. Results indicate that matric suction significantly affects shear strength parameters, especially cohesion, thereby influencing the bearing capacity of the pile. This research provides valuable insights for improving the accuracy and safety of foundation designs in collapsible soils, offering practical guidelines for engineering applications under seasonally fluctuating moisture conditions.

Keywords: Helical pile, Bearing capacity, Khon Kaen loess, Triaxial test, Consolidated drained

INTRODUCTION

Khon Kaen Loess is a type of collapsible soil [2] that exhibits high strength when dry but experiences rapid settlement upon wetting. The region is generally characterized as arid due to its relatively low average annual rainfall, which ranges from approximately 1,200 to 1,257 mm/year, with most rainfall occurring between May and October. These climatic conditions result in unsaturated soil. Therefore, the increase in soil moisture content during the rainy season can lead to structural damage.

Helical piles are deep foundations that are installed by screwing into the ground, thus avoiding excavation. Additional advantages of helical piles include minimal disturbance to the surrounding environment, suitability for limited-access sites, and the ability to be installed in a wide range of soil conditions and low vibration, quick installation. It provides resistance to both compressive and tensile loads [3]. Their load capacity depends on the surrounding soil properties, especially shear strength.

Designing helical piles for Khon Kaen Loess requires a deep understanding of unsaturated soil behavior, particularly the influence of matric suction on shear strength. This study utilizes results from Consolidated Drained (CD) triaxial tests conducted under varying suction levels (0, 10, 100, and 200 kPa). It focuses on the saturation, transition, and residual regimes in the Soil-Water Characteristic Curve (SWCC) of Khon Kaen Loess to analyze the soil strength parameters. Incorporating these parameters into design calculations improves the accuracy of estimating soil resistance around the pile under different suction conditions, leading to more efficient helical pile designs that align with the complex and seasonally variable behavior of the soil.

The scope of this research is to design helical piles and compare their ultimate bearing capacity based on the results of unsaturated triaxial tests.

Extended Mohr-Coulomb failure envelope

The extended Mohr-Coulomb failure envelope consists of shear stress at failure (τ_f), the net stress ($\sigma - u_a$) and matric suction ($u_a - u_w$). The equation of unsaturated soil was proposed by [1], as shown in Eq. (1) and (Fig. 1).

$$\tau_f = c' + (\sigma - u_a)_f \tan\phi' + (u_a - u_w)_f \tan\phi^b \quad (1)$$

Where;
τ_f = shear stress at failure
c' = effective apparent cohesion
u_w = pore water pressure
u_a = pore air pressure
$(u_a - u_w)_f$ = matric suction at failure
$(\sigma - u_a)_f$ = the net stress at failure
ϕ' = friction angle of effective stress
σ = total normal stress
ϕ^b = angle indicating the rate of increase in shear strength relative to the soil suction at failure plane

$$c = c' + (u_a - u_w) \tan\phi^b \quad (2)$$

Where
c = the cohesion intercepted

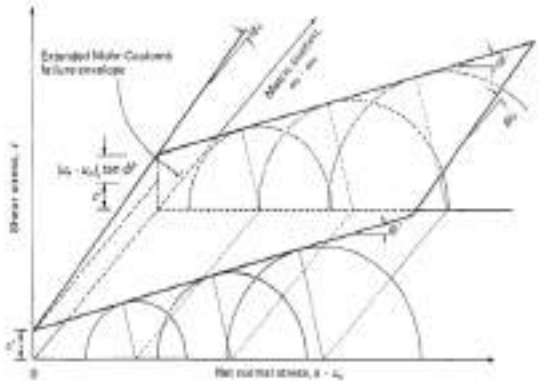

Fig.1 Extended Morh-Coulomb failure envelope for unsaturated soils.[1]

RESEARCH SIGNIFICANCE

Incorporating parameters that vary with matric suction into the design of helical piles can enhance the accuracy of soil resistance analysis and evaluation. This results in pile designs that are better suited to actual environmental conditions and more effectively accommodate the seasonally variable behavior of soils.

METHODOLOGY

Unsaturated CD Triaxial Test

Preparation of Specimens

The Khon Kaen loess soil sample was collected as an undisturbed sample from a depth of 2 m. The basic soil properties are presented in Table 1.

Table 1 Basic properties of soil

Properties	
Liquid limit (LL), %	19
Plastic limit (PL), %	NP
Plasticity index (PI), %	-
Specific gravity	2.65
Dry density (γ_d), t/m^3	1.73
Sand (%)	54.87
Silt (%)	28.09
Clay (%)	17.04
USCS classification	SM

Due to the difficulty in obtaining undisturbed soil samples, a multistage triaxial testing method is used. In this method, each stage applies a different confining pressure to a single soil specimen. According to the study by [4], the results of multistage testing on compacted Khon Kaen loess soil were found to be comparable to those obtained from single stage testing. Therefore, the multistage method is adopted in this research.

Table 2 Program of this study.

Sample No.	stage	σ_{net} (kPa)	u_a (kPa)	u_w (kPa)	ψ (kPa)
1	1	150	0	20	0
	2	300			
	3	450			
	4	600			
2	1	150	30	20	10
	2	300			
	3	450			
	4	600			
3	1	150	120	20	100
	2	300			
	3	450			
	4	600			
4	1	150	220	20	200
	2	300			
	3	450			
	4	600			

The soil specimens used for the consolidated drained triaxial test were 50 mm in diameter and 100 mm in height.

The unsaturated soil shear strength testing using the consolidated drained triaxial test [5] can be divided into the following steps.

Step 1, The soil specimen was placed into the triaxial compression apparatus. Water pressure was applied to the specimen until it became saturated, indicated by a B-value of 95%, as calculated using "Eq. (3)"

$$B = \frac{\Delta u}{\Delta \sigma_3} \quad (3)$$

Where
Δu = pore pressure change in the chamber pressure when drainage valves closed
$\Delta\sigma_3$ = isotropic change in the chamber Pressure

Step 2, The specimen was consolidated by increasing the net confining pressure. Both air and pore water pressures were applied according to Table 2. The drainage valve was opened to allow air and water to escape from the specimen.

Step 3, The specimen was shared at the rate determined in Eq. (4). The shearing process continued until the specimen approached the peak of the stress-strain curve. After reaching near-maximum stress, the axial load was reduced to 0 kPa to complete the test.

Steps 2 and 3 were repeated. After the final stage, which is stage 3 (σ_{net} = 600 kPa), the specimen was sheared to failure.

$$\text{Shear rate} = \frac{4\%}{16t_{90}} \quad (4)$$

Where

t_{90} = square root time derived from x- intercept in the relationship of the graph between total volume change and square root time.

RESUALS

Soil water characteristic curve

The results of the soil-water characteristic curve (SWCC) of compacted Khon Kaen Loess [8], shown in (Fig.2), indicate the first and second air entry values at 3 kPa and 650 kPa, respectively. At the first residual point, the degree of saturation is 42%. In this study, the soil parameters are compared across different suction ranges: Saturation Regime (0 kPa), the 1st Transition Regime (10 kPa), and the 1st Residual Regime (100kPa and 200 kPa).

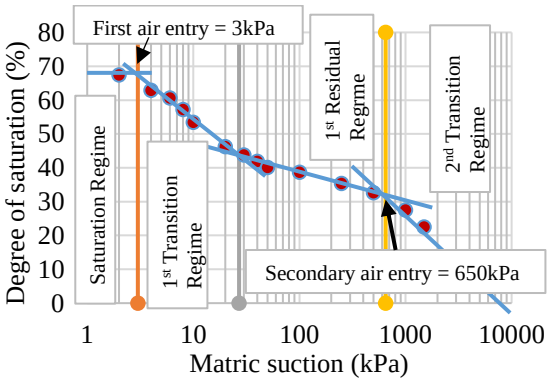

Fig.2 Khon Kean Loess Soil-Water Characteristic Curve.[8]

Consolidated drained triaxial test

The consolidated drained triaxial test was conducted saturated and unsaturated from Khon Kaen Loess using a multistage method. The confining pressures applied were 150, 300, 450, and 600 kPa,

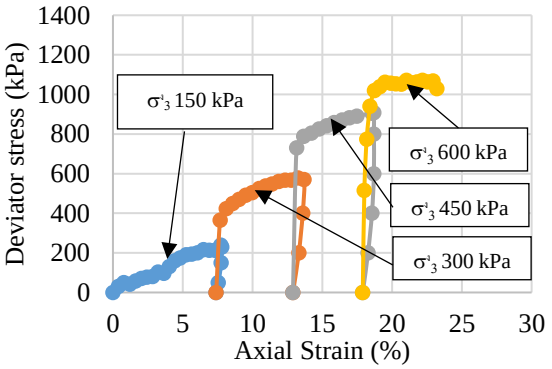

Fig.3 The stress-strain curve form multistage testing at saturated (Matric suction = 0 kPa).

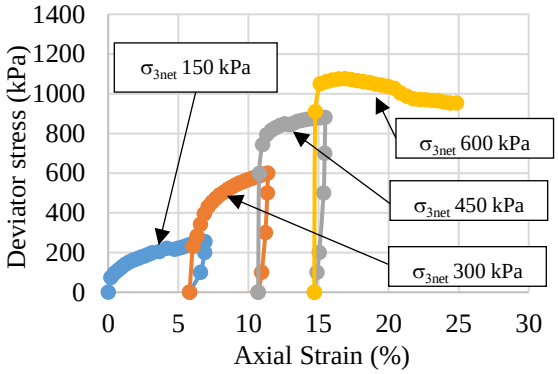

Fig.4 The stress-strain curve form multistage testing at matric suction of 10 kPa.

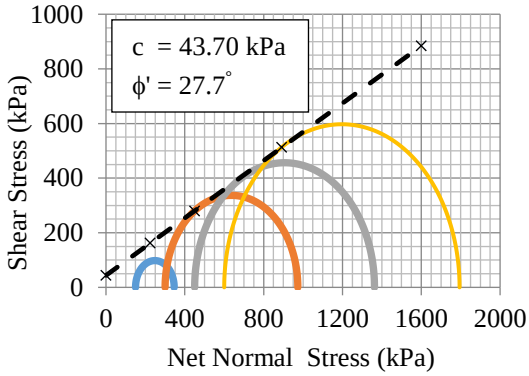

Fig.10 Mohr-Coulomb failure envelope at matric suction of 200 kPa

Table 3 Result of Unsaturated shear strength parameter

Sample No.	Matric suction	Cohesion Intercept (c)	ϕ' (deg)	ϕ^b (deg)
1	0	0	29.1	29.1
2	10	4.5	28.6	24.2
3	100	28.1	29.6	14.7
4	200	43.7	27.7	8.9

The relationship between matric suction shown that in (Fig.11), the value of ϕ^b, and the ϕ'are equal in saturation regime. The value of ϕ'remains relatively constant across the saturation regime, transition regime, and residual regime, whereas the angle ϕ^b decreases, which is consistent with the study of [4].

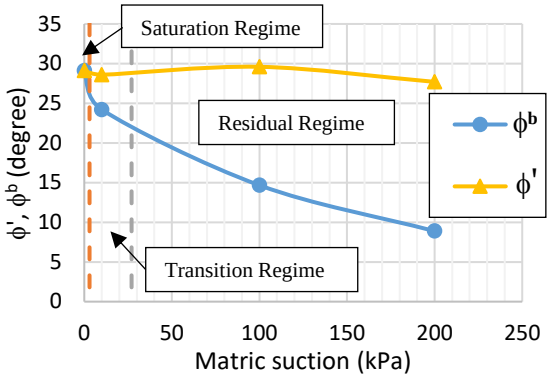

Fig.11 The relationship between matric ϕ^b, ϕ' between matric suction.

The relationship between matric suction and cohesion, as shown in (Fig.12), indicates an increase in cohesion across the saturation regime, transition regime, and residual regime, respectively.

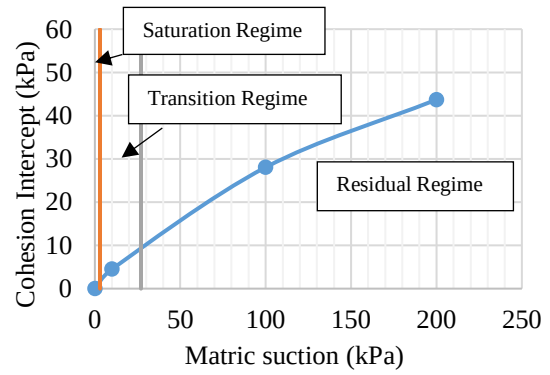

Fig.12 The relationship between matric suction and cohesion intercept.

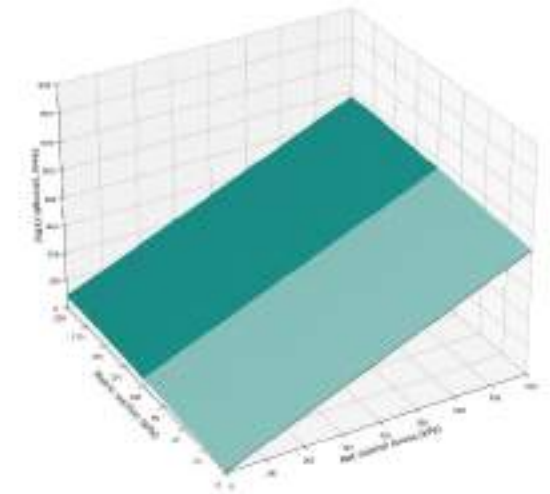

Fig.13 The 3D graph extended Mohr-Coulomb failure envelope.

ANALYSIS AND DISCUSSION

The bearing capacity calculation of helical piles can be performed using two methods: the individual bearing method and the cylindrical shear method, as presented by [3]. The individual bearing method involves summing the bearing capacity at each helix plate along the pile and shaft friction. The cylindrical shear method calculates the bearing capacity at the lowest helix plate, combined with the shear resistance of the soil between the helix plates and the undisturbed soil, as well as shaft friction. According to laboratory experiments by [10], to switch the calculation method from the cylindrical shear method to the individual bearing method, the pile must have a ratio of the spacing between helix plates to the diameter of the helix plate (S/D) greater than 2.1 to 3.4.

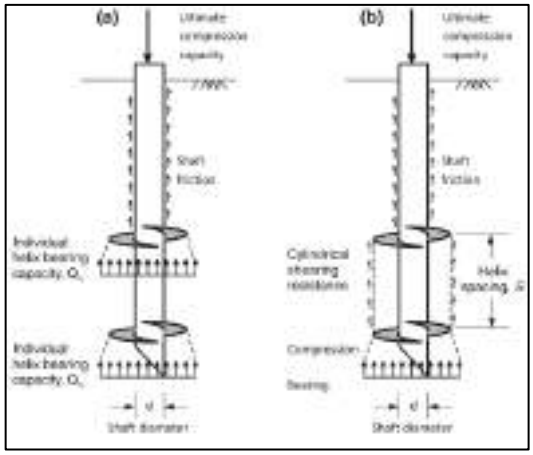

Fig.14 Analytical for estimating helical pile bearing capacity; (a) The individual bearing method, (b) The cylindrical shear method.[7]

This study designed the helical pile with a length of 6.5 m, a pile shaft diameter of 6 inches, a helix diameter of 45 cm, and a helix spacing ratio (S/D) = 3, applying the individual bearing method to calculated ultimate bearing capacity. The result shows that in (Fig.15)

$$Q_u = \sum Q_{helix} + Q_{shaft} \quad (5)$$

$$Q_{helix} = A_n(cN_c + qN_q + 0.5\gamma' BN_\gamma) \quad (6)$$

$$Q_{shaft} = \sum q_{si}\Delta L_i \pi d \quad (7)$$

Where
Q_u = ultimate bearing capacity.
A_n = area of the helical bearing plate.
N_c, N_q, N_γ = the bearing capacity factor [6]
d = diameter of helical pile.

DL_i = the pile segment length in soil layer *i*
q_{si} = the average unit shaft friction of soil layer *i*

The unit shaft friction for the sand layer can be estimated using $q_{si} = \sigma'_v K_0 \tan(\delta)$ where σ'_v is the effective vertical stress at the mid-depth of each soil layer [9], K_0 is the coefficient of lateral earth pressure.

Based on the design results from Eq. (5-7), it was found that the ultimate bearing capacity of the helical pile increases from the saturation regime to the residual regime. However, within the residual regime, the ultimate bearing capacity remains relatively constant. It is also observed that the bearing capacity behavior of helical piles primarily relies on the capacity of the helix plates.

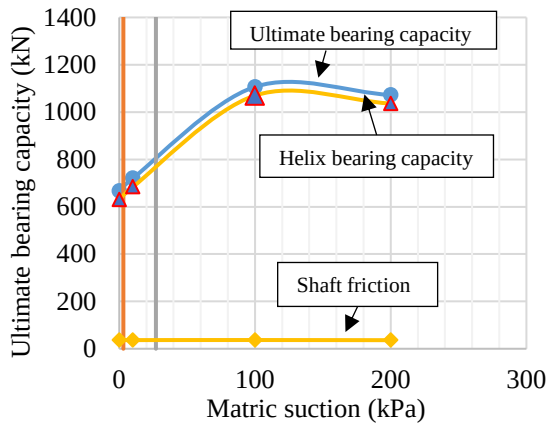

Fig.15 The Ultimate bearing capacity compares with increasing the matric suction.

CONCLUSIONS

This study focused on analyzing the influence of matric suction on the shear strength parameters of unsaturated Khon Kaen Loess and its impact on the design of helical piles. Consolidated Drained (CD) triaxial tests were conducted under various suction levels (0, 10, 100, and 200 kPa), and an extended Mohr-Coulomb failure envelope was developed to reflect the shear strength behavior of unsaturated soil.

The results of the consolidated drained triaxial tests show that increasing matric suction has a significant effect on cohesion, while the effective internal friction angle (ϕ') remains relatively constant across all suction levels, whereas ϕ^b was decreased. Based on the calculation of the ultimate bearing capacity of helical piles using the individual bearing method, it was found that the ultimate bearing capacity of pile increases 7.4% in Transition Regime and 63.3% in Residual Regime, compared to the Saturation Regime.

Due to the nature of Khon Kaen Loess, the soil exhibits high strength in dry conditions but collapses easily upon wetting. Therefore, seasonal moisture variations and the influence of matric suction must be carefully considered to achieve more accurate and stable foundation designs. In the case of helical pile foundations, it is recommended that design parameters be derived from laboratory testing rather than the site investigation data. Applying unsaturated soil mechanics in the design process can significantly improve the efficiency and safety of geotechnical structures in similar soil environments.

ABSTRACT

In recent years, the construction of photovoltaic power generation facilities has been actively promoted in mountainous areas and on idle farmland in Hokkaido, a region characterized by snowy and cold climates. However, significant damage due to the frost heave phenomenon—where the foundations and piles are lifted, leading to deformation of the panel mounts and warping of the panels themselves—has been occurring with increasing frequency. Continued deformation may lead to panel tilting, damage, or even collapse. Moreover, Japan has seen an increasing trend in extreme weather events such as heavy rainfall and sudden gusts of wind. If frost heave occurs during the winter and compromises the pile bearing capacity and pull-out resistance, these weakened conditions may lead to severe damage—such as the collapse of solar power facilities—when subjected to heavy rain or strong winds during the summer. This study aimed to clarify the frost heave behavior of spiral piles and straight piles, commonly used in the construction of photovoltaic power generation facilities, under freeze-thaw history. In addition, a series of three pull-out tests were conducted—from immediately after installation through the summer months—to examine the effects of freeze-thaw history on the pull-out resistance of the piles. The results indicated that frost heave displacement was suppressed in spiral piles, whereas residual frost heave displacement remained in straight piles during spring. Furthermore, it was confirmed that the pull-out resistance of both pile types decreased following exposure to freeze-thaw history.

Keywords: Freeze-thaw History, Frost Heave, Pile, Pull-out Resistance

INTRODUCTION

In recent years, decarbonization—aimed at reducing greenhouse gas emissions to zero—has become a global trend, placing pressure on Japan to transition from fossil fuels to renewable energy sources. As a result, photovoltaic power generation facilities are being actively constructed even in mountainous areas and idle farmland in Hokkaido, a region characterized by snowy and cold climates. However, significant damage due to the frost heave phenomenon has been occurring with increasing frequency.

Figure 1 presents examples of frost heave damage to solar panel mounts that have occurred in eastern Hokkaido. When frost heaving occurs in the ground, the foundations and piles supporting the solar panels are lifted, resulting in the deformation of the panel mounts and the warping of the panels themselves. Continued deformation may lead to tilting, damage, or even collapse of the solar panels. Such damage is not limited to Japan; similar cases have been reported in other cold regions, including Canada (e.g., Levasseur et al. [1]) and parts of North America (e.g., Kibriya [2]).

In Japan, a primary cause of frost heave damage to photovoltaic power generation facilities is the lack of established methods for predicting and mitigating

Fig. 1 Examples of frost heave damage to solar panel mounts.

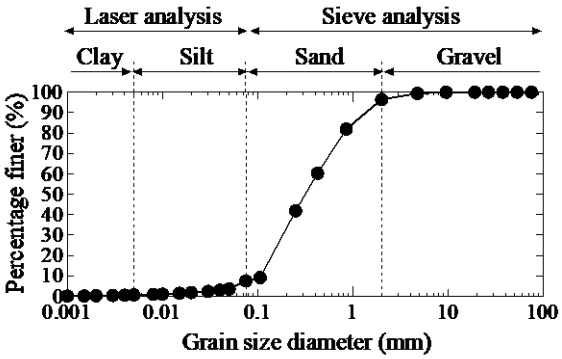

Fig. 2 Grain size accumulation curve.

such occurrences. Accordingly, there is a pressing need for the development of effective countermeasures and corresponding design methodologies.

Moreover, Japan has seen an increasing trend in extreme weather events such as heavy rainfall and sudden gusts of wind. If frost heave occurs during the winter and compromises the pile bearing capacity and pull-out resistance, these weakened conditions may lead to severe damage—such as the collapse of solar power facilities—when subjected to heavy rain or strong winds during the summer.

This study aimed to clarify the frost heave behavior of spiral piles and straight piles, commonly used in the construction of photovoltaic power generation facilities, under freeze-thaw history. In addition, a series of three pull-out tests were conducted—from immediately after installation through the summer months—to examine the effects of freeze-thaw history on the pull-out resistance of the piles.

OVERVIEW OF THE EXPERIMENT

Soil Properties of the Experimental Site

In this study, an embankment was first constructed using locally sourced soil. Then, an excavation was carried out to a depth of 2 meters, after which the excavated area was backfilled with frost-susceptible sandy soil in October 2022. A full-scale pile models of a pile were subsequently installed in the backfilled ground. Various physical properties of the soil at the experimental site were measured through tests conducted in accordance with the Japanese Geotechnical Society Standards.

Figure 2 shows the grain size accumulation curve of a soil sample obtained in accordance with the method stipulated by JIS A 1204 [3]. Based on the coarse-grained and fine-grained contents, the soil sample is classified as sand.

The soil particle density ρ_s is 2.51 g/cm^3, as determined in accordance with the method stipulated by JIS A 1202 [4].

Figure 3 shows the compaction curve of a soil

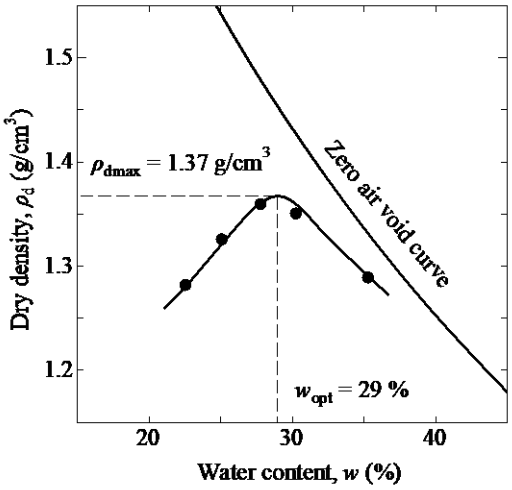

Fig. 3 Compaction curve.

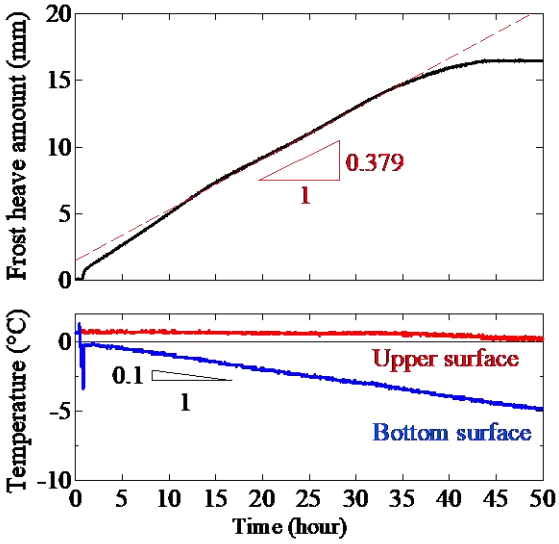

Fig. 4 Frost heave test result.

sample obtained in accordance with the A-a method stipulated by JIS A 1210 [5] (Compaction energy E_c is 550 kJ/m^3 (Standard proctor)). The optimum water content W_{opt} is 29% and the maximum dry density ρ_{dmax} is 1.37 g/cm^3.

The dry density measured at the experimental site using a sampler (100 cm^3 volume) was 1.22 g/cm^3 and the degree of compaction D_c was about 90%.

Figure 4 shows the result of the frost heave test conducted in accordance with the method stipulated by JGS 0172-2020 [6]. The frost heave rate obtained from the temporal change in the frost heave amount is 0.379 mm/hour. This value exceeds 0.3 mm/hour, which is the threshold for high frost susceptibility according to the Japanese Geotechnical Society Standards.

Details of the Installed Piles and the Embedded Sensors

Table 1 Experimental conditions.

Case	Type of pile	Embedment depth (m)	Blade width (mm)	Number of blades (pieces)	Mass (kg)
1	Spiral pile	1.5	0.100	3.5	26
2	Spiral pile	1.5	0.050	6.5	24
3	Straight pile	1.5	0.000	0.0	21
4	Spiral pile	1.5	0.025	9.0	23
5	Spiral pile	1.0	0.100	2.0	19
6	Spiral pile	1.0	0.050	4.0	18
7	Straight pile	1.0	0.000	0.0	16
8	Spiral pile	1.0	0.025	5.5	17

Table 1 summarizes the experimental conditions of this study. In this experiment, the superstructure—including the solar panel and its mounting frame—was not installed. All piles, regardless of type, were made of steel and were installed using the rotary penetration method.

Figure 5 schematically illustrates the installed piles and the arrangement of various measurement instruments. In this study, eight types of piles were used, combining different embedment depths, the presence or absence of blades, and variations in blade width and number. The piles were classified into two categories: spiral piles with blades (Cases 1, 2, 4, 5, 6, and 8) and straight piles without blades (Cases 3 and 7). Two embedment depths were adopted: 1.5 m (Cases 1 to 4) and 1.0 m (Cases 5 to 8). The blade widths for the spiral piles were set to three values: 0.100 m (Cases 1 and 5), 0.050 m (Cases 2 and 6), and 0.025 m (Cases 4 and 8). Notably, the number of blades increases as the blade width decreases.

Temperature measurement rods and soil moisture sensors were embedded as measurement instruments. The temperature measurement rods were installed to monitor the freezing depth of the ground around the piles, while the soil moisture sensors were used to assess the moisture conditions in the surrounding soil. Soil temperature and moisture were automatically measured every hour. The amount of frost heave in each case was observed by conducting leveling surveys periodically (approximately once every one to two weeks). Snow removal was continuously performed around the piles throughout the measurement period.

Pile Pull-Out Test

Figure 6 shows the pull-out test conducted in this study. The test was carried out using a backhoe. First, a tension-type load cell suspended from the arm was connected to a fixture attached to the top of the pile using a wire. Then, a displacement gauge was installed on the top of the pile, and the arm was slowly lifted to pull the pile vertically.

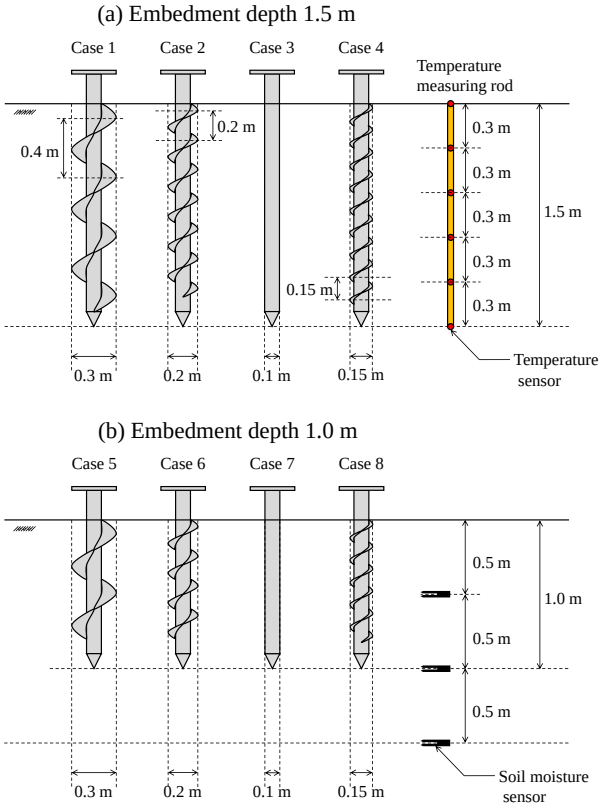

Fig. 5 Schematic diagram of the piles installed in this study.

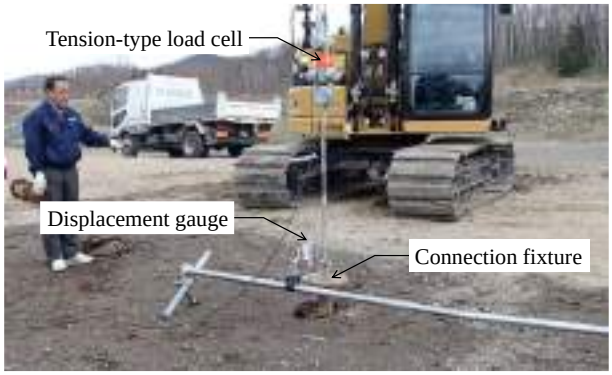

Fig. 6 Pile pull-out test.

The pull-out test was conducted three times: immediately after installation on November 18, 2022; immediately after the freeze-thaw cycle on April 24, 2023; and during summer on September 1, 2023. In addition, to understand the ground conditions before and after each pull-out test, a simplified dynamic cone penetration test and a density test were conducted.

RESULTS AND DISCUSSIONS

Frost Heave and Thaw Behavior of Piles

Figure 7 presents the temporal variations in the freezing depth and volumetric water content of the ground around the pile, and the vertical displacement of the piles.

During the winter of 2022–2023, the maximum frost depth was approximately 0.65 m. However, because the piles were made of steel, the freezing depth in the surrounding ground may have been greater than this value.

Focusing on the vertical displacement during the freezing period, it was observed that piles with greater embedment depths exhibited smaller amounts of frost heave when compared to those with shallower embedment, under the condition of identical blade width. This trend was more pronounced as the blade width increased.

During the thawing period, although most piles generally settled and returned to their original positions, the straight pile without blades and with an embedment depth of 1.5 m (Case 3) did not exhibit any significant settlement. Consequently, the displacement caused by frost heave remained as residual deformation.

These results suggest that in spiral piles with greater embedment depth, the blades are likely to facilitate downward movement during the thawing period by mobilizing earth pressure, thereby contributing to the reduction of residual frost heave deformation.

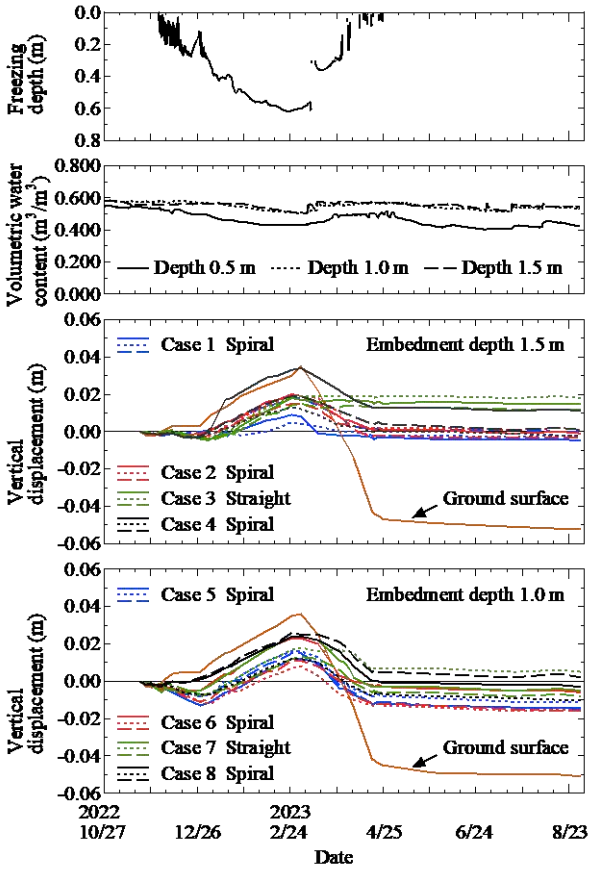

Fig. 7 Temporal variations in the freezing depth and volumetric water content of the ground around the pile, and the vertical displacement of the piles.

Pull-Out Resistance of the Piles

Figure 8 shows the results of the pile pull-out tests conducted before and after the freeze-thaw cycle, and Table 2 presents the average maximum pull-out load of each pile and its relative change.

In the pull-out tests conducted before freezing, all

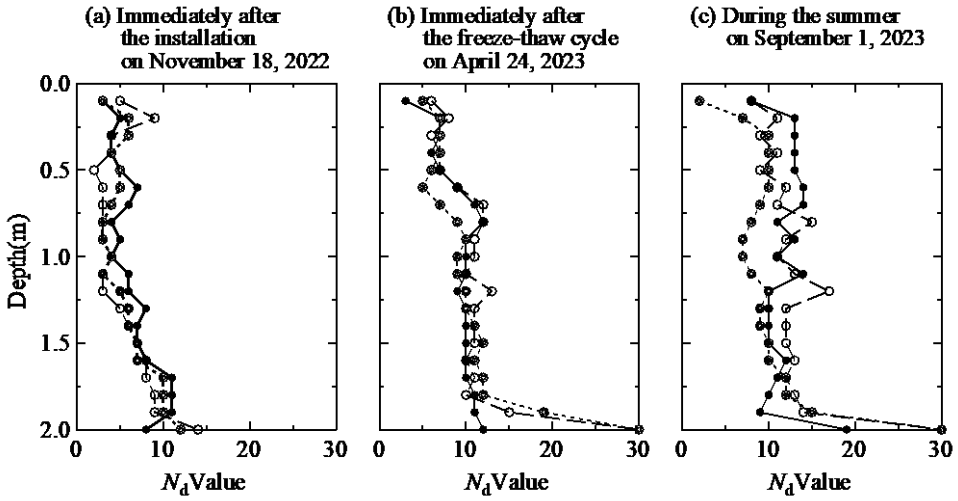

Fig. 9 Results of the simplified dynamic cone penetration tests.

spiral piles were extracted following rotation, which occurred before any soil failure was observed. In contrast, no rotation was observed in any of the piles either immediately after the freeze-thaw cycle or during the summer.

When comparing the results obtained immediately after installation (unfrozen condition) with those obtained immediately after the freeze-thaw cycle, a certain degree of variability was noted in the experimental data. However, the pull-out loads generally decreased after the freeze-thaw cycle, indicating a reduction in pull-out resistance.

In particular, the piles with an embedment depth of 1.0 m appeared to exhibit almost no pull-out resistance after the freeze–thaw cycle.

However, in the case of the spiral pile with a blade width of 0.050 m and an embedment depth of 1.5 m (Case 2), the reduction in pull-out load was relatively small. These results suggest that spiral piles with sufficiently wide blades and a greater number of blades located below the freezing depth are less affected by the freeze-thaw history.

Furthermore, a comparison between the results obtained immediately after the freeze-thaw cycle and those obtained during the summer indicates that the pull-out loads increased in the summer, reflecting an improvement in pull-out resistance.

Investigation of Ground Conditions Using Simplified Dynamic Cone Penetration Test Results

Figure 9 shows the results of the simplified dynamic cone penetration tests, and Table 3 presents the results of the density tests.

Immediately after installation, the N_d values were below 10 down to a depth of approximately 1.5 m, and the degree of compaction D_c was as low as 90%, indicating low ground strength.

Following the freeze-thaw cycle, although the N_d values remained below 10 down to a depth of 0.7 m, they were generally around 10 at greater depths. The depth at which the N_d values fell below 10 roughly corresponded to the maximum freezing depth,

suggesting that the reduction in pull-out resistance observed after the freeze-thaw cycle was due to a weakening of the surface layer of the ground.

During the summer, however, the N_d values exceeded 10 at all depths, and the D_c reached 96%, indicating that the ground had become more compacted after thawing and that its strength had increased.

CONCLUSIONS

In this study, the frost heave behavior of piles used in the construction of photovoltaic power generation facilities was investigated, along with the effects of freeze-thaw history on their pull-out resistance.

Experimental results revealed that the pull-out resistance of piles was low immediately after installation and decreased further in the spring following freeze-thaw cycles. These findings suggest that there may be an increased risk of photovoltaic power generation facilities collapse due to strong winds during the periods immediately after installation and in early spring following freeze-thaw events.

In the future, using the knowledge obtained in this study, we would like to propose a design method for economical and effective frost heave countermeasures for piles.

ACKNOWLEDGMENTS

These findings were obtained as a result of work commissioned by the New Energy and Industrial Technology Development Organization (NEDO), a national research and development agency.

SLOPE STABILITY OF SOIL-ROCK MIXTURE: A CASE STUDY ON LIMESTONE FORMATION AND HIGH RAINFALL AREA

Arief Rachmansyah[1], Adefi Abioga Tiswa[2], Fajar Rahmanto[2]

[1]Civil Engineering Department, Brawijaya University, Indonesia
[2] Geotechnical Independent Consultant, Malang, Indonesia

ABSTRACT

The weathering process of limestone in areas with high rainfall, such as in Java Island, Indonesia, produces soil and rock masses ranging in size from gravel to boulders. The slope stability analysis of the mixed mass cannot be approached from rockslide or landslides, but requires a different approach. The stratification of the rock and soil in the slide zone is complicated because there are several blocks of rock and fine-grained soil. The thickness of the mixed soil-rock mass layer also needs to be known. Electrical resistivity tomography (ERT) survey and geotechnical drilling were conducted to create a subsurface model of soil–rock mixture stratification. The properties of the soil-rock mixture (SRM) were estimated by rock block proportion on the slope. A transient model of slope stability analysis was created using the SEEP/W program to simulate slope seepage and SLOPE/W to compute slope stability. The elevation of the groundwater level and the pore water pressure on the slope are altered by antecedent rainfall. When examined, these phenomena will have an impact on the slope's safety factor. The slope safety factor (FoS) was reduced by 31.48% from 1.542 to 1.057 in the event of extreme rainfall, which does not satisfy the requirement for a slope safety factor of 1.25.

Keywords: slope stability, soil-rock mixture, limestone formation, high rainfall area.

INTRODUCTION

In 2010, the East Java Provincial Government began construction of the South Coast Road to accelerate economic growth in the south region, which had been left behind compared to the northern part. Most of the route passes through hilly areas composed of limestone or karst areas. One of the problems faced during the construction of the road was mass movement.

Mass movement is a common disaster in areas with high rainfall and seismicity, because both are triggering factors. Many slope failures occur on soil-rock mixture slopes, where the slip plane is the boundary between the fresh or impermeable rock layer and the layer of soil or weathered material above it. To calculate slope stability and plan for mass movement mitigation, it is generally approached from the factor of safety. The initial factor of safety of a slope is primarily controlled by slope geometry, material properties, and the initial depth of the water table. In some cases, the occurrence of mass movement is largely influenced by changes in material properties induced by rainfall [1].

Soil-rock mixtures (SRM) are a combination of soil and rock blocks, and the shear strength of these mixtures depends on the volume of rock that are mixed into the soil. [2,3,4]. The size distribution, rock position, shape and roughness of the rock shape affect the stability of the slope [5,6]. Nevertheless, numerous engineers frequently disregard the impact of rock mixed with soil, presuming that SRM is an authentic form of soil. While simplifying the behavior of slopes with this specific type of SRM to pure soil may enhance slope safety, it is important to note that the behavior and properties of SRM slopes remain uncertain [7].

The effect of the proportion of rock matrix in the soil on the SRM slope was studied using a combination of physical modeling and numerical modeling by the finite difference method approach. The results indicated that an increase in the proportion of rock in the slope resulted in an enhanced safety factor. However, this study employed a statistical approach to determine the position of rocks in the slope [8,9].

The position and size of rocks in the SRM can be determined using electrical resistivity tomography (ERT) investigation [10,11]. The quantity of rock matrix present on the slope can be calculated using the resistivity value obtained through the application of the ERT method [12]. Nevertheless, this approach is limited by its reliance on soil moisture, which can significantly influence the outcome [13] Therefore, verification of ERT results using boring is required.

Several studies have attempted to statistically approximate the critical rainfall conditions that cause slope failure [14.15.16]. In general, it is recognized that heavier rainfall might result in a more substantial rise in the slope's negative pore water pressure and a larger decrease in the groundwater table [17,1]. Under the same rainfall conditions, a higher value of k_{sat} (saturated soil permeability) will result in a higher pore water pressure buildup than the initial condition resulting in a reduced slope safety factor. Soils with lower k_{sat} values will reduce matric suction and a rise in groundwater level [18]. Rainfall duration and intensity, however, are correlated variables. Antecedent rainfall can cause a decrease in the safety

factor of low conductivity soil slopes up to 45% and a decrease in the safety factor of high conductivity soil slopes up to 13% before the occurrence of major rainfall [19].

In the rainfall-induced landslides the soil properties are determined by hydraulic properties including soil water characteristic curve properties (SWCC) and unsaturated soil permeability [20]. A landslide caused by rainwater analysis using SLOPE/W and SEEP/W showed that a severe rainstorm that lasted for 16 hours and with an intensity of 112.5 mm/h was the cause of the landslide [21]. The total amount of precipitation that fell before the landslide was 306.5 mm. Slope instability resulted from the antecedent rainfall's impact on the slope's initial state, which raised the soil pore water pressure. The occurrence of slope failure is significantly influenced by the characteristics of topographic hollows [22].

Experiment modeling slopes subjected to artificial rainfall to determine the effect of slope angle on slope stability that can be validated by numerical show the slope's vulnerability to abrupt collapse during rainstorms rises with slope angle. Failure is caused by the loss of soil suction when the slope angle is 1.2 times more than the soil friction angle, and by positive pore water pressure at the slope's toe when it is smaller or equal to 1.2 times the soil friction angle [23]. These studies demonstrate that slope failure variables rely on slope geometry in addition to soil characteristics and rainfall.

RESEARCH SIGNIFICANCE

The goal of this study is to establish the safety factor of post-failure slopes at the research site by analyzing the slope stability of soil-rock mixture slopes while considering the impact of previous rainfall. Slope stability calculations are generally carried out using only soil or rock approach, however the moving material is composed of a mixture of both, especially in weathered limestone.

This paper discusses the results of landslide research on soil rock mixture materials, and the effect of rainfall on landslide mechanisms. The landslide slip plane, and the percentage of material mixture are determined based on the results of geoelectric investigations combined with drilling data. Combination between Electrical Resistivity Tomography (ERT) and boring investigations are used to proposed model of subsurface material and its stratification. This model will be used for numerical analysis using the SLOPE/W and SEEP/W programs, so the results are like natural condition.

RESEARCH LOCATION

The site of the study is located at coordinates 112.069852° E and 8.294235° S (Figure 1.). Administratively a landslide occurred in Bululawang village, Blitar Region.

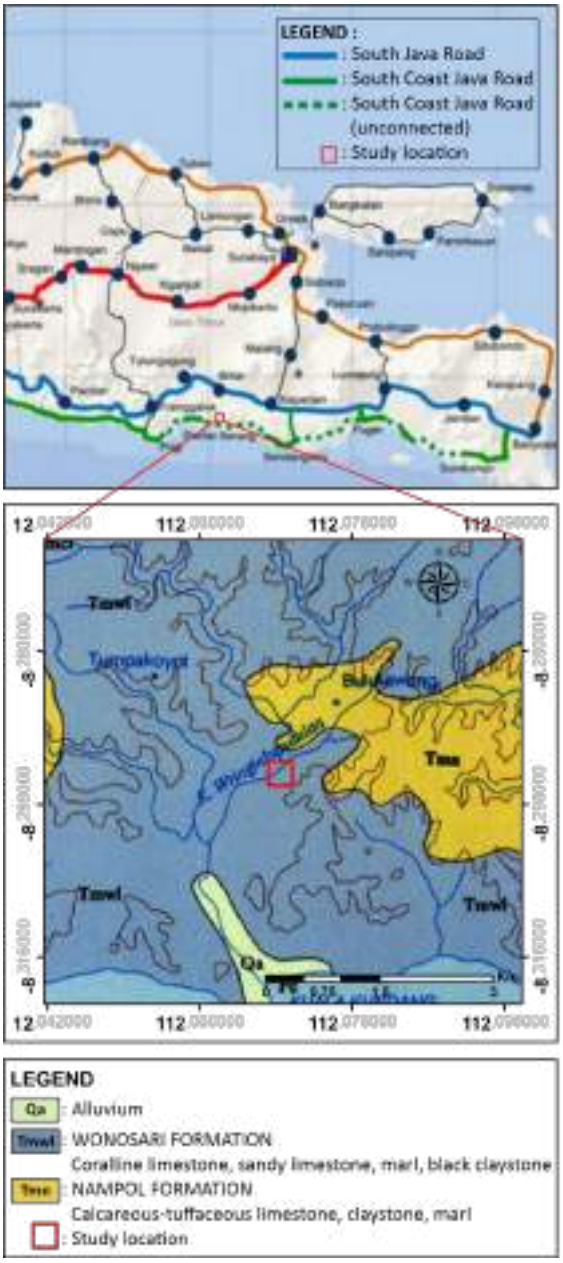

Figure 1. National Road Network on East Java Province Indonesia, and Geological Map of Study Area

According to the geologic map of Blitar sheet [24], this study site is in the Wonosari Formation – (Tmwl). This unit consists of coralline limestone, argillaceous-tuffaceous-sandy limestone, marl, black claystone with peats. A visual of the slope at the study site shows limestone gravel and boulder mixed with soil, limestone blocks are spread over the landslide area. This material is known as soil rock mixture (SRM) or debris (Figure 2).

Figure 2. Soil Rock Mixture (SRM) on Research Location

RESEARCH METHOD

Soil - Rock Properties and Stratification

The slope elevation results are plotted into the CAD Civil 3D program and a closed polygon is created according to the equipment elevation readings to form the slope geometry. Several boring geotechnical and geophysical surveys are required to determine soil stratigraphy. Electrical resistivity tomography (ERT) is one of the most reliable techniques for generating images of the subsurface condition. Soil resistivity can reflect groundwater content, porosity, and clay content. Therefore, the ERT results are integrated with boring can be used as a basis for creating subsurface soil stratification.

Geoelectric data acquisition carried out at the research location consists of 3 lines, with each having a length of 200 meters. The line consisted of 2 lines aligned east-west, BLL-2 and BLL-3, and 1 line (BLL-1) cutting perpendicular to both lines BLL-2 and BLL-3 with a north-south direction. The configuration used for this geoelectric survey is Wenner-alpha. The ERT survey line, boring position and cross section used for this research can be seen in Figure 3.

.

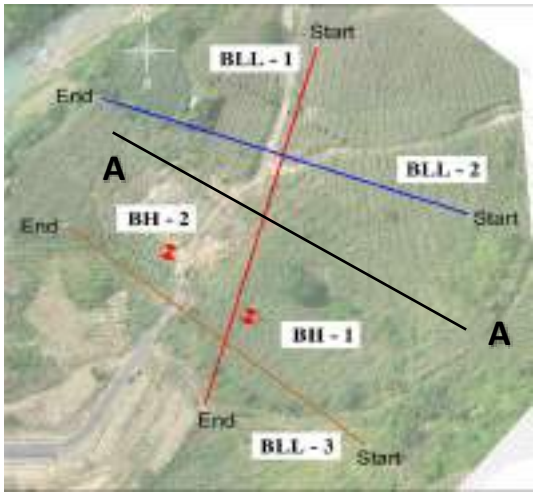

Figure 3. ERT Line and cross section of the slope and location of geotechnical boring

Permeability of the soil at saturated state was determined using the falling head method. Shear strength of silty clay soil are investigated using triaxial unconsolidated undrained method. To determine the shear strength of the debris or SRM, which was predominantly composed of sand, clay, and boulders, an empirical approach proposed by Zhang et al [25] was employed. The shear strength of unsaturated soil is determined by the Vanapalli equation [26] which is a function of volumetric water content, soil shear strength and residual water content.

Rainfall

The lack of a weather station in close approximation to the research location, as well as the absence of rain records with hourly time intervals, directed to the utilization of GPM satellite data. The rainfall data used is from the Giovanni Online Data System website developed by NASA GES DISC. The data is Integrated Multi Satellite Retrieval for Global Precipitation Measurement (GPM-IMERG), which contains rain infiltration data throughout the world. Precipitation data at the research site was collected in hourly time intervals in the time frame of 2014 to 2023 (10 years).

Antecedent rainfall was evaluated because it can alter the pore water pressure profile on the slope [27]. Antecedent rainfall has a duration of 5 days with 3 different rain patterns. The rain patterns are called delayed, normal, and advanced. This antecedent rain pattern uses cumulative maximum rainfall data for 5 days [19].

Numerical Modeling

In this study, permeability, shear strength parameters, and soil water characteristic curve parameter (SWCC) are random variables. Limit equilibrium base analysis will be conducted using the SEEP/W and SLOPE/W programs.

Safety factors of the slope calculated using General Limit Equilibrium (GLE) in unsaturated condition provided by SLOPE/W program. A water flux boundary condition is used above the slope model to simulate rainwater infiltration, a constant head boundary condition is used on the right side, and a no flow boundary condition is used on the left and bottom sides to stop water from flowing in the area. Flowchart for modelling in SLOPE/W and SEEP/W for this study can be seen in Figure 4.

RESULT AND DISCUSSION

Antecedent Rainfall

When satellites conduct observations of precipitation, the data may not reflect the immediate precipitation events, as it takes time for the precipitation to reach the earth's surface [28]. The

satellite data is validated using several statistical techniques, including the linear correlation coefficient (R^2), the observation standard deviation ratio (RSR) and the Nash-Sutcliffe efficiency (NSE). These are used to determine the extent of any discrepancy between the data collected at the rain station and that obtained from the GPM satellite.

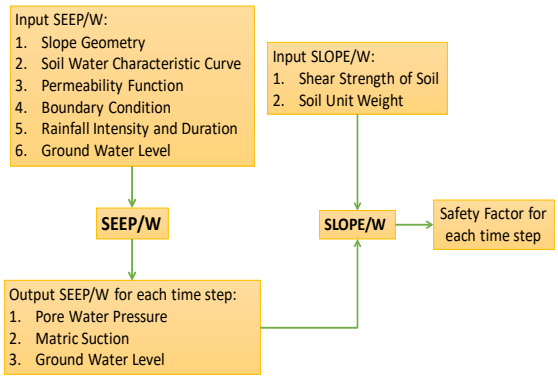

Figure 4. Modeling in SEEP/W and SLOPE/W

Monthly precipitation data from the GPM satellite have been validated with data from a rainfall station, which is 105 km from the research location [29]. The results of the calibration of GPM rain data and rain stations demonstrate a strong correlation, as indicated by the RSR, NSE, and R^2 values of 0.359, 0.917, and 0.964, respectively. Statistical testing on the GPM satellite indicates that the mean accuracy value for GPM data is 0.75 and showed a relatively high degree of correlation [30].

The available data from GPM, the maximum cumulative rainfall for 5 days at the study site was 428.853 mm. Figure shows the antecedent rainfall pattern used in this analysis. The delayed type of rain is low in intensity and increases over time, the advance type is a rain that is high in intensity and then steadily decreases, and the normal pattern is a rain that increases in intensity until a certain time and then decreases in intensity like a normal distribution.

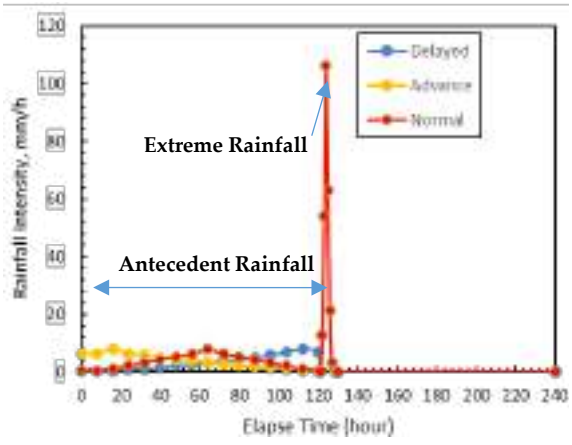

Figure 5. Rainfall pattern on the study area after GPM

The extreme rainfall event has been applied to the slope after the end of the antecedent rainfall event. Extreme rainfall was obtained from the maximum hourly rainfall over a 10-year period. Extreme rainfall was applied for 8 hours with a normal pattern and the maximum rainfall was 106,144 mm/hr (Figure 5).

Subsurface Profile

The ERT measurement results are processed in the Res2div program, and the results can be seen in Figure 6. Soil interpretation was conducted using the ERT profile results combined with borehole BH-1 and BH-2. The boring results can be seen in Figure 7.

The correlation was carried out on BLL-1 with BH-1 at the 160 m position and the BH-2 boring was correlated with BLL-1 at the 105 m position. From the correlation results, the resistivity pattern of the soil conditions from the boring results is obtained. The resistivity value of 1 - 15 ohm is debris dominated by sand and clay, 15 - 20 ohm is Silty clay, 20 - 30 ohm is debris dominated by boulder, and the value above that is limestone block.

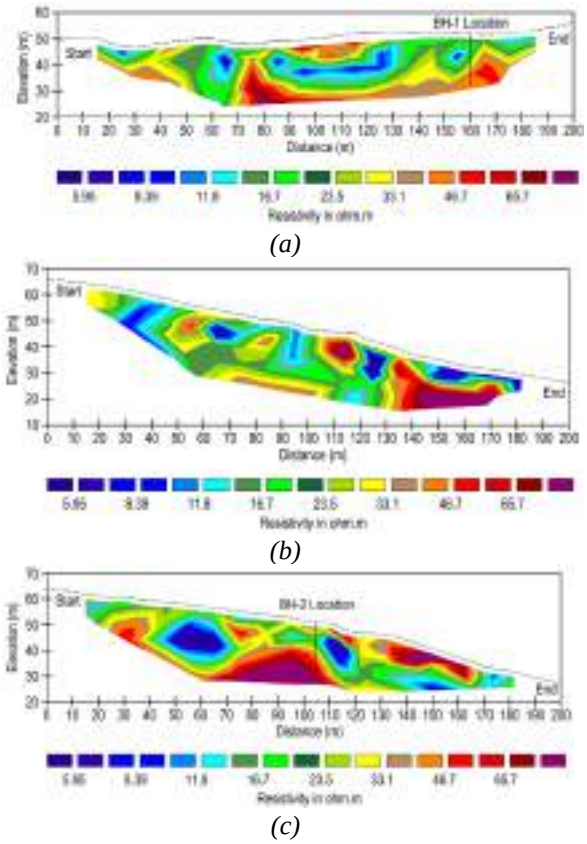

Figure 6. Electrical Resistivity Tomography (a) BLL-1 Cross Section; (b) BLL-2 Cross Section; (c) BLL-3 Cross Section

Soil - Rock Properties and Stratification

The soil at the study location varies, such as silty clay, SRM (debris) dominated by boulder, SRM dominated by sand and clay, and limestone block.

Properties of silty clay were obtained from laboratory tests. The limestone block was modeled as a high strength material with a unit weight of 21.62 kN/m^3. Table 1 is a recapitulation of the soil properties. The results of soil stratification in cross section BLL-1, BLL-2, BLL-3 can be seen in Figure . The results of soil stratification in cross section A-A are obtained from interpolation of the results of soil stratification BLL-1, BLL-2, BLL-3 and boring. The results are presented in Figure 8.

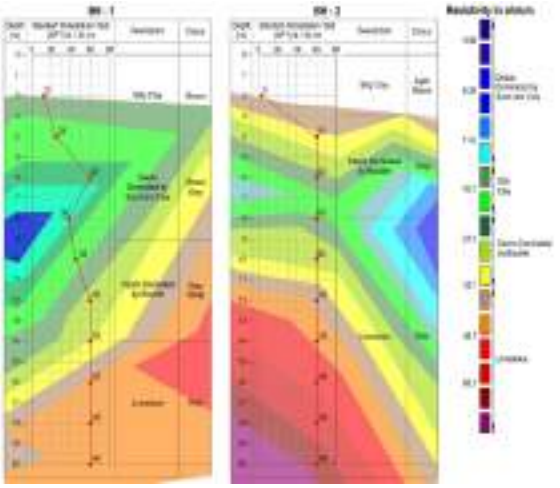

Figure 7. ERT Verification with boring data

Table 1. Soil Properties

Material Description	γ_b (kN/m^3)	Cohesion (kN/m^2)	Internal friction (deg)	Saturated Permeability (cm/s)	Void Ratio	Plasticity Index (%)	Fine Content (%)
Silty Clay Soil	17.464	21	9	4.20E-04	1.11	40.26	68.37
SRM Dominated by Sand and Clay	19.58	15.14	14.69	1.32E-03	0.65	41.11	71.78
SRM Dominated by Boulder	19.24	8.00	20.38	1.39E-02	0.72	38.30	68.90

The shear strength of SRM depends on the rock block proportion (RBP) of the soil and the compressive strength of the SRM. The SRM compressive strength is a function of the strength of the soil-rock contact surface (Parameter A) and the soil compressive strength. Parameter A in the calculation of SRM shear strength can be determined from the approach by Kalender, et al [31] which depends on the roughness of block surface and angle of repose of rock block. The average SPT value of debris dominated by sand and clay had N-SPT value of 35, from Hara, et al [32] the compressive strength of soil can be correlated with SPT after correction and the compressive strength of debris dominated by sand and clay is 386 kPa. Parameter A is set at 0.50 and the RBP value used for this analysis in debris dominated by sand and clay is 30%.

Debris dominated by boulder had average corrected N-SPT value of 49.68 had compressive strength of 494 kPa. Parameter A was determined to be 0.52 with an RBP of 50%.

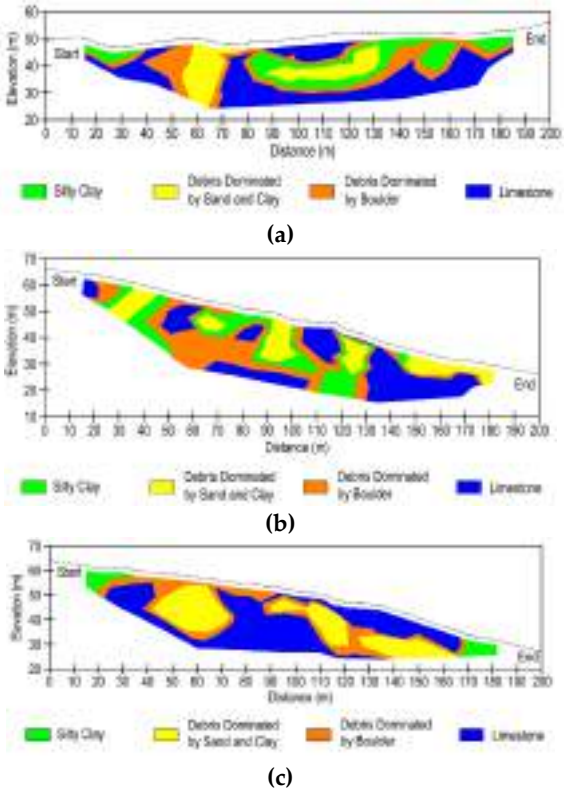

Figure 8. Soil Stratification (a) BLL-1 Cross Section; (b) BLL-2 Cross Section; (c) BLL-3 Cross Section

Rain infiltration's impact on soil saturation level is examined using the soil water characteristic curve (SWCC). The equation to estimate the SWCC is based on the Fredlund, et al method [33]. Because the soil has a high proportion of plastic clay and silt, a plastic soil approach was used to calculate the curve fitting SWCC parameters using the estimation method developed by Zapata et al [34]. The calculation of hydraulic conductivity was used Fredlund grafts. [35]. Permeability and matric suction curves have different slopes depending on the shape of the SWCC curve. Soil permeability with zero matric suction is the permeability when the soil is saturated.

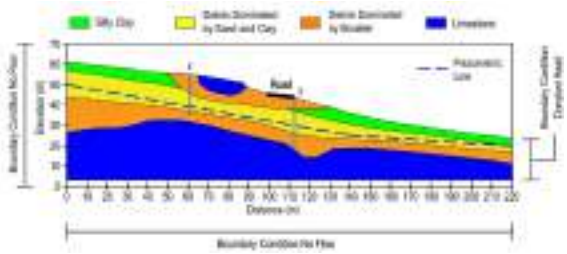

Figure 9. Soil stratification model in section A-A, initial condition, and boundary condition used in model

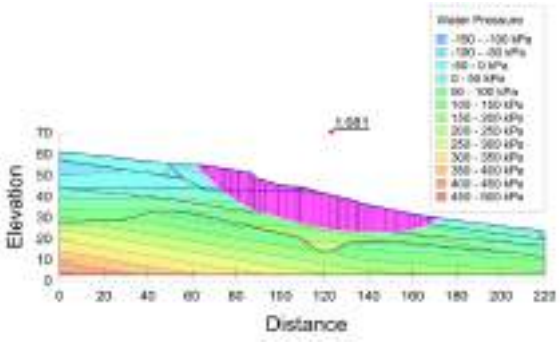
Depending on the level of soil saturation, the model's soil unit weight will change. The soil's unit weight will rise in proportion to its saturation level. The original unit weight at the time the soil samples were gathered is the γ_b value (Table 1). Initial

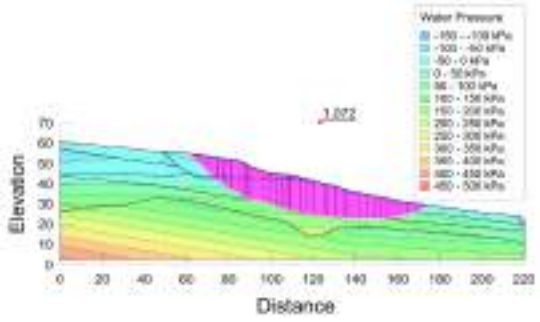
moisture content of silty clay is 41.97%, initial moisture content of sand and clay-dominated debris is 24.65%, and initial moisture content of boulder-dominated SRM is 27.14%.

Numerical Modelling

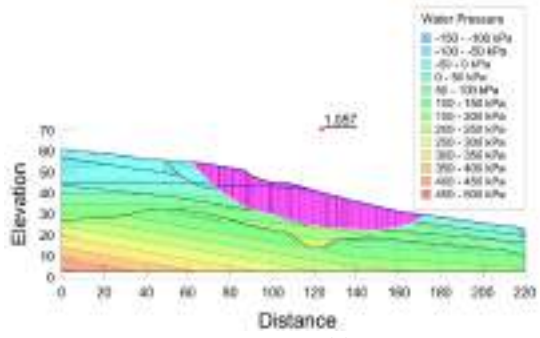
Slopes subjected to antecedent rainfall have a difference in FoS, which is 30.37% for delayed pattern, 30.69% for advance pattern and 31.48% for normal pattern from the initial FoS (t = 0 h). Therefore, the value of the slope safety factor is greatly influenced by the antecedent rainfall factor. The results of the analysis were that slope failure does not occur in extreme rainfall alone, but significant antecedent rainfall can cause slope failure, which is consistent with this study [36].



(a)



(b)



(c)

Figure 20. Shape of the Sliding Plane, t = 130 h (a) Delayed; (b) Advance; (c) Normal

Table 2 illustrates the lowest possible value of Factor of Safety (FoS) in each antecedent rain pattern. The lowest FoS value is observed in the Normal pattern, with a value of 1.057, followed by the Advance pattern (1.072) and the Delayed pattern (1.081). The greatest disparity in FoS values between t = 120 h and 130 h is observed in the Advance pattern, with a difference of 0.196 (15.44%), followed by the Normal pattern with a difference of 0.186 (14.96%) and the Delayed pattern with a difference of 0.149 (12.09%). The maximum discrepancy in FoS values for each rain pattern is 0.024 (2.22%), which is not particularly indicative of a significant difference. This is because there is a correlation between precipitation intensity and saturated soil permeability. The maximum rainfall intensity on the slope is 106.144 mm/hour, which is less than the maximum soil permeability coefficient on the slope, which is 498.60 mm/hour ($1.39x10^{-2}$ cm/sec) with a rainfall intensity of 0.2128 x saturated soil permeability.

Therefore, the infiltration of water into the soil will be absorbed into the soil, resulting in a significant increase in groundwater level and, consequently, slope instability. This result is in accordance with the states that high permeability soil (>10^{-5} m/s) is highly influential in extreme rainfall with short duration and intensity [1]. A rainfall intensity of less than 1 x saturated permeability is sufficient to result in the lowest FoS for the slope.

Figure 20 illustrates the configuration of the sliding plane and the distribution of pore water pressure on the slope in the event of extreme rainfall. In general, regardless of the rainfall pattern, the configuration of the sliding plane remains consistent and the groundwater level (pore water pressure = 0 kPa) contacts the slope surface, thus resulting in a saturated slope.

Table 2. Factor of safety reduction from t = 120 h to t = 130 h

Pattern	Value of FoS t = 120 h	FoS Minimum t = 130 h	FoS Reduction	
Delayed	1.229	1.081	0.149	(12.09%)
Advance	1.268	1.072	0.196	(15.44%)
Normal	1.242	1.057	0.186	(14.96%)

CONCLUSIONS

The combination of electrical resistivity tomography (ERT) and soil boring is an effective method for modeling soil and rock stratification of slope. The use of soil boring data is beneficial for supporting the results of ERT that are highly sensitive to the presence of water.

For analyzing the stability of limestone slopes in areas with high rainfall, where block and gravel-sized rock fragments are common, a soil-rock-mixture (debris) material approach is very logical.

The safety factor of slopes is affected by antecedent rainfall prior to the application than extreme rainfall. It was found that the cumulative infiltrated water in the slope resulted in a reduction of the lowest factor of safety, which was greatest for the normal pattern, followed by the advance and delayed patterns. The location and depth of the sliding plane in this slope stability analysis did not change significantly for each antecedent rainfall pattern.

ABSTRACT

This research paper focuses on the load capacity of piles anchored in sedimentary rock, specifically sandstone and siltstone, which often present unique challenges in pile design and construction. The study emphasizes the importance of considering factors such as the degree of weathering when designing pile capacity in rock formations. The authors conducted static load tests on 16 large-diameter bored piles, applying loads of 2.5 times the working load (1,625-2,500 tons). Following these tests, back-analysis calculations were performed to determine critical parameters and equations used in pile capacity design, including adhesion factors. The research also proposes a method for adjusting the rock strength to more accurately reflect its condition based on the degree of weathering. Key findings from the study show that the bearing capacity of sandstone is comparable to that of clay, while siltstone has a bearing capacity approximately 60% higher than clay. This research provides valuable insight into the field of geotechnical engineering, particularly in the design of pile foundations in sedimentary rock formations, by addressing the effects of weathering on pile bearing capacity.

Keywords: Bored piles, Weak rocks, Degree of weathering, Siltstone and sandstone, Pile capacity

INTRODUCTION

The study of pile bearing capacity in soil has been extensively studied. In general, soil layers present greater homogeneity compared to rock layers, resulting in relatively straightforward calculations of pile bearing capacity. In contrast, evaluating the bearing capacity of piles in rock is more complex due to the presence of inhomogeneity. Rock masses often contain imperfections such as fractures and weathering, which pose additional challenges in the design of pile capacity in these materials. In the pile construction industry, piles socketed in rocks are frequently designed with high conservation due to insufficient geotechnical investigation and adequate understanding of pile behavior, leading to uneconomic designs.

This research focuses on the calculation of design parameters for evaluating the bearing capacity of bored pile socketed in weak rock, based on back-calculation from pile test data obtained through static load test method. Skin friction equations of piles socketed in weak rocks are proposed, along with a method for adjusting rock strength by considering the degree of weathering.

RESEARCH SIGNIFICANCE

In this research, an attempt was made to identify appropriate parameters for the design of bored piles constructed in weak sedimentary rocks such as sandstone and siltstone. These rocks are characterized by their high susceptibility, especially when the construction is carried out using the wet-process bored pile system, which causes these rocks to exhibit slaking behavior. Consequently, the pile capacity observed in practical situations often deviate from calculated values. This research therefore attempts to identify pile design parameters that provide engineers with more accurate data, leading to further design developments and reduced material usage.

DATA AND ANALYSIS

Static Pile Load Test Results

The data analyzed for this research were obtained from 16 test piles, all of which were constructed using the wet-process bored pile construction method using polymer mixed with bentonite solution as a borehole stabilization. After drilling was complete, the borehole was left to allow for sedimentation and then cleaned with a cleaning bucket to ensure a stable pile base prior to concrete placement.

Static load tests were conducted on all 16 bored piles subjected to varying applied loads. Each test involved three cycles of loading, corresponding to 1.25, 1.25 and 2.5 times the allowable load, respectively. The test piles had diameters of 1.2 and 1.5 m., with pile lengths ranging from 9.3 m. to 36 m., and socketed lengths in rocks varying between 0.3 m. and 9.8 m. The allowable working load ranged from 650 to 750 tons for piles with a diameter of 1.2 m. and 1,000 tons for piles with a diameter of 1.5 m. General

information of piles is summarized in Table 1.

Table 1 General information of test piles

Pile no.	d (m.)	Pile Length (m.)	Soil or rock at the pile tip	Socket length (m.)	Allowable working load (tons)	Max. applied load (tons)
1	1.2	9.3	Siltstone	0.3	700	1,750
2	1.2	36	Clay	-	700	1,750
3	1.2	14.5	Siltstone	4.0	700	1,750
4	1.2	35.3	Clay	-	700	1,750
5	1.2	19.8	Sandstone	3.3	700	1,750
6	1.2	20.3	Siltstone	8.3	700	1,750
7	1.2	18.6	Siltstone	7.6	700	1,750
8	1.2	15	Siltstone	4.5	700	1,750
9	1.2	15.5	Clay	-	700	1,750
10	1.2	16.5	Sandstone	2.5	700	1,750
11	1.2	15	Sandstone	1.0	700	1,750
12	1.2	18.5	Sand	-	700	1,750
13	1.2	35	Sand	-	700	1,750
14	1.2	22	Clay	-	650	1,625
15	1.2	14	Siltstone	9.5	750	1,875
16	1.5	14.3	Siltstone	9.8	1,000	2,500

The test results of 16 piles illustrate the relationship between the applied load (P) and the pile head settlement (δ_h), as shown in Fig. 1. The data indicate that, for most piles, pile heads settlement increases progressively with applied load up to approximately 2.25 times the allowable load. Beyond this point, a remarkable increase in the pile head settlement is observed, indicating that the load starts to transfer to the pile tip. This indicates that all test piles exhibit generalized load-settlement behavior, where the applied load is resisted through a combination of shaft friction along the pile surface and end bearing resistance at the pile tip.

In addition, most piles exhibit the pile head settlement values ranging from 5 to 11 mm. When considering the influence of ground conditions, it is found that the piles socketed in weak rocks exhibit lower pile head settlement compared to those embedded in soil.

To compare the load-settlement behavior of all piles with varying allowable working loads and pile diameters (d), the maximum settlement under the maximum applied load was normalized by the diameter of each pile, as presented in Table 2. The pile head settlement of the most piles was less than 1% of the pile diameter (except for Pile no.2, which exhibited a soft base due to an improper cleaning of the borehole). According to Eurocode7 [1], a pile under compressive load is considered to have reached a failure state when the pile head settlement equals 10% of the pile diameter. Additionally, Ng et al. (2001a) [2] suggested that a moderately conservative estimate for the pile toe mobilization in large-diameter bored piles has been determined to be 4.5% of the pile diameter. Based on these criteria, the settlement of all piles in this study remained below both thresholds proposed. Nevertheless, in this study, the mobilization between soil-pile and rock-pile interfaces is determined based on strain gauge measurements, which will be discussed in the following chapter.

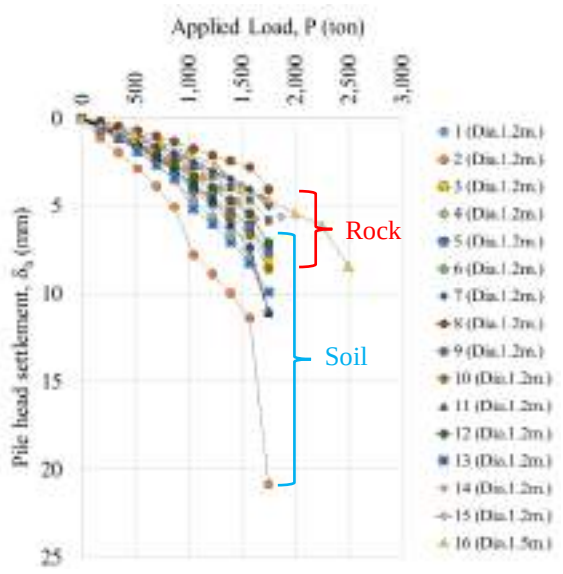

Fig. 1 Applied load vs pile head settlement for 16 test piles

Table 2 Maximum pile head settlement normalized by pile diameter

Pile no.	Maximum pile head settlement (δ_h, mm.)	Pile diameter (d, mm.)	δ_h/d (%)
1	11.09	1200	0.74
2	20.86	1200	1.39
3	8.11	1200	0.54
4	11.02	1200	0.73

16	8.44	1500	0.56

Skin Friction (f_s) Discussion

Skin friction (f_s) and displacement were measured using strain gauges on each test pile. The data indicate that most rock layers did not reach full mobilization, with an average maximum displacement of approximately 3 mm. In contrast, all soil layers showed soil-pile displacements in the range of 5–10 mm, indicating full mobilization in those layers. Extrapolation is therefore applied by using a hyperbolic equation to predict the fully mobilized skin friction for rock layers. The skin friction (f_s) at a displacement of 5 mm. was chosen to represent the maximum displacement of the rock layer (Horvath et

al. 1983) [3]. Skin friction values of all soil and rock layers are shown in Table 3 to Table 5. The data in Table 4 and Table 5 are arranged according to skin friction (f_s) and the degree of weathering. From the tables, they are shown that skin friction (f_s) of siltstone and sandstone varies in the range from 22-120 t/m^2. A comparison between the uniaxial compressive strength (σ_i) of intact rocks and the skin friction (f_s) reveals inconsistencies in the data. In certain cases, rock layers exhibiting high uniaxial compressive strength (σ_i) values correspond to relatively low skin friction (f_s) values. However, when considering the degree of weathering as described by BS5930 (1981) [4], a consistent correlation with skin friction (f_s) is observed. Rock layers classified as having a low degree of weathering tend to exhibit high skin friction (f_s) values.

Accordingly, in this research, the strength of intact rock was adjusted by considering the influence of weathering to better reflect practical performance.

Table 3 Ranges of mobilized skin friction for each type of soil and rock

Soil or rock type	Mobilized skin friction (ton/m^2)
Stiff clay	2.5-15.0[(1)]
Hard clay	15.0-84.0[(1)]
Loose sand	6.0-8.0[(1)]
Dense sand	8.0-75.0[(1)]
Rock salt	20.0[(1)]
Siltstone	22.0 – 120.0[(2)]
Sandstone	27.0 – 95.0[(2)]

Note: [(1)]Fully mobilized, [(2)]Extrapolated

Table 4 Mobilized skin friction from strain gauges for siltstone

Pile no.	Depth of layer	σ_i (ton/m^2)	f_s (ton/m^2)	Degree of weathering
1	-8.0 to -9.0	2,920	120.1[(1)]	Fresh
3	-10.5 to -12.0	1,318	107.0[(2)]	Fresh
3	-12.0 to -13.0	1,318	92.0[(2)]	Slightly weathered
15	-10.0 to -13.0	2,114	82.7[(2)]	Moderately weathered
7	-11.0 to -15.0	1,270	81.4[(1)]	Moderately weathered
6	-12.0 to 15.5	1,900	68.2[(2)]	Moderately weathered
6	-15.5 to -19.0	1,900	60.7[(2)]	Moderately weathered
16	-10.0 to -13.0	2,114	55.3[(1)]	Moderately to highly weathered
8	-10.5 to -14.0	746	33.6[(2)]	Moderately weathered
15	-4.5 to -10.0	2,114	23.8[(2)]	Highly weathered

Note: [(1)]Fully mobilized, [(2)]Extrapolated

Table 5 Mobilized skin friction from strain gauges for sandstone

Pile no.	Depth of layer	σ_i (ton/m^2)	f_s (ton/m^2)	Degree of weathering
10	-14.0 to -15.5	3,146	98.7[(2)]	Fresh
5	-16.5 to -18.5	1,898	38.1[(2)]	Slightly to moderately weathered
7	-15.0 to -18.0	1,270	37.4[(2)]	Slightly weathered
13	-16.5 to -22.0	1,663	28.9[(1)]	Slightly weathered
13	-22.0 to -28.0	1,663	26.8[(1)]	Slightly weathered

Note: [(1)]Fully mobilized, [(2)]Extrapolated

The data obtained from the static load tests were back-analyzed to determine critical parameters and equations applied in pile capacity design, including adhesion factors (α) and skin friction (f_s) for weak rock. The details of the results are presented in the following content.

RESULTS

Adhesion Factor (α) for Clay and Weak Rock

The adhesion factor (α) of clay is back-calculated from skin frictions obtained from strain gauges. The corresponding results are presented in Fig. 2, plotted on a logarithm scale on both axes and compared with the empirical relationship proposed by Kulhawy and Phoon (1993) [5]. The undrained shear strength of the clay (S_u) is normalized by atmospheric pressure (p_a). It is important to note that all unit skin friction values for the clay represent fully mobilized conditions. The equation of adhesion factors for clay, derived from this study, is as follows:

$$\alpha = x(S_u/p_a)^{-0.5} \quad (1)$$

Where x is equal to 0.6. To cover 90% of the data points, the upper and lower bounds of the x value would be about 1.2 and 0.3, respectively.

The adhesion factor (α) of weak rocks is back-calculated from the mobilized skin friction obtained from strain gauges, which were extrapolated as previously described. It is acknowledged that the strength of in-situ rock is generally lower than that of intact rock. Therefore, the analysis is adopted by considering a reduction factor based on the degree of weathering of the rock, as proposed by Kulhawy and Prakoso (2007) [6], who indicated that the uniaxial compressive strength of weathered rocks can decrease to about 15 to 20 % of that of unweathered rocks. The resulting values are presented in Fig. 3.

The uniaxial compressive strength of the rock (σ_c) is normalized by atmospheric pressure. The adhesion factor data are plotted from both extrapolated and fully mobilized data in logarithm graph. The regression of adhesion factor for the siltstone is given by the following equation:

$$\alpha = 1.02(\sigma_c/2p_a)^{-0.5} \quad (2)$$

Which can be simplified as follows:

$$\alpha = (\sigma_c/2p_a)^{-0.5} \quad (3)$$

Equation (3) corresponds to Kulhawy and Phoon (1993)'s approach where x is equal to 1 to 3 for weak rocks. For the sandstone, the regression line is:

$$\alpha = 0.50(\sigma_c/2p_a)^{-0.5} \quad (4)$$

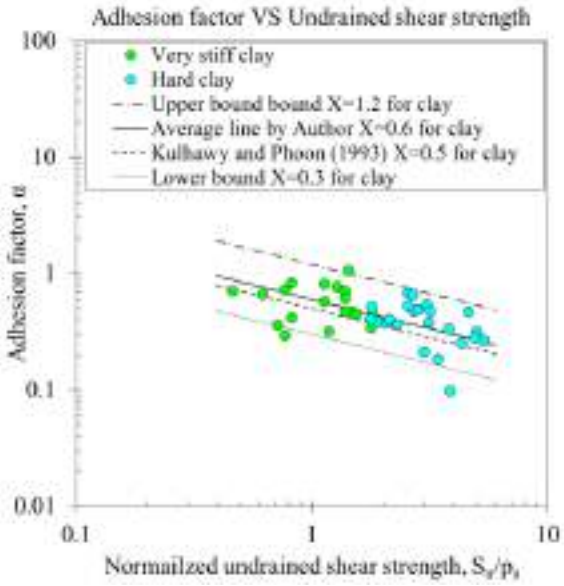

Fig. 2 Adhesion factors for clay (logarithm plotting)

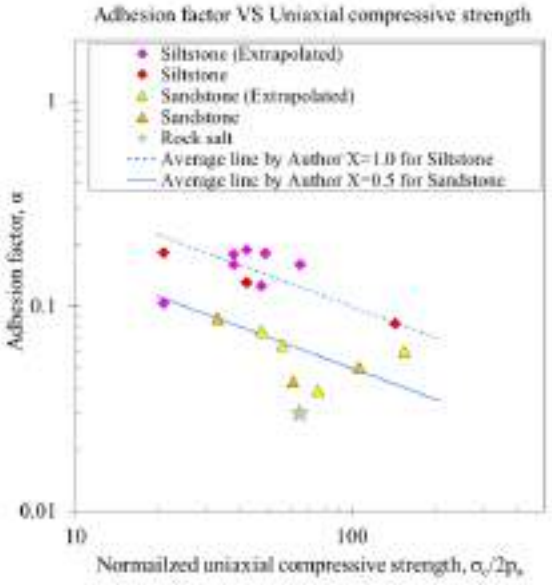

Fig. 3 Adhesion factors for weak rock (logarithm plotting)

Skin Friction (f_s) for Weak Rocks

The skin friction derived from stress gauge measurements and extrapolations can be directly expressed as an equation without the need to determine the adhesion factor. The relationship commonly presented by other researchers is shown in Equation (5), which is in the form of an exponential equation representing the relationship between skin friction (f_s) and uniaxial compressive strength of rock (σ_c).

$$f_s = x\sigma_c^{0.5} \quad (5)$$

Various values of parameter x have been proposed by different researchers. For example, Ng et al. (2001b) [7] studied the skin friction of decomposed granitic rocks in Hong Kong and, based on a displacement of 1% of the pile diameter (approximately 10 mm), proposed a value of x = 0.19. Kulhawy et al. (2005) [8] conducted a comprehensive review of available data and proposed x = 0.31 and x = 0.08 for drilled and grouted piles, corresponding to 70% and 100% data coverage, respectively. Rowe and Armitage (1987b) [9] proposed x values based on roughness classes, with x = 0.45 for regular clean sockets (R1, R2, and R3 classes), and x = 0.6 for clean-rough sockets (R4 class). Zhang and Einstein (1998) [10] reviewed data from several key researchers and recommended x = 0.8 for rough sockets.

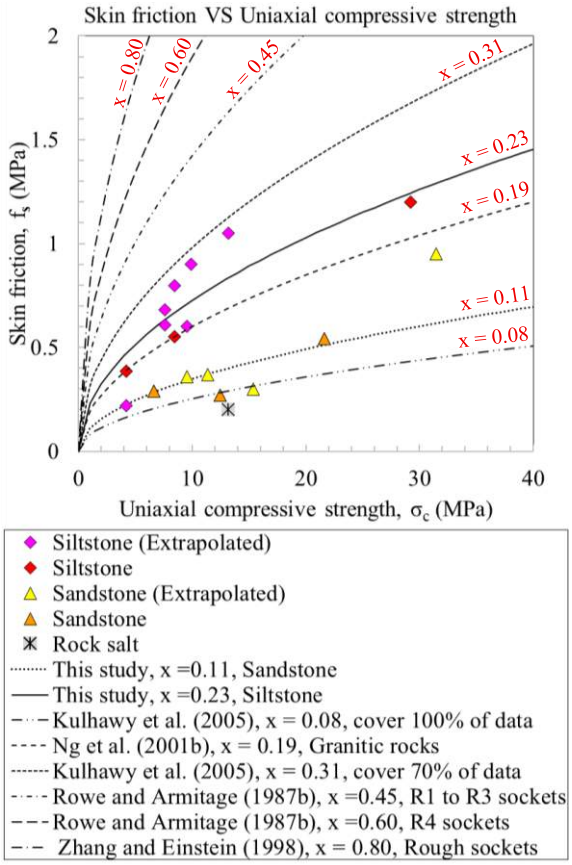

Fig. 4 Side friction resistance for weak rock versus the uniaxial compressive strength of rock (linear fitting)

For this study, the following empirical equation to estimate the skin friction of piles in sandstone is proposed as:

$$f_s = 0.11\sigma_c^{0.5} \quad (6)$$

For piles socketed in siltstone, the skin friction is observed to be higher than that of piles in sandstone.

Based on the analyzed data, the following empirical equation to estimate skin friction is proposed for piles in siltstone:

$$f_s = 0.23\sigma_c^{0.5} \quad (7)$$

The relationship between skin friction (f_s) and uniaxial compressive strength of rock (σ_c) of this study is illustrated in Fig. 4 in comparison with the results reported by the aforementioned researchers. The graph indicates that the skin friction values for siltstone in this study are comparable to those proposed by Ng et al. (2001b) and Kulhawy et al. (2005). Nonetheless, the siltstone in this study is more comparable to the rock group investigated in the research of Kulhawy et al. (2005), which also included sedimentary rocks. For sandstone, the obtained values are relatively low but align with the lower bound of the data presented by Kulhawy et al. (2005), who proposed an x value covering the full range of observed data.

CONCLUSION

This study demonstrates that the bearing capacities of piles in both sandstone and siltstone are relatively comparable when evaluated at equivalent degrees of weathering. When the adhesion factors are calculated back, key findings reveal that the bearing capacity of sandstone shares the same trend as that of clay, whereas siltstone exhibits a bearing capacity approximately 60% higher than that of clay. The corresponding equations for adhesion factors are presented in Table 6.

When skin friction is directly evaluated as a function of the uniaxial compressive strength of rock for both siltstone and sandstone, the results are represented in Table 7. In this context, it is essential to account for the degree of weathering of rock in order to appropriately adjust the strength of intact rock when calculating skin friction values.

Table 6 the adhesion factors of clay, siltstone and sandstone

Clay	Siltstone	Sandstone
$\alpha = 0.60(S_u/p_a)^{-0.5}$	$\alpha = 1.02(\sigma_c/2p_a)^{-0.5}$	$\alpha = 0.50(\sigma_c/2p_a)^{-0.5}$

Table 7 Summary of the results of skin friction for rocks

Method	Siltstone	Sandstone
Exponential fitting	$f_s = 0.23\sigma_c^{0.5}$	$f_s = 0.11\sigma_c^{0.5}$

Note that the load-bearing behavior of rock is typically characterized by a bilinear relationship. The compressive strength of rocks should be limited to not exceed the 28-day compressive strength of concrete.

ACKNOWLEDGMENTS

I would like to thank SEAFCO Public Limited Company, a bored pile construction company, for providing me rock core samples and static load test reports that made this research possible.

INTEGRATION OF SOIL RESISTIVITY AND BOREHOLE DATA TO EVALUATE GEOMATERIALS AND N_{60}-VALUE USING CLUSTERING ANALYSIS

Ratchadakorn Chumkhiao [1], Sukit Yindeesuk [2], Kuo Chieh Chao [3] and Shinya Inazumi [4]

ABSTRACT

Geotechnical data is the foundation of geotechnical engineering. Primarily, drilling was the technique for obtaining subsurface data. In recent decades, non-intrusive methods such as electrical resistivity surveys, enhanced by machine learning, have proven to be very useful for in-depth geotechnical site investigations. The goal of this study is to use 2D Electrical Resistivity Imaging (2D ERI) and Standard Penetration Test (SPT) data together to sort geomaterials using K-Means Clustering Analysis (KMCA), which will help us learn more about the properties of the subsurface. We created a power equation by analyzing soil electrical resistivity with N_{60}-value along a designated 2D ERI line, which was verified with borehole data. This power equation was then used to calculate estimated N_{60}-value in slope regions where SPT data was not directly accessible. The KMCA proved to be an adaptable tool, facilitated categorizing geomaterials in the study area into three main clusters aligned with different competency levels based on SPT data. These clusters include low competency materials (loose sand), medium competency materials (medium - stiff clay), and high competency materials (stiff - hard clay). The power equation effectively calculated the N_{60}-value for 2D ERI lines 1 and 2, confirmed by borehole data from BH6 and BH7, respectively, achieving high accuracy with R^2 of 0.8396 and 0.9283, MAE of 4.86 and 6.38, and RMSE of 6.21 and 7.39. This framework demonstrates how combining geophysical surveys with machine learning methods can help to better characterize subsurface geomaterials and make conventional methods more useful.

INTRODUCTION

Subsurface properties are essential in engineering projects, including foundation design and slope stability evaluation. Direct data collection through borehole drilling is a fundamental method for acquiring the engineering properties of geomaterials and assessing subsurface conditions at specific locations and depths. The traditional approach is time-consuming and costly, and the data acquired lacks comprehensiveness relative to the broad area, resulting in insufficient data in certain regions and ambiguous subsurface properties. To cope with the constraints of drilling techniques, 2D electrical resistivity imaging (2D ERI) and machine learning (ML) have been utilized.

Ciampi [1] examined subsurface litho-stratigraphy by merging 2D ERI with drilled boreholes through clustering analysis. In a manner, Akingboye [2], they combined seismic wave velocity (v_P) with electrical resistivity and borehole logs to elucidate the surface-subsurface properties of soil and rock, optimizing the analysis using a regression model. Furthermore, Dick [3] employed clustering and regression to characterize the link between resistivity and SPT N-value, subsequently identifying lithologies in the research area. Previous research facilitated the application of combined methodologies in several contexts, including the oil and gas sector, to assess reservoir rocks and slope instabilities. Nonetheless, KMCA has not been extensively utilized alongside drilling and electrical resistivity techniques for geotechnical site investigation procedures.

This study seeks to (1) categorize subsurface geomaterials and (2) estimate the N_{60}-value in an area devoid of SPT data by merging 2D ERI and borehole data analyzed with KMCA. Consequently, a thorough understanding of subsurface conditions can be achieved through integrated methodologies, serving as a framework for geotechnical site investigations to facilitate foundation and slope stability designs, as well as landslide assessments, to implement protective measures and forecast future events.

RESEARCH SIGNIFICANCE

This study aims to bridge the gap between conventional methods that yield discrete data points and continuous data across various dimensions. Furthermore, it classifies geomaterials, estimates N-

values in areas absence of borehole data, and enhances the understanding of subsurface characteristics by integrating 2D ERI with borehole data, refined through KMCA, thereby covering extensive specific areas while minimizing costs and time through strategically placed boreholes.

Moreover, the developed framework can be applied as a realistic guideline for geotechnical site investigations in various regions to gather subsurface data and subsequently analyze subsurface characteristics with precision and reliability.

METHODOLOGY

Borehole Drilling

Six boreholes were drilled at distinct locations along the upside-down slope area, positioned adjacent to 2D ERI lines 1, 2, 3, and 5 (Fig. 1) using the wash boring method. Boreholes KB1 (9.04 m), KB2 (10.78 m), KB3 (12.09 m), and BH10 (60.45 m), near 2D ERI line 5, were used for analysis, while BH6 (7.8 m) and BH7 (9.45 m), aligned with 2D ERI lines 1 and 2, were used for validation. In situ tests, including Standard Penetration Tests (SPT), were conducted to estimate blow counts per 30 cm, following ASTM D1586. However, SPT N-value is influenced by factors such as hammer operation, guide rod verticality, sampler type, and hammer–anvil dimensions. Therefore, the N-value should be standardized to the standard energy ratio into N_{60} - value deriving from equation provided as shown in Eq. (1), without considering the overburden corrections [4].

$$N_{60} = C_{ER} C_B C_S C_R N_f \quad (1)$$

where N_f, C_{ER}, C_B, C_S, and C_R are SPT N-value measured in the field, energy ratio correction factor, borehole diameter correction factor, sampling method correction factor, and rod length correction factor, respectively.

Corrected N-value obtained from field testing in this study represented details in Table 1.

Soil samples at various levels were obtained for laboratory study to evaluate fundamental soil parameters, including soil classification via sieve analysis to examine grain-sized distribution of soils (ASTM D 422), Atterberg Limits to measure the critical water contents of fine-grained soils (ASTM D 4318), and water content to measure the mass of water contained in the pore spaces of soil (ASTM D 2216), as detailed in Table 2.

2D Electrical Resistivity Imaging

2D ERI studies primarily employ multi-electrode configurations, necessitating extensive data coverage

across a broad area, particularly for assessing the subsurface resistivity distribution in both vertical and lateral continuity. Consequently, the 2D ERI is the most suitable technique for this study in comparison to alternative electrical resistivity methods.

2D ERI was conducted at the slope of Highway No.1088 for six 2D ERI lines to cover the entire slope area (Fig.1). To collect data and comprehend the subsurface conditions, the electrical resistivity meter as ABEM Terrameter LS tool accompanied with multi-electrode for 81 electrodes (and up to 141 electrodes with roll-along cable and electrodes technique) were employed and protocol for multiple-gradient array was conducted via electrode spacing 3 m constantly along 2D ERI lines (Table 3) with a maximum depth of investigation reaching approximately 46 m from the surface. After data acquisition, the data in each profile lines were processed with ABEM Terrameter LS toolbox, then RES2DInv software was used for data inversion based on the least-square method and reveal into two dimensional distribution of apparent resistivity subsurface model called pseudo-section.

Table 3 Arrangements in individual 2D ERI lines.

2D ERI lines/ distance (m)	No. of electrodes	Orientation	RMS error (%)
1 (0 – 420 m)	141	E - W	1.8
2 (0 – 300 m)	101	E - W	1.1
3 (0 – 240 m)	81	E - W	1.6
4 (0 – 240 m)	81	N -S	1.6
5 (0 – 240 m)	81	N -S	1.0
6 (0 – 240 m)	81	N -S	1.2

The reliability of inversion result was proved by absolute error (RMS error, %) comparing between measured and calculated apparent resistivity.

Thereafter, the inverted data was extracted [5] by deriving from Eqs. (2-3).

$$X_{\rho_a} = X_{MN} \quad (2)$$

$$Z_{\rho_a} = min\{(X_{MN} - X_A),\ (X_B - X_{MN})\}/3 \quad (3)$$

where X_{MN}, X_A, X_B, X_{ρ_a}, and Z_{ρ_a} are distance between a pair of potential electrodes (MN), distance of current electrode A from the first electrode, distance of current electrode B from the first electrode, distance of apparent resistivity data points from the first electrode (x-axis), and depth of apparent resistivity data points at X_{ρ_a} (y-axis), respectively.

K-means Clustering Analysis

K-means is a partitioning clustering technique that segments an N-dimensional dataset into k groups based on sample data. Each cluster is associated with a centroid, assuming a spherical or circular distribution of data within each cluster. The method minimizes the sum of squared errors (SSE) between data points and centroids, using Euclidean distance to assess similarity. The variance within clusters is minimized, while the variance between clusters is maximized [6] and their corresponding cluster centroids, as demonstrated in Eq. (4).

$$SSE = \sum_{i=1}^{k} \sum_{x_j \in P_i} \left\| x_j - c_i \right\|_2^2 \quad (4)$$

where x indicates data points inside k number of P clusters; $\|.\|_2$ indicates Euclidean L2 norm; and c corresponds to cluster centroids.

The modeling commences with a specified number of clusters. Subsequently, the Elbow approach and Silhouette analysis were utilized to determine the prospective number of initial clusters. The Elbow technique determines the optimal number of clusters at the elbow where the error stabilizes.

However, if the Elbow technique plot does not exhibit a distinct elbow, it may be beneficial to utilize Silhouette analysis as an alternative or supplementary approach to the elbow method. The Silhouette analysis assesses clustering effectiveness by analyzing intra-cluster similarity and inter-cluster dissimilarity, as illustrated in Eq. (5). In the Eq. (5), the coefficient values (S, Silhouette Score) span from "-1" to "1". A number near “1” signifies that the sample inside one cluster is far from other clusters, but a value near “-1” implies that the sample may have been erroneously allocated to the wrong cluster. If the coefficient is 0, the sample is in close contact with adjacent clusters.

$$S = \frac{(b-a)}{max(a,b)} \quad (5)$$

where a is Mean distance to other points in the same cluster (intra-cluster distance); and b is Mean distance to points in the nearest neighboring cluster (inter-cluster distance).

When applying KMCA, it is essential to use standardized data to avoid distortion from variables with larger variances. Additionally, KMCA does not account for cluster dimensions, which may result in varying cluster sizes **[7]**.

This study employs KMCA using the Python platform. The procedure begins with data pre-processing, which entails preparing and selecting suitable parameter inputs for clustering analysis, as these inputs affect the outcome. This encompasses: (1) data integration and feature selection, (2) data cleansing, (3) statistical imputation for managing missing data, (4) data abstraction to condense the data into a usable format while maintaining its critical attributes for effective processing and cross-platform collaboration, and (5) feature engineering, including feature rescaling. Table 4 presents processed data, consisting of 30 data points, with soil resistivity and N_{60}-value. Fig. 2 shows the complete KMCA process.

RESULTS AND DISCUSSIONS

Borehole Drilling and 2D ERI by KMCA

Six 2D ERI lines and six boreholes were conducted at the slope site to interpret the subsurface conditions. Line 5, located near boreholes BH10, KB1, KB2, and KB3, revealed four main geomaterial groups. (1) Clayey gravelly sand (SC) occurs from the surface to 2 m depth with resistivity of 100-500 Ω.m. (2) Sandy clay and silty clay (CL) are found between 2-6 m and 8-24 m, with resistivity of 50-100 Ω·m and 10-20 Ω·m, respectively. (3) Saturated silty clay (CH) appears at 6-8 m (20-50 Ω.m). (4) Moist fractured rock (>24 m) shows 20-500 Ω.m resistivity. These classifications are summarized in Table 5.

According to 30 data points of soil resistivity and N_{60}-value along 2D ERI line 5, they were clustered with KMCA. The subsurface geomaterials along the 2D ERI line 5 were categorized as follows: Cluster 1, characterized by a centroid at (27.51, 25), was categorized as soft to very stiff clay (CH); Cluster 2, with a centroid at (75.06, 14), was defined as medium to stiff clay (CL); and Cluster 3, identified by a centroid at (114.55, 8), was designated as medium clay (CL). These classifications are based on the combination of resistivity values and corrected N_{60}-value as details shown in Table 6 and Fig. 3.

The classification of geomaterials utilizing 2D ERI and borehole logging at designated depths revealed four principal geomaterial categories. Nonetheless, KMCA findings, linking soil resistivity with N_{60}-value, identified three primary geomaterials. This mismatch may result from dependence solely on the N_{60}-value, which limits the ability to differentiate between very stiff clay and highly weathered rock at higher depths.

Table 5 Data interpretation along 2D ERI line 5 combining with borehole logs

Materials	Depth from surface (m)	Resistivity (Ω.m)
Topsoil, Clayey gravelly sand (SC)	0 - 2	100 – 500
Sandy clay (CL)	2 - 6	50 -100
Silty clay (CH)	6 - 8	20 – 50
Silty clay (CL)	8 - 24	10 – 20
Silty clay (CL) to highly weathered bedrock	24 - 46	20 - 500

Table 6 K-means clustering with soil resistivity and N_{60}-value inputs along 2D ERI line 5

Line 5 Cluster No.	Centroid values		Relative soil stiffness*	Soil type**
	Resistivity, *x* (Ω.m)	N_{60} -value, *y* (blow counts/ ft)		
1	27.51	25	Soft-very stiff clay	CH
2	75.06	14	Medium-stiff clay	CL
3	114.55	8	Medium clay	CL

*Note: *Relative soil stiffness is referred to N_{60}-value, **USCS.*

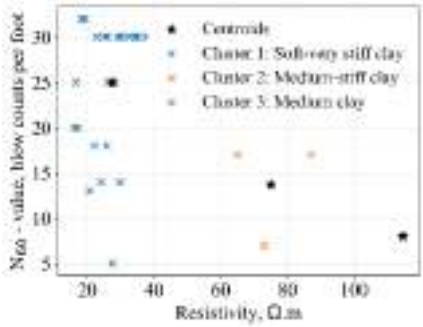

Fig. 3 K-means clustering with resistivity and N_{60}-value inputs along 2D ERI line 5

Relationship between soil resistivity and N_{60}-value could be derived with pairs of centroids plotting, then deriving the power equation Eq. (6) with R^2=0.9774, indicating that N_{60}-value decreases as resistivity increases as shown in Fig. 4.

$$N_{60} = 323.58\rho_a{}^{-0.762} \quad (6)$$

Where N_{60} represents N_{60}-value; and ρ_a is soil resistivity (Ω.m).

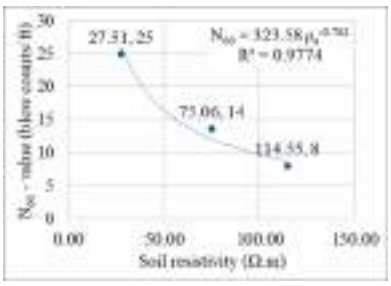

Fig. 4 Correlation between soil resistivity and N_{60}-value

To predict N_{60}-value in the area without SPT N-value data, therefore, 2D ERI lines 1 and 2 were selected. Then soil resistivity values along the two lines were extracted and clustered with KMCA. The result shows that along 2D ERI line 1, geomaterials could be classified into three groups, including loose sand, soft-medium clay, and medium-hard clay as depicted in Fig. 5.

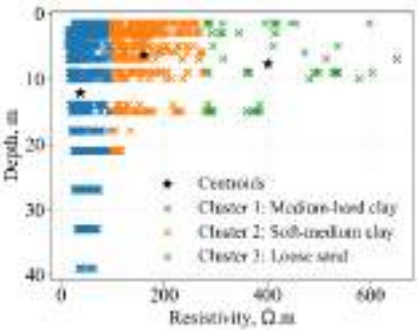

Fig. 5 Clustering results along 2D ERI line 1

While 2D ERI line 2, geomaterials could be classified into four groups, composing loose sand, loose-medium dense sand, soft-medium clay, and medium-hard clay (Fig. 6). The geomaterial categorization along 2D ERI lines 1 and 2 reveals consistent results.

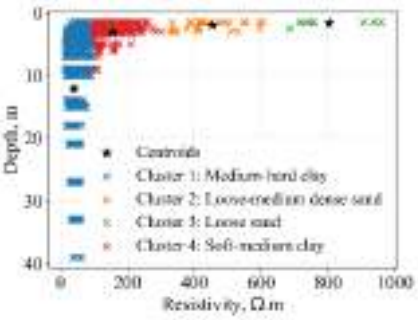

Fig. 6 Clustering results along 2D ERI line 2

After categorizing geomaterials based on soil resistivity at various depths, resistivity values from lines 1 and 2 were applied in Eq. (6) to estimate the N_{60}-value. The estimated N_{60}-value were then compared with the actual N_{60}-value from BH6 and BH7 for validation. As shown in Figs. 7, the trends of actual and estimated N_{60}-value are similar. However, some discrepancies exist in BH6 with R^2= 0.8396, MAE = 4.86, RMSE = 6.21 that could be interpreted as the estimated N_{60}-value will shift from the actual average by 5-7 blow counts/ft. In Fig. 8 shows that BH7 with R^2= 0.9283, MAE = 6.38, RMSE = 7.39 this means the estimated N_{60}-value will shift from the actual value averaged by 6-8 blow counts/ft. The limitation is soil resistivity varies that are influenced by factors such as water content, fine-grained components, and grain size distribution that result in discrepancies of estimated N_{60}-value derived from

Ep. (6) (Table 2). At shallow depths (loose sand to medium clay), both actual and estimated N_{60}-value are closely aligned, registering low values below 10 blow counts/ft. However, at greater depths, as the geomaterials transition to medium-hard clay, a significant gap between the actual and estimated N_{60}-value emerges.

At greater depths, overburden pressure increases soil density, enhancing shear strength and raising the N_{60}-value. Soil resistivity, influenced by factors such as water content, fine-grained content, and grain size distribution, contributes to discrepancies between the red and blue lines at deeper depths. Elevated fine-grained content and moisture lead to lower resistivity, causing the estimated N_{60}-value, derived from Eq. (6), to be lower than the actual value.

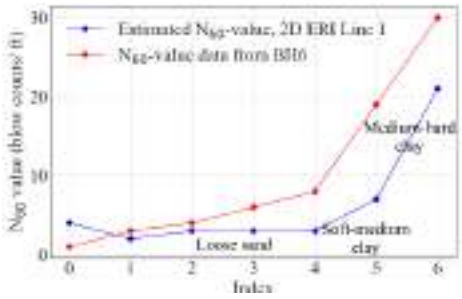

Fig. 7 Comparation between actual and estimated N_{60}-value along 2D ERI line 1, yielding R^2 = 0.8396, MAE = 4.86, and RMSE = 6.21

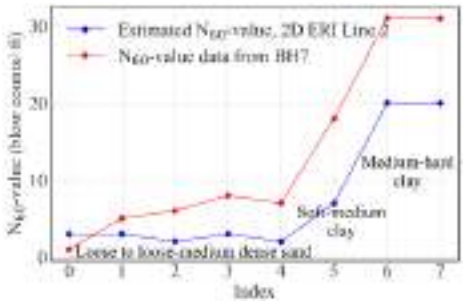

Fig. 8 Comparation between actual and estimated N_{60}-value along 2D ERI line 2, yielding R^2 = 0.9283, MAE = 6.38, and RMSE = 7.39

CONCLUSIONS

This study categorizes the underlying geomaterials in the area into three primary soil types: loose sand, medium-stiff clay, and stiff-hard clay, based on the integration of 2D ERI and borehole data with KMCA. The association between soil resistivity and the N_{60}-value is expressed as a power equation with R^2 = 0.9774 illustrating negative relationship between soil resistivity and N_{60}-value of soil.

Additionally, the N_{60}-value could be inferred in regions devoid of SPT data by utilizing soil resistivity for estimation. The estimated N_{60}-value aligns with the actual N_{60}-value derived from borehole data, evidenced by a high R^2 and moderate loss functions as the following values. BH6 yields R^2= 0.8396, MAE = 4.86, and RMSE = 6.21. While BH7 yields R^2= 0.9283, MAE = 6.38, and RMSE = 7.39.

Consequently, 2D ERI facilitated by KMCA encompasses extensive regions with necessary drilled boreholes, potentially reducing costs and time as being conducted in the real-world project at Highway no.1088 in Chiang Mai, Thailand.

Moreover, the framework derived from this study could be applied as an achievable guideline for geotechnical site investigations in different regions to gather data and enhance understanding of subsurface properties.

ABSTRACT

This study proposes an integrated framework combining Finite Element Method (FEM)-based permeation analysis and Artificial Intelligence (AI) models to assess chemical grout behavior in heterogeneous sandy soils with low-permeability zones. FEM analysis was performed to investigate grout flow patterns and permeation risks in such soils, revealing that proximity to low-permeability zones significantly affects grout flow velocity and grout distribution. Simplified regression equations were developed to efficiently predict permeation risks. AI models, including neural networks and gradient boosting trees, were trained on FEM datasets and accurately predicted permeation velocities and ranges with high accuracy (R^2 = 0.849). Even with 5.5% low-permeability content, average fill rates reached 94.5% (FEM) and 96% (AI), with worst cases at 81% and 83%, respectively. The results demonstrate that the effectiveness of integrating FEM, regression models, and AI-based modeling to optimize chemical grouting strategies and mitigate permeation risks due to soil heterogeneity. The proposed framework offers an effective approach to improve chemical grouting practices in heterogeneous soil conditions.

Keywords: Chemical grouting, Low permeability zone, Permeation analysis, FEM, AI prediction model

INTRODUCTION

Liquefaction poses a major threat to infrastructure in Japan, as demonstrated by the 2011 Great East Japan Earthquake, highlighting the critical importance of soil improvement techniques to mitigate liquefaction risks [1]. Among various soil improvement techniques, chemical grouting is widely recognized for mitigating liquefaction risks by replacing pore water and solidifying the ground through injection [2]. While homogeneous sandy soils permit uniform grout permeation, the presence of low-permeability zones can disrupt flow paths, leading to uneven treatment and diminished performance [3].

This study aims to understand how soil heterogeneity influences chemical grout permeation and to accurately predict permeation risk and range by integrating FEM-based analysis with AI-based predictive models. To achieve this, an innovative framework is proposed that uses random soil models with low-permeability zones, simplified regression equations for risk prediction, and an integrated approach combining FEM-based permeation analysis with AI-based predictive models for rapid and practical assessment of grout permeation behavior in real-world projects. FEM captures detailed flow behavior in various soil types [4], while AI enhances prediction even when input variables are uncertain or missing [5]. Therefore, this integrated approach combines the precision and reliability of FEM-based permeation analysis with the flexibility and efficiency of AI, improving the predictive accuracy and practical applicability of chemical grouting methods.

RESEARCH SIGNIFICANCE

This study addresses the challenge of predicting chemical grout permeation in heterogeneous soils, where low-permeability zones hinder uniform treatment. By integrating Finite Element Method (FEM) simulations with regression models and AI-based predictive models, the proposed framework offers a novel and practical solution for assessing grout flow behavior in such soil. This research contributes to improving the reliability and efficiency of chemical grouting permeation, especially under complex soil conditions commonly encountered in real-world geotechnical projects.

FEM-BASED PERMEATION ANALYSIS FOR RISK ASSESSMENT

This study presents the assessment of permeation risk using 2D FEM simulations of chemical grouting in heterogeneous soils containing low-permeability zones. Risk, which means inadequate grout flow, was calculated based on permeation velocity and proximity to these zones. The high-risk cases (≥10%) were used as inputs for multiple regression analysis. Key inputs included permeation velocity, distance to low permeability zone, its size, and geometry.

Grout permeation behavior was modeled using VGFlow 2D, a FEM-based program solving

Richards' equation for saturated–unsaturated flow derived from Darcy's Law that describes fluid flow through porous media [6]. A 1.5 m × 0.75 m rectangular, fully saturated, isotropic sandy soil domain with 5.5% (550 cm^2) low-permeability zone was used. All boundaries were modeled as leaky, with a central injection point and a grouting rate of 16 L/min. The low-permeability zone, comprising 100 cells, was positioned as shown in Fig. 1. It used vertical and horizontal permeability coefficients of 5.200×10^{-5} cm/sec and 2.080×10^{-4} cm/sec for sand layer, and 4.525×10^{-7} cm/sec and 1.810×10^{-6} cm/sec for the low-permeability soil zone, respectively.

Three configurations of low-permeability zone were analyzed, each zone sized 0.025 m × 0.025 m. Case 1 (Fig. 2) included one zone; Case 2 (Fig. 3), two horizontally aligned zones; and Case 3 (Fig. 4),

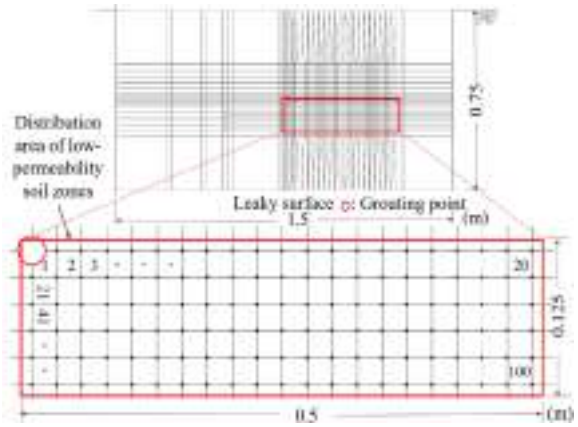

Fig.1 Configuration of the FEM analytical section

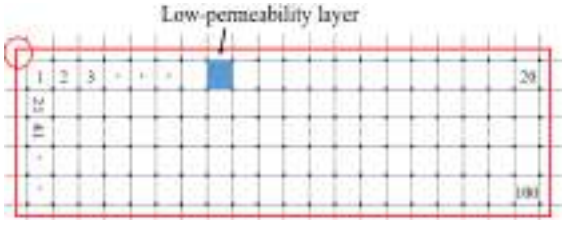

Fig.2 Case 1: Single low-permeability soil zone configuration

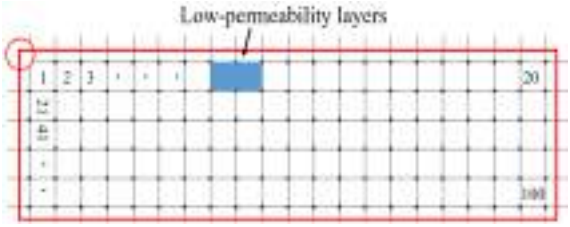

Fig.3 Case 2: Two horizontally aligned low-permeability soil zones

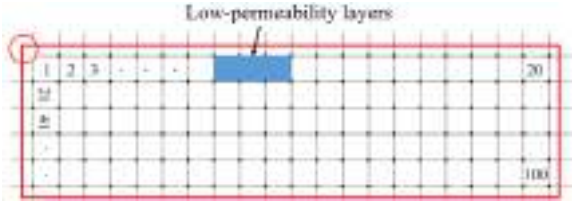

Fig.4 Case 3: Three horizontally aligned low-permeability soil zones

three horizontal zones. The model mesh was subdivided into rectangular sections, each split into four cells, serving as an evaluation rectangular section and then yielding 400 data points per analysis. Permeation velocities were calculated using Eq. (1). The velocity of permeation flow in homogeneous soil without low-permeability soil zone is v_{1i} (m/s), and the velocity of permeation flow in soil with low-permeability soil zone is v_{2i} (m/s). Then, permeation risk in this study were calculated using Eq. (2).

$$\boldsymbol{v}_{\mathrm{i}} = \sqrt{\boldsymbol{v}_{\mathrm{xi}}{}^{2} + \boldsymbol{v}_{\mathrm{yi}}{}^{2}} \tag{1}$$

$$R_{1\mathrm{i}} = 1 - \frac{v_{2\mathrm{i}}}{v_{1\mathrm{i}}} \tag{2}$$

STATISTICAL MODEL FOR PERMEATION RISK PREDICTION

In this study, the predicted risk is calculated by multiple regression analysis as shown in Eq. (3).

$$R_{2\mathrm{i}} = \beta_1 x_{1\mathrm{i}} + \beta_2 x_{2\mathrm{i}} + \beta_3 x_{3\mathrm{i}} + \beta_4 x_{4\mathrm{i}} + \beta_5 x_{5\mathrm{i}} + u_{\mathrm{i}} \tag{3}$$

Where, $x_{1\mathrm{i}}$ is horizontal distance of low-permeability soil zone from grouting point, $x_{2\mathrm{i}}$ is vertical distance from grouting point to the zone, $x_{3\mathrm{i}}$ is horizontal distance from the zone to evaluation section, $x_{4\mathrm{i}}$ is vertical distance from the zone to evaluation section, $x_{5\mathrm{i}}$ is horizontal length of the zone, and u_{i} is the error term. For regression analysis, only data from the right side of the zone were used, assuming sufficient grout permeation on the left. These data were further categorized vertically into upper, middle, and lower sections, and later grouped by horizontal distance: within 0.05 m and beyond 0.05 m, yielding 6 total cases (Fig. 5). Only evaluation sections with risk >10% (from Eq. 2) were included in the regression; risks <10% were treated as zero, indicating minimal influence.

In this study, each node was assigned coordinates, such as grouting point (x_{i}, y_{i}), lower left corner of the low-permeability zone (x_{pl}, y_{pl}), upper right corner (x_{pr}, y_{pr}) and the coordinates of the evaluation section (X,Y). The required distances are calculated by Eqs. (4) to (8).

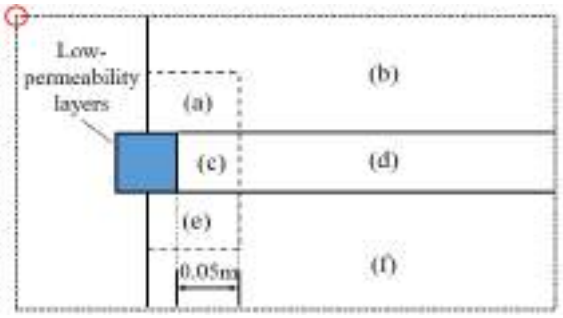

Fig.5 Classification of evaluation sections based on distance from low-permeability soil zones.

$$x_1 = x_{pl} - x_i \tag{4}$$

$$x_2 = \frac{y_{pl}+y_{pr}}{2} - y_i \tag{5}$$

$$x_3 = \begin{cases} X - x_{pr} & (X > x_{pr}) \\ 0 & (x_{pl} < X < x_{pr}) \\ X - x_{pl} & (x_{pl} > X) \end{cases} \tag{6}$$

$$x_4 = \begin{cases} Y - y_{pr} & (Y > y_{pr}) \\ 0 & (y_{pl} < Y < y_{pr}) \\ Y - y_{pl} & (y_{pl} > Y) \end{cases} \tag{7}$$

$$x_5 = x_{pr} - x_{pl} \tag{8}$$

EVALUATION OF PERMEATION RANGE USING FEM-BASED ANALYSIS

This section describes the FEM-based permeation analysis used to develop and validate AI models that evaluate permeation behavior in heterogeneous soil. In this study, FEM analysis captures complex permeation behavior under both homogeneous and heterogeneous conditions. A model spans 120 cm × 120 cm, centering a 100 cm × 100 cm improvement area to account for grout-induced distortions. Due to computational constraints, low-permeability zones were confined to a 70 cm × 70 cm region (Fig. 6).

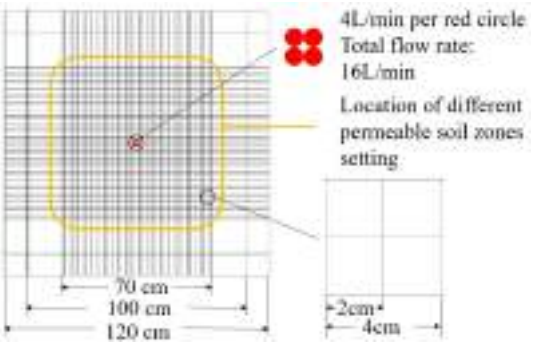

Fig.6 Model geometry and finite element mesh

Grouting points were positioned at central nodes with an injection rate of 16 L/min (4 L/min per node), reflecting the double-pipe strainer method. Leaching boundaries were applied to the model edges. Each element was treated as an evaluation section, generating 3,721 data points per analysis. A total of 88 simulations were conducted to assess the influence of low-permeability zones on permeation behavior. The range of chemical grout permeation is calculated using a geometric formula shown in Eq. (9). Permeation efficiency was evaluated by comparing these permeation areas with a reference permeation area.

$$S = \frac{1}{2}\sum_{l=1}^{n}(x_l - x_{l+1})(y_l + y_{l+1}) \tag{9}$$

AI-BASED PREDICTIVE MODELING FOR PERMEATION BEHAVIOR

Artificial Intelligence (AI) offers powerful capabilities for modeling complex processes and analyzing large, incomplete, or nonlinear datasets [5]. In this study, AI was integrated with FEM-based permeation analysis to predict permeation flow and range in sandy soils with low-permeability zones. The FEM analysis provided element-specific permeation velocities, which served as input for two AI models: a neural network and a gradient boosting decision tree (GBDT). Input features comprised element coordinates, distances from the grouting point, and permeability coefficients.

To assess the effect of input feature, models X-11 and Y-11 used all 11 input features, while X-9 and Y-9 excluded x- and y-coordinates. Adjustments to permeation velocity values (scaled by 1.2 and 1.5) generated refined variants such as X-11-1.2, X-11-1.5, Y-9-1.2, and Y-9-1.5 to correct overestimation. Model performance was evaluated using the coefficient of determination (R^2) and five additional performance metrics which are mean distance (D_m), standard deviation distance (D_{SD}), hausdorff distance (D_H), total distance (D_R) and least squares distance (D_{SLS}). A final performance was calculated by combining these metrics with appropriate weights, as shown in Eq. (10).

$$\text{Score} = D_m + 2D_{SD} + 2D_H + 0.5D_R + D_{SLS} \tag{10}$$

RESULTS AND DISCUSSION

Permeation Behavior Analysis and Risk Mapping

The permeation analysis results flow direction and velocity for each mesh element, enabling visualization through a heat map. Fig.11 illustrates the Case 3 heat map, highlighting how the low-

permeability zones influence flow velocity.

From Fig. 7, flow velocity is most affected at the center of the low-permeability soil zone, with noticeable changes along the line connecting it to the grouting point. However, the figure alone does not quantify this impact. Therefore, multiple regression analysis was conducted to assess this effect quantitatively. Eq. (11) to (16) present the regression results, with coefficient frequencies shown in Table 1, highlighted in red for high risk and blue for low risk. Fig. 8 displays uniform grout distribution in homogeneous soil while Fig. 9 shows flow disruption and uneven permeation caused by low-permeability zones.

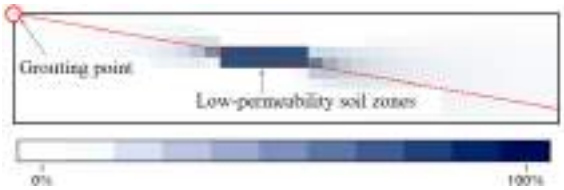

Fig.7 Heatmap visualization of permeation risk based on flow velocity distribution

case (a), $$R_{2i} = -0.09x_{1i} + 0.09x_{2i} + 0.61x_{3i} - 5.48x_{4i} + 0.3x_{5i} - 0.12 \quad (11)$$

case (b), $$R_{2i} = -0.01x_{1i} + 0.44x_{2i} - 11.5x_{3i} + 1.25x_{5i} + 0.55 \quad (12)$$

case (c), $$R_{2i} = -0.64x_{1i} - 0.64x_{2i} - 4.79x_{3i} - 8.92x_{4i} + 2.46x_{5i} + 0.36 \quad (13)$$

case (d), $$R_{2i} = -0.35x_{1i} - 0.03x_{2i} + 0.03x_{3i} - 8.92x_{4i} + 2.46x_{5i} + 0.36 \quad (14)$$

case (e), $$R_{2i} = -0.19x_{1i} + 0.30x_{2i} - 1.12x_{3i} + 0.04x_{5i} + 0.26 \quad (15)$$

case (f), $$R_{2i} = -0.42x_{1i} + 0.60x_{2i} - 0.66x_{3i} - 1.52x_{4i} + 0.66x_{5i} + 0.27 \quad (16)$$

Table 1 Frequency distribution of coefficients in multiple regression analysis equations

	x_{1i}	x_{2i}	x_{3i}	x_{4i}	x_{5i}
(a)	1.4%	1.4%	9.3%	83.4%	4.6%
(b)	0.1%	3.3%	87.1%	0.0%	9.5%
(c)	3.7%	3.7%	27.4%	51.1%	14.1%
(d)	3.0%	0.3%	0.3%	75.7%	20.9%
(e)	11.5%	18.2%	67.9%	0.0%	2.4%
(f)	10.9%	15.5%	17.1%	39.4%	17.1%

Note: High and low influence of regression coefficients are indicated by red and blue colors, respectively.

In case (a), the vertical distance to the evaluation section is the dominant factor, accounting for 83.4% of the influence. Similarly, in the case (d), vertical distance remains critical, though the horizontal length of the zone also plays a notable role (20.9%). According to both cases, the risk decreases as the evaluation rectangular section moves away from the low-permeability soil zone in the vertical direction. In cases (d) and (f), increasing the horizontal length of the zone significantly hinders grout permeation, due to reduced initial inflow caused by pressure differences.

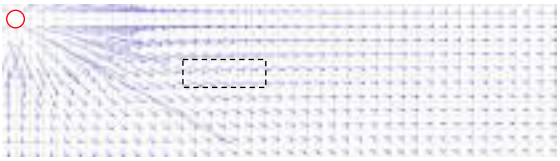

Fig.8 Vector map illustrating grout permeation behavior in homogeneous soil conditions

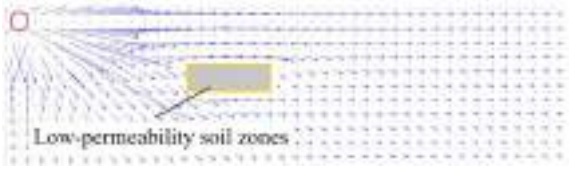

Fig.9 Vector map showing disrupted grout flow due to the presence of low-permeability soil zones

In case (e), horizontal distance contributes to risk reduction, unlike in case (b). The coefficient for vertical distance from the grouting point to the low-permeability zone is consistently negative, indicating that greater separation lowers risk. In cases (c) and (f), other parameters, especially the distances from the grouting point and the size of the low-permeability zone, show stronger influence. As the zone grows larger, it more effectively blocks grout penetration, increasing risk. Overall, the risk predictions maintained an error margin within approximately 10%, indicating reliable model performance.

Performance Comparison of FEM and AI-Based Models

To evaluate the effectiveness of AI-based predictive models, a total of 300 cases were generated. Permeation velocities were predicted using trained AI-based models and compared with FEM-based results. As shown in Table 2, models X-11-1 and Y-9-1.5 are closest to the reference. Model X-11-1 performed best, requiring no correction to the target variable. As shown in Fig.10, AI model predicted a wider permeation range than the FEM-based analysis. Table 3 summarizes the model scores, and Table 4

along with Fig.11 shows the filling rate distribution. Although the AI model slightly overestimated results, the difference was small. Model reliability was validated through FEM comparisons and previous studies, showing high accuracy (R^2 = 0.849). The average fill rate difference is less than 2% (AI: 96%, FEM: 94.5%), with the worst-case values of 83% (AI) and 81% (FEM), confirming the model's effectiveness even in heterogeneous soils.

Table 2 Coefficient of determination (R^2) values for different AI models.

Model	Coefficient of determination
X-11-1	0.849
X-11-1.2	0.828
X-11-1.5	0.819
X-9-1	0.810
X-9-1.2	0.803
X-9-1.5	0.805
Y-11-1	0.836
Y-11-1.2	0.818
Y-11-1.5	0.789
Y-9-1	0.834
Y-9-1.2	0.821
Y-9-1.5	0.814

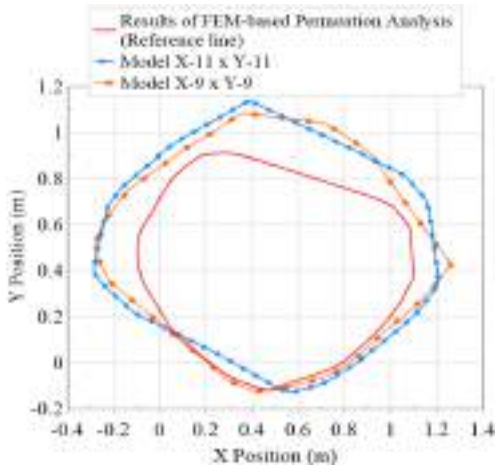

Fig.10 Comparison of permeation ranges predicted by the AI model and FEM-based analysis.

Table 3 Performance evaluation of the most accurate AI-based model

Name	Average result of 88 cases
D_m	0.06
D_{SD}	0.05
D_H	0.31
D_R	1.55
D_{SLS}	0.15
Score	2.58

Even with the same percentage (5.5%) of low-permeability soil, variations in shape and properties caused large fill rate differences. This underlines the need to understand permeation risks in heterogeneous soil. Unlike FEM, which takes 30–40 minutes per case, AI models provide similar accuracy in under 2 seconds, making them practical tools for quick assessment and design support.

Table 4 Distribution of predicted permeation fill rates from the AI-based model

Permeation fill rate (%)	Frequency	Probability (%)
81～85	5	1.7
86～90	5	1.7
91～95	78	26.2
96～100	210	70.5

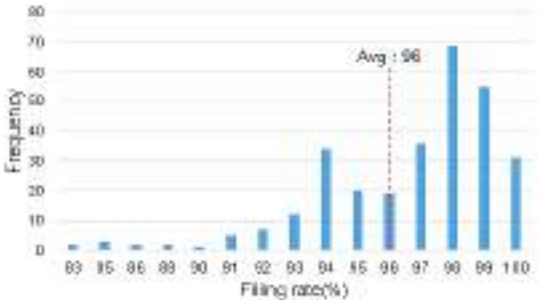

Fig.11 Histogram of fill rates derived from AI-based predictive modeling

Practical Implications for Chemical Grouting Techniques

Fig.12 shows the permeation areas in both homogeneous and heterogeneous soils. In homogeneous conditions, the nearly circular shape

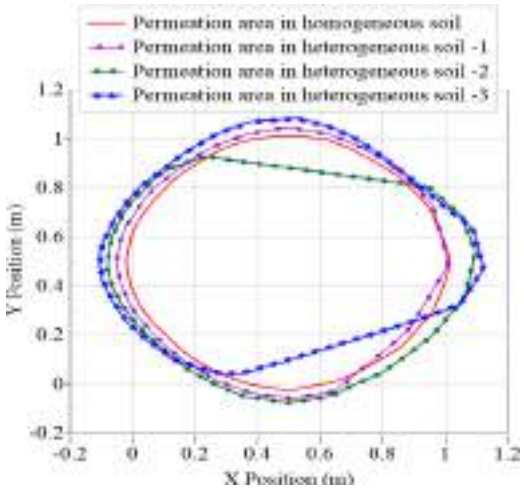

Fig.12 Permeation area comparison between homogeneous and heterogeneous soil conditions

confirms the model accurately reproduces expected permeation behavior under uniform permeability. In heterogeneous soils, however, permeation shapes vary, some remain circular, while others deviate significantly, reflecting the impact of low-permeability zones on flow patterns. Table 5 shows a 54.3% probability of achieving fill rates between 96% and 100%, indicating that design expectations are met in about half the cases. A key concern is the 45.7% probability of "risky events" where fill rates fall between 81% and 95%, indicating that nearly half of the cases may result in sub-optimal fill and pose risks to soil improvement.

Table 5 Distribution of permeation fill rates obtained from FEM-based permeation analysis.

Permeation fill rate (%)	Frequency	Probability (%)
81～85	4	4.3
86～90	12	12.8
91～95	27	28.7
96～100	51	54.3

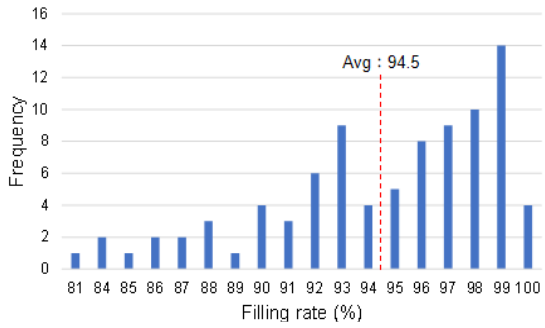

Fig.13 Histogram of fill rates obtained from FEM-based permeation analysis.

CONCLUSIONS

The study developed an integrated approach combining FEM-based permeation analysis and AI-based predictive modeling to evaluate chemical grout permeation behavior in heterogeneous soil. The FEM-based analysis clarified the impact of low-permeability zones on grout flow, while AI-based predictive models provided predictive capabilities for permeation range. A statistical regression model was also introduced to effectively estimate permeation risk. The key findings of this study are as follows:

(1) The FEM analysis revealed that the location of low-permeability zones is the most influential factor in permeation risk, as it disrupts flow velocities and patterns, narrows permeation ranges, and increases permeation risk.

(2) Simplified regression models accurately estimated permeation risk using simple inputs such as soil geometry and proximity to low-permeability zones, reducing the need for computationally intensive FEM simulations.

(3) FEM-based permeation analysis and AI-based predictive models showed consistent results, with a strong R^2 value of 0.849 and prediction fill rates closely matching within 2%, even in soil with 5.5% low-permeability material. However, the AI models showed a tendency to overestimate in some cases, highlighting the need for further refinement.

Future work should include experimental field validation to enhance model reliability. Expanding the diversity of training data and conducting sensitivity analyses can reduce overestimation. Moreover, extending the FEM model to simulate unsaturated soil conditions would significantly enhance the applicability of the framework. Finally, integrating grout rheology, injection parameters, and soil properties into the simulations will provide a more realistic modeling approach.

MOVING PARTICLE SIMULATION VALIDATION AND APPLICATION TO CONCRETE FLOW IN CAST-IN-PLACE PILES

Ayumi Morota [1] and Shinya Inazumi [1]

[1] Shibaura Institute of Technology, Japan

ABSTRACT

This study presents a unified framework for evaluating concrete flow behavior in cast-in-place pile construction using the Moving Particle Semi-implicit (MPS) method integrated with Computer-Aided Engineering (CAE) tools. Two core investigations form the basis of this research: a laboratory-based validation of slump behavior through both physical testing and MPS-CAE simulation, and a field-scale simulation of fresh concrete placement in reinforced pile shafts. In the first phase, rheological parameters were determined from B-type viscometer and slump tests, and a bi-viscosity model was used to simulate the viscoplastic behavior of Bingham-type fresh concrete. Simulation results exhibited high fidelity with experimental measurements in terms of slump value, spread, and flow termination. In the second phase, full-scale simulations visualized flow behavior during tremie placement, particularly identifying flow obstructions and segregation zones around rebar cages. Numerical results aligned well with physical element tests, confirming the utility of MPS-CAE as a predictive tool for placement diagnostics. The findings underscore the potential of particle-based modeling for construction planning, quality assurance, and defect mitigation in reinforced concrete applications.

Keywords: MPS-CAE, Bingham fluid, slump simulation, cast-in-place piles, concrete flow

INTRODUCTION

Urban centers in Japan are increasingly situated atop soft or liquefiable soils, making the adoption of reliable foundation techniques essential. Among these, cast-in-place concrete piles are widely employed for their structural adaptability and load-bearing capacity. However, ensuring uniform and complete concrete placement within heavily reinforced shafts presents a persistent engineering challenge. Inadequate filling around reinforcement can lead to structural deficiencies, long-term durability concerns, and costly remediation.

Traditional methods such as full-scale physical testing to evaluate filling performance are laborious and economically restrictive. In contrast, computational techniques—especially those that enable visual and quantitative assessments—offer promising alternatives. Recent advancements in mesh-free numerical methods, particularly the Moving Particle Semi-implicit (MPS) approach, have enabled detailed simulations of complex concrete flow behaviors.

The present study integrates two research components previously reported in Japanese technical literature. The first component involves validating the MPS-CAE approach through slump tests that capture flow dynamics of fresh concrete under standardized conditions. The second component extends the validated model to simulate concrete placement in cast-in-place piles, emphasizing interactions with reinforcement, flow arrest behavior, and the formation of potential defects.

By combining physical testing, rheological modeling, and advanced particle-based simulation, this study aims to contribute to the ongoing development of predictive tools for construction quality management. The outcomes are expected to aid practitioners in optimizing concrete placement techniques and mitigating risks associated with insufficient filling or segregation in reinforced structures.

METHODOLOGY

Theoretical Framework of MPS-CAE

The Moving Particle Semi-implicit (MPS) method is a mesh-free numerical technique suitable for simulating incompressible, free-surface fluid flows [1]. In this approach, the fluid domain is discretized into particles that interact through local kernel functions, enabling direct tracking of deformation, collision, and flow cessation without reliance on fixed computational grids. Each particle carries properties such as velocity, pressure, and density, which evolve according to the incompressible Navier–Stokes equations shown in Eqs. (1) and (2):

$$\frac{\overrightarrow{Du}}{Dt} = -\frac{\nabla P}{\rho} + \nu\nabla^2\vec{u} + \vec{g} \quad (1)$$

$$\frac{D\rho}{Dt} = 0 \quad (2)$$

where u is velocity, ρ is density, P is pressure, ν is kinematic viscosity, and g is gravitational acceleration.

To capture the non-Newtonian characteristics of fresh concrete, a bi-viscosity Bingham model was implemented as shown in Fig. 1. In this model, concrete behaves as a highly viscous material below a yield stress τ_y, transitioning to a lower plastic viscosity η above a critical shear strain rate π_c. The flow stops when 90% of particles experience shear strain rates below π_c, mimicking physical flow arrest.

This assumption allows accurate modeling of viscoplastic behavior, especially for evaluating flow through reinforcement-congested geometries.

Determination of Rheological Properties

The rheological parameters were determined by laboratory tests using B-type rotational viscometers and slump tests based on specimens simulating the poor filling conditions observed in the field. The concrete used had the physical properties shown in Table 1.

Coarse aggregate volume fraction was 35.8%, and solid fraction was 59.6%. The shape coefficient of the aggregate was assumed as 2.4. Using empirical relations derived from previous studies [8], these properties were integrated into the MPS model.

Slump Test and Simulation Setup

To validate the numerical approach, a standard slump test was conducted per JIS A-1101 using a truncated cone mold (height 300 mm, bottom diameter 200 mm, top diameter 100 mm) as shown in Fig. 2. Fresh concrete was poured into the mold and the cone was lifted to initiate free deformation. The slump height, spread diameter, and cessation time were recorded and used as benchmarks for simulation.

The corresponding MPS-CAE model replicated these boundary conditions using a particle spacing of 7.5 mm and a total of 13,182 particles. Flow behavior was observed until flow termination was achieved based on the 90% shear rate criterion. Simulated results were then compared with experimental data for slump height, spread, and time to cessation.

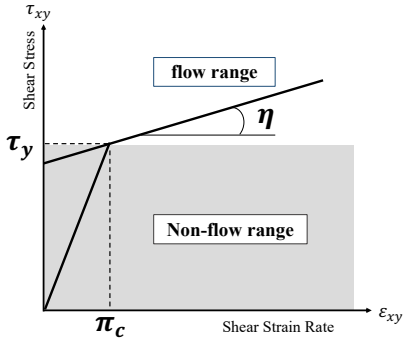

Fig. 1 Bi-viscosity model for simulating Bingham-type fresh concrete behavior

Table 1 Physical properties of fresh concrete used in simulation

Density (kg/m^3)	Yield Stress (N/m^2)	Plastic Viscosity (Pa·s)	Critical Shear Strain Rate (1/s)
2310	1087	19.6	3.84

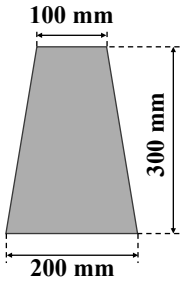

Fig. 2 Slump cone apparatus used for validation tests (JIS A-1101 standard)

VALIDATION OF SLUMP BEHAVIOR

Experimental Observations

The physical slump test produced a final slump height of 19.5 cm and a spread diameter of 29.7 cm. Flow ceased approximately 1.7 seconds after the slump cone was lifted. The flow profile exhibited a smooth radial spread without aggregate segregation, confirming that the tested mix behaved as a homogeneous Bingham fluid. These results served as the reference baseline for evaluating simulation fidelity.

Simulation Results

The MPS-CAE simulation replicated the test under identical rheological and geometric conditions. As shown in Figs. 3 and 4, the particle model achieved a slump height of 9.5 cm and a spread diameter of 30.4 cm. Flow was computationally judged to have ceased at 0.43 seconds, as 90% of the particles registered shear strain rates below the critical threshold.

Snapshots of the slump deformation (see Figs. 3 and 4) illustrate the temporal evolution and shape conformity, consistent with previous simulations of slump flow using MPS methods [1,2]. Despite the shorter flow duration compared to the experiment, the final geometry and radial symmetry were consistent. The timing discrepancy is attributed to idealized frictional and drag assumptions in the model, which slightly accelerate settling. However, the dimensional accuracy supports the reliability of the chosen rheological parameters and flow-termination criteria.

Comparative Analysis

As illustrated in Fig. 5, the simulated and experimental slump behaviors exhibit high correlation in spread magnitude, although slight deviations occur in time-dependent dynamics. This is consistent with prior findings [8] regarding measurement limitations in plastic viscosity

determination using rotational viscometers. Nonetheless, the simulation's ability to reproduce deformation geometry and terminal behavior affirms its validity for use in predicting fresh concrete placement performance.

APPLICATION TO CAST-IN-PLACE PILE FOUNDATIONS

Simulation Model Configuration

To extend the MPS-CAE model beyond laboratory conditions, a field-scale simulation was conducted to replicate concrete placement in a cast-in-place pile. The pile shaft was modeled as a vertical cylinder 2300 mm in diameter and 11,500 mm in depth. As illustrated in Fig. 6, the reinforcement cage consisted of a single-layer lower segment and a double-layer upper segment, emulating real-world reinforcement complexity.

Concrete was introduced from the base via a tremie pipe at a velocity of 1.69 m/s. The model adopted particle spacing of 50 mm to balance detail with computational cost [3]. Rheological properties derived from slump tests were used, and additional sensitivity analyses were conducted based on previous studies.

Visualization and Flow Analysis

Simulation results, shown in Figs. 7 and 8, revealed distinct differences in flow behavior between lower and upper regions of the shaft. While concrete filled the lower region uniformly, significant stagnation and incomplete replacement of pore water occurred in the upper segment, especially around the dense rebar network.

As depicted in Fig. 9, turbulence near the tremie discharge induced mixing zones with entrapped water, highlighting potential risks for cold joints and void formation. The observed water retention correlated with flow obstructions caused by reinforcement congestion [4].

Fig. 10 Experimental results showing internal concrete distribution in hardened specimens

Fig. 11 Simulation results of concrete distribution corresponding to experimental observations

Experimental Validation

Comparative element tests were conducted using 3D CAD-modeled formworks and reinforcement cages (see Figs. 10 and 11). Concrete was cast through a tremie at controlled velocities, and the internal distribution was assessed by cutting hardened specimens. The results confirmed the presence of unfilled regions and entrapped water in the upper cage zone [5].

Engineering Implications

These findings demonstrate that MPS-CAE simulation is effective not only for visualizing complex flow patterns but also for proactively identifying risks such as insufficient filling and entrapped fluid. By adjusting boundary conditions or tremie insertion strategies within the model, practitioners can refine placement procedures before field execution. The simulation also provides a valuable communication tool for conveying internal construction behavior to project stakeholders.

CONCLUSIONS

This study developed and validated a computational framework combining the Moving Particle Semi-implicit (MPS) method with Computer-Aided Engineering (CAE) techniques to simulate and assess the flow behavior of fresh concrete in both controlled and field-scale scenarios.

Key conclusions are as follows:

(1) MPS-CAE simulations accurately replicated slump test results, achieving dimensional agreement within 1 cm and capturing radial flow symmetry and final deformation profiles. The bi-viscosity Bingham model and critical shear rate threshold effectively reproduced flow cessation behavior.

(2) The simulation model successfully predicted flow obstructions and segregation zones in large-scale pile placements. Especially in double-reinforced regions, incomplete filling and water entrapment were visualized, aligning with physical test outcomes.

(3) The integrated framework enables predictive evaluation of fresh concrete flow, supporting construction planning and defect mitigation. By simulating different material and operational parameters, engineers can identify high-risk areas and optimize placement strategies.

(4) MPS-CAE offers a practical enhancement to traditional construction workflows, allowing virtual prototyping, real-time visualization, and quality control in complex geometries without full-scale physical mockups.

Future work will focus on extending this simulation framework to include real-time sensor feedback, adaptive meshing for finer resolution around reinforcement, and coupling with multi-physics models to capture thermal and hydration effects during curing. These developments will further increase the relevance of particle-based methods in construction engineering.

ABSTRACT

Soil electrical resistivity is a critical parameter in geotechnical engineering, particularly for assessing subsurface conditions in power substation projects. Understanding how resistivity responds to fundamental soil properties can improve both site evaluation and the design of grounding systems. This study investigates the relationship between resistivity and key geotechnical variables, namely water content, plasticity index, and dry density, using both traditional statistical techniques and a Polynomial Neural Network (PNN) approach. Among the tested variables, water content showed the strongest inverse correlation with resistivity ($r_s = –0.92$), confirming its significant influence on soil conductivity. Plasticity index and dry density had only weak correlations. An exponential regression model captured this nonlinear trend reasonably well ($R^2 = 0.439$), while the PNN, constructed with a single hidden layer and third-degree polynomial terms, achieved comparable performance ($R^2 = 0.433$). The strong inverse correlation between moisture and resistivity observed in this study confirms the critical influence across varied soil types and demonstrates the value of PNNs as an interpretable machine learning tool for modeling nonlinear relationships in geotechnical data.

Keywords: Geotechnical parameters; Soil resistivity; Regression; Polynomial Neural Networks

INTRODUCTION

Soil electrical resistivity plays a key role in geotechnical and environmental engineering, assisting engineers assess subsurface conditions, conducting soil investigations, and designing effective grounding systems. Its ability to indirectly reflect changes in soil composition, water content, and structural integrity makes it a non-destructive and cost-effective tool for field investigations. Previous study has established that geotechnical index properties, particularly water content, plasticity index, and dry density, significantly influence resistivity values [1]. However, due to the inherently nonlinear and multivariate nature of these relationships, traditional regression models often fall short in accurately capturing such complex interactions.

Recent developments in machine learning, especially the use of Polynomial Neural Networks (PNNs), offer a compelling alternative for modeling complex systems. PNNs are designed to model nonlinear systems using higher-order polynomial expressions instead of conventional activation functions, enabling the generation of closed-form equations that enhance model transparency and interpretability. These characteristics make PNNs well-suited for geotechnical applications, where understanding feature interactions is essential.

In this study, we aim to investigate the predictive relationship between soil resistivity and three key geotechnical parameters: water content, plasticity index, and dry density. This study aims to: (1) assess the relationships between soil resistivity and key parameters; (2) develop regression models for both single-variable and multivariable cases; (3) apply and evaluate Polynomial Neural Networks (PNNs) to capture nonlinear interactions; and (4) compare the performance and interpretability of regression and PNN-based approaches. The analysis is based on field-collected soil samples from substations across Thailand. The findings aim to improve the accuracy of resistivity prediction models while providing insights into the relative influence of input variables in geotechnical engineering contexts.

METHODOLOGY

This study set out to examine the relationship between soil geotechnical properties and electrical resistivity through a hands-on experimental approach. The research involved collecting soil samples in the field, conducting detailed laboratory tests, and monitoring changes over time under controlled environmental conditions. As illustrated in Fig. 1, the overall process was divided into six main stages, beginning with field sampling and the laboratory measurement of geotechnical properties and electrical resistivity.

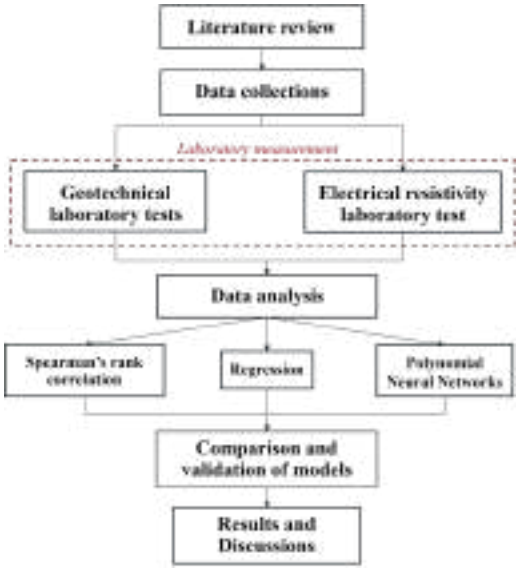

Fig. 1 Workflow diagram of the research methodology.

Data Acquisition

Soil samples were collected from power substations across three different regions of Thailand. These samples were subsequently tested in the laboratory to determine key properties such as moisture content, plasticity index, specific gravity, and compaction behavior. At the same time, electrical resistivity was measured using the Wenner array method, with readings taken at regular intervals to monitor how resistivity responded to changes in moisture content.

In total, 30 samples were collected from shallow backfill layers (approximately 1 meter deep) at the substations. The laboratory tests focused on both geotechnical and electrical properties, including water content, liquid limit, plasticity index, specific gravity, clay content, and compaction characteristics. All tests were conducted in accordance with established ASTM standards.

Electrical resistivity was measured in the laboratory using a one-dimensional, four-electrode Wenner array setup, following ASTM G57 [2] and the method described by Giao [3]. The test employed a cylindrical acrylic mold measuring 6.4 cm in diameter and 12 cm in height. A SYSCAL R2 resistivity meter (IRIS Instruments), powered by a 1.5 V battery, was used to supply current and measure the resulting voltage difference.

In the electrical resistivity laboratory setup, brass discs were positioned at both ends of the soil specimen to serve as current electrodes, while a pair of brass pins, placed 4 cm apart within the sample, acted as potential electrodes. In uniform soil, the electric current spreads evenly in all directions, forming a radial flow pattern.

To ensure consistent results, all soil samples were prepared using the same procedure. Each sample was oven-dried, thoroughly mixed with distilled water, and sealed in a plastic bag for 24 hours to allow the moisture to distribute evenly. The soil was then compacted into the mold to achieve 95% of the maximum dry density and 85% of the optimum moisture content, based on the Standard Proctor Test.

Resistivity readings were taken over a 28-day period at four time points: Days 0, 7, 14, and 28. Before each reading, the samples were weighed, and their moisture content was measured. Throughout the testing period, the laboratory environment was maintained at 25 ± 2 °C with a relative humidity of 50–55% to minimize external influences. These environmental controls were based on previous research indicating that variations in temperature and moisture can significantly affect resistivity values [4].

DATA ANALYSIS

In this study, careful selection of analytical tools allowed us to identify how geotechnical parameters influence soil resistivity. In both scientific and engineering research, selecting the appropriate analytical methods is crucial for helping find trends, understand relationships between variables, and create accurate prediction models. This section introduces three commonly used techniques in quantitative analysis: Spearman's rank correlation, regression analysis, and Polynomial Neural Networks (PNNs), each offering unique strengths for exploring and modeling data in the context of this study.

Spearman's Rank Correlation Coefficient

Spearman's rank correlation coefficient (r_s) is a non-parametric statistical measure used to evaluate the strength and direction of a monotonic relationship between two variables [5].

One of the advantages of Spearman's correlation is that it does not require prior specification of dependent or independent variables, although such designations can still be made when relevant. Instead, it evaluates the degree of agreement between two sets of ranks, reflecting how consistently the values of one variable increase or decrease with those of another. To calculate Spearman's rank correlation coefficient, the following formula is used:

$$r_s = 1 - \frac{6 \sum d_i^2}{n(n^2-1)} \quad (1)$$

where d_i is the rank difference for each pair and n is the number of observations. r_s can be interpreted

as the coefficient ranges from –1 to +1, where values close to +1 indicate a perfect positive correlation, and values near –1 denote a perfect negative correlation. A value of 0 suggests no association between the variables.

Regression

Regression analysis is one of the most commonly applied statistical methods for exploring relationships between variables and determining the extent to which independent variables influence a dependent variable. In its simplest form, linear regression describes the relationship between two variables, typically one predictor and one response, using the following equation:

$$y = \beta_0 + \beta_1 x + \varepsilon \quad (2)$$

In this equation, y is the dependent variable, x is the independent variable, β_0 represents the intercept, β_1 is the slope or regression coefficient, and ε denotes the error term which accounts for variability not explained by the model [6].

Polynomial Neural Network

Polynomial Neural Networks (PNNs) have gained attention as a more interpretable alternative to traditional Artificial Neural Networks (ANNs) for modeling nonlinear systems. Rather than depending on weighted sums and nonlinear activation functions, PNNs incorporate higher-order polynomial expressions within their network layers to approximate complex input–output relationships. This design allows the model to produce closed-form mathematical equations, offering greater transparency and making the model's behavior easier to interpret [7]. One of the most widely used variants of PNNs is the Pi-Sigma Network (PSN). In this architecture, each neuron in the hidden layer calculates the product of several linear combinations of the input features. This structure can be represented mathematically as follows:

$$h_{j,k} = \sum_{i=1}^{I} w_{i,j,k} x_i + b_{j,k}, \;\; u_j = \prod_{k=1}^{K} h_{j,k} \quad (4)$$

where x_i are the input variables, $w_{i,j,k}$ and $b_{j,k}$ denote the weights and biases, respectively, and K is the polynomial degree. The final output of the network is computed through a linear combination of the hidden neuron outputs:

$$y_{PNN} = \sum_{j=1}^{n_H} w_j u_j + b \quad (5)$$

where n_H represents the number of hidden neurons, w_j are the output layer weights, and b is the output bias.

RESULTS AND DISCUSSION

Laboratory test results

The laboratory test results for all collected soil samples revealed key geotechnical characteristics. Based on particle size distribution and Atterberg limits, the samples were primarily classified as either silty clay or clayey silt. Plasticity index (PI) values ranged from 9.8% to 37.2%, with higher plasticity index samples falling above the A-line, indicating clay-type soils, while lower plasticity index values aligned more closely with silt-type classifications [1]. According to the Unified Soil Classification System (USCS), all samples were identified as low-plasticity soils.

Specific gravity measurements ranged from 2.68 to 2.80, while the maximum dry density values were between 1.77 and 1.86 g/cm³. The optimum moisture content varied from 13.2% to 16.4% across all samples. These results reflect a moderate range in physical properties, indicating slight variations in mineral composition and compaction behavior among the tested soils.

The results of the electrical resistivity laboratory tests showed substantial variation in both resistivity and geotechnical properties. Resistivity values ranged from 8.67 to 911.05 Ω·m, with a mean of 148.76 Ω·m and a standard deviation of 189.29 Ω·m, reflecting a strongly right-skewed distribution. Some samples showed unusually high resistivity values, which increased the overall kurtosis and pointed to inconsistent conductivity among the soils. Water content ranged from 0.08% to 16.35%, with an average of 7.24% and a standard deviation of 5.34%.

Soil Resistivity and Water Content

Water content is widely recognized as a key factor influencing soil electrical resistivity. To quantify this relationship, we applied three methods: Spearman's rank correlation, exponential regression, and Polynomial Neural Network (PNN) modeling. As illustrated in Fig. 2 and Table 1, the Spearman's correlation coefficient between water content and resistivity was –0.92, indicating a strong inverse monotonic relationship. This result is consistent with the well-established principle that higher moisture levels increase ionic conductivity, which in turn reduces resistivity. The relationship can be further described using an exponential regression model, expressed as:

$$\rho = 315.50\exp(-0.2037WC) \quad (6)$$

where ρ is the predicted soil resistivity in Ω·m

and WC is water content of the soil.

The exponential model achieved an R^2 of 0.439, with RMSE of 141.00 and MAE of 74.70 (Fig. 3). It successfully captured the nonlinear decrease in resistivity as water content increased and provided a straightforward, easy-to-interpret equation. A more flexible approach using a PNN delivered comparable results, with an R^2 of 0.433, MAE of 86.91 (Fig. 3).

In comparing the three methods, all consistently identified water content as the dominant factor affecting soil resistivity. Spearman's correlation confirmed a strong monotonic relationship, the regression model provided a clear and interpretable mathematical equation, and the PNN demonstrated flexibility and robustness in handling nonlinear patterns. Notably, the similar R^2 values achieved by both the regression and PNN models suggest that exponential regression is a practical and effective method, especially when model simplicity and interpretability are important.

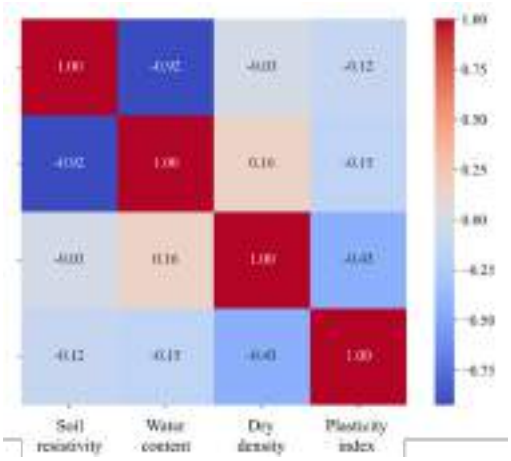

Fig. 2 Heatmap of Spearman's rank correlations among geotechnical variables and soil resistivity.

Soil Resistivity and Plasticity Index

The relationship between plasticity index (PI) and soil resistivity was investigated using Spearman's correlation, simple regression, and a PNN model, as shown in Table 1.

The Spearman's rank correlation coefficient between plasticity index and resistivity was –0.12, indicating a weak negative relationship. This suggests that plasticity index alone has limited influence on resistivity in a monotonic pattern, especially when compared to water content, which exhibited a much stronger correlation.

A simple linear regression was performed using plasticity index as the only input variable, resulting in the following equation:

$$\rho = 189.77 - 1.77PI \quad (7)$$

where ρ is the predicted soil resistivity in Ω·m and PI is plasticity index of the soil.

This model showed very poor predictive performance, with an R^2 of 0.007, an RMSE of 187.60 and an MAE of 138.88. The weak linear trend is consistent with the low correlation observed earlier and confirms that plasticity index alone is not sufficient to explain variations in soil resistivity.

To further investigate possible nonlinear patterns, a PNN model was developed using both the linear and squared terms of plasticity index. However, the model performed poorly, with an average R^2 of –0.099 across five-fold cross-validation. The negative R^2 value indicates that the model did worse than simply predicting the mean of the data.

Overall, all three methods consistently indicate that the plasticity index alone has a weak and unreliable relationship with soil resistivity. While plasticity index is relevant in geotechnical characterization, it is not a dominant predictor of resistivity on its own, though its influence may increase in multivariable models.

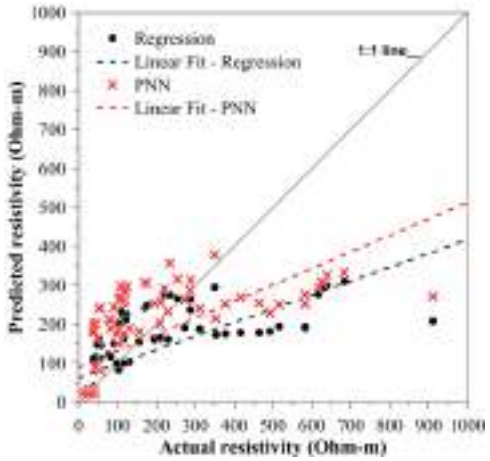

Fig. 3 Comparison of predicted vs. measured soil resistivity with water content is input variable.

Soil Resistivity and Dry Density

The relationship between soil resistivity and dry density was analyzed using Spearman's rank correlation, simple linear regression, and a PNN model, as shown in Table 1.

The Spearman's correlation coefficient between dry density and resistivity was –0.03, indicating a negligible monotonic relationship. This result suggests that variations in dry density alone do not have a consistent effect on soil resistivity.

A simple linear regression using dry density as the only input variable resulted in the following equation:

$$\rho = 460.27 - 190.16\gamma_d \quad (8)$$

where ρ is the predicted soil resistivity in Ω·m

and γ_d is dry density of the soil in g/cm^3.

The model yielded an R^2 of 0.007 and an MAE of 137.99, indicating very poor predictive performance. The near-zero R^2 shows that the model performed worse than simply predicting the average, reinforcing the weak relationship between dry density and resistivity. Overall, these findings suggest that dry density alone does not have a meaningful correlation with soil resistivity, regardless of the modelling method used. However, it may still add value in multivariable models—especially when combined with stronger predictors like water content.

Multiple Variables Analysis Results

Relationship Between Soil Resistivity, Water Content, and Plasticity Index

The combined effects of water content and plasticity index (PI) on soil resistivity were analyzed using both exponential regression and a PNN, as summarized in Table 2. These two approaches provide a comparison between traditional curve-fitting techniques and machine learning-based models for capturing nonlinear relationships.

The exponential regression model produced the following equation:

$$\rho = 578.66\exp[(-0.2082WC) - (0.0247PI)] \quad (9)$$

where ρ is the predicted soil resistivity in Ω·m, WC is water content of the soil and PI is plasticity index of the soil.

This model achieved an R^2 of 0.503, RMSE of 132.75, and MAE of 65.64. The equation reflects that both water content and plasticity index are inversely related to soil resistivity. As illustrated in Fig. 4, the regression residuals do not follow a normal distribution. In particular, the values at the high and low ends stray from the reference line, suggesting the model may have limitations in capturing the full range of variation in the data.

The PNN model, which included both linear and polynomial terms for water content and plasticity index, showed better performance, with an average R^2 of 0.618. As illustrated in Fig. 4, the comparison between the measured soil resistivity and the values predicted by the PNN model aligned more closely with the diagonal line, indicating that the residuals were more normally distributed and the model was better calibrated. Feature importance analysis confirmed that water content remained the most influential factor, while plasticity index played a secondary role—mainly through higher-order and interaction terms.

These results demonstrate that while regression offers a simple and interpretable model, PNN captures more complex patterns and produces residuals that better satisfy model assumptions. Thus, PNN is more suitable when modeling resistivity from multiple interacting soil parameters.

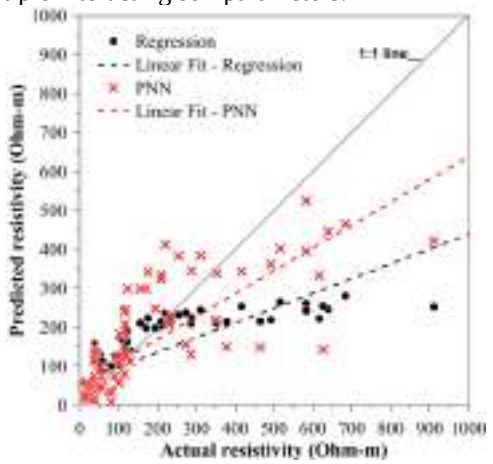

Fig. 4 Comparison of predicted vs. measured soil resistivity with water content and plasticity index are input variables.

Relationship Between Soil Resistivity, Water Content, and Plasticity Index

The combined effects of water content and dry density on soil resistivity were evaluated using both exponential regression and PNN models, as summarized in Table 2.

The exponential regression model produced the following equation:

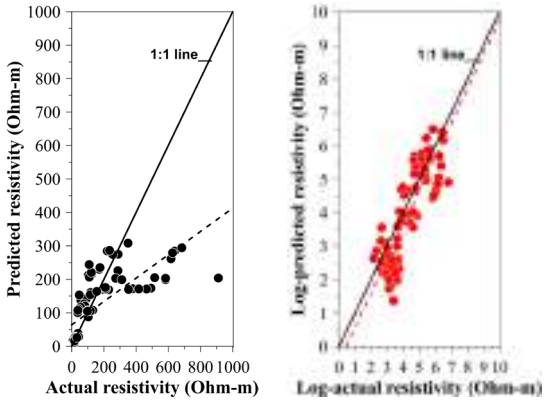
$$\rho = 128.76\exp[(-0.2044WC) + 0.5499\gamma_d] \quad (10)$$

where ρ is the predicted soil resistivity in Ω·m, WC is water content of the soil and γ_d is dry density of the soil in g/cm^3.

This model achieved an R^2 of 0.439, with RMSE is 142.22 and MAE is 74.57. The results suggest that soil resistivity tends to decrease as water content increases but slightly increases with higher dry density. However, the comparison between the measured and predicted soil resistivity values (Fig. 5) revealed clear deviations from the diagonal line—particularly at the ends—suggesting that the regression model may have difficulty capturing the full complexity of the data.

To better capture nonlinear patterns and interactions, a PNN model was developed using water content, dry density, and their polynomial terms. The model showed improved performance, achieving an R^2 of 0.522, with an MSE of 0.66 and an MAE of 0.67 (based on log-transformed resistivity). As shown by the comparison between the measured and predicted soil resistivity values in Fig. 5, the residuals from the PNN model aligned more closely with the expected normal distribution, indicating better model calibration and a more balanced distribution of prediction errors.

These results show that although dry density on its own does not predict soil resistivity well, combining it with water content improves overall model accuracy. The PNN performed better than the exponential regression model in both overall fit and its ability to handle prediction errors, making it a more suitable choice for modeling soil resistivity in complex, multi-variable situations.



(a) (b)

Fig. 5 Comparison of predicted vs. measured soil resistivity with water content and dry density (γ_d) are input variables: (a) Regression model and (b) PNN.

Table 1 Summary of soil resistivity prediction using single-variable models

Input variable	Spearman's Correlation (r_s)	Regression model	Regression R^2	PNN R^2
WC	-0.92	Exponential	0.439	0.433
PI	-0.12	Linear	0.007	-0.099
γ_d	-0.03	Linear	0.007	-0.057

Table 2 Summary of soil resistivity prediction using two-variable models with output (soil resistivity) and input parameters including water content, plasticity index (PI), and dry density (γ_d)

Input variable		Regression model	Regression R^2	PNN R^2
WC	PI	Exponential	0.503	0.618
WC	γ_d	Exponential	0.429	0.522

CONCLUSIONS

This study evaluated how soil resistivity relates to key geotechnical parameters using both statistical and machine learning approaches. The main findings can be summarized as follows:

Water content was identified as the most influential parameter affecting soil resistivity, exhibiting a strong inverse correlation (r_s = –0.92). In contrast, plasticity index and dry density showed weak individual correlations with resistivity and contributed less significantly to model performance.

Regression models were developed for both single-variable and multivariable cases, with exponential regression performing best in the single-variable context.

The Polynomial Neural Network (PNN) achieved comparable R^2 values (~0.43) to regression models and proved more effective in capturing nonlinear interactions among variables. Although PNNs require greater computational effort, they provide valuable and accuracy in predicting soil resistivity for engineering applications.

The findings, based on soil samples collected from substations across Thailand, offer practical insights into variable influence and support more reliable geotechnical site assessments.

ABSTRACT

Global beachrock distribution, characteristics, and formation mechanisms remain subjects of ongoing debate. A comprehensive database incorporating all published research is essential for a clearer understanding of their formation processes and their distribution. However, compiling such a database requires systematic data collection and analysis on a global scale. This study contributes to this effort by developing a database of beachrock occurrences and characteristics, specifically focusing on the tropical Asian region. A comprehensive literature review was conducted, resulting in the compilation of 122 documented records of beachrock occurrences. The collected records were then analyzed to determine sediment compositions, cement types, and cementation mechanisms. The findings reveal that beachrock formations are mostly concentrated in the East China Sea (Western Japan), while regions such as Bhutan, Brunei, and Indonesia have limited reported occurrences, possibly due to limited research or publications generated. Beachrocks primarily consist of quartz, heavy minerals, carbonate shells, and organic materials, with porosity varying based on cementation progress. Cement analysis records reveal that aragonite and High Magnesium Calcite (HMC) are the dominant types. Cementation occurs through seawater precipitation, microbial activity, and freshwater processes, with seawater precipitation being the most prevalent mechanism. The findings contribute to the development of a global beachrock database and offer insights into formation processes in tropical regions.

Keywords: Asian Tropical Coasts, Calcareous Rocks, Carbonate Cements, Formation Mechanism, Shoreline Stability

INTRODUCTION

Beachrocks are unique, naturally occurring consolidated shoreline sedimentary formations commonly found in tropical and subtropical regions [1], particularly within intertidal and supratidal zones. They typically appear as layered deposits inclined towards the sea. They vary in size from small patches to extensive outcrops that extend several kilometers and range from friable to well-cemented [2,3,4]. Beachrocks consist of beach sediments, including sands and gravels derived from siliciclastic, bioclastic, and/or volcaniclastic sources [2], bound together through rapid cementation. This process is primarily facilitated by the precipitation of carbonate cement, predominantly composed of calcite or aragonite [5,6]. Beachrock formation processes, occurrences, and characteristics vary with regional climate zones such as tropical, subtropical, temperate, and Mediterranean and sea water level conditions. To achieve a clear and comprehensive understanding of global beachrock distribution and their characteristics, region-specific studies are essential.

Numerous global studies on beachrocks indicate that over 90% of beachrock occurrences are concentrated between 40°N and the Tropic of Capricorn (~23°S) [7]. Similarly, Vousdoukas et al. (2007) observed that most documented occurrences lie between 20° and 40° latitude and suggested that the apparent scarcity of beachrock formations in tropical regions may not indicate a true absence but rather reflect a lack of focused scientific investigation in those areas [6].

In addition, numerous global studies have consistently shown that beachrocks predominantly form in tropical and subtropical climates. However, more recent research has identified sporadic occurrences in temperate and colder regions, challenging the traditional assumption that beachrock formation is restricted to tropical and subtropical zones [1,8]. Tropical and subtropical beachrocks typically develop as extensive, shore-parallel ledges with a uniform distribution, facilitated by stable, low-energy beach conditions and high temperatures that promote dynamic cementation. In contrast, temperate beachrocks often occur as isolated concretions embedded deeper within the beach profile, forming under more variable conditions that may include erosion and instability. However, some temperate regions, such as Northern Ireland, exhibit beachrock

formations that developed during prolonged periods of stability, highlighting a key distinction from the more dynamic cementation processes commonly observed in tropical environments. Cementation processes in temperate regions may resemble those occurring in tropical areas [1].

The exact mechanisms behind beachrock formation are still not fully understood. However, past studies have proposed several dominant theories to explain them. These include direct cement precipitation, mixing of marine and freshwater, precipitation triggered by the release of carbon dioxide, and biological contributions [6].

This study aims to collect and analyze the existing records on beachrock occurrences and characteristics in the tropical Asian region. This will provide foundational insights into natural beachrock formation in tropical Asian region.

RESEARCH SIGNIFICANCE

The beachrock distribution, characteristics, and formation mechanisms remain subjects of ongoing debate. A comprehensive database compiling all published research is crucial for better understanding their formation, characteristics and distribution. However, compiling such a database requires systematic data collection and analysis on a global scale. This study contributes to this effort by developing a database, with a focus on the tropical Asian region. The findings contribute to the development of a global beachrock database and offer insights into formation processes in tropical regions.

METHODOLOGY

A systematic literature review was conducted using major scholarly search platforms, including *Web of Science, Scopus, Google Scholar, ScienceDirect, SpringerLink,* and *Wiley Online Library*. The search was guided by specific keywords targeting publications from 1960 to 2025. In the first step, all retrieved publications were screened for relevance to tropical regions of Asia based on geographic descriptions. If a publication did not meet this criterion, it was excluded, and the search was repeated. The inclusion criteria were established to ensure the relevance and scientific quality of the records, focusing on peer-reviewed journal articles. Studies were excluded from unpublished reports, Abstract-only publications, lacked sufficient geospatial information. Geospatial coordinates provided in publications were verified using *Google Earth* and *ArcGIS*. When coordinates were missing, maps and contextual descriptions were used to estimate locations. The collected records from each beachrock site were systematically analyzed to identify sediment compositions, cement types, and cementation mechanisms, and the resulting database was referred to as the tropical Asian region beachrock database (TARBD). In cases of conflicting data, original publications were re-examined, and metadata were annotated for discrepancies. The summary of methodology is illustrated in Fig.1 below.

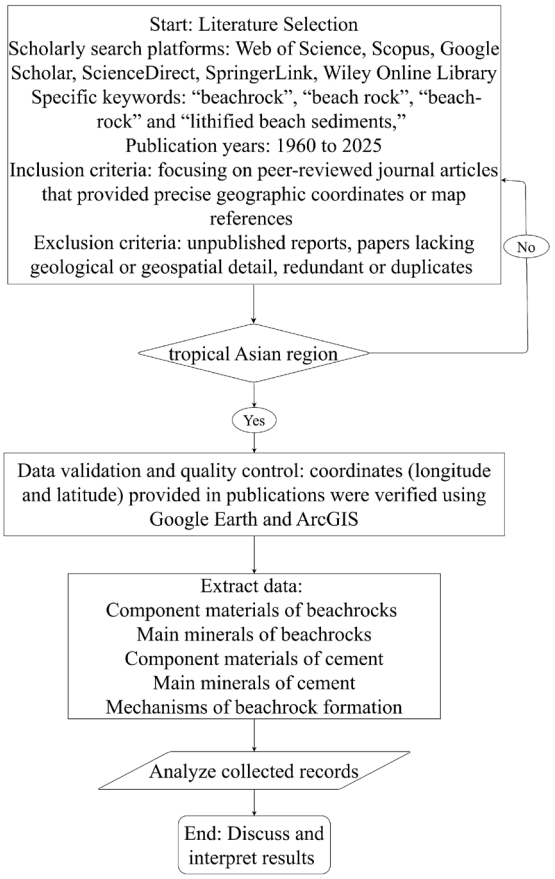

Fig.1 Methodology flowchart

RESULTS AND DISCUSSIONS

Beachrock Occurrences

The TARBD related to this study is openly available in the *Mendeley Data repository* and can be accessed using the *DOI: 10.17632/9ysc29xmx2.1*.

A total of 122 records of beachrock occurrences were compiled from 44 published studies across the tropical Asian region, and their distribution by area or country is presented in Fig. 2. The East China Sea (Western Japan) has the highest number of occurrences, while Bangladesh and the northwestern South China Sea report the fewest. The absence of documented beachrock occurrences along the coasts of Brunei, Cambodia, Myanmar, Papua New Guinea, Indonesia, and Singapore likely reflects limited research attention and insufficient field

investigations, highlighting gaps in the TARBD.

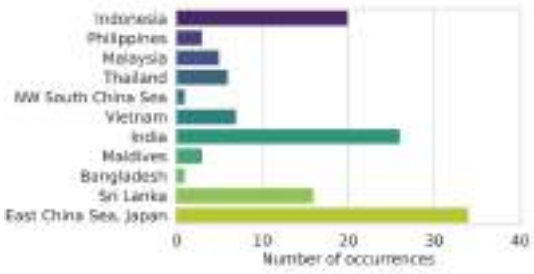

Fig.2 The distribution of beachrock occurrences by area or country

A spatial distribution map of 122 beachrock occurrences was generated using *ArcMap* to validate the geographic coordinates of each record. Fig. 3 presents the spatial distribution of the 122 beachrock occurrence records. Fig. 4 highlights areas of higher occurrence density, primarily concentrated in the East China Sea (Western Japan), as identified through hot spot analysis.

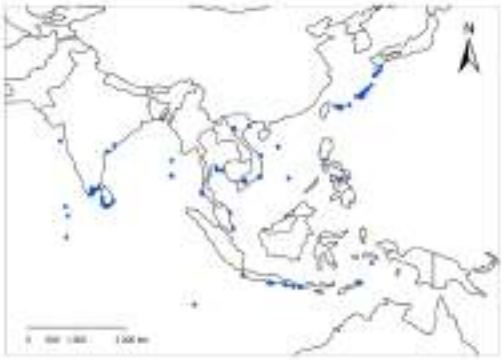

Fig.3 The spatial distribution of the 122 beachrock occurrence records

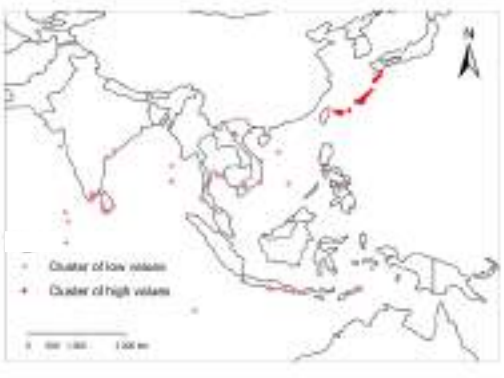

Fig.4 The areas of higher occurrence density, as identified through hot spot analysis

In addition to research limitations, several natural and anthropogenic factors contribute to the lack of recognized beachrock sites. Naturally, rising sea-levels can submerge beachrock formations, making them difficult to access or observe, while wind-driven sediment accumulation may bury them beneath surface layers leading to seasonal exposure. Human activities such as coastal development, dredging, sand mining, and constructions may have disturbed or destroyed beachrocks before they are documented. Furthermore, legal restrictions in protected, historical, or conservation areas may limit scientific access, as regulations often prohibit the extraction of geological materials to preserve cultural and ecological value.

Fig.5 illustrates the increasing number of beachrock-related publications focused on the tropical Asian region from 1960 to 2025. The publication records are grouped into 10-year intervals.

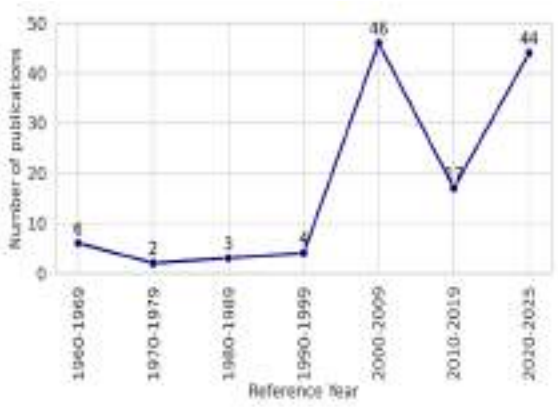

Fig.5 The publication timeline for reported beachrock occurrences

Beachrock-related publications were minimal prior to 1999, reaching their lowest point during 1970–1979. A significant rise occurred between 2000 and 2009, marking the highest number of publications, followed by another notable increase during 2010–2019. These trends suggest that the research gap identified by Vousdoukas et al. (2007), who highlighted the lack of studies in tropical regions [6], is now being progressively addressed.

Fig.6 illustrates the relationship between count of beachrock occurrences and latitudes. The majority of reported beachrock occurrences were associated with coastal regions within latitudes 0–10°N. Based on the TARBD, a notable number of beachrock occurrences were identified within the 20°S to 40°N latitude range. These findings contribute to a slight increase in the percentage previously reported by Danjo and Kawasaki (2014) [7], who observed that over 90% of global beachrock occurrences were concentrated between 40°N and the Tropic of Capricorn (~23°S).

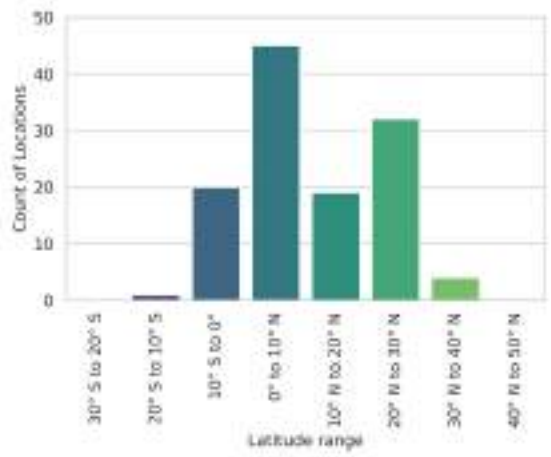

Fig.6 The beachrock occurrence counts across different latitudes

Beachrock Morphology and Coastal Sediments

Based on the extracted records on beachrock morphology from the TARBD, beachrocks typically formed between the high and low tide levels, extending extensively along shorelines and often reaching inland, where they were sometimes buried beneath a thin layer of loose beach sediments. These formations ranged from small, localized patches of cemented sediments to expansive outcrops extending over several kilometers (Fig.7). The thickness of beachrocks varied considerably, from less than 0.5 m to over 2.5 m. Thicker formations were generally located in areas with a significant tidal range, indicating the influence of tidal dynamics on their development [6].

Fig.7 Beachrock outcrops at Uswatakeiyawa beach, Sri Lanka, visibly exposed on land and extending seawards towards the submerged zone

The morphology of beachrocks varied widely due to factors such as sea-level fluctuations, environmental conditions, climatic events, tectonic activity, and coastal morphodynamics [6,9]. Stratified beachrock outcrops (Fig. 8) are common and typically consist of medium-bedded layers with occasional thin layers, often exhibiting graded bedding that may be continuous or discontinuous. These formations occurred along the coast in both underwater and above-water settings, generally extending over a width range of 10 m to 40 m. For example, observations from the Qilian Islets and Cays reveal that beachrock outcrops consisted of multiple beds, typically ranging from 5 to 8 layers. Each bed generally varied in thickness from about ten centimeters to several tens of centimeters, showcasing a complex stratification pattern [9].

Fig.8 Visual representation of stratified beachrock outcrops at Koggala beach, Sri Lanka

Beachrocks buried onshore have smooth surfaces primarily due to their lithification process, protection from erosive forces, limited exposure to weathering, and their similarity in texture to the surrounding sediments [6,9].

The dips of stratified beachrock beds generally align with the coastal slope, exhibiting low inclination angles of 8° to 12° towards the open sea, with their strike oriented parallel to the coastline. These dip angles varied depending on local factors such as beach slope, and sea wave intensity [9].

Coastal hydrodynamic intensity, which refers to the strength and movement of water along the shoreline, plays a critical role in the formation and distribution of beachrocks. It influences their width, the thickness of their layers, and the sedimentary structures and development patterns within the deposition sequence [6,9]. Beachrocks provide valuable insights into past environmental conditions, including sea-level changes, climate variations, and coastal processes. Their sedimentary structures and stratification patterns serve as essential records of historical coastal dynamics [9].

Beachrock beds often display a range of grain textures, including both well-sorted and poorly sorted sediments. This variation in grain textures is largely driven by hydrodynamic conditions. For example, during storms or under strong wave action, large coral and shell fragments are deposited quickly, resulting in poorly sorted and highly porous sediments. In contrast, calmer waves and tides lead to repeated washing of sediments, producing better sorted and

rounded grains, with slower deposition and more uniform porosity [9].

Beachrocks were composed of cemented beach sediments, which include a wide range of particle sizes. The sedimentary particles exhibit significant diversity, reflecting the composition of the surrounding sedimentary environment [1,2,3,6,9]. These particles included quartz, garnet, iron oxides, feldspars, heavy minerals (Fig. 9), recycled clasts, volcanic materials, carbonate ooids, molluscan shells, and skeletal fragments [2,3,5,6]. For example, the beach sediments on the Tiruchendur coast in Tamil Nadu, India primarily consisted of quartz and shells, while the Pag-Asa Reefs feature medium to coarse carbonate sand interspersed with coralline clasts. Additionally, beachrock incorporated organic materials such as wood fragments and coconut shells, as well as man-made objects like bottles and ceramic pieces [6,9]. They contained pore spaces, and their porosity decreased as cementation progressed, with porosity values varying significantly depending on the degree of cementation.

Fig.9 Presence of heavy minerals, primarily ilmenite, observed at Uswetakeiyawa beach, Sri Lanka

Cement and Cementation Mechanism

According to the records analysis of the TARBD, beachrock cement is primarily calcite or aragonite, depending upon factors like temperature, salinity, pH, and abundance of magnesium in the environment. Calcite typically precipitates from freshwater, while aragonite forms from seawater. Calcite occurs in two distinct forms, High Magnesium Calcite (HMC) and Low Magnesium Calcite (LMC), both of which are polymorphs of calcium carbonate ($CaCO_3$). HMC contains more than 1.2 wt.% magnesium carbonate ($MgCO_3$) [6] while LMC contains less than 4 mol% $MgCO_3$. Aragonite is commonly associated with phreatic, shallow-marine, and vadose environments. It typically appears as acicular crystals, fibrous rims, bladed spar rims, and irregular needles, forming isopachous cement rims around grains. It was produced by pelagic organisms like pteropods, corals, algae, and mollusks. Conversely, HMC is formed by benthic organisms like foraminifera and sea urchins, thus it occurs in shallow marine zones and appears in micritic, granular, or bladed crystal forms. LMC was linked to meteoric vadose and phreatic zones, displaying meniscus and spar forms. Environmental changes result in aragonite growing atop existing calcite cements, highlighting dynamic diagenetic processes [6].

Among the 122 beachrock occurrences compiled in the TARBD, 81 records with complete cement mineralogical data were selected for statistical analysis (Fig. 10). The remaining 41 records were excluded due to incomplete or missing mineralogical information. The analysis reveals that aragonite was the most prevalent cement type, followed by HMC. Interestingly, silica was identified as a cement type at only one site. These findings represent the current state of published knowledge, which remains limited and subject to change as more studies are undertaken in this area.

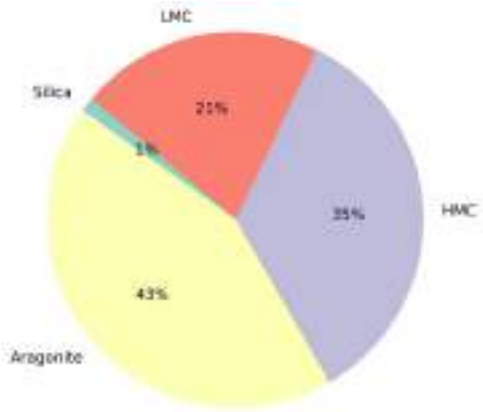

Fig.10 The statistical comparison of cement mineralogy in the tropical Asian region

According to the records analysis of the TARBD, the primary cementation mechanisms in tropical Asian region include precipitation from seawater, precipitation from freshwater, microbial-induced cementation, and cementation from both marine and meteoric water. A total of 60 records with complete cementation mechanism data were selected for statistical analysis (Fig. 11), while the remaining 62 records were excluded due to incomplete or missing information on cementation mechanisms. The analysis indicates that seawater precipitation is the dominant process, followed by the 'various' category, which include sites where multiple mechanisms contribute to beachrock formations.

In contrast, only a limited number of sites exhibit beachrock formation through freshwater precipitation. Lithification driven by biological processes is identified at approximately four sites, while cement precipitation from mixed marine and meteoric waters is observed at nine sites.

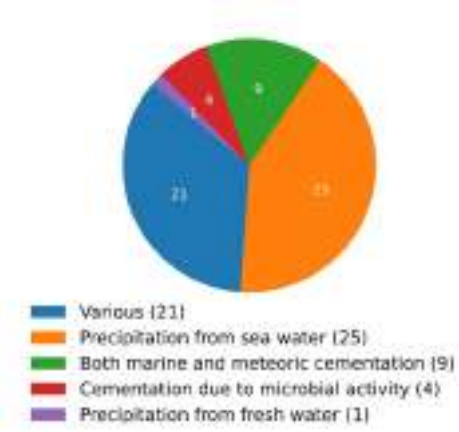

Fig.11 The statistical comparison of cementation mechanisms in the tropical Asian region

CONCLUSIONS

In conclusion, the compiled data of 122 beachrock occurrences from 44 studies highlights significant regional variation across tropical Asia, with the highest concentration in the East China Sea (Western Japan) and the lowest in Bangladesh and the northwestern South China Sea. Several countries lack documented records primarily due to limited research and field access. Beachrock-related publications were limited before 1999, with the lowest record in the 1970s. The notable increase in beachrock-related publications from 2000 onward especially during 2000–2009 and 2010–2019, indicating a progressive response to earlier research gaps in tropical regions. Most beachrock occurrences are concentrated within low latitudes, particularly between 20°S and 40°N, with the highest densities observed around 0–10°N. This supports and slightly expands previous global distribution estimates.

Beachrock formations typically develop between tide levels, varying from small patches to extensive outcrops, often buried under loose sediments. Beachrocks are composed of cemented sediments, including quartz, heavy minerals, shells, organic materials, and even man-made objects, with porosity depending on the degree of cementation.

Beachrock cement is primarily composed of calcite and aragonite, influenced by temperature, salinity, and pH. HMC and aragonite dominate cement composition. The main cementation mechanisms include seawater precipitation, microbial activity, and freshwater precipitation, with seawater precipitation being the most prevalent.

ABSTRACT

The loose regolith on the lunar surface presents significant challenges for base construction. Microbially induced calcium carbonate precipitation (MICP) has been proposed as a promising method for enhancing lunar regolith strength. However, the microgravity environment may affect microbial growth and mineralization efficiency, potentially influencing the feasibility of MICP-based stabilization. This study investigated the microbial growth behavior, urease activity, and microstructural changes of *Lederbergia lenta* (RII-2) under different culture medium and gravitational conditions. Experiments were conducted using NH4-YE, R2A, and R2A-Urea medium to assess bacterial performance over 168 h. The results indicate that RII-2 exhibited the highest OD_{600} value in R2A-Urea medium, significantly surpassing NH_4-YE and R2A. Urease activity tests revealed that R2A-Urea medium exhibited the highest overall enzymatic activity among the three media. Under microgravity conditions, RII-2 showed a 40% increase in OD_{600} and a 22-28% decline in urease activity compared to normal gravity. These findings suggest that the experimental conditions affect bacterial growth and enzymatic function, which may impact the efficiency of regolith stabilization by MICP in space environments.

Keywords: Lunar regolith stabilization, Microbially induced calcium carbonate precipitation (MICP), Microgravity, Bacteria growth, Urease activity,

INTRODUCTION

The establishment of permanent infrastructure on the Moon is a key objective in advancing extraterrestrial exploration. However, this goal is significantly constrained by the need to transport large quantities of construction materials from Earth, which imposes severe logistical and economic burdens. As a result, attention has shifted toward utilizing in-situ resources, particularly the abundant lunar regolith, as a primary construction material. The lunar surface is covered by a layer of regolith formed through continuous meteoritic bombardment and space weathering [1-3]. This layer is characterized by its fine-grained, angular texture, low density, and lack of cohesion [4], resulting in poor bearing capacity and high susceptibility to dust dispersion and surface instability [5]. These properties not only hinder direct construction but also pose risks to equipment operation and structural safety. Therefore, effective solidification and mechanical reinforcement of the regolith are essential prerequisites for enabling stable and sustainable lunar surface operations.

Among various ground improvement strategies, Microbially Induced Calcium Carbonate Precipitation (MICP) has attracted increasing attention as a biologically mediated method for stabilizing loose granular soils [6, 7]. MICP utilizes the urease activity of specific microorganisms to catalyze urea hydrolysis, leading to the formation of carbonate ions that react with calcium to precipitate calcium carbonate ($CaCO_3$), which serves as a bonding agent between particles [8]. In contrast to conventional solidification methods that often depend on energy-intensive processing and externally supplied materials [9], MICP operates under mild conditions using biologically derived reactions [10]. These features make it a promising approach for in-situ ground stabilization in constrained environments such as the lunar surface. However, as a biologically driven process, its performance may be influenced by external physical conditions, including gravity.

Microgravity is known to influence a wide range of biological processes [11], including bacteria morphology, nutrient transport, metabolic activity, and gene expression [12]. These effects arise from the absence of buoyancy-driven convection, altered fluid dynamics, and the lack of sedimentation under reduced gravitational acceleration. In microbial systems, such changes can affect growth behavior, enzyme production, and the formation of biofilms or precipitates—all of which are critical to the effectiveness of MICP. Although studies have investigated microgravity impacts on higher organisms and mammalian cells, research on how microgravity affects microbial biomineralization processes remains limited. Therefore, clarifying how microgravity affects microbial behavior and carbonate precipitation is an important step toward evaluating the potential use of MICP in low-gravity

environments.

In light of these considerations, the present study explores the potential of MICP under simulated microgravity conditions, focusing on microbial growth behavior and urease activity. By comparing these processes with those observed under normal gravity, the work aims to clarify how microgravity may influence the biological behavior involved in MICP, thereby providing a basis for future application in space-related environments.

MATERIALS AND METHODS

Materials

Bacteria

The ureolytic bacterium *Lederbergia lenta* (RII-2), isolated in previous studies at Hokkaido University, was used in this study. Glycerol stocks were prepared and stored at –80°C, and pre-cultures were initiated in NH_4-YE liquid medium before experimental use.

Culture medium

To accurately evaluate bacterial growth and urease activity under varying conditions, it was first necessary to identify an appropriate culture medium. Since medium composition strongly affects bacterial proliferation and enzyme expression, three media were selected to systematically examine the influence of nutrient availability and urea supplementation on RII-2. The detailed compositions of the three media are listed in Table 1.

Table 1 Composition of three types of culture medium (per 100 mL, solvent: distilled water)

Medium	Component	Amount （g）
NH_4-YE	Yeast Extract	4.00
	Ammonium Sulfate	2.00
	Tris aminomethane	1.58
R2A	R2A Medium	0.32
R2A-Urea	R2A Medium	0.32
	Urea	0.60

(1) NH_4-YE Medium: A nutrient-rich medium used extensively in previous MICP research, known to support rapid cell growth and high biomass. It served as a benchmark for optimal conditions [13].

(2) R2A Medium: A minimal medium typically used for environmental isolates, chosen to simulate low-nutrient environments similar to those encountered in extraterrestrial settings where resource input must be limited [14].

(3) R2A-Urea Medium: A variation of R2A containing urea as a direct substrate for urease activity. This medium was included to assess whether urease induction could be achieved under minimal nutritional conditions without relying on ammonium-based nitrogen.

Methods

Bacteria Cultivation

Pre-cultures of RII-2 were prepared by inoculating 1 mL of glycerol stock into 5 mL of sterilized NH_4-YE medium in test tubes, followed by incubation at 30°C with shaking at 160 rpm for 24 h.

For the main cultivation, 0.4 mL of the pre-cultured suspension was transferred to 25 mL vented-cap flasks (Falcon® 353018) containing 42 mL of one of the three test media (NH_4-YE, R2A, or R2A-Urea). Care was taken to prevent air bubbles during filling. For each condition, six replicate flasks were prepared.

Microgravity and Normal Gravity Experimental Setup

To evaluate the effect of gravitational conditions on bacterial behavior, cultures were incubated under both simulated microgravity and standard gravity. Simulated microgravity was generated using a rotating wall vessel bioreactor (Zeromo CL-1000, Yamato Scientific Co., Ltd.), where the culture flasks were mounted horizontally and rotated continuously during incubation. By maintaining a constant rotational speed that prevents sedimentation, the direction of the gravitational vector is randomized over time. This dynamic state suppresses convective flow and mimics a low-shear, microgravity-like environment suitable for biological studies [15]. In contrast, control cultures were placed statically in an incubator under normal gravity. Both setups were maintained at 30°C, and humidity was kept high by placing water-saturated towels inside the incubators to minimize evaporation. As shown in Fig. 1, sampling was performed at 48, 120, and 168 h for OD_{600} and urease activity measurements.

(a) NH_4-YE (b) R2A (c) R2A-Urea

Fig. 1 After 48,120,168 h of culture medium

Optical Density (OD_{600}) Measurement

To evaluate the growth behavior of RII-2 under different nutrient and gravitational conditions, OD_{600} was measured as an indicator of bacteria concentration over time. Sampling was performed at 48, 120, and 168 h after the start of cultivation. Prior to measurement, each flask was gently agitated to

ensure a homogeneous suspension. A portion of the culture liquid was then transferred to a disposable cuvette, and OD_{600} was measured using a UV-visible spectrophotometer (V-730, JASCO Corporation). Measurements were conducted in triplicate for each condition to ensure reproducibility.

Urease Activity Test

To evaluate the enzymatic activity of RII-2 under varying medium and gravity conditions, urease activity was measured using two methods: the indophenol colorimetric method and the electrical conductivity (EC) method.

The indophenol colorimetric method was employed to quantify urease activity by indirectly measuring the concentration of NH_4^+ produced during urea hydrolysis. In this method, NH_4^+ released from the enzymatic breakdown of urea react with phenol nitroprusside and sodium hypochlorite to form a blue-colored compound, indophenol, whose absorbance at 630 nm is proportional to the amount of ammonium generated. Since the production of NH_4^+ is stoichiometrically linked to urease activity, the rate of absorbance increase over time provides a quantitative indicator of enzymatic performance.

The EC method estimates urease activity by measuring the increase in ionic concentration resulting from urea hydrolysis. As urease catalyzes the breakdown of urea, ions such as NH_4^+ and HCO_3^- are released, increasing the electrical conductivity. For each measurement, 0.5 mL of culture was added to 50 mL of urea solution pre-equilibrated at 30°C. Conductivity was measured every 5 min for 20 min using a portable conductivity meter (LAQUAtwin EC-33, HORIBA).

RESULTS AND DISCUSSIONS

To evaluate the biological feasibility of applying MICP under space-relevant conditions, the performance of RII-2 was assessed across varying culture medium and gravitational environments. The analysis focused on two fundamental biological indicators, that is bacterial growth and urease activity, which directly influence the efficiency of carbonate precipitation in MICP. By examining how these parameters respond to environmental variations, particularly under reduced gravity, insights can be gained into the potential adaptability of ureolytic bacteria for use in extraterrestrial construction.

Bacterial growth

Fig. 2 presents the growth curves of RII-2 cultivated in three different media: NH_4-YE, R2A, and R2A-Urea. At 48 and 120 h, the NH_4-YE medium exhibited the highest OD_{600} values, indicating superior cell proliferation under nutrient-rich conditions. The consistent growth observed in NH_4-YE is attributed to the availability of both organic nitrogen and inorganic nitrogen, which together support rapid microbial metabolism.

In contrast, the R2A medium displayed negligible growth during the initial 120 h, followed by a sharp increase in OD_{600} to approximately 0.45 at 168 h. This pattern suggests an extended lag phase in low-nutrient conditions, potentially due to slower metabolic activation or delayed adaptation. Once the bacteria adapted to the minimal nutrient environment, exponential growth was initiated, resulting in the sudden OD_{600} increase observed at 168 h. This suggests that RII-2 can eventually activate key metabolic pathways even under nutrient-limited conditions, albeit with significant delay. The R2A-Urea medium showed moderate and steady growth throughout the cultivation period, with OD_{600} values increasing gradually from 0.23 to 0.26, indicating that the addition of urea partially improved nitrogen availability but did not fully compensate for the nutrient limitations inherent in the base R2A formulation.

These results demonstrate that NH_4-YE is the most effective medium for promoting early-stage bacterial growth, while R2A supports delayed but significant proliferation. R2A-Urea provides an intermediate growth environment, with modest improvement over R2A alone. The differences in OD_{600} trends underscore the importance of medium composition in regulating bacterial growth dynamics.

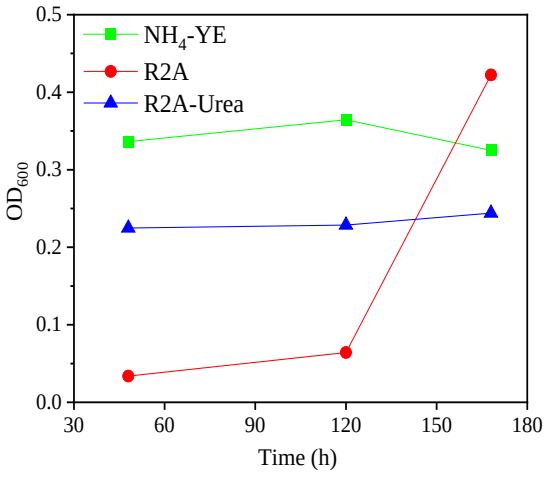

Fig. 2 OD_{600} with different culture medium

Urease activity

Urease activity of RII-2 was examined in three different media using both the indophenol colorimetric method and EC method. As shown in Fig. 3 to 5, the NH_4-YE medium supported vigorous cell growth but yielded lower urease activity values, with negative values observed particularly at 48 h. This

phenomenon may be attributed to the chemical complexity of the medium, which can introduce background signals or interfere with ion-sensitive measurements, especially under conditions where enzymatic activity remains low relative to baseline conductivity or optical density.

In the R2A medium, moderate urease activity was observed, with values generally decreasing over time. This decline may reflect a gradual loss of enzyme functionality under nutrient-limited conditions. Additionally, a wider discrepancy between the two measurement methods was observed, likely due to the limited buffering and ionic capacity of the base medium, which amplifies variability in both optical and conductivity-based assays.

In contrast, the R2A-Urea medium demonstrated stable and reproducible urease activity profiles across all time points, with consistent agreement between the two analytical methods. The inclusion of urea provided a direct and sustained substrate source, while the simpler background composition minimized interference with both optical and electrochemical measurements.

In terms of total urease activity, R2A-Urea medium exhibited the highest values among the three tested media, indicating strong overall enzyme production. However, when normalized by OD_{600} to reflect catalytic efficiency per unit biomass, R2A showed the highest specific activity, reaching approximately 3.22 U/mL, compared to 1.29 U/mL in R2A-Urea and 0.31 U/mL in NH_4-YE. Despite not having the highest unit activity, R2A-Urea was ultimately selected for microgravity experiments due to its stable and reproducible measurements, low bacterial aggregation, and good consistency between the EC and indophenol methods. These characteristics made it the most practical and reliable medium for evaluating MICP performance under space-relevant conditions.

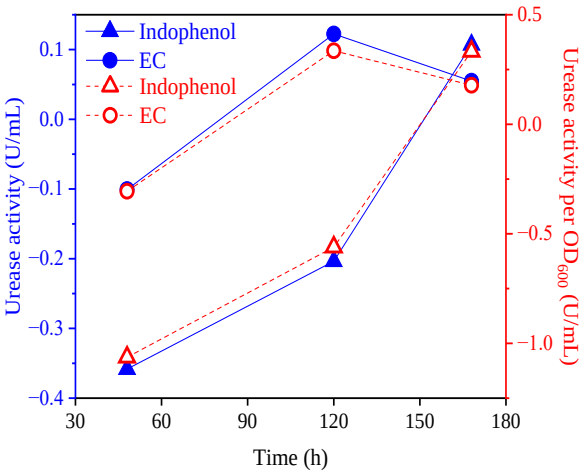

Fig. 3 Urease activity of RII-2 in NH_4-YE medium

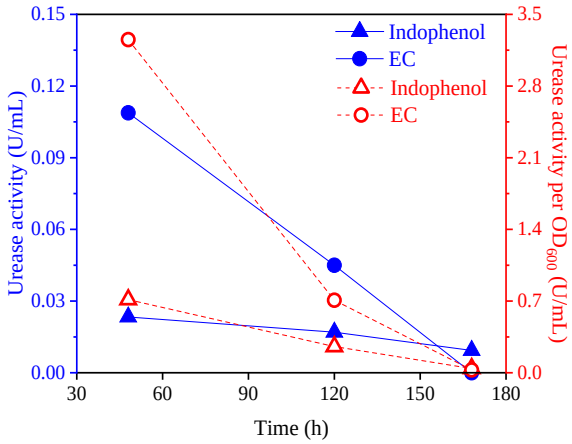

Fig. 4 Urease activity of RII-2 in R2A medium

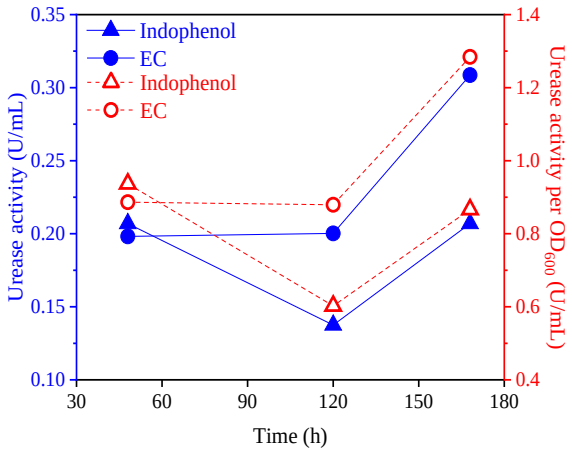

Fig. 5 Urease activity of RII-2 in R2A-Urea medium

Microgravity and normal gravity

To evaluate the effects of gravitational conditions on microbial growth, RII-2 was cultivated in R2A-Urea medium under simulated microgravity and normal gravity. R2A-Urea was selected based on prior evaluation of growth stability and minimal aggregation, making it suitable for use in rotating wall vessel systems. As shown in Fig. 6, cultures under simulated microgravity consistently exhibited higher OD_{600} values than those incubated under normal gravity. After the initial 24 h, OD_{600} values in the microgravity condition stabilized within the range of 0.33 to 0.41, whereas those under normal gravity remained between 0.22 and 0.30. The maximum difference between the two conditions reached approximately 0.12, corresponding to a relative increase of nearly 40% in bacterial suspension density under microgravity.

In the microgravity system, continuous horizontal rotation of the culture vessel disperses the gravitational vector over time, thereby reducing

sedimentation and suppressing shear forces. This creates a low-shear, diffusion-dominated environment in which bacteria remain suspended and experience more uniform access to nutrients. The microgravity environment may also contribute to more stable local environments around bacteria, supporting sustained metabolic activity and biomass accumulation.

These findings suggest that RII-2 is capable of maintaining active proliferation under microgravity, with growth levels exceeding those observed under normal gravity despite the low-nutrient conditions provided by the R2A-Urea medium. This implies that reduced gravitational forces do not impair, and may even enhance, the growth of ureolytic bacteria under appropriately controlled conditions.

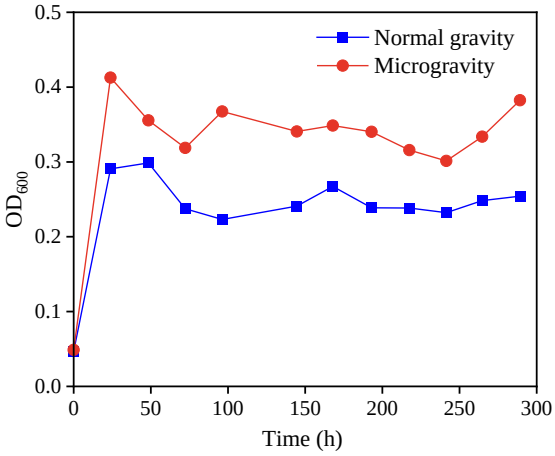

Fig. 6 OD_{600} under different gravity environments

Fig. 7 illustrates the variation in urease activity under microgravity and normal gravity conditions. While both conditions supported sustained enzymatic activity, urease efficiency was consistently lower under microgravity at most time points. The difference was particularly evident after 96 h, where activity values under microgravity generally ranged between 0.5 and 0.7 U/mL, while those under normal gravity were maintained at 0.7 to 0.9 U/mL. On average, urease activity under microgravity was 22–28% lower across the cultivation period.

This trend may reflect disruptions in the regulatory processes governing urease expression in bacteria. As an inducible enzyme, urease production involves multi-level control, including transcriptional activation, cofactor incorporation, and protein maturation. Microgravity may interfere with intracellular organization or spatial gene regulation, impairing the coordinated responses required for efficient enzyme expression. Furthermore, gravitational changes can affect ribosomal function and protein folding kinetics in bacteria, potentially reducing the yield or catalytic integrity of urease even in growing populations.

These results suggest that the reduction in urease activity per OD_{600} under microgravity may compromise the overall efficiency of MICP. Even if sufficient bacteria are present, a slower rate of urea hydrolysis could lead to delayed or insufficient $CaCO_3$ precipitation, especially in time-sensitive or structurally demanding applications. In addition, lower enzymatic output may affect the spatial uniformity of precipitation, potentially resulting in uneven solidification. This limitation should be considered when evaluating the feasibility of MICP-based soil stabilization in extraterrestrial environments, where consistent strength development and process controllability are essential. Moreover, it is important to note that all experiments in this study were conducted under a controlled temperature of 30°C. However, maintaining such a stable thermal environment in outer space is technically challenging. Therefore, the impact of temperature fluctuations on microbial activity and carbonate precipitation should also be investigated in future studies.

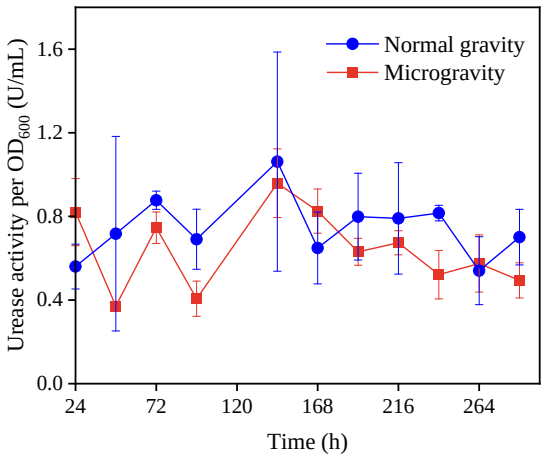

Fig. 7 Urease activity under different gravity environments

CONCLUSIONS

This study systematically evaluated the growth behavior and urease activity of the ureolytic bacterium RII-2 under varying culture media and gravitational conditions, with the aim of assessing the feasibility of MICP in space environments. The conclusions are summarized as follows:

(1) R2A-Urea supported the most robust microbial growth and the highest total urease activity among the three tested media. While NH_4-YE facilitated moderate bacterial proliferation, it showed low and unstable enzymatic output. R2A, despite exhibiting higher specific activity per biomass, was limited by poor growth, resulting in lower overall enzyme production. These characteristics established

R2A-Urea as the most suitable medium for subsequent microgravity experiments.

(2) Bacterial growth, as measured by OD_{600}, was not impaired under simulated microgravity. In fact, proliferation was enhanced compared to static controls, likely due to reduced sedimentation and improved suspension homogeneity.

(3) Despite increased biomass, urease activity per OD_{600} was moderately reduced under microgravity. This indicates that gravitational changes may influence enzyme regulation or cofactor dynamics, which could limit the overall carbonate precipitation rate in MICP processes.

EVALUATION OF SHEAR PROPERTIES AT CONSTRUCTION BOUNDARIES FOR LATTICE-SHAPED GROUND IMPROVEMENT

Miu Kanagawa [1], Kouta Kanno [2], Kenji Niwa [2] and Shinya Inazumi [1]

[1] Shibaura Institute of Technology, Japan
[2]Kato Construction Co., Ltd., Japan

ABSTRACT

Ground improvement using grid-type deep mixing methods is a widely adopted countermeasure against soil liquefaction, particularly in seismic regions where ground deformation poses serious risks to infrastructure. However, practical constraints during construction often necessitate segmented execution, resulting in construction boundaries, discontinuities formed between adjacent improved bodies, that compromise the mechanical continuity and uniformity of the treated ground. This study presents a comprehensive investigation into the shear characteristics of cement-stabilized ground both with and without construction boundaries, through an integrated approach combining systematic laboratory direct shear testing and finite element method (FEM) simulations employing joint elements. Experimental results demonstrate a pronounced reduction in peak shear strength, exceeding 200 kN/m^2, along with a transition from cohesive-frictional to friction-dominated failure characteristics due to the presence of boundaries. Stress–displacement behavior further reveals the loss of ductility and interlocking at boundary planes. Numerical analyses, calibrated using inverse analysis of the experimental data, show that joint elements are effective in replicating boundary mechanics, particularly in capturing residual strength behavior. The modeling framework enables quantitative evaluation of boundary performance and highlights the influence of boundary parameters on global ground behavior. The findings not only clarify the mechanical impact of construction boundaries on the performance of deep mixing ground improvement systems, but also establish a robust foundation for performance-based design and objective quality control. This contributes to enhancing the safety and reliability of ground improvement practices in liquefaction-prone and seismically active areas.

INTRODUCTION

Soil liquefaction, often induced by seismic events, results in a sudden loss of soil strength and stiffness, leading to severe ground deformation and structural damage. To counteract these effects, grid-wall soil improvements, comprising orthogonally arranged soil-cement columns or panels, have been widely employed. This method enhances the shear rigidity of liquefiable layers and mitigates lateral spreading by confining the soil matrix within a reinforced grid structure [1,2].

Despite its effectiveness, the practical implementation of grid-wall soil improvement often involves segmented construction processes due to limitations in equipment reach, scheduling, or site conditions. This segmented execution inevitably produces construction boundaries as shown in Fig. 1, contact surfaces between adjacent improved columns or panels formed at different times. These boundaries, typically resulting from cold joints or differential curing, represent potential planes of weakness due to incomplete bonding and discontinuity in material properties.

The mechanical behavior of such boundaries, particularly their shear strength and failure characteristics, remains insufficiently understood. In design practice, these zones are frequently treated as homogeneous with the surrounding improved soil, potentially overlooking localized reductions in strength and stiffness. Moreover, current quality control practices for boundary integrity largely rely

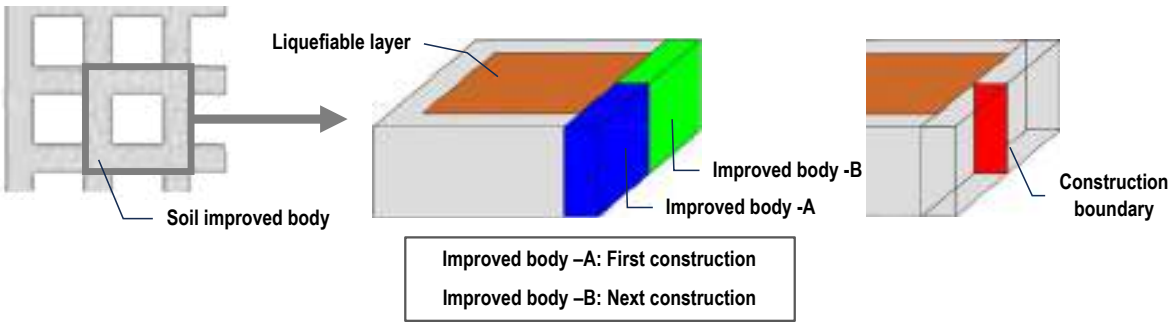

Fig. 1 Schematic illustration of construction boundarys in grid-type deep mixing improvement

on visual inspection, which lacks the objectivity and resolution needed to detect subtle but critical mechanical deficiencies.

Addressing this knowledge gap requires a rigorous, mechanics-based investigation into the influence of construction boundaries on the overall performance of improved ground. In particular, a quantitative understanding of how these boundaries alter stress transfer, shear strength, and failure characteristics is essential for ensuring structural safety, especially under seismic loading conditions where slip or separation at boundaries may trigger progressive failure.

The present study combines laboratory-scale direct shear testing with finite element modeling to comprehensively evaluate the mechanical role of construction boundaries. Two types of specimens, monolithic (without boundaries) and jointed (with construction boundaries), were subjected to controlled shear testing to extract key strength parameters and failure behaviors. Parallel to this, a finite element analysis framework incorporating joint elements was developed and calibrated to simulate boundary mechanics with high fidelity.

Through the integration of empirical and numerical approaches, this research aims to elucidate the fundamental mechanics governing construction boundary behavior and to establish a rational basis for their evaluation in engineering practice. The findings are expected to contribute not only to improved design accuracy but also to the development of objective, performance-based quality control methods in ground improvement engineering.

MATERIALS AND EXPERIMENTAL METHODS

Specimen Preparation

To evaluate the shear behavior of construction boundaries, two types of cylindrical specimens were prepared to simulate conditions representative of grid-type ground improvement using cement-stabilized clay. Each specimen had a diameter of 6 cm and a height of 10 cm, designed to provide sufficient resolution of shear failure while ensuring compatibility with the direct shear apparatus (see Fig. 2).

- Monolithic Specimens (No Boundary): These were prepared in a single pour to represent homogeneously mixed and continuously constructed soil-cement bodies, serving as a control condition with no discontinuity.
- Specimens with boundary (With Construction Boundary): These were fabricated by casting and curing the lower and upper halves of the specimen separately. After a predetermined curing period for the first layer, the second layer was placed on top, simulating the time-lagged construction sequence commonly encountered in segmented deep mixing operations. This process intentionally introduced a horizontal construction boundary at mid-height, representing a cold joint.

Both specimen types were prepared using a consistent clay-cement mixture, formulated to reflect field-representative material conditions. Mixing ratios, moisture content, and curing regimes were carefully controlled to ensure uniformity. The material properties of the untreated clay and the stabilized mixture, along with detailed mixing and curing protocols, are summarized in Table 1.

To minimize variability, the same batch of clay and cement was used throughout specimen preparation, and all specimens were cured under standardized temperature and humidity conditions. This ensured that any observed differences in mechanical behavior could be attributed primarily to the presence or absence of construction boundaries.

Direct Shear Testing

Direct shear testing was employed to quantify the shear strength parameters and failure characteristic of the specimens under controlled normal stress conditions. This method was selected for its ability to provide continuous monitoring of shear stress–displacement responses and to isolate the shear plane, making it particularly suitable for specimens with boundary [1,3,4].

Each specimen was trimmed to a testing height of either 2 cm or 1 cm, depending on the intended shear plane and specimen configuration. The specimens were then placed within a shear box apparatus, where the boundary plane in jointed specimens was aligned with the horizontal shear plane to facilitate targeted evaluation.

Tests were conducted under four distinct normal stress levels: 30, 100, 200, and 300 kN/m^2. These

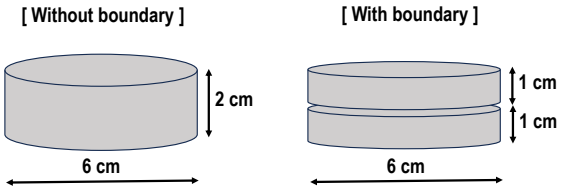

Fig. 2 Dimensions of shear test specimens

Table 1 Physical properties of untreated clay and cement-stabilized specimens

(a) Untreated clay

Soil type	Gairome-clay
Wet density (g/cm^3)	1.535
Natural water content (%)	75.28
Dry density (g/cm^3)	0.876
Particle density (g/cm^3)	2.640

(b) Cement stabilized clay (specimens)

Cement addition (kg/m^3)	250
Curing age (days)	10
Unconfined compressive strength (kN/m^2)	1,000

stress levels were chosen to span a range representative of both shallow and moderately deep subsurface conditions in typical geotechnical applications. For each normal stress level, three replicate tests were performed on both monolithic and specimens with boundary, resulting in a total of 24 tests. Additionally, shear tests were conducted on untreated clay to provide a baseline for assessing the effects of stabilization (see Table 2).

The shear loading was applied at a constant rate to ensure quasi-static conditions. Throughout each test, both shear stress and horizontal displacement were continuously recorded until post-peak behavior was clearly observed, allowing for a detailed evaluation of peak and residual strength parameters.

Data Collection and Analysis

The following data were systematically collected during testing:

- Shear stress–displacement curves for all specimens under each normal stress condition
- Peak and residual shear strengths, extracted from the stress–displacement profiles
- Failure characteristics, determined through visual observation and post-test examination of the shear plane

After each test, the failure planes were inspected to evaluate boundary integrity, evidence of interlocking, surface roughness, and bonding characteristics. Particular attention was given to the contrast between the shear planes of monolithic and specimens with boundary, as these observations provide qualitative insight into the failure characteristics (e.g., brittle slippage, ductile shear, or mechanical interlock).

The collected data formed the basis for subsequent statistical analysis, including regression modeling to fit the Mohr-Coulomb failure envelope and to compare the mechanical responses between specimen types. These results also informed the calibration of material and joint parameters used in the numerical simulations (see Table 3).

EXPERIMENTAL RESULTS AND INTERPRETATION

Shear Strength and Failure Characteristics

The results of the direct shear tests reveal a clear and consistent distinction in mechanical behavior between monolithic specimens and those containing construction boundaries. Under all tested normal stress conditions, monolithic specimens exhibited significantly higher peak shear strengths, approximately 250 kN/m^2 greater on average, compared to specimens with boundary (see Fig. 3). This reduction underscores the critical role that cohesive bonding plays in resisting shear failure

Table 2 Specimen configuration and direct shear test matrix

Normal stress (kN/m^2)		30	100	200	300
Number of tests	Without boundary	3	3	3	3
	With boundary	3	3	3	3

Table 3 Shear strength parameters derived from direct shear tests

Boundary condition	Without boundary	With boundary
Cohesion (kN/m^2)	245.61	3.65
Internal friction angle (°)	28.27	27.07

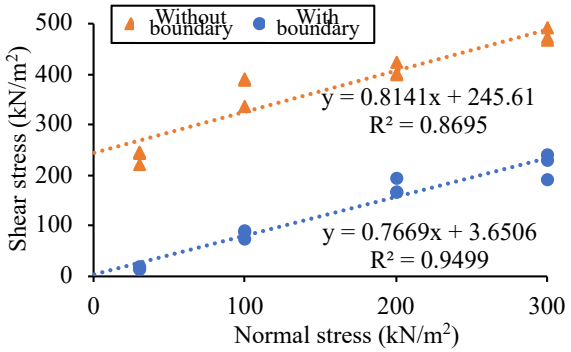

Fig. 3 Peak shear strengths under different normal stress conditions

within stabilized soils.

In monolithic specimens, the shear strength was mobilized through a combination of internal cohesion and friction. These specimens consistently demonstrated failure along well-developed, rough shear planes, indicative of significant material interlocking and bond continuity. The roughness and irregularity of the failure planes suggest substantial energy dissipation through internal cracking and frictional engagement at the microstructural level.

Conversely, specimens with construction boundaries exhibited drastically different behavior. Shear failure predominantly occurred along the planar boundary between the two separately cast segments, where bonding was weak or absent. These failures were characterized by smooth, featureless shear surfaces with minimal evidence of interlocking, leading to markedly lower resistance and stable residual strength. The data indicate that in the presence of boundaries, the shear strength was governed almost entirely by frictional resistance, with cohesion approaching negligible values.

This contrast in failure characteristics is particularly relevant in the context of ground improvement design, where assumptions of monolithic behavior may significantly overestimate actual performance when boundaries are present. The suppression of cohesion and lack of interfacial roughness fundamentally alter the stress transfer capacity of the improved ground under shear loading.

Stress–Displacement Behavior

Analysis of the stress–displacement curves further clarifies the mechanical response differences between specimen types. Specimens with boundary exhibited a rapid rise in shear stress, reaching peak strength within approximately 1 mm of horizontal displacement. This was followed by an immediate and sustained drop to a relatively constant residual strength level. Such behavior is characteristic of brittle boundary failure with minimal energy absorption and post-peak ductility (see Fig. 4).

In contrast, monolithic specimens showed a broader range in peak displacement values and a more gradual decline to residual strength. Notably, several monolithic specimens displayed secondary increases in shear resistance after the initial peak, suggesting the mobilization of additional interlocking or shear surface roughness during deformation. These fluctuations imply a more complex characteristic involving progressive damage and potential dilation along the shear plane (see Figs. 4 and 5).

The differences in stress–displacement responses not only reflect distinct failure processes but also carry implications for deformation behavior under service loading conditions. Specimens with boundary, with their lower ductility and reduced peak strength, may be more susceptible to sudden displacement or progressive failure under seismic or cyclic loading.

Statistical and Reproducibility Analysis

To evaluate the consistency and reliability of the experimental results, regression analysis was conducted using the Mohr-Coulomb failure criterion. The shear strength data for both specimen types were plotted against normal stress, and linear fits yielded

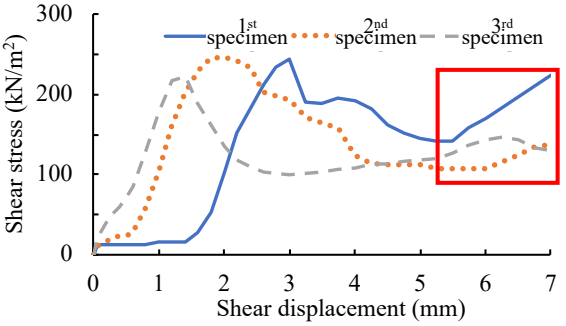

Fig. 4 Shear stress–displacement behavior under 30 kN/m^2 (without boundary)

Fig. 5 Surface roughness of post-failure shear planes (monolithic vs. boundary specimens)

high coefficients of determination ($R^2 \approx 1$), indicating excellent agreement with the theoretical model.

For monolithic specimens, the linear fit confirmed the presence of both cohesive and frictional components in shear resistance. In contrast, the regression line for specimens with boundary passed near the origin, reinforcing the earlier observation that these specimens exhibited negligible cohesion and friction-dominated behavior.

The tight clustering of data points and low variability across repeated tests for each condition further validate the experimental methodology and suggest that the observed differences are systematic and reproducible. This robustness is critical for the subsequent calibration of numerical models and for establishing generalizable conclusions about the role of construction boundaries in ground improvement.

NUMERICAL SIMULATION USING FINITE ELEMENT METHOD

Model Construction

To simulate the shear behavior observed in the direct shear tests, a two-dimensional finite element method (FEM) model was developed, replicating the experimental geometry and boundary conditions with high fidelity. The model geometry represented a simplified cross-section of the shear box, including upper and lower soil-cement blocks in contact at a defined shear boundary.

A key feature of the model was the incorporation of joint elements at the boundary between the upper and lower blocks in the specimens with boundary. These joint elements are specialized numerical constructs that allow discontinuous displacement and independent assignment of mechanical properties, specifically, normal and shear stiffness, friction angle, and cohesion. This formulation enables realistic simulation of boundary slip, separation, and post-peak behavior, which are not adequately captured by standard continuum elements (see Figs. 6 and 7).

The surrounding improved ground was modeled using linear elastic–perfectly plastic material properties, calibrated to match the experimentally observed behavior of monolithic specimens. Mesh resolution was refined near the joint elements to enhance numerical accuracy in regions of expected high stress gradients.

Parameter Calibration

Accurate simulation of boundary behavior critically depends on the selection of appropriate joint element parameters. To this end, an inverse analysis approach was employed, wherein the FEM model output was iteratively compared to experimental shear stress–displacement curves, and the parameters were adjusted to minimize the deviation.

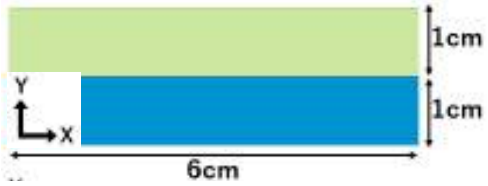

Fig. 6 FEM model configuration for simulating direct shear tests

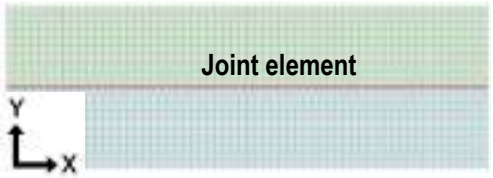

Fig. 7 Assigned position of joint elements in the FEM model

The optimal parameter set for the joint elements was determined as follows:

- Normal stiffness: 1×10^6 kN/m^3
- Shear stiffness: 50 kN/m^3
- Cohesion: 100 kN/m^2
- Friction angle: 15°

These values were selected to reflect the observed frictional nature of the boundary and to reproduce the residual strength levels documented in the specimens with boundary.

The high normal stiffness value ensured realistic constraint against dilation and separation under compressive loading, while the relatively low shear stiffness allowed for slip behavior that matched experimental deformation profiles. The low cohesion and moderate friction angle captured the diminished bonding and interfacial friction characteristic of cold joints (see Fig. 8).

Model Validation

Model validation was performed by comparing the FEM results with the experimentally measured shear stress–displacement curves for both specimen types. For specimens with boundary, the model successfully replicated the initial peak shear strength and subsequent transition to a constant residual strength, with discrepancies limited to within ±10 kN/m^2 across all normal stress conditions.

However, for monolithic specimens, the model underpredicted the observed peak strengths. This discrepancy is attributed to the inability of the current model to capture interlocking effects and surface roughness at the failure plane (see Fig. 9), mechanisms which contribute significantly to peak resistance but are not explicitly modeled in a continuum or joint element framework.

Despite this limitation, the model accurately reflected the residual behavior, confirming its reliability for simulating friction-governed failure characteristics typical of construction boundaries.

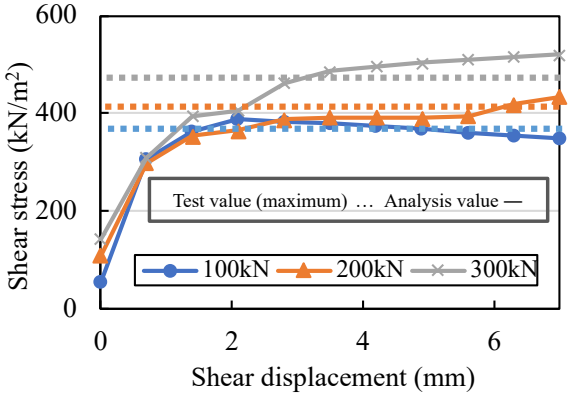

Fig. 8 Comparison between experimental and simulated results using inverse analysis parameters

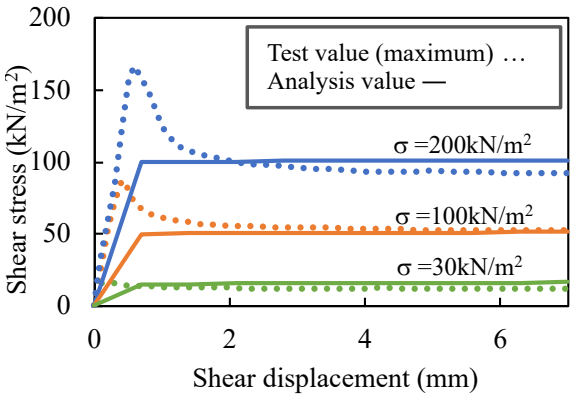

Fig. 9 Comparison of simulated and experimental results for monolithic specimens

The results demonstrate that joint elements are well suited for capturing post-peak behavior, which is particularly important in performance-based design and safety assessments.

DISCUSSION FOR GEOTECHNICAL IMPLICATIONS OF CONSTRUCTION BOUNDARIES

Mechanical Implications of Construction Boundaries

The experimental and numerical findings clearly demonstrate that the presence of construction boundaries substantially alters the shear resistance characteristics of cement-treated ground. The loss of cohesion and reduction in interfacial roughness result in a transition from mixed-mode (cohesive–frictional) failure, as seen in monolithic specimens, to predominantly frictional failure in specimens with boundary. This shift in failure characteristic leads to a decrease in peak shear strength of over 200 kN/m^2, highlighting the critical vulnerability introduced by construction discontinuities [1,2,3,5].

From a geotechnical design perspective, this reduction in shear capacity cannot be neglected. Grid-type deep mixing systems are typically assumed to act

as a continuous shear-resisting skeleton. However, the introduction of construction boundaries compromises this assumption, potentially enabling localized slippage under shear loading. In seismic regions, this becomes especially significant, as the combination of cyclic loading and reduced boundariestrength may accelerate strain accumulation and increase the risk of progressive failure.

Comparison with Previous Studies

The experimental results align well with previous studies on geomaterial boundaries, such as those involving clay–concrete and soil–geosynthetic systems [3-5]. In these studies, reductions in boundaries strength and cohesion were also observed when discontinuities or weak bonding were present. The failure mode transition, from adhesion-dominated to friction-dominated behavior, has been widely reported, reinforcing the generality of the present findings across boundary types and material systems.

Practical Applications and Quality Control

One of the primary contributions of this study is the development of a practical, mechanics-based framework for evaluating construction boundary behavior. The combination of direct shear testing and calibrated FEM simulations provides both quantitative insight and predictive capability. Specifically, the use of joint elements allows designers to account for boundariespecific parameters in numerical models, enabling realistic simulation of field conditions.

This approach offers a pathway toward more objective and performance-driven quality assurance in ground improvement projects. While current field practices rely heavily on visual inspection and indirect indicators of quality, the results presented here support the introduction of mechanical metrics, such as boundarieshear strength and friction angle, as quantifiable indicators of construction integrity.

CONCLUSIONS

This study investigated the shear characteristics of cement-stabilized ground with and without construction boundaries through laboratory direct shear testing and finite element simulations employing joint elements. The key findings are summarized below:

(1) Construction boundaries lead to significant strength reduction, with peak shear strength decreasing by more than 200 kN/m^2 due to the loss of cohesion and interfacial bonding. Friction-dominated failure was observed in specimens with boundary.
(2) Failure characteristics differ between specimen types, with specimens with boundary showing brittle, low-ductility behavior, while monolithic specimens exhibited rough shear planes and interlocking-driven resistance.
(3) FEM modeling with joint elements successfully captured residual shear behavior in specimens with boundary when calibrated with experimental data, demonstrating its applicability for simulating boundary mechanics.
(4) The integrated testing–modeling approach offers a rational framework for assessing construction boundary effects in ground improvement, contributing to more objective and performance-based design and quality control.

These insights lay the groundwork for the rational design, evaluation, and management of construction boundaries in ground improvement engineering, contributing to the safety and reliability of infrastructure in liquefaction-prone regions.

UNRAVELING THE MECHANISMS OF LIQUEFACTION-INDUCED SOIL EJECTA: A RULE-BASED APPROACH

Emerzon S. Torres[1], and Jonathan R. Dungca[1]

[1]Department of Civil Engineering, De La Salle University, Philippines

ABSTRACT

Soil ejecta, commonly observed as sand boils, is a prominent manifestation of soil liquefaction during earthquakes, often leading to ground settlement, structural damage, and post-earthquake site instability. Despite their impact, traditional liquefaction models largely focus on triggering mechanisms and rarely address the conditions that govern ejecta formation. This study applies Rough Set Machine Learning (RSML), an interpretable rule-based algorithm, to analyze 96 historical case histories of liquefaction, including 85 cases with observed soil ejecta. Six geotechnical and seismic parameters—moment magnitude, peak ground acceleration, groundwater table depth, average critical layer depth, corrected SPT N-value, and fines content—were used as model inputs. IF–THEN rules were induced and evaluated using support, strength, certainty, and coverage metrics. Sensitivity and interaction analyses revealed the critical influence of corrected penetration resistance, groundwater conditions, and fines content on ejecta occurrence. Notably, soil ejecta was found to occur even in moderately dense or fine-grained soils, challenging conventional assumptions. The parameter interaction map further highlighted the combined effects of seismic and subsurface conditions. This interpretable model provides valuable insights into post-liquefaction behavior and supports improved hazard assessment, mitigation planning, and resilience strategies. The findings contribute to the advancement of data-driven approaches in earthquake geotechnical engineering.

Keywords: Sand boils, Interpretable machine learning, Rough set theory, Liquefaction hazard assessment, Artificial intelligence

INTRODUCTION

Soil liquefaction is still considered one of the most important and complex phenomena in soil dynamics [1]. Soil liquefaction's complex relationships refer to the dynamic and nonlinear interactions between multiple factors, including seismic parameters (magnitude, frequency), soil properties (grain size, density), hydraulic conditions (pore water pressure, drainage), and other geotechnical factors (soil stratification, confining pressure) that determine how soil responds to stress.

Sand boils, or soil ejecta, are a prominent manifestation of soil liquefaction during earthquakes, contributing to ground settlement, structural damage, and post-earthquake site instability [2].

The ejection of subsurface material can result in differential settlement, tilting, and structural cracking, while also compromising foundation support and damaging underground utilities. Despite these significant consequences, traditional liquefaction assessment models primarily focus on triggering mechanisms and often overlook the factors governing the formation of soil ejecta. Some studies have calculated liquefaction indices based on SPT and validated by sand boil observations [3]. Others have explored the mechanisms of lateral spreading as a major effect of liquefaction [4]. However, a notable gap remains in the analysis of historical liquefaction databases that explicitly account for the presence and characteristics of soil ejecta.

This study employs Rough Set Machine Learning (RSML), an interpretable machine learning algorithm, to analyze and extract patterns from historical case histories of liquefaction-induced soil ejecta. IF–THEN rules were generated to identify and understand the parameters contributing to the susceptibility of soil ejecta. Further data analyses were also conducted to determine which individual parameters and parameter combinations most significantly influence the occurrence of sand boils.

RESEARCH SIGNIFICANCE

The outputs of this study—decision rules, sensitivity, and parametric analyses—provide valuable insights for researchers and engineers aiming to understand the mechanisms underlying soil ejecta. Furthermore, the results may guide the selection of suitable ground improvement techniques and disaster risk reduction strategies tailored to specific site conditions and project requirements. The unconventional patterns revealed by the induced rules may highlight potential directions for future research.

METHODS

The research flow is illustrated in Fig. 1. From the soil liquefaction database [5-6], a total of 96 case histories involving soil ejecta were utilized in this

study. Minor data cleansing was performed, followed by discretization to prepare the data for machine learning. The Rough Set Exploration System (RSES 2.2) [7], a rough set-based software, was employed to induce decision rules from the constructed decision table. Rule pruning and shortening were applied to eliminate redundant and weak rules. The resulting rule sets were evaluated to identify the most robust and informative set. The optimal rule set was subsequently subjected to sensitivity and parametric analyses to assess the influence of individual parameters and their interactions.

Soil Ejecta Database

From the available global database of liquefied sites, 96 events were selected for this study, as summarized in Table 1. Among these, 85 sites exhibited manifestations of soil ejecta, while 11 showed no such occurrence. Six conditional attributes (input parameters) and one decision attribute (output parameter) were collected and used for the simulation. The field names and definitions, along with the discretization schemes and frequency distributions of the variables, are presented in Table 2. The decision attribute represents the presence or absence of observed soil ejecta.

Rough Set Machine Learning

Rough Set Theory (RST), developed by Pawlak (1982), addresses vagueness and uncertainty in knowledge-based systems [8]. In RST, knowledge is typically represented using a decision table composed of rows and columns, where attributes are categorized into condition and decision attributes. Each row in the decision table represents a rule in the form: IF (conditions) … THEN (decision). An inductive process is applied to extract rules from the data contained in the decision table. RST has been successfully applied in various machine learning tasks, including clustering, feature selection, and rule induction. In this study, rule induction was carried out to generate interpretable IF-THEN statements that define patterns associated with soil ejecta occurrence. The induced rules were evaluated using four key validation statistics: *support*, *strength*, *certainty factor*, and *coverage*. *Support* indicates the number of observations that follow a given rule, while *strength* is the proportion of these supports relative to the total number of observations in the dataset. The *certainty factor* reflects the likelihood that an observation belongs to the decision class when the conditions of a rule are met. Lastly, *coverage* measures the extent to which a particular rule accounts for the instances within the decision class.

Sensitivity and Parametric Analyses

Ablation-based sensitivity analysis was conducted to assess the importance of each input attribute in the rule-based model. By systematically removing one condition attribute at a time and measuring the change in model accuracy through cross-validation (10 and 50 k-folds), the analysis revealed each attribute's contribution to model performance. This method provided valuable insights into the stability and robustness of the model and the interplay between input parameters.

To enhance interpretability, a parametric analysis in the form of a parameter interaction map was developed using insights from sensitivity analysis and rule-based interactions. Ablation analysis measured the impact of removing individual parameters on model accuracy, classifying their importance as high, moderate, or low based on performance delta from 100-fold cross-validation. Additionally, parameter interactions were quantified by the frequency of co-occurrence within the induced rule set, categorized as strong, moderate, or weak. The interaction map visually represents these relationships, offering a clearer understanding of how parameters influence each other and contribute to soil ejecta susceptibility.

RESULTS AND DISCUSSION

This study developed a liquefaction-induced soil ejecta rule-based model using RSML. Its primary objective was to identify and understand the key factors influencing the occurrence of soil ejecta. The model incorporates six conditional attributes and a single decision attribute—the presence or absence of soil ejecta.

To improve model performance, an iterative optimization of the discretization process was conducted until the best rule-based model emerged, yielding the most favorable validation statistics. The model is characterized by a highly imbalanced distribution of decision classes, with 85 events showing the presence and only 11 showing the absence of soil ejecta. This imbalance reflects the frequent occurrence of ejecta in liquefaction events and introduces challenges in rule induction. The selected optimal model was selected, achieving 96.4% accuracy and 87.5% coverage, balancing predictive performance with reliable representation of liquefaction-induced soil ejecta.

Table 3 Sample decision table used in this study.

M	a_{max} (g)	Avg depth (m)	Depth GWT (m)	$(N_1)_{60}$	FC	Sand boil?
H	L	L	H	L	L	No

Table 4 presents the optimal rule set for the soil ejecta rule-based model, comprising 24 rules—1 for the absence and 23 for the presence of soil ejecta. This distribution reflects the common occurrence of soil ejecta in liquefaction events. As shown in Fig. 2, several rules (specifically Rules 2–8 and 14) exhibit coverage factors exceeding 20%, indicating strong explanatory power within the dataset.

Notably, soil ejecta was observed even at lower ranges of moment magnitude and peak ground acceleration, suggesting that ejecta can occur under varied seismic conditions once liquefaction is initiated. This observation aligns with recent findings by [9] on the complex nature of liquefaction-induced ground deformation. Furthermore, the presence of ejecta was associated with corrected SPT N-values ranging from 10.3 to 24.1 and high fines content (60.5–92%).

These findings suggest that excess pore pressure generation may occur even in moderately dense or

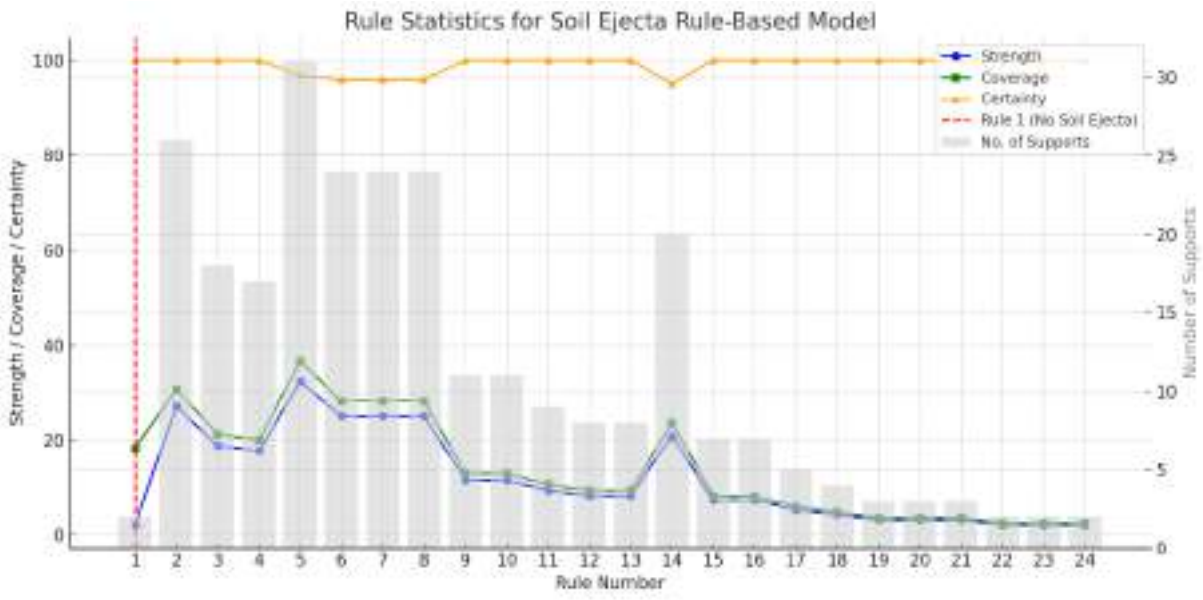

Fig. 2 Validation rule statistics for the generated rules.

fine-grained soils—challenging conventional assumptions. Similar conclusions were drawn by [5,10], who emphasized the nuanced behavior of silty soils under liquefaction conditions. These insights highlight the multifaceted nature of soil ejecta formation and underscore the importance of data-driven approaches in advancing our understanding of liquefaction phenomena.

While the model demonstrates high certainty factors across its 24 rules, the strength and coverage factors—generally below 33%—suggest limited generalizability. This limitation is likely due to the relatively small dataset (96 cases). Despite this, Rule 5 emerged as the most influential, exhibiting the highest coverage. It can be expressed as follows:

"If the maximum acceleration is low and the groundwater table is shallow, then soil ejecta is likely to occur."

This rule indicates that even with peak ground acceleration below 0.28g, the occurrence of soil ejecta remains probable when the groundwater table is shallow (approximately 1.7 meters). This finding highlights the critical role of groundwater conditions in soil ejecta formation, even under moderate seismic loading [2,10].

The sensitivity analysis of the soil ejecta rule-based model demonstrates its strong predictive capability, with baseline accuracies of 77.8% (10-fold cross-validation) and 78.0% (50-fold). These values are within the published efficiency of other state-of-practice liquefaction models [11]. Among the parameters analyzed, corrected penetration resistance emerged as the most critical, as its removal resulted in the largest drop in accuracy (62.2% and 60.0%, respectively), highlighting the importance of soil density and stiffness in resisting liquefaction. Groundwater table depth was the second most influential factor, with its removal decreasing accuracy to 65.6% and 66.0%, affirming that high water tables increase susceptibility to liquefaction by reducing effective stress. The average depth of the critical layer also significantly impacted model performance, aligning with observations that shallow liquefiable layers facilitate the upward movement of fluidized soil. Notably, fines content showed a strong influence, reflecting its role in both liquefaction potential and soil erodibility.

The parameter interaction map highlights interactions spanning various levels of importance and strength. The most significant interaction occurs between moment magnitude and groundwater table depth, emphasizing their joint role in enhancing liquefaction potential and driving soil ejecta formation.

Table 5 Soil ejecta sensitivity analysis.

Attribute Removed	Total Accuracy (k=10 folds)	Total Accuracy (k=50 folds)
No Attribute Removed	77.8	78.0
Moment Magnitude	70.0	70.0
Maximum Acceleration	75.6	76.0
Average Depth of Critical Layer	70.0	72.0
Depth of Groundwater Table	65.6	66.0
Corrected Penetration Resistance	62.2	60.0
Fines Content	64.9	62.0

Prolonged shaking enables pore pressure build-up, while shallow groundwater conditions reduce effective stress, promoting upward movement of liquefied soil. These conditions also contribute to uneven ground settlements and extensive ejecta in stratified subsurface profiles. Moderate interactions—such as those between corrected SPT N-values and fines content, and between maximum acceleration and fines content—underscore the combined influence of soil density, composition, and seismic energy. The model's interaction patterns mirror those of the other published RSML-based models [4,10], indicating that the same parameters influencing liquefaction triggering also govern post-liquefaction surface manifestations. This continuity highlights the importance of interpretable models in uncovering the physical dependencies behind complex geotechnical behavior.

CONCLUSIONS

This study developed and evaluated a rule-based model for liquefaction-induced soil ejecta using RSML, offering an interpretable, data-driven framework for understanding soil behavior under seismic loading. By analyzing 96 case histories and generating IF-THEN rules, the model identified key parameters influencing soil ejecta, including corrected SPT N-value, groundwater table depth, fines content, and an average depth of the liquefiable layer.

Sensitivity and interaction analyses revealed that ejecta occurrence is not solely dependent on strong seismic events but also significantly influenced by shallow groundwater conditions and soil composition—especially in silty soils.

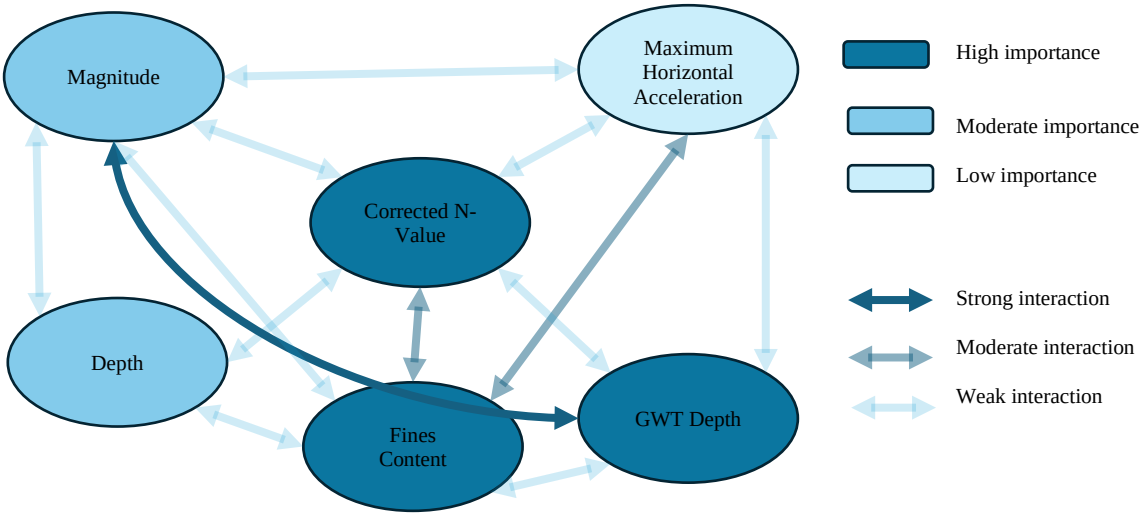

Fig. 3 Parameter interaction map for liquefaction-induced soil ejecta.

The model achieved a high accuracy of 96.4% and a coverage of 87.5%, demonstrating its robustness despite the dataset's class imbalance. Although the generalizability is limited by the small sample size, the model's findings align with field observations and existing literature. The interaction map further highlighted complex interdependencies between parameters, emphasizing the need for multi-parameter analysis in liquefaction studies.

Overall, this study contributes to the current understanding of soil ejecta that can be used for hazard assessment, risk reduction, and resilience planning. Future research should expand the dataset and explore hybrid models to further refine predictive capabilities and support infrastructure safety in earthquake-prone regions.

SOME FEATURES OF EARTHQUAKE DISTRIBUTION IN TURKMENISTAN

Valeriy Burmin [1], Goharik Petrosyan [2]

[1,2] Institute of Physics of the Earth named after. O.Yu. Schmidt, RAS, Moscow, Russia

ABSTRACT

To date, not many works have been published on the issues of seismicity in the territory of Turkmenistan and the Northeast of Iran. At the same time, some areas of Turkmenistan are characterized by high seismicity, along with the most seismically active zones of the former USSR. It is enough to mention the famous destructive Ashgabat earthquake, which occurred on October 5, 1948.

This article compares the distributions of earthquake hypocenters in Turkmenistan obtained from the ISC catalog data for the period from 1964 to 2021 and the results of the recalculation of hypocenters according to the ISC bulletin for the same period. In total, the ISC catalog for the specified period contains about 6000 events with a magnitude greater than 2.5. The authors recalculated the hypocenters of slightly more than 2100 earthquakes. It is shown that the depths of earthquake sources in the areas under consideration can be located at depths of up to 600 km, while according to the ISC catalog, the maximum depths of earthquake sources do not exceed 100 km. In this work, to determine the coordinates of hypocenters, the method of minimizing the functional of the residuals of theoretical and observed travel times of seismic waves is used, which was first proposed in [1,2].

Keywords: Turkmenistan, ISC Catalog, Times of Arrival Seismic Waves, Determination of Coordinates, Recalculation

INTRODUCTION

The first documented information about earthquakes in Turkmenistan appeared in the catalog of I.V. Mushketov and A.P. Orlov [3]. The study of seismicity in Turkmenistan itself began after a strong earthquake that occurred on May 1, 1929, in the Kopetdag Mountains south of Ashgabat [4].

G.P. Gorshkov, in his work, identified two areas of increased seismicity: in the Krasnovodsk region (now Turkmenbashi) and south of Ashgabat in the Central Kopetdag region [5,6]. The idea that it is necessary to identify two isolated areas with high seismic intensity in Turkmenistan was first expressed in the work [7]. The most complete coverage of modern seismicity in Turkmenistan is given in the periodicals of the Unified Geophysical Service of the Russian Academy of Sciences "Earthquakes of Northern Eurasia" (see, for example, [8]).

Based on geological and seismotectonic characteristics, the territory of Turkmenistan can be divided into three regions: Prikopetdag region (Central Turkmenistan); Krasnovodsk region (Western Turkmenistan); Eastern Turkmenistan [9]. According to the results of earthquake observations, the highest seismic activity is observed in the region of Western Turkmenistan, Ashgabat, and the Shirvan-Kuchan region (Khorasan province) bordering it in the South in Northern Iran [10].

In recent years, events that have occurred have revealed the high seismicity of Turkmenistan. On December 6, 2000, the Balkan earthquake (also known as the Western Turkmen earthquake) became one of the strongest in Turkmenistan in recent decades and one of the strongest in the Balkan region of Turkmenistan in 100 years. The magnitude at the epicenter was 7.3. According to the MSK-64 intensity scale, shaking exceeded 8 points.

The earthquake was accompanied by aftershocks, especially strong on December 7, with a magnitude of more than 3.5. Just a couple of weeks earlier, another strong earthquake occurred in the region, which is associated with the Balkan earthquake due to common causes (Baku, November 25, 2000). The magnitude was 6.2. The epicenter of the earthquake was in the Balkan corridor, on a flat plain between the Big and Small Balkan ridges, east of the city of Nebit-Dag and northwest of the city of Kazandzhik.

Among the large settlements where the intensity was greatest, the city of Kazandzhik (now Bereket) suffered. The shaking reached 7-8 points.

In the regional administrative center of Nebit-Dag (now Balkanabad) they reached 6-7 points. 8-magnitude tremors were recorded at the Pereval railway station.

More than 150 thousand people lived in the zone where the intensity of the shaking exceeded 6 points.

In Turkmenbashi (Krasnovodsk) the intensity was about 5 points, in Kizyl-Arvat 5 points, in Ashgabat 4 points.

Currently, the Seismic Service of Turkmenistan includes 19 stationary and 22 autonomous stations, which are located in all regions of the country. All

stationary seismic stations are equipped with sets of modern GEOSIG equipment, and records of seismic events are processed. Data from all stations is collected and processed in the Service located at the Institute of Seismology and Atmospheric Physics of the Academy of Sciences of Turkmenistan [8].

Over the course of a number of years, an analysis of the seismic study of the region has shown the need to increase the density of the seismological observation network, as well as to equip the Seismic Service of Turkmenistan with modern recording equipment. Today, the registration of seismicity in the Central Kopetdag is controlled by stationary seismic stations located in Ashgabat, the villages of Manish, Yzgant, Germab, Archabil and Suncha.

As part of the implementation of the State Program for the Comprehensive Development of Seismological Science in Turkmenistan for 2022–2028, the Institute is carrying out a lot of work to create a unified nationwide seismic monitoring system for the territory of Turkmenistan. The Institute prepared technical specifications for the tender announced by the Academy of Sciences of Turkmenistan for the purchase of equipment for the construction of fiber-optic communication lines between digital seismic stations located throughout the country, modern seismic geophysical equipment and office equipment.

RESEARCH SIGNIFICANCE

In our previous works and in this work, from the analysis of modern seismicity in Turkmenistan and Northern Iran, it follows that over the past fifty-seven years, the seismic activity of the region has changed from year to year. Moreover, from 1964 to 1984, seismic activity increased noticeably, and from 1985, seismic activity stabilized, until 2000. From 2001 to 2004, there was a sharp decline in seismic activity in Turkmenistan and Northern Iran. From 2005 to 2016 there is a gradual increase in seismic activity in the region, and then again its decline. But since 2019, there has again been a noticeable increase in activity [3,5,7,11-14].

DISTRIBUTION OF EPICENTERS AND HYPOCENTERS OF EARTHQUAKES IN TURKMENISTAN ACCORDING TO THE ISC CATALOG DATA

Fig.1 shows a map of epicenters on the territory of Turkmenistan and Northeast Iran according to the ISC catalogue.

Fig.2 and Fig.3 show the distribution of hypocenters according to the ISC catalog in the latitude and longitudinal planes.

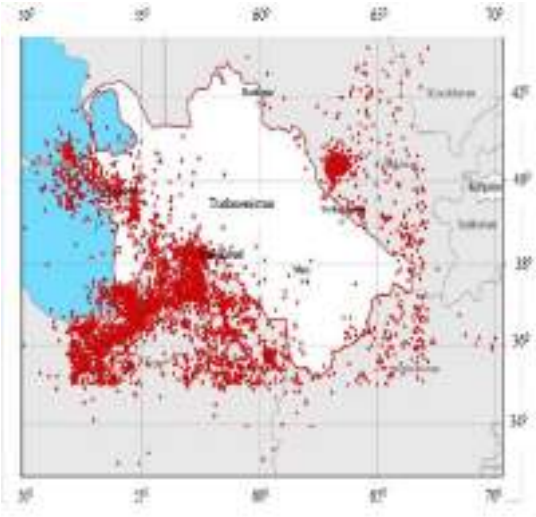

Fig.1 Distribution of epicenters in the territory of Turkmenistan and Northern Iran according to the ISC catalog

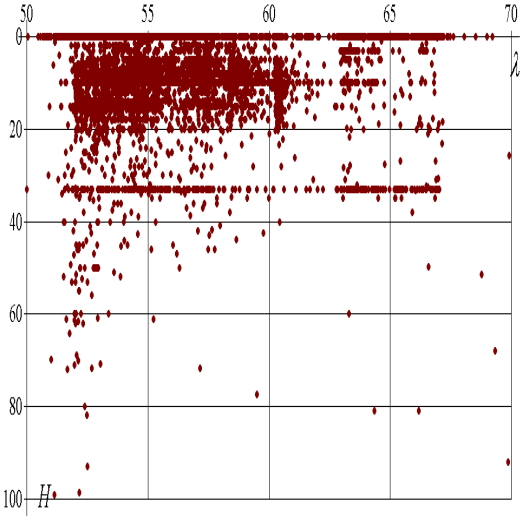

Fig.2 Distribution of hypocenters in the latitudinal plane in the territory of Turkmenistan and Northern Iran according to the ISC catalog

As can be seen from these figures, the bulk of the hypocenters are located in the depth range of 0-20 km. It is worth noting two horizons at depths of 0 and 33 km, where earthquake foci are concentrated. Both of these horizons are most likely determined by the method used to determine earthquake hypocenters. Moreover, the location of the hypocenters at zero depth, in our opinion, is due to the fact that it was not possible to determine the true depth of the foci. The depths of earthquake sources mainly in the Krasnovodsk region reach 100 km.

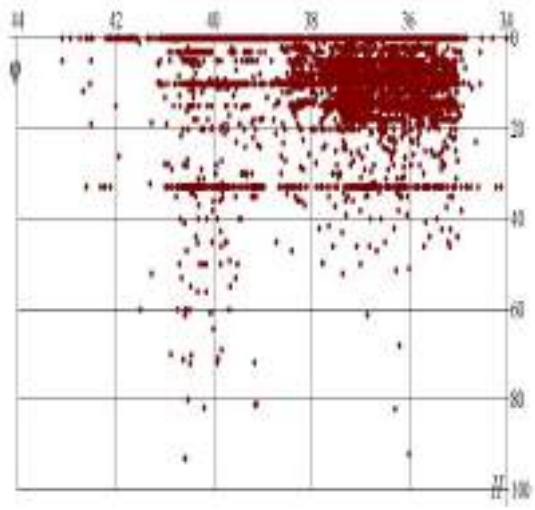

Fig.3 Distribution of hypocenters in the longitudinal plane in the territory of Turkmenistan and Northern Iran according to the ISC catalog

REDEFINITION OF COORDINATES OF EARTHQUAKE FOCI IN TURKMENISTAN

In fact, almost all methods for determining the coordinates of hypocenters come down to minimizing the functional of the residuals of theoretical and observed travel times of seismic waves, which was first proposed in (1), [1,2]:

$$S_t = \sum_{i=1}^{n} (t_i - \tilde{t}_i)^2 \qquad (1)$$

where t_i is the theoretical travel time of seismic waves; $\tilde{t}$ is the travel times of seismic waves obtained from observed data.

However, as shown in [15,16], this approach to determining the coordinates of hypocenters is not optimal. In these works, the problem of determining the coordinates of earthquake hypocenters is posed as a problem of minimizing the functional (2) [15],

$$S = \sum_{i=1}^{n} \rho_i (D_i - d_i)^2 + \mathrm{Y}(H - h)^2 \qquad (2)$$

where D_i and H are determined from the solution of the system of nonlinear equations (3)

$$(X - x_i)^2 + (Y - y_i)^2 + H^2 = v_i^2 (t_i - t_0)^2 \qquad (3)$$

The values of h are specified on a one-dimensional grid Δh in the interval $[0, \mathrm{h_M}]$ and $\mathrm{h_M}$ is calculated from the condition (4):

$$\tau_{\min} = \int_0^{\mathrm{h_M}} \frac{dz}{v(z)} \qquad (4)$$

where $\tau_{\min}$ is the travel time of the seismic wave to the seismic station closest to the source.

For each h, the values of d_i are determined by solving the direct kinematic seismic problems from the condition of proximity of theoretical times t_i the seismic waves travel (determined, for example, from the Wadati plot) with observed times $\tilde{t}_i$.

DISTRIBUTION OF EPICENTERS AND HYPOCENTERS OF EARTHQUAKES IN TURKMENISTAN AFTER RECALCULATION

To clarify the parameters of earthquake hypocenters on the territory of Turkmenistan, we carried out work to redefine the coordinates of earthquake hypocenters using the method mentioned above. The results of the recalculation are presented (Figs.4-6).

Fig.4 shows the distribution of earthquake epicenters after the recalculation. The map shows the epicenters of those earthquakes for which the errors in determining the coordinates are no more than 25 kilometers. The average absolute value of the errors is approximately 8.3 km.

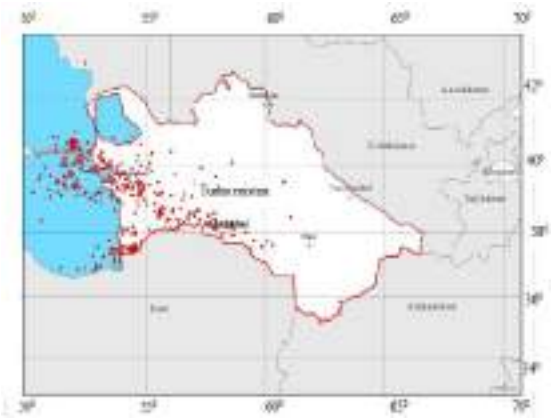

Fig.4 Distribution of epicenters on the territory of Turkmenistan after recalculation

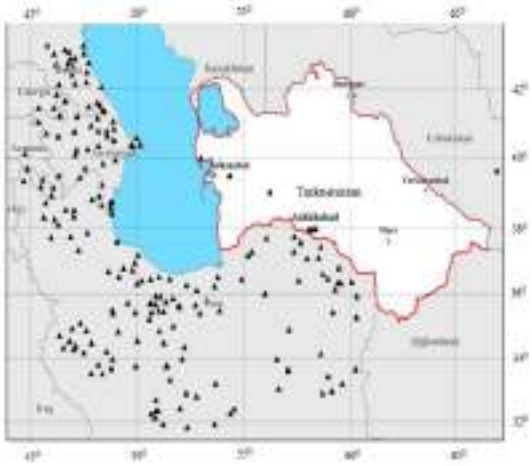

Fig.5 Seismic stations that recorded earthquakes in Fig.4

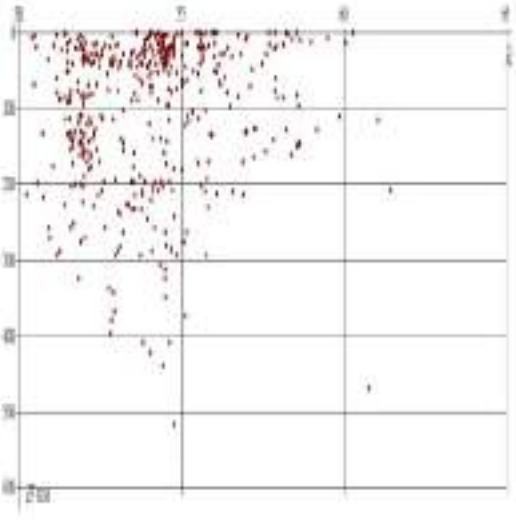

Fig.6 Distribution of hypocenters in the latitudinal plane on the territory of Turkmenistan after recalculation

As can be seen from a comparison of Fig.1 and Fig.4, the distributions differ mainly only in the density with which the epicenters are located.

In Fig.5 shows seismic stations that recorded the earthquakes shown in Fig.4. Each earthquake was recorded by from three to seventy stations.

Fig.6 and Fig.7 show the distributions of earthquake hypocenters after recalculation in the latitude and longitudinal planes. It is clear from the figures that the bulk of the earthquake foci are located in the depth range of 0-40 km. At the same time, a fairly large number of foci are located at depths from 60 to 300 km. At depths from 300 to 500 km there are also a sufficient number of foci. And several foci are located in the range of 500-600 km.

In Figure 8 shows the distribution of earthquake epicenters on the territory of Turkmenistan with foci deeper than 150 km.

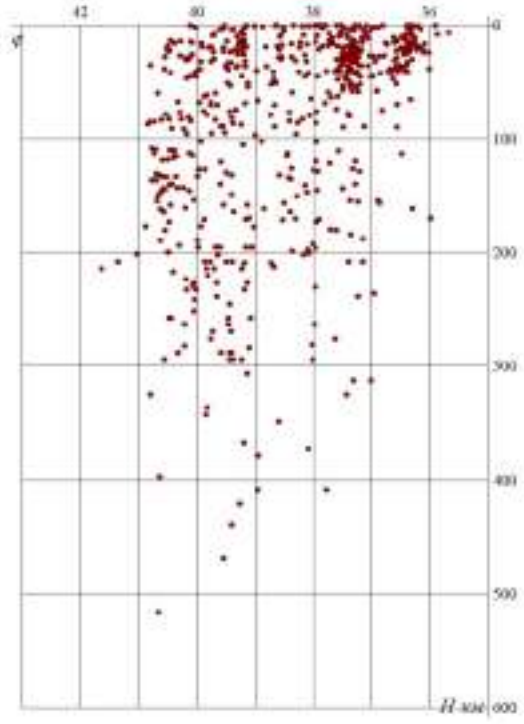

Fig.7 Distribution of hypocenters in the longitudinalplane on the territory of Turkmenistan after recalculation

Fig.8 Distribution of earthquake epicenters on the territory of Turkmenistan with foci deeper than 150 km.

ACKNOWLEDGMENTS

Gratitude to the chief researcher of laboratory 302 of the Schmidt Institute of Physics of the Earth of the Russian Academy of Sciences Valery Yurievich Burmin for his great contribution and for his role as the main author.
The work was carried out within the framework of the state assignment of the Schmidt Institute of Physics of the Earth of the Russian Academy of Sciences No. 0144-2019-0011.

CONCLUSIONS

From the analysis of the ISC catalog data, it follows that the bulk of the hypocenters are located in the depth range of 0-20 km. There are two horizons at depths of 0 and 33 km, where earthquake foci are concentrated. Both of these horizons are most likely determined by the method used to determine earthquake hypocenters. Moreover, the location of the hypocenters at zero depth, in our opinion, is due to the fact that it was not possible to determine the true depth of the foci. The depths of earthquake foci mainly in the Krasnovodsk region reach 100 km.

The recalculation of earthquake hypocenters in Turkmenistan was carried out according to the methodology outlined in [1]. As can be seen from a comparison of the catalog data and the results of recalculation, the distributions of epicenters differ mainly only in the density with which they are located on the surface.

At the same time, the results of the recalculation showed that the bulk of the foci are located in the depth range of 0-300 km. At depths from 300 to 500 km there are also a sufficient number of sources. And several foci are located in the range of 500-600 km.

In conclusion, we can say that the existence of deep earthquakes is not unique. Thus, for the Crimean-Black Sea region, earthquake foci with depths of up to 300 km have been recorded [17], and in the Caucasus to depths of 500 km [18]. On the territory of Turkmenistan, the depths of the foci reach 600 km.

The issues of data reliability are of fundamental importance when constructing certain theories or conclusions. In this case, three factors influence the results of determining the coordinates of earthquake hypocenters in Turkmenistan. The first factor is the accuracy of determining the time of occurrence of the earthquake (time at the source). The second factor is the assignment of the velocity distribution of seismic waves adequate to the true distribution. And the third factor is the choice of the method for determining the coordinates of earthquake hypocenters.

CORRELATION BETWEEN STANDARD PENETRATION TEST AND CONE PENETRATION TEST FOR LIQUEFACTION ASSESSMENT

Nami Nitta [1], Misko Cubrinovski [2] and Shinya Inazumi [1]

[1] Shibaura Institute of Technology, Japan; [2] University of Canterbury, New Zealand

ABSTRACT

Currently, the Standard Penetration Test (SPT) and the Cone Penetration Test (CPT) are widely used for ground investigations. In Japan, SPT is the most commonly adopted method due to its long history of use and has well-established correlations with geotechnical design standards. However, since SPT measurements are taken at 1-meter intervals, it has some limitations, such as missing thin layers and reduced accuracy in identifying loose soils. On the other hand, CPT is widely used in many other countries because it provides continuous data, allowing for a more detailed and accurate assessment of subsurface conditions. When combined with SPT, CPT can improve the reliability and accuracy of ground investigations. However, despite its advantages, it is not widely used in Japan, as the country's geotechnical design standards mainly rely on SPT data. To effectively utilize CPT into ground investigations in Japan, an appropriate conversion framework between SPT and CPT parameters is essential. This research aims to analyze the relationship between SPT and CPT using a liquefaction evaluation method. Specifically, it examines the correlation between the corrected SPT blow count $(N_1)_{60cs}$ and the normalized CPT tip resistance q_{c1Ncs} is examined using the QNR ratio, which is defined as $QNR = q_{c1Ncs}/(N_1)_{60cs}$, to evaluate the accuracy and reliability of conversions between these two parameters. Furthermore, this research discusses the benefits of using both SPT and CPT in combination and evaluates their effectiveness in improving ground investigations, ultimately contributing to the establishment of more reliable ground investigation techniques.

Keywords: Standard penetration test (SPT); Cone penetration test (CPT); Liquefaction assessment; QNR ratio

INTRODUCTION

Soil liquefaction is one of the most critical geotechnical phenomena associated with seismic activity. It occurs when saturated loose soils, typically sands or silty sands, temporarily lose strength and stiffness in response to ground shaking, behaving like a liquid. Liquefaction has caused severe infrastructure damage in numerous earthquakes, highlighting the importance of accurately evaluating its potential, especially in earthquake-prone countries like Japan.

Among various investigation methods, the Standard Penetration Test (SPT) and the Cone Penetration Test (CPT) are the most commonly used for assessing liquefaction potential. The SPT has long been the standard in Japan, valued for its simplicity and the large empirical database developed over decades. However, it provides only discrete data at intervals (typically every 1 m), potentially missing thin weak layers. In contrast, CPT offers continuous, high-resolution data, making it especially suitable for detecting weak layers that are susceptible to liquefaction. Despite its advantages, CPT is not widely adopted in Japan due to design standards and evaluation methods being primarily based on SPT results. Japanese engineers are generally more familiar with SPT-based procedures. Therefore, to promote CPT use, it is essential to develop reliable conversion relationships between CPT and SPT parameters. This would enable engineers to interpret CPT data within the existing SPT based framework, enhancing both the accuracy and efficiency of liquefaction evaluations.

This study aims to address this need by investigating the correlation between SPT and CPT using the liquefaction evaluation procedure developed by Boulanger and Idriss (2014). In particular, it focuses on the relationship between the corrected SPT blow count $(N_1)_{60cs}$ and the normalized CPT tip resistance q_{c1Ncs}, using the QNR ratio defined as $QNR = q_{c1Ncs}/(N_1)_{60cs}$. This research investigates the accuracy and reliability of such conversions and examines the potential advantages of combining SPT and CPT to improve liquefaction assessment and promote more integrated and flexible ground investigation methods.

RESEARCH SIGNIFICANCE

The reliability of liquefaction assessments directly affects the safety, design, and long-term performance of infrastructure in seismic regions. The SPT is widely used due to its long history, extensive empirical database, and high familiarity among engineers, but it has several limitations such as operator dependency, low repeatability, and discontinuous data collection. In contrast, the CPT provides continuous, high-resolution measurements

and more objective, reproducible data. This study aims to systematically compare these two methods and analyze their interrelationships in order to improve the accuracy, reliability, and practicality of liquefaction evaluations.

OVERVIEW OF SPT AND CPT

Standard Penetration Test (SPT)

The Standard Penetration Test (SPT) is a widely used field test for evaluating subsurface conditions in Japan and many other countries. In this test, a 63.5 kg hammer is dropped from a height of 76 cm to drive a sampler into the ground. The number of blows required to drive the sampler 30 cm is recorded as the N-value, which serves as an indicator of soil stiffness and density. The N-value is extensively used for liquefaction assessment and foundation design. SPT can be applied to a wide range of soil types, including sand, clay, and gravel, enabling a comprehensive evaluation of ground conditions. A key benefit is that it allows for the collection of disturbed soil samples, which can be analyzed in the laboratory to determine properties such as grain size distribution and moisture content. However, SPT also has some limitations. Laboratory testing is required to analyze the samples, which increases both time and cost. Additionally, the reproducibility of test results is relatively low, and accuracy may vary depending on field conditions. Since measurements are taken at 1-meter intervals, thin weak layers may be overlooked. In very loose soils where the N-value is 0, the accuracy of strength estimation is reduced.

Cone Penetration Test (CPT)

The Cone Penetration Test (CPT) involves pushing a cone shaped probe into the ground at a constant rate while continuously measuring cone resistance q_c, sleeve friction f_s, and pore pressure u, as shown in Fig. 1. This test provides detailed information about soil stratigraphy, density, and strength characteristics. CPT offers continuous, high-resolution data in real time, allowing for accurate detection of subtle changes in soil composition. Compared to SPT, CPT results are more reproducible and consistent. Furthermore, because it does not require soil sampling or borehole drilling, it minimizes disturbance to the ground and has a lower environmental impact. However, CPT is not suitable for all ground conditions. Penetration can be difficult in very dense soils or gravelly layers, limiting its applicability in such situations. Moreover, unlike SPT, CPT does not provide physical soil samples, so additional sampling is required for laboratory analysis of properties such as particle size distribution or chemical composition.

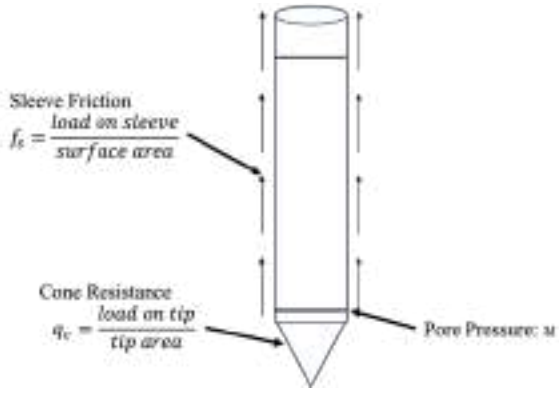

Fig. 1 Overview of the Cone Penetration Test (CPT)

Effectiveness of Combined Use

The SPT and CPT each have their own strengths, so using them together provides a more comprehensive and accurate understanding of ground conditions than relying on just one method. Each test performs better under certain circumstances depending on soil type, site conditions, and the required level of detail. For example, in areas with coarse or gravelly soils, CPT may not perform well or might fail to reach the target depth. In such cases, SPT can still be conducted and provide valuable information about soil strength. On the other hand, CPT offers continuous, high-resolution data at small depth intervals, which helps detect subtle variations in soil layers that SPT might overlook. By combining both methods, the strengths of one can compensate for the limitations of the other. CPT data can fill in the gaps between SPT boreholes, improving the overall understanding of the subsurface conditions. This combined approach enhances the accuracy of ground surveys and supports the development of better liquefaction hazard maps, especially in areas with complex ground conditions. Therefore, using both SPT and CPT together is a highly effective way to assess liquefaction risk and ground stability at specific sites.

RESEARCH METHODOLOGIES

Boulanger & Idriss (2014) Procedure

This study investigates the correlation between the SPT and the CPT using the liquefaction assessment method proposed by Boulanger and Idriss (2014). The cyclic resistance ratio (CRR) under conditions of moment magnitude $M = 7.5$ and effective vertical stress $\sigma_v' = 1atm$ is expressed by

Eq. (1) for SPT and Eq. (2) for CPT. Since liquefaction occurs based on the relative relationship between liquefaction resistance and the applied shear stress, it is common practice to compare the CRR with the cyclic stress ratio (CSR). Based on the derived CRR values, the corresponding CSR values under the same conditions were also computed. Fig. 2 and Fig. 3 illustrate the relationships between CSR and $(N_1)_{60cs}$ as well as $q_{C1N_{CS}}$, respectively. The analysis focuses on clean sand, defined as having a fines content FC of 5% or less.

$$CRR_{M=7.5,\sigma'_v=1atm} = exp\left(\frac{(N_1)_{60_{cs}}}{14.1} + \left(\frac{(N_1)_{60_{cs}}}{126}\right)^2 - \left(\frac{(N_1)_{60_{cs}}}{23.6}\right)^3 + \left(\frac{(N_1)_{60_{cs}}}{25.4}\right)^4 - 2.8\right) \quad (1)$$

$$CRR_{M=7.5,\sigma'_v=1atm} = exp\left(\frac{q_{C1N_{CS}}}{113} + \left(\frac{q_{C1N_{CS}}}{1000}\right)^2 - \left(\frac{q_{C1N_{CS}}}{140}\right)^3 + \left(\frac{q_{C1N_{CS}}}{137}\right)^4 - 2.80\right) \quad (2)$$

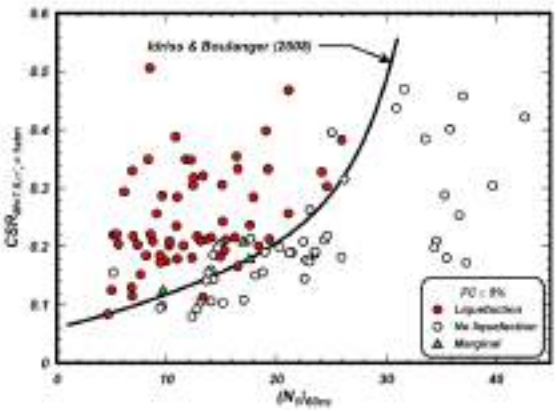

Fig. 2 Curves of $CSR_{M=7.5,\sigma'_v=1atm}$ versus $(N_1)_{60cs}$

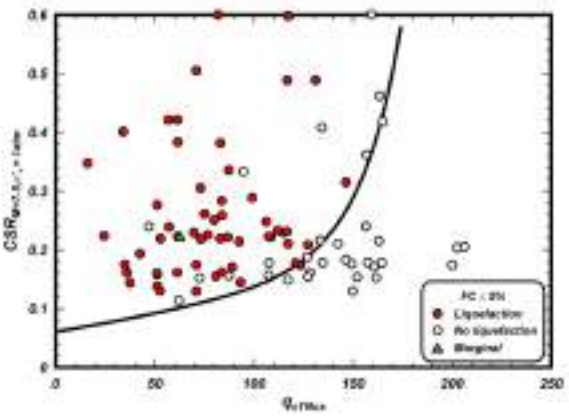

Fig. 3 Curves of $CSR_{M=7.5,\sigma'_v=1atm}$ versus $q_{C1N_{CS}}$

QNR Ratio

To investigate the correlation between SPT and CPT data, this study introduces the QNR ratio, a normalization approach that enables the conversion between normalized cone resistance $q_{C1N_{CS}}$ and corrected SPT blow count $(N_1)_{60cs}$. The QNR ratio is defined as $QNR = q_{c1Ncs}/(N_1)_{60cs}$. This equation provides a common basis for comparing and integrating data obtained from both testing methods. By using QNR, it becomes possible to cross validate results from CPT and SPT, thereby improving the consistency and reliability of subsurface evaluations. This is particularly valuable in multi-method site investigations, where data from different sources need to be interpreted together to develop a coherent and accurate geotechnical model. The introduction of QNR thus enhances data compatibility and supports more robust site characterization, especially in areas with variable soil conditions.

CORRELATION BETWEEN QNR AND $(N_1)_{60cs}$, $q_{C1N_{CS}}$

The correlation between $q_{C1N_{CS}}$ and QNR, derived using the aforementioned method, is shown in Fig. 4. It indicates that QNR remains relatively constant at approximately 8 when $q_{C1N_{CS}}$ is below 100. However, as $q_{C1N_{CS}}$ increases beyond this threshold, the QNR value gradually decreases, eventually reaching around 6 when $q_{C1N_{CS}}$ approaches 150. This observed trend suggests a nonlinear relationship between the two parameters and is consistent with findings from previous research on liquefaction resistance correlations. The noticeable decrease in QNR at higher $q_{C1N_{CS}}$ values may be attributed to a range of geotechnical factors influencing soil behavior. Specifically, soil characteristics such as particle size distribution D_{50} and fines content FC are likely to have a significant impact on cone penetration resistance. These soil properties may affect the measurements obtained by CPT and SPT in different ways, leading to variability in QNR values. This observation highlights the importance of accounting for soil type and composition when applying QNR based conversions in practical site investigations to ensure accurate interpretations.

Furthermore, in order to further investigate the relationship with SPT, which is commonly used in Japan, a correlation between $(N_1)_{60cs}$ and QNR was created and is illustrated in Fig. 5. It shows that QNR remains relatively stable, staying close to approximately 8 when $(N_1)_{60cs}$ is below 10. This indicates a relatively stable relationship in this range. However, as $(N_1)_{60cs}$ increases and approaches around 25, the QNR value gradually declines to about 6. This suggests that the correlation between the two

parameters weakens at higher $(N_1)_{60cs}$. This trend might be reflective of changes in soil behavior or composition as soil resistance increases, emphasizing the need to account for such variations when interpreting test results.

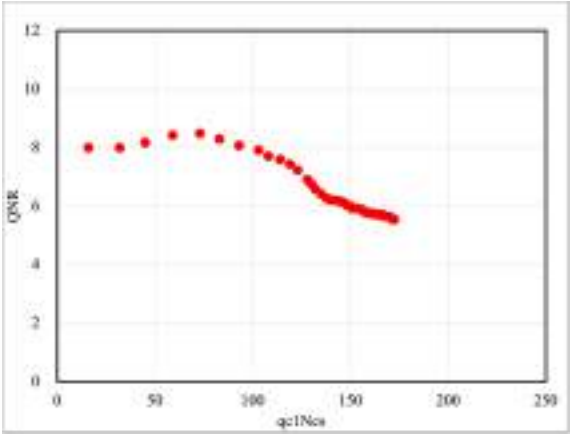

Fig. 4 Correlation between $q_{C1N_{CS}}$ and QNR

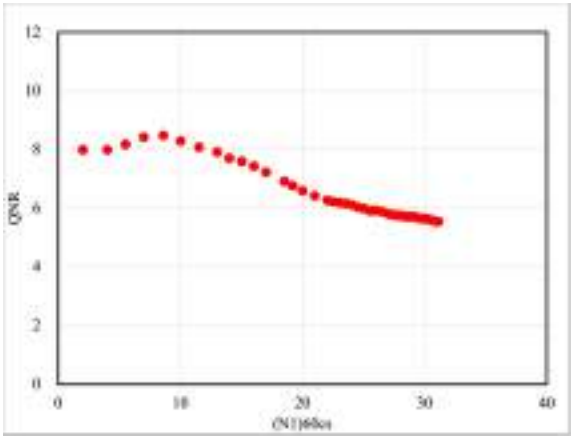

Fig. 5 Correlation between $(N_1)_{60_{cs}}$ and QNR

In addition, to better visualize and understand the correlation between SPT and CPT results, a detailed correlation plot between $(N_1)_{60cs}$ and $q_{C1N_{CS}}$ was created and is shown in Fig. 6. As illustrated in the figure, the data points collectively follow a smooth and continuous curve, which clearly indicates a stable and consistent relationship between these two important geotechnical parameters. Specifically, $q_{C1N_{CS}}$ exhibits a gradual increase as $(N_1)_{60_{cs}}$ rises, reaching values of approximately 100. Beyond this threshold, the rate of increase in $q_{C1N_{CS}}$ becomes noticeably more rapid, implying a change or shift in the underlying correlation pattern between the parameters. This observed nonlinear trend highlights the complex nature of soil behavior captured by these tests. Building upon this established relationship, a set of conversion equations were then derived to enable the mutual transformation between SPT and CPT data, facilitating seamless comparison and integration of results obtained by either method. These conversion equations serve as a practical and valuable tool for geotechnical engineers, providing a reliable means to interpret and correlate data from both testing techniques. The specific formulas for these conversions are presented as Eq. (3) and Eq. (4).

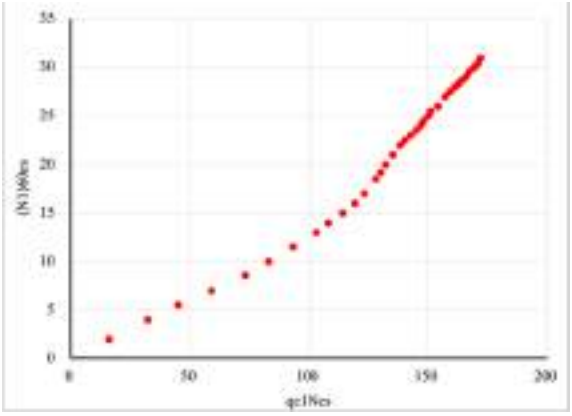

Fig. 6 Correlation between $q_{C1N_{CS}}$ and $(N_1)_{60_{cs}}$

$$(N_1)_{60_{cs}} = 0.12q_{C1N_{CS}} + 0.04 \quad (0 \le q_{C1N_{CS}} \le 100) \tag{3}$$

$$(N_1)_{60_{cs}} = 0.27q_{C1N_{CS}} - 15.48 \quad (q_{C1N_{CS}} > 100) \tag{4}$$

These conversion equations are useful for evaluating SPT and CPT data on a unified basis and enable adjustments between the test methods in liquefaction assessments.

COMPARISON BETWEEN ESTIMATED AND MEASURED N-VALUE

Observed Data Profiles

Fig. 7 presents the cone resistance q_c, sleeve friction f_s, pore pressure u_2, and measured SPT N-values at locations where both SPT and CPT data were obtained. Since the CPT data were recorded at 2 cm intervals, which is much finer than the standard SPT sampling interval, the CPT values were averaged using the mean over the corresponding depth range to enable a meaningful comparison with the SPT results. Using the mean CPT data, N-values were estimated by applying an empirical correlation proposed by Boulanger and Idriss (2014), which is widely used for converting CPT parameters into equivalent SPT N-values. These estimated N-values were then compared with the actual measured N-values obtained from the SPT tests conducted at the same locations.

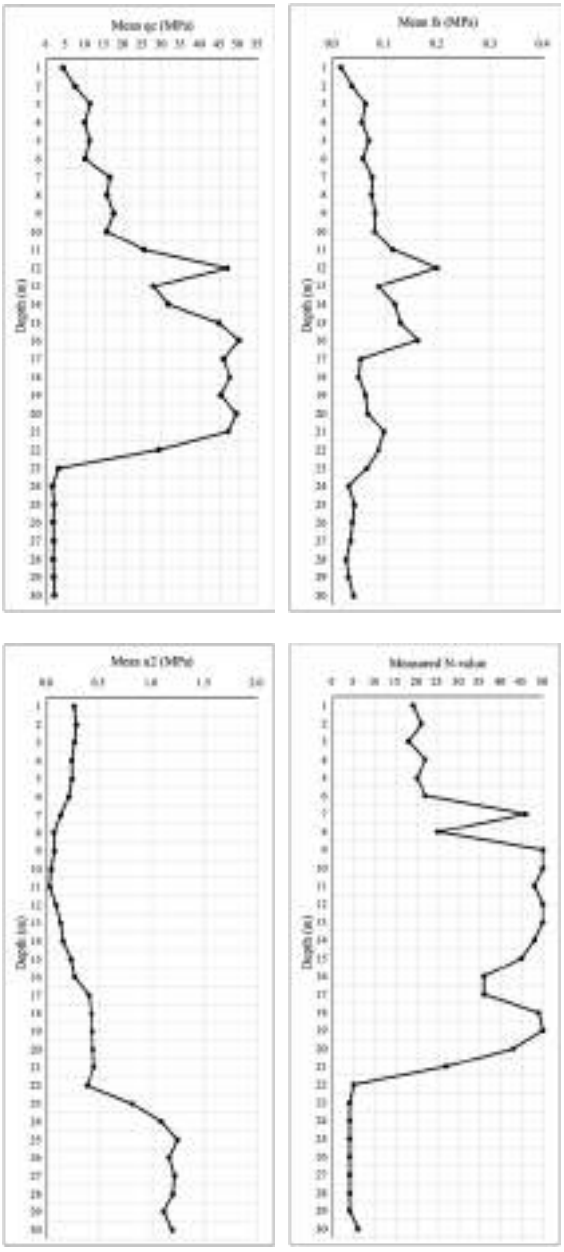

Fig. 7 Measured profiles of q_c, f_s, u_2, and N-value

Results

Using the following equation proposed by Boulanger and Idriss (2014), estimated N-values were calculated from the CPT data. A comparison between the measured and estimated N-values is shown in Fig. 8.

In this study, although the dataset was limited and caution is required when generalizing the results, a moderate correlation was observed between the estimated and measured N-values. The coefficient of determination R^2 was 0.602, indicating a weak but consistent linear relationship between the two. This suggests that the conversion between SPT and CPT penetration resistances may serve as a preliminary reference for liquefaction evaluation, even though it may not yet be considered sufficiently robust for practical application. In addition, the estimated N-values tend to be slightly lower than the measured values overall. This discrepancy may be attributed to the accuracy of the conversion formula and its underlying assumptions, as well as the influence of soil properties critical to liquefaction, such as fines content and particle size distribution. These soil characteristics can affect SPT and CPT measurements differently, potentially impacting the precision of the conversion.

Future research should focus on expanding the dataset to include a wider range of soil conditions and on developing improved estimation formulas that incorporate fines content and particle size. Such efforts will enhance the consistency between SPT and CPT results and improve the reliability of liquefaction assessments in practical geotechnical investigations.

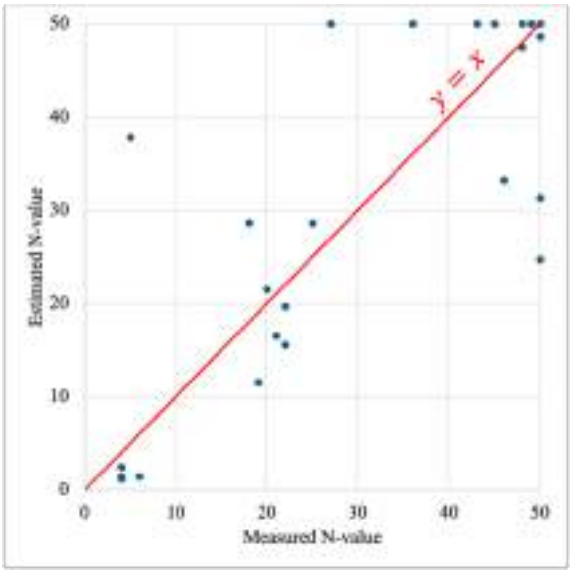

Fig. 8 Comparison between the measured N-value and estimated N-value

CONCLUSIONS

In this study, the relationship between the SPT and CPT was analyzed based on the liquefaction evaluation framework proposed by Boulanger and Idriss (2014). Specifically, the correlation between the corrected SPT blow count $(N_1)_{60cs}$ and the normalized cone resistance $q_{c1N_{CS}}$ was examined using the QNR ratio. This normalization method enabled consistent comparison across datasets obtained from different in-situ testing methods.

Through this analysis, a conversion formula was developed to express the relationship between $(N_1)_{60cs}$ and $q_{c1N_{CS}}$, allowing for more reliable translation of CPT data into equivalent SPT based parameters. This conversion is particularly useful for integrated liquefaction hazard assessments in cases

where both SPT and CPT data are available or when one type needs to be estimated from the other. Practicing engineers can apply the QNR ratio and the developed conversion equations to estimate missing data based on the available in-situ test (SPT or CPT). For example, when only CPT data is available, the conversion formula allows estimation of equivalent SPT blow counts, making it possible to use SPT-based liquefaction evaluation methods. This supports appropriate decision-making even when only one type of data is available. However, it is important to recognize the uncertainties and limitations of such conversions and apply them with caution.

The key findings and conclusions drawn from this study are summarized below.

1) As shown in Fig. 4, QNR is approximately 8 when $q_{C1N_{CS}}$ is below 100 and gradually decreases to around 6 as $q_{C1N_{CS}}$ approaches 150.
2) From the correlation between $(N_1)_{60cs}$ and QNR in Fig. 5, it was observed that QNR is approximately 8 when $(N_1)_{60cs}$ is below 10, and decreases to about 6 when $(N_1)_{60cs}$ reaches 25. This indicates that $(N_1)_{60cs} = 10$ serves as a useful threshold for the conversion between SPT and CPT.
3) The data trend shown in Fig. 6 follows a smooth curve, where $q_{C1N_{CS}}$ increases gradually up to around 100, followed by a sharp rise beyond that point. Based on this relationship, conversion equations between SPT and CPT were derived, as presented in Eq. (3) and Eq. (4).
4) Fig. 8 compares the estimated and measured N-values, showing a coefficient of determination $R^2 = 0.602$, which indicates a weak but consistent linear relationship between the two. In addition, the estimated values tend to be slightly lower than the measured ones, possibly due to assumptions in the conversion formulas and the influence of soil properties such as fines content and particle size distribution.

For future research, developing correction factors for soil particle size and fine content, which influence QNR reduction, is essential for accurate liquefaction assessment. Incorporating these factors into corrections will enhance precision. Additionally, further test data should be collected under different ground conditions to expand the applicability of the derived conversion formula. This will contribute to the development of a more versatile conversion formula that can be applied to a wider range of ground conditions, improving its practical use in engineering applications.

STRENGTH OF BAGASSE ASH GEOPOLYMER-STABILIZED RECYCLED MATERIALS FOR PAVEMENT BASE: MLR AND PATH ANALYSIS

Sattawat Chatchawan [1], Ratamanee Nuntasarn [2], Supakorn Tirapat

[1,2,3] Faculty of Engineering, Khon Kaen University, Thailand

ABSTRACT

Thailand faces an increasing demand for natural aggregates due to road infrastructure expansion and a corresponding rise in demolition waste. Recycling these materials and stabilizing them with bagasse ash (BA), which is a byproduct of biomass power plants, provides an eco-friendly alternative to cement stabilization. This research investigates the stabilization of construction and demolition (C&D) waste, consisting of recycled crushed rock (RCR) and recycled asphalt pavement (RAP), using a BA-derived geopolymer for pavement base applications. The study examines the effects of alkali solution content, NaOH concentration, BA content, and RAP quantity on unconfined compressive strength (UCS) using multiple linear regression (MLR) and path analysis. Results indicate that material density has the strongest positive influence on UCS, while higher NaOH concentration and alkali solution content also improve UCS. However, increased BA content and RAP quantity reduce UCS by lowering material density. Overall, most of these materials met the UCS criteria set by Thailand's Department of Highways (DH.-S. 203/2556) for cement-modified crushed rock for high-traffic pavement base applications. The findings demonstrate that recycling C&D waste stabilized with BA geopolymer can serve as a viable alternative to cement stabilization for pavement base layers.

Keywords: Bagasse Ash Geopolymers, Pavement Base, Recycled Materials, Construction and Demolition Waste

INTRODUCTION

Thailand is currently expanding its road network to accommodate increasing traffic volumes driven by economic growth [1]. Traditional road construction relies heavily on natural aggregates for the base structure of flexible pavements. However, the availability of these aggregates is declining, while construction and demolition (C&D) waste is rising, totaling approximately 6–9 million tons annually [2]. This situation leads to environmental impacts and disposal challenges. Recycling C&D waste to replace natural aggregates can help reduce dependence on new materials and minimize waste.

Recycled asphalt pavement (RAP) and recycled crushed rock (RCR), derived from deteriorated roads, are often used; however, Previous research indicates that recycling these materials without quality enhancement leads to substandard products. For instance, Akinwumi [3] found that mixing RAP with clay reduces both density and strength, consistent with findings from other studies [4-6]. While improving these materials with Portland cement is effective and widely practiced, it also contributes nearly 7% of global GHG emissions annually [7]. Consequently, the sustainable binder known as 'geopolymer' has garnered significant interest.

Geopolymer is a synthetic material derived from precursors containing silica (SiO_2) and alumina (Al_2O_3). When mixed with an alkaline solution, these precursors form a sodium aluminosilicate hydrate (N-A-S-H) compound with binding properties comparable to those of cement [8]. Typical precursors include fly ash and rice husk ash, as well as bagasse ash (BA)—a by-product of biomass energy generation in the sugar industry. Several studies have demonstrated that BA geopolymer can significantly enhance the compressive strength of materials [9–11]. However, its potential in road construction remains underexplored and its usage limited. In Thailand, the use of BA is minimal, leading to waste management challenges associated with landfill disposal.

To address these challenges, this study analyzes the stabilization of RAP and RCR using bagasse ash (BA) as the primary precursor in geopolymer synthesis to develop eco-friendly pavement base materials. The unconfined compressive strength (UCS) is assessed against the standards of the Department of Highways, Thailand. Multiple linear regression and path analysis, conducted using IBM SPSS Statistics and IBM AMOS, are employed to examine the influence of key variables—particularly mix ratios—on UCS, aiming to optimize the performance of BA and other biomass ash-based geopolymers.

RESEARCH SIGNIFICANCE

This study addresses the critical need for sustainable construction practices in Thailand by investigating recycled materials, specifically recycled asphalt pavement (RAP) and recycled crushed rock

(RCR), and improving their strength with bagasse ash geopolymer. Analyzing the influence of the mix ratio on compressive strength properties will reveal potential pathways for improving these alternative materials. The findings are expected to promote the adoption of eco-friendly materials for pavement base applications, influencing industry practices and enhancing environmental conservation and resource management in civil engineering.

MATERIALS AND METHODS

Materials

Recycled aggregates

Recycled asphalt pavement (RAP) and recycled crushed rock (RCR) were obtained from the demolition of roads within the Khon Kaen area, Thailand. The basic properties of both types of aggregates are summarized in Table 1.

Table 1. Basic properties of RAP and RCR aggregates

Properties	Standards	RCR	RAP
Gradation	ASTM C136-06	Well-graded (C_u = 17.43, C_c = 2.27)	Well-graded (C_u = 14.81, C_c = 2.37)
Specific gravity, G_s	ASTM C127-15	2.63	2.29
Water absorption (%)	ASTM C127-15	2.45	0.82
Percentage of wear (%)	ASTM C131/C131M-20	21.07	29.39
Liquid Limit (%)	ASTM D4318-17e1	-	-
Plasticity Index (%)	ASTM D4318-17e1	NP	NP
Unified Classification	ASTM D-2487	SM	SM
AASHTO Classification	AASHTO T-234	A-1-a	A-1-a

Bagasse ash

The bagasse ash (BA) used in this study was a byproduct of biomass power generation at the Nam Phong Sugar Mill in Khon Kaen, Thailand. The average particle size (D_{50}) was 450 microns, and the specific gravity (G_s) was 2.15. The ash exhibited irregular shapes with angular edges and a highly porous structure, as shown in Fig. 1. Results from X-ray fluorescence (XRF) testing indicated that the BA contained 72.75% silica (SiO_2), 2.02% alumina (Al_2O_3), and 1.17% calcium oxide (CaO).

Alkaline solution

The alkaline solution used in this study consists of industrial-grade sodium silicate (Na_2SiO_3) with the following composition: Na_2O = 13.44%, SiO_2 = 32.39%, and H_2O = 54.17%. Additionally, sodium hydroxide (NaOH) solutions at concentrations of 8, 10, and 12 M were used, maintaining a ratio of Na_2SiO_3 to NaOH of 1:1.

Mixing Ratios

In the unconfined compression tests, specimens were compacted using the dry density and alkaline solution content obtained from the modified compaction test (ASTM D1557-12). UCS tests were conducted at three compaction conditions: the optimum alkaline liquid content (OLC), OLC−3%, and OLC+3%, using bagasse ash (BA) contents of 0%, 5%, 10%, and 15% by weight, and NaOH concentrations of 8, 10, and 12 M. Each mix design was tested in triplicate, as summarized in Table 2.

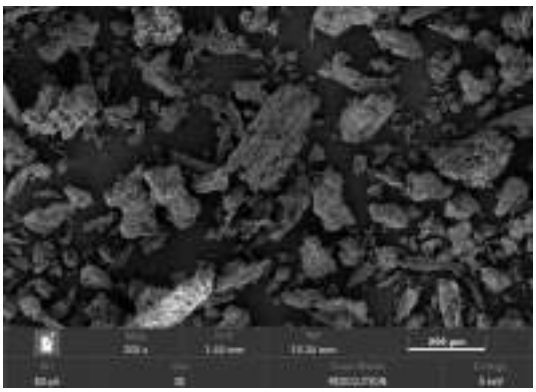

Fig. 1 SEM image of the bagasse ash used in this study

Table 2. Mix details for unconfined compression test.

Recycled material	BA (%)	NaOH Concentration (Molar)	Alkaline solution condition
RCR RCR+RAP RAP	0, 5, 10 and 15	8, 10 and 12	OLC-3% OLC OLC+3%

Laboratory Testing Methods

The strength of the materials was evaluated by determining the unconfined compressive strength (UCS) through unconfined compression tests conducted according to ASTM D2166/D2166M-24. The samples were cylindrical specimens with a diameter of 15 cm and a height of 30 cm. They were cured at ambient temperature for 7 days and submerged in water for 2 hours prior to testing, as specified by the standards for cement-modified crushed rock base materials in Thailand (DH.-S. 203/2556). Subsequently, the samples were applied to compression at a loading rate of 0.5% strain per minute until failure. The UCS results were analyzed to determine the suitability of the material for pavement base applications, following the DH-S. 203/2556 standards, which set a minimum requirement of 2,413 kPa for heavy-traffic roads.

Statistical Analysis

Multiple linear regression

The multiple linear regression (MLR) in this study was conducted using the Enter method with IBM SPSS Statistics 28 software. The analysis set the confidence interval level at 95% ($\alpha = 0.05$) and considered the preliminary assumptions of linear regression to obtain appropriate prediction results [12][13].

The statistical significance of the independent variables on the dependent variable was tested according to the following statistical hypotheses: H_0: The independent variable does not have an effect on the dependent variable; H_1: The independent variable has an effect on the dependent variable. Decision criteria: If sig. < 0.05, reject H_0 and accept H_1; if sig. > 0.05, accept H_0 and reject H_1.

The regression model is expressed as a linear equation: $Y = a + b_1x_1 + b_2x_2 + \ldots + b_nx_n + c$, and the influence of the independent variables is evaluated using standardized regression coefficients (Beta).

Path analysis

Path analysis was conducted to further clarify the influence pathways from independent variables to the dependent variable. The analysis used IBM AMOS V.28 software, under the assumption that the relationships between mixture ratios and UCS may involve both direct and indirect effects. Model evaluation followed the fit criteria recommended in the IBM AMOS Manual [14], including: p-value > 0.05, relative Chi-square (CMIN/DF) < 3, Goodness of Fit Index (GFI) > 0.90, and Root Mean Square Error of Approximation (RMSEA) < 0.08.

Independent variables used

The independent variables (mixture ratios) in this study include RAP aggregate content, alkaline solution content, NaOH concentration, and bagasse ash (BA) content. The symbols and value ranges for these variables used in the statistical analysis are shown in Table 3. The dependent variable is the unconfined compressive strength (UCS), based on data from 81 laboratory test results.

Table 3. Independent variables used

Variable	Symbol	Unit	Range
RAP content	RAP_Content	% w/w	0 to 100
Bagasse ash content	BA_Content	% w/w	5 to 15
Alkali solution content	Alkali_Content	% w/w	*6 to 19.5
NaOH concentration	NaOH_Molar	Molar	8 to 12

*Note: *According to the results of the modified compaction tests.*

RESULTS AND DISCUSSIONS

Unconfined Compressive Strength (UCS)

The unconfined compressive strength (UCS) results of the mixture, as specified in Table 2, indicate that most mixtures met the minimum DH.-S. 203/2556 requirement (UCS > 2,413 kPa), as presented in Fig. 2. These results indicate that stabilizing recycled materials with BA-based geopolymer is a viable alternative to cement stabilization for base layers.

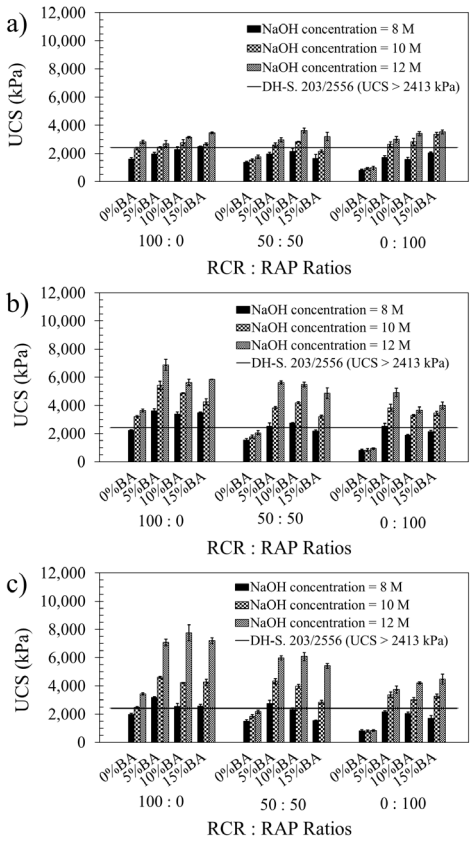

Fig. 2 UCS values of materials at alkaline solution contents of a) OLC-3%, b) OLC, and c) OLC+3%

A preliminary assessment indicates that mixtures failing to meet the DH.-S. 203/2556 standard typically used low NaOH concentrations (8 M) and low alkaline solution content (OLC-3%). The UCS increased with higher NaOH concentrations but decreased with greater RAP proportions in the mix.

The results also showed that mixtures containing BA had significantly higher UCS values than those without, indicating effective geopolymer formation and improved strength. However, increasing BA content from 5% to 10% and 15% did not yield substantial UCS gains, likely due to interactions with other influencing variables. Therefore, multiple linear regression and path analysis were employed to better understand these effects.

Statistical Analysis Using Multiple Linear Regression and Path Analysis Models

Multiple linear regression

The multiple linear regression (MLR) analysis revealed that the independent variables significantly influenced the unconfined compressive strength (UCS) at the 0.001 level (ANOVA; sig. of F < 0.05). The null hypothesis (H_0) was rejected, and the alternative hypothesis (H_1) was accepted, confirming the combined effect of the independent variables on UCS. The model explained 73.3% of the variance (R^2 = 0.733), with a multiple correlation coefficient (R) of 0.856 and a standard error of ±750.871, as shown in Tables 4–5.

The results of the partial t-test for the significance of each independent variable on the UCS of the materials, as shown in Table 6, indicated that all independent variables significantly influenced UCS ($p < 0.05$), including NaOH concentration, BA content, alkaline solution content, and RAP aggregate content. NaOH concentration had the strongest positive effect ($\beta = 0.696$), followed by alkaline solution content ($\beta = 0.507$). In contrast, RAP content ($\beta = -0.454$) and BA content ($\beta = -0.378$) had negative effects, with BA content being the least influential. The predictive MLR equation for UCS is shown in Eq. (1). The comparison between predicted and observed UCS values reveals that most data points lie along the X = Y line within the 95% confidence interval (Fig. 3). Furthermore, the residuals followed a normal distribution, supporting the MLR assumptions.

Table 4: Summary of multiple linear regression model analysis (model summary)

Model Summary[b]				
Model	R	R Square	Adjusted R Square	S.E. of the Estimate
1	0.856[a]	0.733	0.719	750.871

Note: [a]. Predictors: (Constant), NaOH_Molar, AlkaliContent, RAPcontent, BAcontent.
[b]. Dependent Variable: UCS.

Table 5: Results of the simultaneous F-test

ANOVA[a]					
	Sum of Squares	df	Mean Square	F	Sig.
Regression	117685016.92	4	29421254.230	52.183	<.001[b]
Residual	42849358.94	76	563807.355		
Total	160534375.86	80			

Note: [a]. Dependent Variable: UCS.
[b]. Predictors: (Constant), NaOH_Molar, AlkaliContent, RAPcontent, BAcontent.

From the output of this model, the B values in the unstandardized coefficients section, as shown in Table 6, provide the regression equation for predicting the UCS, presented in Eq. (1) as follows:

$$UCS = -15.65(RAP_content) - 130.40(BA_content) + 216.82(Alkaline_content) + 599.86(NaOH_Molar) - 3257.52 \quad (1)$$

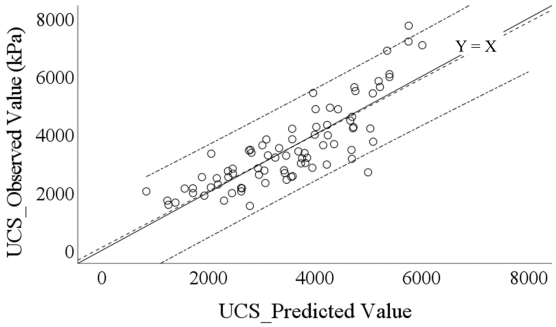

Fig. 3 Comparison of predicted and actual UCS

Path analysis

The prediction of UCS using multiple linear regression (MLR) explained 73.3% of the variance (R^2), but with a relatively high standard error (±750.871), indicating that UCS is influenced by more complex interactions than captured by direct effects alone. Given the importance of compaction in base layer materials, dry density was introduced as a mediator variable to account for indirect effects in a path analysis framework. Initial MLR analysis showed that the alkaline solution content had the lowest tolerance (0.569) and highest VIF (1.757), suggesting a relatively high correlation with other variables. Therefore, a path model was developed using BA content, RAP content, and NaOH concentration as independent variables, and alkaline solution content and dry density as mediators.

Path analysis confirmed that UCS is influenced by both direct and indirect effects of the independent variables through mediator variables. The final model (Fig. 4) best explains the variance in UCS and satisfies the model fit criteria from the IBM Amos Manual [14], with p = 0.427 (p > 0.05), CMIN/DF = 0.962, GFI = 0.985, and RMSEA = 0.000. This model accounts for 79.0% of the variance in UCS (R^2), providing a more accurate explanation than the MLR analysis. Some variables influence UCS directly, while others act through mediators, highlighting complex relationships, as follows:

1) The NaOH concentration (8–12 M) did not significantly affect the dry density (p = 0.443) or the optimum alkaline solution content (p = 0.895), as both p-values exceeded the 0.05 significance level.

2) The mediator variables—dry density and alkaline solution content—were influenced by BA and RAP contents. BA, with a low specific gravity (G_s = 2.15), significantly reduced material density as its content increased, with a regression weight of −0.78, consistent with previous findings [15].

Table 6: Results of partial t-test for the significance of each independent variable on the UCS of the materials

Coefficients [a]							
Independent variable	Unstandardized Coefficients		Standardized Coefficients	t	Sig.	Collinearity Statistics	
	B	Std. Error	Beta			Tolerance	VIF
(Constant)	-3257.517	617.003		-5.280	<0.001		
RAP_content	-15.651	2.182	-0.454	-7.173	<0.001	0.877	1.140
BA_content	-130.398	25.983	-0.378	-5.019	<0.001	0.619	1.617
Alkali_content	216.821	33.585	0.507	6.456	<0.001	0.569	1.757
NaOH_Molar	599.859	51.090	0.696	11.741	<0.001	1.000	1.000

Note: [a] Dependent Variable: UCS.

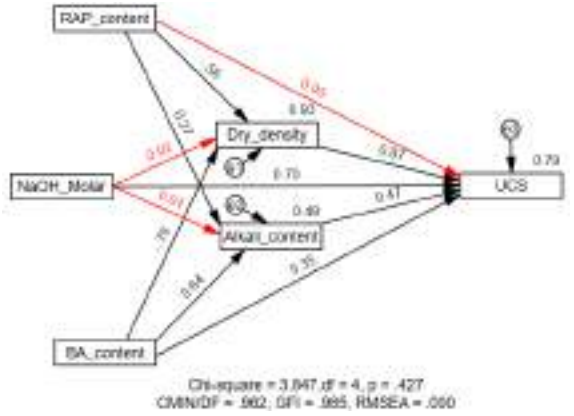

Fig. 4 Path analysis model

RAP, with G_s = 2.45, also reduced material density (regression weight = −0.56) compared to RCR (G_s = 2.63), due to its asphalt coating [16]. Moreover, BA content strongly increased the alkaline solution demand (regression weight = 0.64), attributed to its porous structure, which aligns with results showing increased moisture requirements in BA-soil [17].

3) Dry density had the strongest direct positive influence on UCS (regression weight = 0.87), suggesting that denser mixtures result in greater strength. NaOH concentration followed, with a direct effect of 0.70, due to its role in enhancing silica and alumina dissolution, thereby improving geopolymer gel formation and interparticle bonding [18, 19].

4) The alkaline solution content has a direct positive effect on UCS, with a regression weight of 0.47. This effect may arise from adequate liquid in the system, combined with the increased concentration of NaOH, both of which enhance the material's potential for geopolymerization reactions and effective development of compressive strength.

5) RAP content had no significant direct effect on UCS (p = 0.701). However, it indirectly affected UCS through two pathways: a negative influence via reduced dry density (regression weight = −0.56), resulting in an indirect effect size of −0.487 (−0.56 × 0.87), and a positive influence via increased alkaline solution content (regression weight = 0.27), giving an effect size of 0.127 (0.27 × 0.47). The total effect of RAP content on UCS was −0.360, confirming that higher RAP content tends to decrease compressive strength, as supported by previous studies [4–6, 20].

6) BA content had a direct positive effect on UCS (regression weight = 0.351) and an additional indirect positive effect through alkaline solution content (0.301; 0.64 × 0.47). However, the indirect negative effect through reduced dry density (−0.679; −0.78 × 0.87) slightly outweighed the positive effects. Thus, the net total effect of BA content on UCS was −0.027 (0.351 + 0.301 − 0.679), indicating that while moderate BA content (e.g., 5%) is beneficial, excessive BA reduces UCS due to its impact on compaction quality and density. These findings are consistent with [21], which reported peak strength at 5% BA in expansive soil mixtures.

CONCLUSION

Recycled aggregates from C&D waste (RCR and RAP) were stabilized using bagasse ash (BA)-based geopolymers with 5%, 10%, and 15% BA by weight. A 1:1 alkaline solution of NaOH and Na_2SiO_3 at concentrations of 8, 10, and 12 M was used, with compaction at optimum alkali content and ±3%. Most mixtures achieved UCS values exceeding the DH.-S. 203/2556 standard (UCS > 2,413 kPa), confirming their suitability for flexible road base applications under heavy traffic. This method reduces dependence on natural aggregates and cement stabilization.

MLR and path analysis clarified the influence of mix design variables on UCS, offering valuable guidance for optimizing BA-geopolymer-stabilized recycled aggregates. Key findings are as follows:

1) MLR analysis showed that all independent variables significantly influenced UCS, with NaOH concentration having the strongest positive effect, followed by alkaline solution content. The regression equation is presented in Eq. (1), with an R^2 of 0.733.

2) Path analysis showed that the independent variables affect UCS through both direct and indirect effects, mainly via dry density and alkaline solution content. It explained a greater proportion of variance (R^2 = 0.790) than MLR.

3) NaOH molarity and the alkaline liquid content improve UCS via geopolymerization, but excessive levels are not cost-effective. A 10 M NaOH solution in the NaOH–Na_2SiO_3 activator with compaction at OLC–3% is sufficient.

4) Dry density is a key factor in enhancing biomass ash geopolymer for road construction, with path analysis showing it has a greater impact on UCS than NaOH concentration.

5) Although BA improves compressive strength by contributing to geopolymer formation, excessive amounts reduce dry density and hinder strength. Therefore, 5% BA by weight is optimal.

6) The UCS decreases with higher RAP content; however, a 50:50 RAP:RCR ratio remains viable and supports waste management of both materials.

ABSTRACT

In the field of geotechnical engineering, there are various methods in pile construction. One of these is the pre-cast pile method, a type of embedded pile construction technique. This method involves injecting and mixing cement milk—a blend of cement and water—into the excavated gravel bed to form an enlarged grouted base. A pre-cast pile is then installed into this base to achieve proper anchorage. However, during the mixing and stirring processes involved in constructing the base, soil clods, or accumulation of soil particles, may inadvertently become incorporated into the cement milk. The formation of the base under such conditions may lead to a reduction in its strength. To address this concern, this study investigates the failure mechanisms and the degree of strength reduction caused by soil clods inclusion within the enlarged grouted base. Specimens with various rates of soil clods inclusion representing the enlarged grouted base were prepared, and laboratory load tests were conducted. The effects of failure modes and soil clods inclusion on the maximum bearing capacity and the ultimate bearing capacity of the enlarged grouted base were analyzed. The results revealed that tensile and compressive failures occurred at the bottom of the pile, creating a conical wedge within the enlarged grouted base below the pile tip, which subsequently penetrated the concrete. It was also observed that the inclusion of soil clods in the enlarged grouted base adversely affected both the pile's maximum and ultimate bearing capacities.

Keywords: Pre-cast pile method, End bearing capacity of pile, Unconfined compression test, Triaxial compression test, Failure mechanism

INTRODUCTION

In the field of geotechnical engineering, there are various methods in pile construction. One of which is the pre-cast pile method. This is a type of embedded pile construction technique that uses cement milk, a blend of cement and water, which is injected and mixed within the excavated bedrock to create an enlarged grouted base. A prefabricated pile is then installed into this zone to ensure proper anchorage. During the mixing and stirring processes involved in constructing the enlarged grouted base, soil clods may inadvertently become incorporated into the cement milk. These are lumps or accumulation of soil particles. If the enlarged grouted base is formed under such conditions, there is a risk of reduced strength in the enlarged grouted base.

Chen et al. conducted both theoretical and experimental analyses on the bearing capacity of cylindrical and prismatic concrete blocks under rigid punch loading. Applying upper- and lower-bound limit analysis within a perfect-plasticity framework, they demonstrated that the bearing capacity increases with block height and base friction, and that their theoretical predictions closely align with laboratory observations. These findings support the use of rigid-punch mechanics to interpret pile–grouted base interactions, offering a sound theoretical basis for understanding load transfer and failure mechanisms in enlarged grouted bases [1].

Previous studies have reported uniform or localized gravel inclusion in completed piles due to sedimentation effects [2]. Mixing tests show that greater gravel content reduces unconfined compressive strength [3], consistent with concrete studies reporting similar trends with aggregate size or content [4]. In terms of load-bearing characteristics, studies have investigated how the dimensions of the enlarged grouted base and the type and amount of inclusions influence initial stiffness and failure modes [5][6]. Kusakabe [7] reported that increasing the height of the enlarged grouted base improves load-bearing capacity and alters failure modes, based on results from triaxial compression and loading tests. Few studies have quantitatively addressed how clay, crushed stone, or sand inclusion affects bearing characteristics. In a study by Kuze [8], it was shown that the inclusion of clay and clay clods significantly reduces the initial stiffness of the enlarged grouted base.

Despite these findings, systematic investigations focusing specifically on the inclusion of cohesive soil clods remain limited, and a comprehensive understanding of their influence has yet to be established. Since the inclusion of such clods is often unavoidable in actual construction sites, clarifying their impact on the mechanical properties of the enlarged grouted base holds considerable practical significance.

To address this concern, this study investigates the

failure mechanisms and the degree of strength reduction in the enlarged grouted base caused by soil clods. Focusing on embedded piles constructed using the enlarged grouted base method, varying amounts of cohesive soil clods were examined focusing on compressive strength, load-bearing characteristics (including tip resistance and settlement behavior), and failure modes using various experimental procedures like unconfined compression tests, triaxial compression, and loading tests.

UNCONFINED COMPRESSION TEST

Experimental Setup

Fig. 1 provides an overview of the specimen configuration. Cement milk with a water–cement ratio of 0.6 was poured into a φ50 mm × H100 mm mold in four layers, and soil clods were incorporated during the pouring process. The specimens were then cured for one week. The soil clods were designed to simulate clay or mudstone, having a uniaxial compressive strength of 1.00 N/mm². Each clod was prepared with a volume of approximately 1 cm³, using a water–cement ratio of 0.6 and a cement-to-clay ratio of 2:8. These clods were cured for four days prior to incorporation to the specimens. Both the cement milk and soil clods were formulated to have the same specific gravity. Under these conditions, five types of specimens were prepared with soil clod inclusion rates of 0%, 5% (10 clods), 10% (20 clods), 15% (30 clods), and 20% (40 clods). The inclusion rate was calculated as the volume ratio of soil clods to the total volume of the cemented portion.

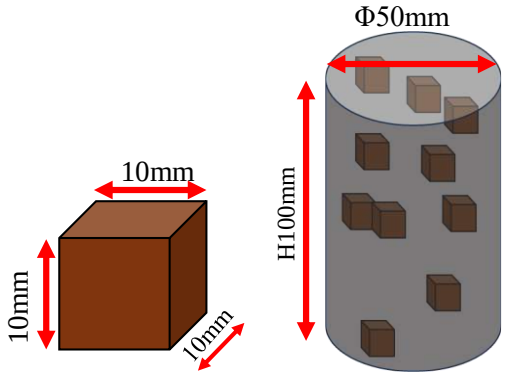

Fig. 1 Overview of a soil clods and specimen

An unconfined compression test was conducted to evaluate the strength of the enlarged grouted base in isolation, without considering earth pressure. An Autograph (Shimadzu corporation) universal testing machine was used with a loading speed of 0.1 mm/s and a maximum load capacity of 30 kN. Given the potential variability in specimen strength due to the positional distribution of the soil clods, six specimens were tested and labeled as Tests 1 to 6.

Experimental Results

After conducting the compression tests, the results obtained were compiled and shown in Fig. 2 This illustrates the relationship between the soil clod inclusion ratio and the maximum compressive stress. Due to variability in the results, the maximum and minimum values (excluding outliers) are shown as error bars, and the average values are plotted. The results indicate that the maximum compressive stress tends to decrease as the inclusion ratio of soil clods increases, suggesting a reduction in strength associated with the presence of clods. The results,

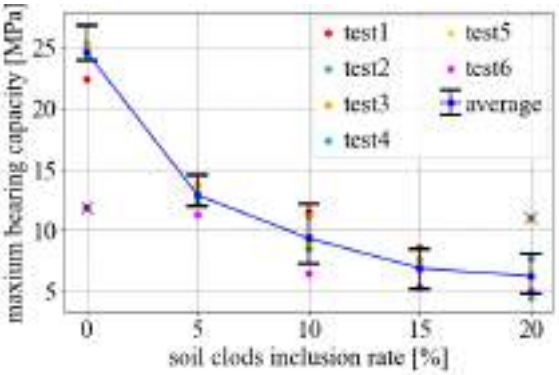

Fig.2 Relationship between maximum bearing capacity and soil clos inclusion rate

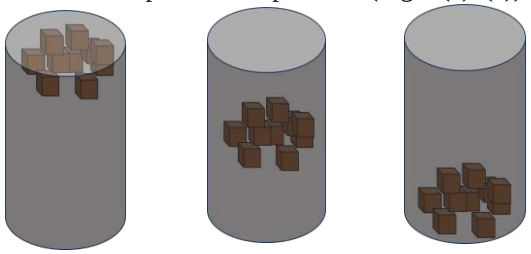
however, were associated with the assumption that the clods were uniformly distributed throughout the specimen. But this is not always the case in the real-world setting. Localized placement of soil clods may happen which may incur a different effect to the maximum bearing capacity.

Special Case: Localized Soil Clods Placement

To investigate how the inclusion rate and placement of soil clods affect the bearing capacity of the enlarged grouted base, additional testing was made. The cement and soil clod mix proportions and conditions were kept the same. In addition to the five types of specimens with varying soil clod inclusion rates, three additional patterns were prepared, in which the soil clods were concentrated in the upper, middle, or lower part of the specimen (Fig. 3(a)–(c)).



(a)upper part (b)center part (c)lower part

Fig.3 Overview of specimens

This created a localized, or a non-uniform placement of soil clods. Similar uniaxial compression tests were done and the relationship between the location of soil clods, the maximum compressive stress, and the soil clod inclusion ratio, along with the average values from the uniform distribution case, are compiled in Fig. 4 The soil clod inclusion ratio was calculated based on the volume ratio of soil clods to the cement-treated part excluding the pile in the specimen. Similar to the uniform case, the compressive strength tended to decrease with increasing inclusion of soil clods, even when they were unevenly distributed. It was also observed that the maximum compressive stress was lower when the clods were concentrated in the upper part of the specimen compared to the middle and lower parts. The average values for the middle and lower concentration cases fell within the range of the average values for the uniform distribution. Therefore, within the scope of this experiment, it was confirmed that uneven placement of soil clods did not have a significant effect on the maximum compressive stress.

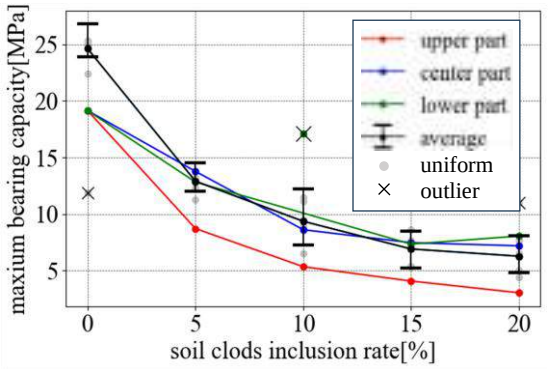


Fig.4 Relationship between soil clod inclusion rate, position and maximum bearing capacity

LOADING TEST OF AN ENLARGED BASE PILE UNDER CONFINING PRESSURE

To investigate the influence of soil clods inclusion under confining stress conditions, triaxial compression tests were performed. Specimens were fabricated by installing steel rods that resembled piles to simulate actual construction conditions. A schematic diagram of the specimen is shown in Fig. 5 The piles were made of S45CD round-cut steel rods with a diameter of 25 mm, which was half the diameter of the enlarged grouted base. The height was made to be 66 mm, equivalent to two-thirds of the root section height, in accordance with the tip-rooted pile method. To simulate the surrounding soil and concentrate surface-applied loads onto the pile, each pile was inserted into a 10 mm-high expanded polystyrene (EPS) mold with an outer diameter of 50 mm and a central hole of 25 mm. The pile was then placed inside a cylindrical mold (φ50 mm × H100 mm), and cement milk with a water–cement ratio of 0.6 was poured in four layers, incorporating soil clods in the process. The mix proportions of the cement milk and soil clods, as well as the specimen preparation procedure, were consistent with those used in the rooting experiment.

Five patterns were prepared with soil clod inclusion rates of 0%, 5% (7 clods), 10% (15 clods), 15% (22 clods), and 20% (30 clods). The inclusion rate was calculated as the volume ratio of soil clods to the cemented portion of the specimen, excluding the steel rod. After curing, the specimens were removed from the molds and positioned with the pile facing upward, as shown in Fig. 6

Triaxial compression tests were conducted on the specimens prepared as described above. These tests were designed to evaluate the strength of the enlarged grouted base embedded in soil, under the assumption that confining pressure from surrounding ground is present. Each specimen was enclosed in a rubber membrane and placed in a triaxial compression apparatus. Confining pressures of 100 kPa and 200 kPa were applied using compressed air. Loading was performed using the universal testing machine testing machine at a loading speed of 0.1 mm/s, with a maximum load capacity of 50 kN.

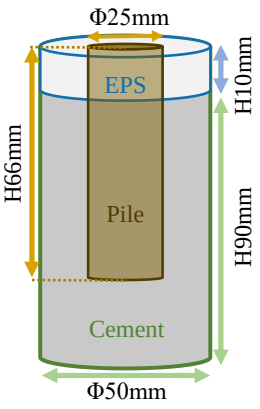

Fig.5 Overview of a specimen
Fig.6 Photo of a specimen

Loading Test Of An Enlarged Base Pile Under Confining Pressure Triaxial Compression Test Results

Fig. 7 shows a cross-section of the model pile after loading. The image reveals that failure occurred near the lower end of the pile. Upon removing the fractured section, a conical failure surface was observed at the bottom cemented part of the model pile, as shown in Fig. 8.

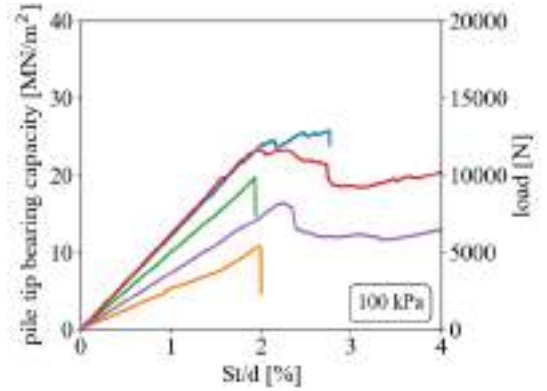
Although the precise sequence of failure is unclear, the lower end of the cemented portion appeared to have undergone punching failure due to concentrated stress. As deformation progressed, a wedge-shaped zone formed at the pile base, leading to horizontal expansion of the transition zone. Longitudinal cracks, transverse cracks caused by

relative displacement between the pile and the rooting section, and cracks due to lateral movement of the transition zone were observed on the side face of the rooting portion.

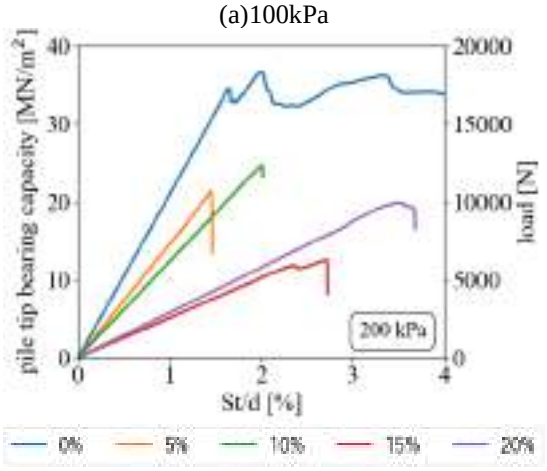
Fig.7 cross-section of the model pile after loading

Fig.8 the bottom cemented part of the model pile

Fig. 9 presents the relationship between the pile tip bearing capacity and the normalized settlement (St/d), where St is the settlement and d is the pile diameter. The pile tip bearing capacity was calculated by dividing the applied load by the cross-sectional area of the pile. After the onset of failure, stiffness tended to decrease as the maximum compressive stress decreased under each confining pressure. While



(a)100kPa



(b)200kPa

Fig.9 Relationship between the pile tip bearing capacity and the normalized settlement (St/d)

some variation was observed due to soil clod inclusion, the maximum compressive stress was highest in the 0% inclusion case, indicating that soil clods reduced the bearing capacity.

Fig. 10 shows the relationship between the maximum compressive stress and confining pressure for various soil clod inclusion rates. Each data point represents a result from a triaxial compression test, with average values indicated by a dotted line. The 0 kPa confining pressure corresponds to the results of the uniaxial compression test. It was observed that, for all levels of confining pressure, the bearing capacity tended to decrease as the soil clod inclusion rate increased. A comparison of the average values at each confining pressure confirmed that the maximum compressive stress was influenced by the confining pressure and increased in the 0% to 10% inclusion range.

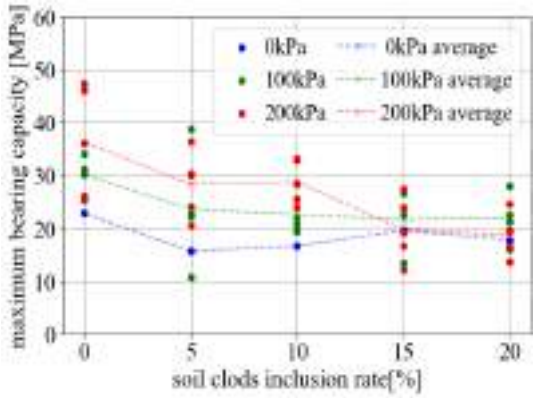


Fig.10 Relationship Between Soil Inclusion Rate, Maximum Bearing Capacity, and Confining Pressure

LOADING TEST OF AN ENLARGED BASE PILE

To investigate the effect of soil clods inclusion in the enlarged grouted base in sandy ground, gravity loading tests were conducted using a cylindrical soil tank. Silica sand No. 6 was used for the soil, with Dr=90% for the bearing layer and Dr=80% for the area above the specimen. After the air-drop method, the soil was compacted by vibration and tamping, and the relative density was controlled by measuring the thickness of the soil layer using a laser instrument. The pile diameter of the specimens was set to 25 mm, half the radius of the rooted portion, as in the tip-rooted pile method. The pile length was 416 mm, and H66 mm, which is two-thirds of the root-cast radius, was built into the cement. Three types of piles, (1) H66mm (used for the rooting portion), (2) H100mm x 2 piles, and (3) H50mm x 3 piles, were connected

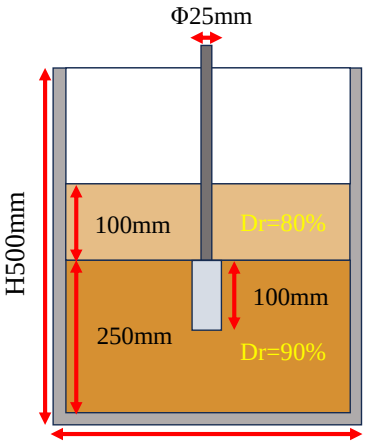

Fig.11 Schematic diagram of the model ground

by screws to achieve the set length. When preparing the specimens, (1) H66 mm piles were fixed to the bottom of a φ50 mm-H100 mm mold using double-sided tape, and then soil clods were mixed into the mold by pouring cement milk with a water-cement ratio of 0.6 into the mold in four separate batches. The conditions for the cement milk and soil mass and the procedure for preparing the specimens were the same as those used in the rooting experiment. The specimens were allowed to cure for one week, and after demolding, the piles (2) and (3) were connected to form the root-consolidation section. Under the conditions described above, three different specimens were prepared: 0%, 10% (15 clods), and 20% (30 clods). To give the specimens roughness and increase their adhesion to the ground, silica sand No. 6 was bonded to the sides of the specimens using epoxy resin. When the specimens were placed in the ground, the center position was set by placing a guard, and the specimens were fixed vertically with a leveler. The finished cross section of the soil model is shown in Fig. 11 The specimens were loaded and quantified using a loading tester (Shimadzu AutoGraph) at 0.09 mm/s.

Gravity Loading Test Results

Different failure mechanisms were observed with the specimens. Fig. 12 shows the specimen with a 0% soil inclusion rate after the loading test. It can be observed that failure occurred around the bottom end of the pile. This kind of failure is attributed to punching failure between the bottom of the pile and the bottom of the root-compacted zone, which caused horizontal tensile cracks on the sides of the root zone due to shear resistance generated by the punching failure. Fig. 13 shows the specimen with a 20% soil inclusion rate after the loading test. Unlike the 0% soil inclusion case, a conical active zone was formed

Fig.12 & 13. Failure mechanism of 0% and 20%

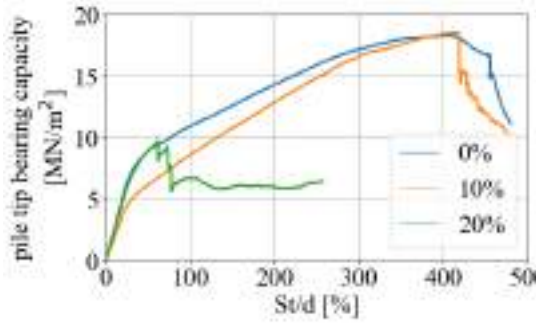

Fig.14 Relationship between pile tip bearing capacity and settlement

at the pile tip and penetrated through the pile. Although punching failure also occurred in this case, the compressive strength was lower than in the 0% soil inclusion case, resulting in a wedge-shaped slip line extending from the bottom end of the pile. The failure shape for the specimen with a 10% soil inclusion rate was similar to that of the 20% inclusion case.

The relationship between pile tip bearing capacity and the normalized settlement (St/d), where St represents the displacement and d is the pile diameter, is illustrated in Fig. 14. When comparing the maximum bearing capacity, the 0% and 10% soil inclusion rates yielded similar values, while the 20% soil inclusion rate produced a value approximately half of 0% and 10% cases. Similarly, the settlement values were comparable between the 0% and 10% inclusion rates. With this, it can be inferred that the increased amount of soil clods can lower the maximum bearing capacity of the pile.

In all cases, following the attainment of the maximum bearing capacity, the stress briefly recovered before failing again, resulting in a sharp decline. Looking at the 20% soil inclusion specimen, the initial drop in stress was attributed to punching failure around the pile, failure shown in Fig. 13. The subsequent drop may be caused by the bottom end of the pile penetrating through the soil. After the second decline, the bearing capacity stabilized, suggesting the formation of residual stress. These residual stresses were found to be approximately 60% of the maximum bearing capacity. Although this was not confirmed in the 0% and 10% soil inclusion cases, it may be possible that residual stress might have been generated with additional settlement. In the 0% and

10% inclusion cases, the maximum bearing capacity was experienced when St/d exceeded 400%. A settlement of four times the pile diameter is impractical in real-world scenarios. Therefore, a settlement ratio (St/d) of 10% is used as the practical reference. The bearing capacity at this 10% St/d ratio is referred to as the ultimate bearing capacity. Fig. 15 shows the range of normalized settlement for inclusion rates between 0% and 20%. Comparing the ultimate bearing capacity of each specimen, approximately 20% reduction in strength was observed between the best and worst performing specimen. Therefore, like the maximum bearing capacity, the presence of soil clods within the enlarged grouted base affects the ultimate bearing capacity.

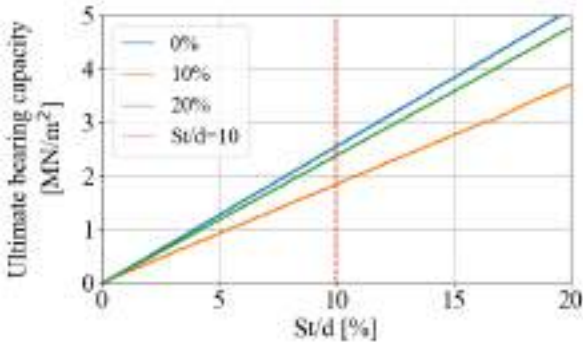

Fig.15 Comparing the ultimate bearing capacity

CONCLUSIONS

Various experimental investigations were conducted to evaluate the effect of the soil clods inclusion rate on the enlarged grouted base in the pre-cast pile method. The following findings were obtained from the results.

- The maximum compressive stress tended to decrease as the soil clods inclusion rate increased across all experiments, with a reduction to less than half observed at a 20% inclusion rate.
- In triaxial compression tests, the maximum compressive stress increased with confining pressure, confirming the influence of lateral constraint. Specifically, it rose by approximately 1.5 to 1.8 times as the confining pressure increased from 0 kPa to 200 kPa, within the inclusion range of 0% to 10%.
- The location of soil clods—whether concentrated or distributed—had little effect when placed in the lower or middle sections, but upper concentration resulted in approximately 1.5 times lower compressive strength.
- Failure typically initiated at the bottom end of the pile, where a conical wedge was formed and propagated upward under continued loading
- On average, the ultimate bearing capacity decreased by approximately 20% when soil clods were included. However, this reduction was relatively minor, suggesting that the effect of soil contamination on the ultimate capacity is limited under the tested conditions.

These results indicate that although the inclusion of soil clods leads to a reduction in compressive strength, its influence on the ultimate bearing capacity is not substantial. Future studies will include loading tests using centrifuge models in soil tanks to further investigate the influence of soil clods in more realistic ground conditions.

STUDY ON IMPACT FORCE OF GRANULAR FLOW ACTING ON RETAINING WALL

Makoto Kobayashi[1], Akinobu Ogasawara[1] , Naoto Naito[2] and Tatsuya Matsuda[2]

[1]Department of Civil Engineering, National Institute of Technology, Toyota College, Japan, [2]Toyohashi University of Technology, Japan

ABSTRACT

It has been pointed out that retaining walls, which protect against granular flow due to soil slips, are designed to be overly cautious. Centrifuge model tests are often carried out in research on slope failure. This is done by applying centrifugal acceleration to a model ground to match the stress level due to its own weight to that of a full-scale structure. Thus, although centrifugal model tests are useful as a method for observing the development process of large-scale phenomena. In this study, the objectives are to verify the feasibility of conducting highly reproducible granular flow tests under centrifugal conditions, and to perform DEM analysis based on these test results using a model that faithfully replicates the application of centrifugal acceleration, in order to validate its accuracy. In the experiment, alumina balls with particle sizes of 1 mm and 3 mm were used as soil particles, loadcells were installed on the retaining wall, and a soil slip test was carried out in a centrifugal acceleration field of 30G. The behavior of the soil particles during the experiment was photographed with a high-speed camera to verify the reproduction of the flow phenomenon. It was confirmed that the particles flowed at a speed of 4.75 m/s can be said that the soil slip phenomenon was reproduced. Furthermore, DEM analysis, which accounted for the Coriolis force, was able to successfully reproduce the experimental results.

Keywords: Granular Flow, Impact Force, Centrifuge Model Test, Discrete Element Method

INTRODUCTION

The slope failures triggered by heavy rainfall cause the loss of human life and serious threat infrastructure [1]. In addition, the impact forces acting on protective structures due to slope failures caused by earthquake has been studied [2,3].

In Japan, where mountainous regions account for approximately 70% of the national land area, it is crucial to understand the behavior of granular flows associated with slope failures. Research has been conducted on the effects of dry condition of granular flows, used as simplified models of granular flow, on rigid and flexible protective structures [4-7]. However, given that the local climate condition of Japan, it is rare for natural ground surfaces to remain dry. In fact, the mountainous areas are generally in a wet or saturated condition. Although some experiments on wet granular flows have been conducted [8], the number of previous research is relatively small compared to those on dry granular flows, especially in terms of evaluating impact forces. When assessing the impact forces acting on protective structures, it has been pointed out that the flow velocity of granular flows decreases significantly on flat terrain at the base of slopes. Therefore, when there is a clearance between the base of the slope and the protected structures such as roads or buildings, it is desirable to evaluate the impact forces by considering the velocity reduction effect within that clearance [9].

A predictive equation for the impact forces exerted by dry granular flows on rigid walls has been proposed, but the void ratio of the granular materials used in the numerical simulations that form the basis of the model is small [10]. From the standpoint of modeling high void ratio of granular materials flowing down steep slopes, further investigation is needed.

A series of study of centrifuge model tests measuring pressure distribution produced by dry granular flows on rigid walls, along with their Discrete Element Method (DEM), have been carried out [11-13]. These analyses simulated the behavior of individual particles under acceleration equivalent to Coriolis force. While this series of studies has provided significant insights into dry granular flows, it has also been reported that experimental results show considerable variability. On the other hand, in Japan, there are indications that the impact forces acting on retaining walls with a design are often overestimated in current practice [14].

In light of these issues, it is desirable to generalize findings based on systematic results from centrifuge model tests and to visualize the progression of phenomena through validated DEM simulations, with the aim of appropriately evaluating the impact forces acting on retaining walls and rationalizing the design and improving the maintenance of protective structures. Therefore, the present study aims to obtain knowledge useful for designing impact forces acting on retaining walls. This is achieved by reproducing granular flow phenomena using a centrifuge, focusing on highly reproducible experiments with minimized

variability, and confirming the validity of DEM analysis through comparison with experimental results under diverse flow conditions.

CENTRIFUGE MODEL TESTS

Cross section of a series of centrifuge model tests are illustrated in Fig.1. The acrylic board was placed at an angle of 45 degrees as slope which has flow distance of 190 mm in model scale. In order to reproduce the granular flow, alumina balls with a density of 3.26 g/cm^3 were used. To examine the effect of particle size, two particle sizes, diameter 1 mm and 3 mm, were employed. The sample, with a total weight of 242.2 g, was deposited in the same initial shape as shown in Fig.1, above a gate installed perpendicular to the slope. Fig.2 shows the arrangement of the load cells. To measure the impact force of granular flow model, the wall surface at the bottom of the slope model, regard as a retaining wall, was divided into three sections, with two load cells installed on each section in depth direction.

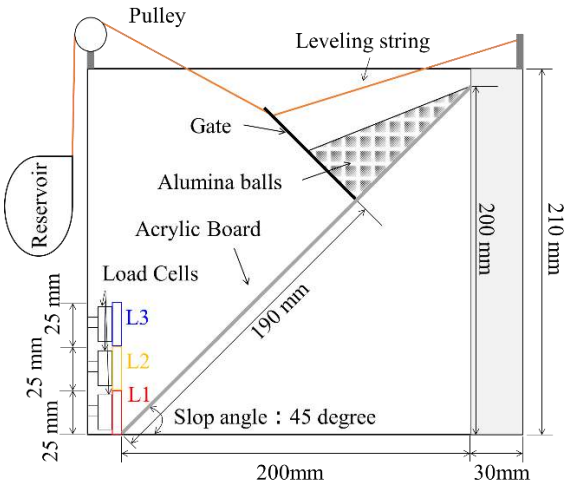

Fig.1 Cross section of the model tests

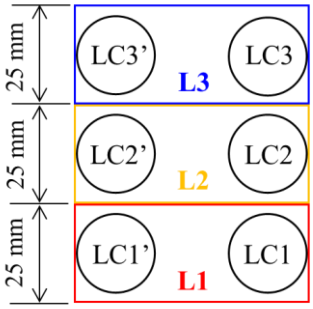

Fig.2 Arrangement of the load cells

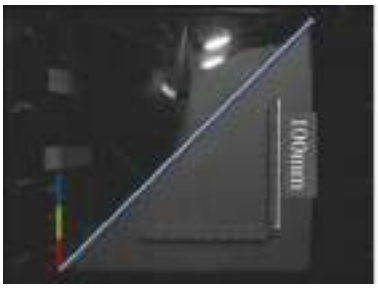
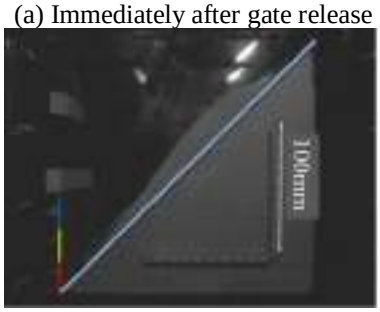
After applying a centrifugal acceleration 30 times greater than gravitational acceleration to the model ground, water is supplied to the reservoir from outside the centrifugal apparatus which opens the gate connected to a pulley, allowing the granular flow model to flow down. The granular flow phenomenon is recorded inside the centrifuge apparatus using a high-speed camera. The centrifuge model tests were conducted more than twice to confirm their reproducibility.

THE EFFECT OF PARTICLES SIZE OF GRANULAR FLOW ON IMPACT FORCE

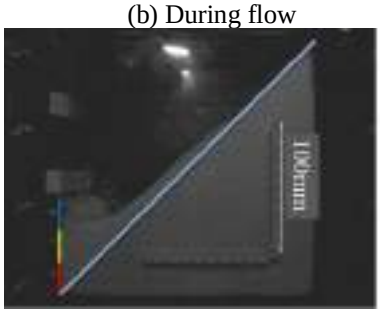
Fig. 3 shows images captured at three time points during the granular flow reproduced using 3 mm alumina balls: immediately after gate release, during flow, and immediately after collision with the retaining wall.



(a) Immediately after gate release



(b) During flow



(c) Immediately after collision with the retaining wall

Fig.3 Images captured by high-speed camera during the granular flow (3 mm alumina balls)

In all test cases, the time for the alumina balls front to flow, as observed in the high-speed camera images, is 0.04 seconds, indicating a flow velocity of 4.75 m/s. Since the general velocity range of granular flows is 2–20 m/s, it indicates that the centrifugal model test can be considered an effective means of

observing the development process of granular flow. Moreover, the Fig.3 reveals that the flowing material is not a uniform soil mass of constant thickness but rather consists of individual soil particles flowing independently. This can be regarded as a particularly distinctive result, because conventional designs for collapsing debris have been based on the assumption that the granular flows as a solid mass [14].

Fig.4 shows the temporal changes in the layer thickness of the granular flow at the midpoint of the slope model, located 95 mm from the gate, as determined from the images recorded by the high-speed camera. It is confirmed that the layer thickness increases with larger particle sizes. This is presumed to be because, as the particle size increases, the particles collide and rebound against each other, resulting in an increased apparent layer thickness.

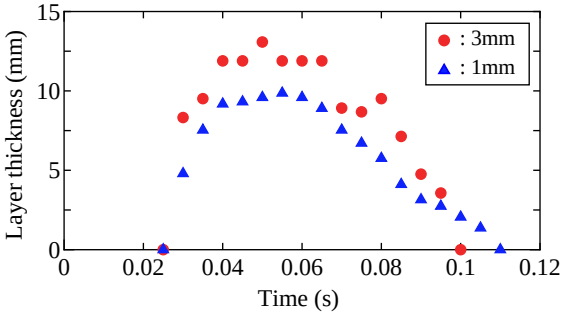


Fig.4 Temporal changes in the layer thickness of the granular flow.

Fig.5 and 6 shows the temporal changes of the impact force acting on the retaining wall. These results indicate that the impact force on the bottommost segment (L1) of the segmented retaining wall is the largest. Furthermore, comparing the two cases, it can be pointed out that the magnitude of the impact force acting on the retaining wall depends more on the weight of the flowing debris than on the particle size, as there is no significant difference in the impact force between the two cases. On the other hand, in the case of 3 mm particles, the peak impact force at the time of collision is slightly higher and exhibits fluctuations, which suggests that larger particles tend to rebound against each other more strongly. Subsequently, in both test cases, the impact force stabilizes at a constant value as the granular flow accumulates.

Based on the formula published by the Ministry of Land, Infrastructure, Transport and Tourism (MLIT) [14], the impact force acting on a retaining wall under the ground conditions used in this study was calculated as Fsm=144.4 kN/m². On the other hand, the maximum total impact force measured in the centrifuge model tests which divided by the area of the retaining wall is 23.5 kN/m². When compared, the experimental result is found to be one-sixth of the impact force obtained through calculation. This difference is considered to be due to the fact that, in the experiment, the collapsing sediment did not behave as a soil mass but rather as individual particles colliding with each other while flowing. In other words, even if the collapsing sediment has the same total weight, factors such as increased void leading to a lower density of the sediment mass, and the reduction in velocity due to particles rebounding off one another, are considered to have influenced the result.

DEM ANALYSIS CONDITIONS

In this study, DEM simulations were conducted using LIGGGHTS [15]. Spherical particles were used in the analysis. The contact interactions between particles were modeled using Hertzian contact theory and a rolling resistance model. When the main contact parameters such as Young's modulus, Poisson's ratio, friction coefficient, rolling friction coefficient, and restitution coefficient were defined, the remaining mechanical parameters were calculated based on elasticity theory. Previous studies have shown that Young's modulus has little effect on the flow behavior of granular materials [16]. Therefore, in this study, the friction and viscous parameters were determined based on rebound and dam-break tests,

following the approach of a previous study [17].

The particle size was set equal to 3 mm, which matches the alumina balls used in both the centrifuge and dam-break experiments as a model of soil particles. The Poisson's ratio was set to 0.24, a typical value for alumina, and the Young's modulus was set to 3×10^7 N/m². Based on the rebound test, the restitution coefficient between particles and acrylic was set to 0.7925. To reproduce the flow velocity distribution and final deposition shape observed in the dam-break experiment, the following parameters were used in the simulation: particle friction coefficient was set to 0.2, wall friction coefficient to 0.38, rolling friction coefficient to 0.2, and particle restitution coefficient to 0.4. Using the above simulation parameters, a particle assembly was generated, deposited, and trimmed, as shown in Fig. 7, to reproduce the initial conditions consistent with the experiment.

DEM ANALYSIS RESULTS OF THE CENTRIFUGE MODEL TEST

As the first case (Case01), an acceleration of 30G in the vertical direction and 1G in the longitudinal direction of the container was applied in the DEM analysis to simulate the same acceleration conditions as in the physical experiment. Gate movement was identified from sequential images taken during the experiment, and the simulation was adjusted to reproduce the observed gate behavior. Fig.8 shows the temporal changes in the layer thickness of the granular flow obtained from both the centrifuge model tests and the DEM analysis. In Case01, the simulated flow layer thickness was greater than that measured in the experiment under the same 30G vertical acceleration.

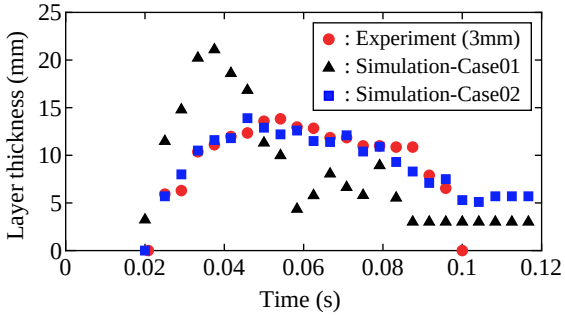

Fig.8 Temporal changes in the layer thickness of the granular flow from centrifuge model test and DEM simulation.

Based on this result, the simulation was further improved by rotating the container, as in the experiment. In Case02, the container was rotated with an effective radius of 0.55 meters at the center of the container, which created a vertical centrifugal acceleration of 30G. Therefore, the simulation conditions in Case02 completely matched those of the experiment. Figure 3 shows that in Case02, where the centrifugal acceleration was applied by rotating the container, the flow layer thickness matched the experimental result. The difference between Case01 and Case02 was the presence or absence of the Coriolis force. As shown in Figure 1, the rotation direction of the container generated a leftward Coriolis force relative to the velocity vector of the particles. This force acted in the slope-normal direction and pressed the particles downward. Therefore, the difference in flow layer thickness between Case01 and Case02 can be explained by the effect of the Coriolis force.

CONCLUSIONS

In this study, the impact force of granular flow acting on retaining walls were reproduced through centrifugal model tests and also verified the reproduction of the experimental results using DEM analysis. Following conclusions were obtained.

1) Centrifuge model tests with extremely simplified particle size, particle shape, and slope roughness were found to be a highly reproducible method for investigating the impact force acting on a retaining wall.

2) Since the impact force of the granular flow is exerted by individual soil particles flowing independently, it was suggested that the actual impact

force may be lower than the value calculated using the design formula.

3) The DEM analysis, which accounted for the Coriolis force, was able to successfully reproduce the experimental results.

ABSTRACT

Bentonite is considered as a buffer material between vitrified waste and bedrock in the geological disposal of high-level radioactive waste because of its high swelling and low permeability properties. Swelling pressure is one of the most important material properties for evaluating the self-sealing performance of buffer materials and is being investigated through swelling pressure tests. In a geological disposal facility, the bentonite buffer material is subjected to high temperatures due to the decay heat generated from the waste. At the same time, as groundwater infiltrates the buffer, its mechanical properties change due to swelling and deformation, gradually leading to saturation. Therefore, understanding the swelling characteristics of bentonite buffer materials under thermal effects is crucial for designing buffer material specifications. In this study, swelling pressure tests were on Na-bentonite and silica sand mixtures compacted to a dry density of 1.6 Mg/m^3 at different initial water contents and temperature, to establish a database and experimentally investigate how thermal effects influence the time-dependent changes in swelling pressure.

Keywords: Bentonite, Swelling Pressure, Temperature, Initial Water Content

INTRODUCTION

Geological disposal has been considered as a promising disposal method for long-lived radioactive waste, such as the high-level radioactive waste generated from the nuclear fuel cycle in 1950s Japan. To date, scientific and technological studies have investigated the safety and feasibility of geological disposal. The objective of geological disposal is to physically isolate a geological repository from the human environment. This is achieved by constructing a multi-barrier system, in which engineering measures (engineered barriers) are applied to enhance confinement within deep underground rock mass (natural barriers) that exhibit isolation properties [1].

While nuclear power plants are designed to operate for a period of about 40 years, geological disposal is required to ensure long-term safety for tens of thousands of years, considering the half-life of radio nuclides.

In geological disposal, bentonite is used as a buffer between the vitrified waste and the bedrock, because of high swelling and low permeability. The buffer material is expected to self-sealing barriers to water channels by swelling, provide stable support for the overpack, and relieve stress when the rock mass is subjected to creep, thereby ensuring and maintaining performance over the long term. Therefore, attempts have been made to understand various material properties, such as swelling pressure.

Swelling pressure of bentonite has been determined through swelling pressure tests [2-5].

The swelling behavior that occurs during the transition from the unsaturated to the saturated state is a coupled hydraulic and mechanical behavior that is extremely complex. In geological disposal, bentonite buffer material is in an unsaturated state when the engineered barrier is installed and is exposed to a high temperature environment due to radioactive decay heat from the waste body. At the same time, bentonite buffer absorbs water as it is infiltrated by groundwater from the surrounding area and gradually shifts to a saturated state while changing its mechanical properties. In this process, thermal, hydraulic, and mechanical factors interact with each other in the bentonite buffer material, a so-called coupled thermo-hydro-mechanical (THM) process. To evaluate the long-term mechanical performance of buffer materials, it is essential to understand their mechanical behavior, especially at high temperatures. Therefore, when bentonite is used as an engineered barrier, the effect of heat on the material properties must be considered in the evaluation.

In this study, swelling pressure tests were conducted on Na-bentonite and silica sand mixtures compacted to a dry density of 1.6 Mg/m^3 at different initial water contents and temperature. The purpose of this study was to construct a database based on the test results and to experimentally understand the

effects of each initial condition on the change in swelling pressure over time.

RESEARCH SIGNIFICANCE

Long-term evaluations of the mechanical performance of bentonite buffer materials are greatly affected by the mechanical state during transient periods of continuous high-temperature environments. Therefore, it is essential that the characteristics of coupled phenomena, including thermal effects, be properly considered in the design of engineered barriers using bentonite.

The results of this research will contribute to the expansion of the basic database for the specification and design of bentonite buffer materials and can also be used as reliable test data to verify the validity of numerical analysis, contributing to the development of rational performance evaluation methods.

MATERIALS AND METHODS

Materials

This study used KuniGel V-1, a sodium type bentonite from Tsukinuno Mine, Japan. The swelling properties of this bentonite have been widely studied. Table 1 shows the physical properties and chemical composition of KuniGel V-1. It is composed mainly of montmorillonite (about 55%), quartz, feldspar, calcite, and clinoptilolite. The cation exchange capacity is 80.0 (meq/100g), and the major exchange cautions are Na^+ (53.4 mmol/100g), Ca^{2+} (4.7 mmol /100g), Mg^{2+} (0.4 mmol/100g) and K^+ (0.4 mmol/100g). Soil particle density was measured by measuring the volume excluded by gas expansion using a Micromeritics helium pycnometer (Accu Pyc) to obtain the true volume.

The sample used bentonite mixed with Tohoku silica sand No. 8, mined from the Ōishida Mine, Japan. Mixing sand with bentonite enhances both thermal conductivity and compaction properties, making this mixed buffer material an important subject of investigation [1]. The soil particle density of the Tohoku silica sand was 2.702 Mg/m³.

Method for producing test material

All samples used in the swelling pressure tests were bentonite-silica sand mixtures with a bentonite content of 70%. The natural water content of the bentonite mixture was approximately 7%. To compare the change over time in swelling pressure at different initial water contents, this test was conducted twice at higher initial water contents of 12% and 17%. In adjusting the initial water content, water was added by misting ion-exchanged water. of the vessel to prevent water droplets from accumulating, and the water content of the sample gradually increased while alternating between kneading and water addition.

Specimen details for the swelling pressure tests are presented in Table 2. The water-adjusted cylindrical specimens used in the swelling pressure tests were prepared by static compaction with a dry density of 1.6 Mg/m^3, a diameter of 28 mm, and a height of 10 mm. To prepare a specimen, the sample was first placed in a metal mold with an inner diameter of 28 mm, and a stick was inserted into the mold. A piston was then lowered into the top of the

rod, and the specimen was compacted with a hydraulic jack so that its height was 10 mm. The compaction pressure was approximately 6 to 8 MPa, depending on the initial water content, and the pressurization holding time was 10 minutes. After unloading, the compaction rod was removed, and the specimens were placed in the mold for testing.

Test method

The main components of the swelling pressure test apparatus are the reaction frame, load cell, compressor, air cylinder, water tank, temperature control device, and thermocouple. Figure 1 shows a schematic diagram of the swelling pressure test apparatus. The load cell is connected to a data logger and PC, and data can be collected every second. The specimen was transferred to the pedestal of the testing machine one mold at a time, and the upper and lower pedestals were fixed with screws. Membrane filters and porous metal were inserted between the specimen and the pedestal as filter materials. To prevent swelling and deformation of the specimen during the test, the piston was lowered onto the top plate of the testing machine and vertical displacement was fixed with a clamp knob. The vertical load at this time was taken as the initial vertical load, which was approximately 0.08 MPa. The swelling pressure was then measured by supplying ion-exchanged water to the tank. Water was supplied only from the underside of the specimen to expel air from inside the specimen. Ion-exchanged water was used as the test water, and the test temperature was set at 30°C,60°C, and 90°C.

The water temperature was controlled to be ±1°C above the target temperature, and the temperature was measured using thermocouples. The water level was maintained at approximately 100 mm from the top of the specimen. The test period was about one week, when the swelling pressure of the bentonite was expected to reach equilibrium.

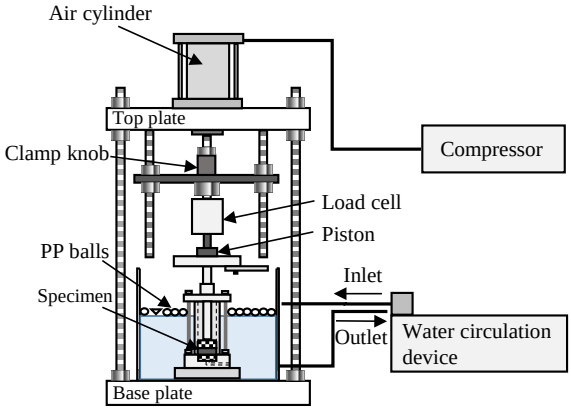

Fig.1 Schematic diagram of the swelling pressure test apparatus.

EXPERIMENTAL RESULTS

Figure 2 to Figure 10 shows the change over time of swelling pressure for each initial water contents and temperature. In this study, swelling pressure tests were conducted multiple times under each condition, which were categorized based on the initial water content as follows: 7% was defined as small, 12% as medium, and 17% as large.

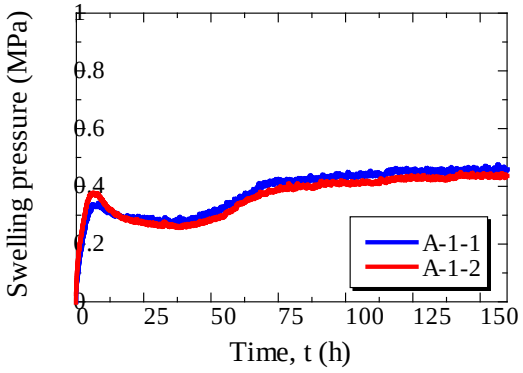

Fig.2 Time history of swelling pressure. (Initial water content: small, Temperature: 30°C)

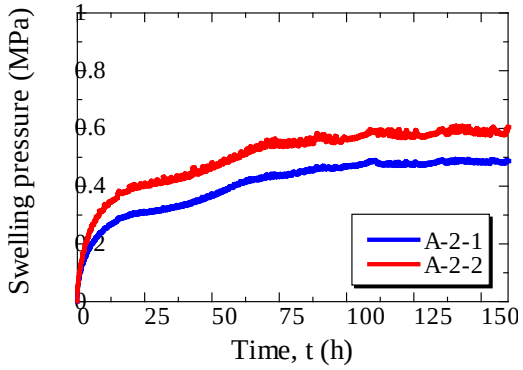

Fig.3 Time history of swelling pressure. (Initial water content: middle, Temperature: 30°C)

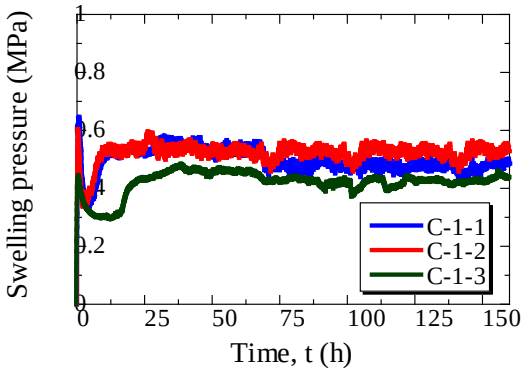

Fig.8 Time history of swelling pressure. (Initial water content: small, Temperature: 90℃)

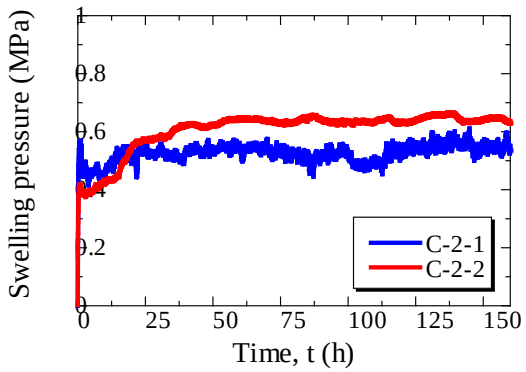

Fig.9 Time history of swelling pressure. (Initial water content: middle, Temperature: 90℃)

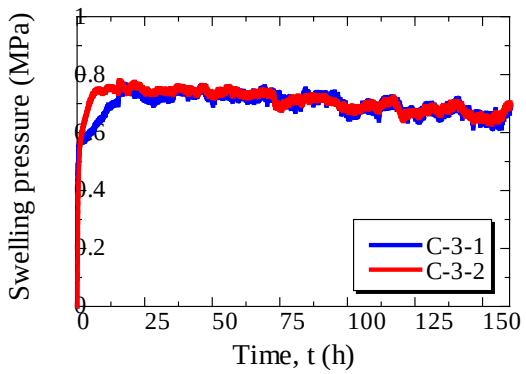

Fig.10 Time history of swelling pressure. (Initial water content: large, Temperature: 90℃)

Effect of initial water content on swelling pressure change over time

Figure 2 to Figure.4 shows the change over time of swelling pressure for each initial water content at 30°C. In the initial water content is relatively small, swelling pressure increased, then temporarily decreased and then increased again. On the other hand, as the initial water content increases, the swelling pressure did not decrease under the condition of low initial moisture content, and it increased relatively slowly. Furthermore, where the initial water content was large, the swelling pressure tended to increase monotonically, and the change over time in the swelling pressure differed depending on the initial water content.

A possible cause of the difference in swelling pressure with time depending on the initial water

content due to the presence or absence and wetting-induced collapse in the unsaturated region and its magnitude, which affected the swelling behavior. Since swelling pressure tests are conducted under volume-constrained conditions, swelling and compaction associated with water absorption are considered to occur continuously within the specimen [6]. Under conditions of initial water content is small, it is assumed that collapses occur due to increased water absorption, and the entire specimen tends to compress, resulting in a temporary decrease in swelling pressure. On the other hand, under the condition of initial water content is high, the effect of collapses is weak due to relatively low water absorption, and the swelling pressure is considered to increase monotonically.

Effect of temperature on swelling pressure change over time

Figure 5 to Figure 10 shows the change over time of swelling pressure for each initial water content at temperatures of 60°C and 90°C. In the initial water content is relatively small, the swelling pressure increased after the start of water supply, reached a peak, temporarily decreased, and then increased again to reach equilibrium for all temperature conditions. In particular, the initial swelling pressure peaked after the start of water supply tended to increase as the temperature increased. In addition, the time required for the swelling pressure to reach the equilibrium state tended to be shortened at higher temperatures. When the test temperature was 30°C, it took about 60 hours for the swelling pressure to increase again after the initial peak, while at 60°C it took about 24 hours and at 90°C it took about 10 hours. These trends were also observed at high initial water contents.

The increase in the initial swelling pressure peak is caused by the increase in osmotic pressure. Kanazawa [7] reported that the increase in maximum swelling pressure in a swelling pressure test that considered temperature history and temperature variation was due to the increase in osmotic pressure and the expansion of the diffusion electric double layer. In the swelling pressure test, ion-exchanged water was used and it is considered that the concentration difference between the montmorillonite interlayer and the external solution caused water to move into the interlayer, and the increase in temperature accelerated this movement, resulting in the increase in the initial peak. In addition, Towhata [8] investigated the effects of elevated temperature on the volume-change behavior of clays. They reported that, in swelling clays with low permeability, thermal expansion of pore water results in an instantaneous increase in sample volume. In this study, specimens with high initial water content exhibited pore spaces saturated with considerable amounts of pore water. As a result, the thermal expansion of pore water with increasing temperature may have contributed to the increase in initial swelling pressure.

On the other hand, the shortening of the time required to reach equilibrium is caused by the increase in hydraulic conductivity due to the rise in temperature. Matsumoto [9] conducted hydraulic permeability tests on bentonite with temperature as a parameter and reported that at 60°C and 90°C, the hydraulic conductivity increased approximately 2 to 3 times compared to that at room temperature, which they attributed to temperature changes in the density and viscosity of water. In this test, the viscosity of the water decreased as the temperature increased, and the permeability of the bentonite increased, which is thought to have shortened the time required to reach equilibrium. In addition, the time required to reach equilibrium was significantly shorter at 90 °C, suggesting that, in addition to the improvement in permeability, the effect of osmotic pressure may have facilitated water movement between the layers.

Effect of temperature on equilibrium swelling pressure

Under all test conditions, the equilibrium swelling pressure tended to increase with increasing temperature. Specifically, it increased by approximately 0.05 to 0.1 MPa as the temperature rose. However, the equilibrium swelling pressures at 60°C and 90°C were nearly the same, suggesting that the effect of temperature on equilibrium swelling pressure is relatively small when the effective clay density is approximately 1.36 Mg/m³.

Previous studies have pointed out the following four main factors in the effect of temperature on equilibrium swelling pressure [10]. 1) change in the state of adsorbed water in the interlayer, 2) expansion of the diffused electric double layer, 3) volume expansion of free water, and 4) thermal expansion of mineral particles.

Montmorillonite, the primary constituent of bentonite, swells by absorbing water into its interlayer spaces upon water infiltration. As the montmorillonite swells, it begins to fill the pore spaces within the material, and under saturated conditions, these pores become almost entirely occupied. Consequently, in the saturated state, the influence of temperature changes on the volume expansion of free water in the pores and on the behavior of interlayer-adsorbed water is minimal. The observed increase in equilibrium swelling pressure with rising temperature can be attributed to the expansion of the diffuse electric double layer and the thermal expansion of the mineral particles.

The surface of clay minerals carries either a positive or negative charge, attracting oppositely charged ions and forming an electric double layer around the particles. The thickness of this electric

double layer increases with rising absolute temperature, and when the double layers of adjacent particles overlap, repulsive forces are generated. In the present study, the electric double layer was observed to expand with increasing temperature, leading to an increase in repulsive forces and, consequently, an increase in the equilibrium swelling pressure. However, the increase in the thickness of the electric double layer at 90°C was only about 1.1 times greater than that at 30°C. Therefore, although the effect of enhanced repulsion was evident, it is presumed to have been limited.

In addition, Shimizu [11] conducted consolidation tests on both swollen and unswollen clays under varying temperature conditions and determined the thermal expansion coefficient of each sample based on the relationship between temperature and soil particle density. The results indicated that the thermal expansion coefficient of montmorillonite, a major component of bentonite, is higher than that of other minerals due to the weak bonding between its crystal particles. During the temporal evolution of swelling pressure, swelling and compression induced by water absorption occur continuously within the specimen. In this process, the thermal expansion of mineral particles caused by the rise in temperature is believed to contribute to compression, thereby resulting in an increase in swelling pressure.

CONCLUSION

In this study, swelling pressure tests were conducted, considering initial water contents and temperature, to experimentally understand the effect of each initial condition on the change in swelling pressure over time. The following is a summary of the findings.

(1) No clear dependence of the temporal evolution of swelling pressure on the initial water content was observed. Although the overall trend of swelling behavior remained largely unaffected by temperature variations, an increase in temperature led to higher permeability and a reduction in the time required to reach equilibrium swelling pressure.

(2) Under conditions of low effective clay density, it was confirmed that changes in temperature have a significant effect on the initial swelling pressure peak. Furthermore, the combined effects of osmotic pressure, increased repulsion due to the expansion of the diffuse electric double layer, and thermal expansion of the mineral affect the change in swelling pressure over time and the equilibrium swelling pressure.

EFFECT OF LONG-TIME SEEPAGE ON MULTI-LAYERED GROUND

Yixuan Li [1], Yamato Kadoi [2] and Mari Sato [3]

[1]Faculty of Life and Environmental Science, Shimane University, Japan; [2] Japan Conservation Engineers & Co., Ltd., Japan; [3] Academic Assembly, Shimane University, Japan

ABSTRACT

We investigated the effects of long-term seepage behavior and internal erosion on the stability of simulated ground comprising multiple soil layers with different hydraulic conductivities, such as a reservoir or river embankment. Special focus was placed on the movement of soil particles due to seepage flow and the resulting changes in the soil interior. A two-layer experimental soil model with high-permeability in the lower part and fine-grained sand in the upper part was constructed. Water was supplied to the lower soil layer from the walls for an extended period and drainage was facilitated through a slit at the center of the bottom surface. During water supply, the upper surface gradually expanded, albeit to a small extent. After the water supply was completed, the ground contracted and grain size tests showed that the specific range of fine grains decreased at the left and right edges near the upper soil layer boundaries, whereas the same range of fine grains increased at the center. These results indicate that long-term infiltration into multiple layers of ground with varying permeabilities may result in the gradual movement of fine-grained sediment within the ground. The small amount of sediment movement in this experiment did not directly affect soil strength. However, the risk of disasters such as boiling may increase owing to the accumulation of sediment that cannot escape from the coarse-grained sediment and the local decrease in permeability. Future studies are required to determine whether similar phenomena can be observed in actual levees.

Keywords: Boiling, Grain size distribution, Internal erosion, Ground deformation

INTRODUCTION

Internal erosion phenomena within the ground can cause various disasters in the earth's structures [1,2].

In river embankments, piping becomes a significant issue when infiltration occurs in the underlying permeable layers at high water levels, particularly in ground conditions where a surface layer of fine-grained soil is present [3].

This study aims to clarify the effects of internal erosion caused by repeated daily infiltrations into the underlying permeable layers prior to any damage. Model experiments were conducted to investigate behavior during infiltration as well as the strength reduction and changes in particle size distribution after infiltration.

Previous research [4] has pointed out the possibility of local changes in fine particle content due to sediment movement within the ground and an increased risk of boiling. However, in this study, the coarse-grained soil layer was replaced with a sample of even larger particles to reproduce the conditions that facilitate sediment movement.

Specifically, during water supply, sensors installed within the ground were used to continuously measure changes in the volumetric water content, surface displacement of the ground, and inflow and outflow volumes. After the water supply ended, changes in the particle size distribution and the presence of density reduction were examined.

This study aimed to elucidate the factors that promote boiling and piping during heavy rainfall events and contribute to the safety management of embankment structures.

RESEARCH SIGNIFICANCE

In this study, a model-scale experiment was conducted. This revealed that the soil particle migration and change in the local grain size distribution by the long-term seepage in the surface layer consisted of fine sand above a highly permeable layer. The influence of soil migration on permeability and ground looseness was estimated. A slight expansion during penetration may facilitate soil transportation. Long-term seepage increases the risk for generation of localized clogging and high-permeability zones near the boundary between the two layers.

EXPERIMENTAL METHOD

For the model ground preparation, a box-shaped acrylic soil chamber with a width of 30 cm, depth of 10 cm, and height of 40 cm (Fig.1) was used. Silica sand No.1 was compacted into the lower layer and silica sand No.7 was compacted into the upper layer, each to a height of 15 cm, resulting in a total ground height of 30 cm. The actual height of each layer was measured after the preparation, as shown in Fig.1.

To observe deformation in the silica sand No.7 layer, the colored sand was thinly layered on the front side of each compaction layer (at approximately 4 cm intervals). The filter rule D_{15}/d_{85} between silica

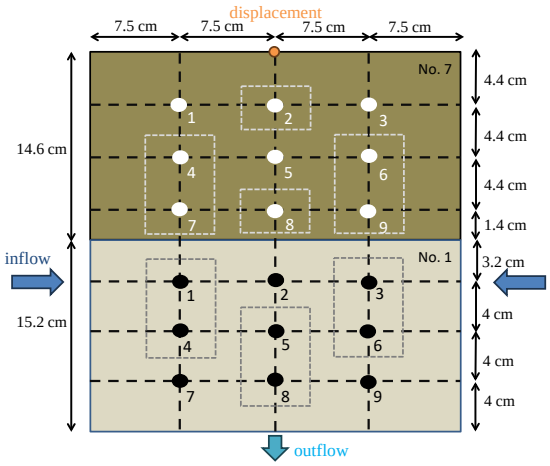

Fig.1 Schematically figure of the model ground

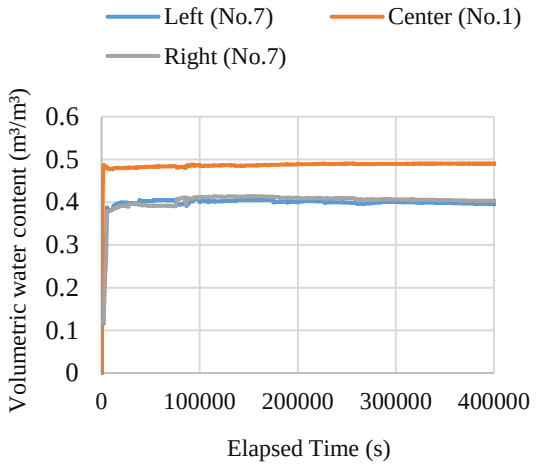

Fig.2 Change in volumetric water content (overall)

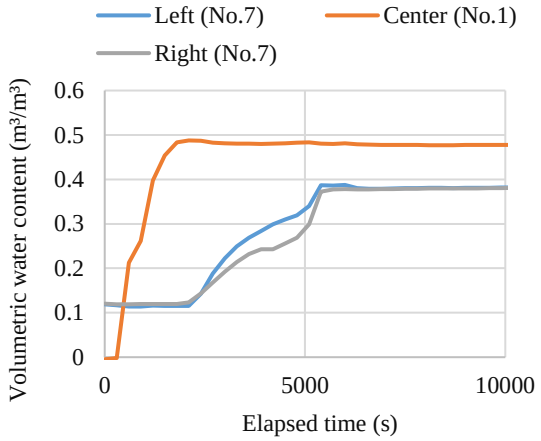

Fig.3 Change in volumetric water content (detailed)

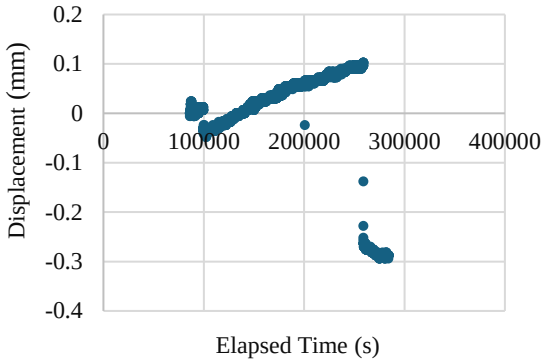

Fig.4 Variation in surface displacement

sand No. 1 and No. 7 was approximately 12.5. The initial water content during compaction was adjusted to 4% for silica sand No.1 and 10% for silica sand No.7. The relative density was set to 40% for silica sand No.1 and 60% for silica sand No.7.

Water was supplied from the same height as the top of the silica sand No.7 layer by overflowing a funnel connected to the tubing. The water entered the upper part of the silica sand No.1 layer through 12 cm-high and 8 mm-diameter holes located on both sidewalls of the soil chamber. Drainage was conducted through a 5 mm-wide slit filled with sponge at the center of the bottom of the tank. The sponge prevents soil particles from escaping and restricts water outflow. Consequently, several hours after the water supply was started, the surface of silica sand No.7 became visibly saturated.

Water supply was continued for 72 h (3 days). During this time, soil moisture sensors were used to measure the volumetric water content inside the model ground. The sensors were installed at three locations: one at a height of 12 cm from the bottom in the center (within the silica sand No.1 layer), and two at a height of 23 cm from the bottom and 7.5 cm from each side edge (within the silica sand No.7 layer). Measurements were taken at 5-minute intervals.

A flow meter was attached near the water inlet of the right-side tube to measure the inflow rate (mL/min) during water supply. A laser displacement meter was installed at the top center of the soil chamber to measure the vertical displacement of the surface layer. These meters were measured at 30-second intervals. In addition, the outflow volume was measured eight times over three days at several-hour intervals, each over a 10-minute period.

After the water supply was completed, the model ground was left undisturbed for several days. The front cover of the soil chamber was then removed, and the chamber was placed face up. Soil hardness was measured at nine points in the silica sand No.1 layer and six points in the silica sand No.7 layer using a Yamanaka-type soil penetrometer. From around one or two of the measurement points, samples were collected for grain size distribution tests: three from silica sand No.1 layer and four from silica sand No.7 layer. Fig.1 shows the measurement and sampling points for the soil hardness and grain size analyses.

EXPERIMENTAL RESULTS

From Water Supply to Pre-Drainage Completion

Observations during water supply are described in terms of the elapsed time since the start of supply and daily progress from day 1 to day 3 of supply.

Approximately two hours after the start of the water supply on day 1, the water level rise was less than expected. An additional sponge was inserted to adjust the drainage conditions. Around this time, both inflow and outflow rates began to decrease and remained nearly constant thereafter, with only minor fluctuations. The initial changes in flow may have been influenced by the added sponge. In particular, for outflow measurements, leakage from the soil chamber was observed. Therefore, quantitative evaluation based on inflow and outflow values remains a topic for future improvement. After the sponge was added, the ground surface became visibly saturated, and silica sand No.7 layer was confirmed to contain water. No distinct deformation of color sand was observed during the water supply.

Fig.2 and Fig.3 show the changes in volumetric water content during water supply. As shown in the graph, the sensor installed in the central part of the silica sand No.1 layer recorded an increase in volumetric water content until approximately 1,800 seconds from the start of the water supply on day 1, after which it remained nearly constant. The sensors installed in the left and right sections of the silica sand No.7 layer showed a continued increase in water content until approximately 5,400 seconds after the end of increase in that in Silica sand No. 1, after which the values stabilized with no significant fluctuations. No noticeable differences were observed between the left and right measurements, indicating that the water level increased uniformly.

During drainage, unlike the findings of a previous study [4], the volumetric water content in silica sand No.1 layer showed only a slight decrease. This may be due to insufficient drainage resulting from the increased amount of sponge. Therefore, the post-infiltration drainage conditions observed in previous experiments could not be reproduced in this study.

Fig.4 shows the results of vertical displacement measurements at the central surface of the model. Owing to the malfunction of the displacement sensor,

0.85	0.02	0.00	0.00	0.00
0.43	0.00	0.00	0.00	0.00

no data were collected for the first 24 hours (from 0 to 86,371 seconds on day 1), and this period was excluded from the analysis. The value was set to zero at the resumption of measurement on day 2. After 100,000 seconds from the start of water supply, the ground gradually exhibited expansion, followed by a sudden contraction of approximately 0.4 mm at approximately 259,231 seconds on day 3, indicating the end of the water supply period. Following the rapid contraction, almost no further volumetric changes were observed.

Post-Drainage Observations

The results of the soil hardness measurements are listed in Table 1. Data from measurement points 1 to 3 in the silica sand No.7 layer were missing because, upon tilting the soil chamber onto its back, the high moisture content caused a collapse due to self-weight before measurements could be conducted. No significant differences in the bearing strength were observed among the various measurement locations. In the silica sand No.1 layer, owing to the large particle size, substantial variation was observed in the measured values, depending on how the penetrometer tip contacted the individual particles. Because the results were not suitable for evaluating looseness, they were omitted from the analysis.

The results of the particle size distribution tests for silica sand No. 7 and silica sand No.1 are shown in Fig.5 and 6, respectively. In the legends, "Original" refers to the original gradation determined separately prior to infiltration. The values in parentheses indicate the sampling locations around the measurement points shown in Fig. 1, following the completion of infiltration. The lower part of Fig.5 shows a magnified view of the portions showing large difference among original and other cases within the overall range depicted in the upper part.

For the central sampling locations (2) and (8) in the silica sand No.7 layer, the mass-passing ratio in the 0.055–0.075 mm particle size range increased compared to the pre-experiment sample. Conversely, the mass-passing ratio decreased at the lateral sampling locations (4, 7) and (6, 9). Around the 0.106 mm particle size, the mass-passing ratio increased at all locations relative to the original gradation. In the silica sand No.1 layer, no significant differences were observed in the mass-passing ratio across all sampling locations before and after infiltration.

DISCUSSION

The slight expansion observed during the water supply phase was most likely due to a decrease in the effective stress caused by the infiltration pressure from the water inflow of silica sand No.1 into silica sand No.7. Therefore, it is presumed that the expansion ceased immediately after the water supply ceased. However, because the extent of expansion from the beginning of the experiment was not measured, the movement of fine particles may have also contributed to this behavior. Although the impact of such an expansion on the ground remains unclear, it may increase the likelihood of fine particle migration during infiltration. As described later, localized changes in permeability due to particle size distribution variations may have occurred within the soil. However, no significant changes were observed in the measured inflow or outflow rates during the infiltration test, suggesting that the overall permeability was not significantly affected.

Regarding localized permeability changes, the permeability of the silica sand No.7 layer was estimated at each sampling location based on the 20% particle diameter using the Creager formula. Compared to the original gradation, the permeability at locations (2) and (8) was estimated to be approximately 0.6 times lower, indicating a localized permeability reduction owing to clogging near the interface, consistent with previous studies [4,5]. Even at location (2), which is closer to the surface than location (8), a decrease in the permeability was observed. In contrast, the permeability at location (4,7) and (6,9) was estimated to be approximately 1.3 and 1.4 times higher, respectively. Migration of soil particles induced both concentration and clogging.

In an infiltration flow analysis study using a similar two-layer soil configuration [5], it was shown that water infiltrated through silica sand No.1 layer into silica sand No.7 layer, and downward infiltration occurred near two-layers' interface above the drainage outlet, allowing infiltration back into silica sand No.1. According to Kenny and Lau [6], in narrowly graded (NG) materials such as silica sand No.7, particles with diameters below 20% are considered fines and are capable of movement within the pores. This aligns with the present experimental results, where particles approximately 0.05 mm, corresponding to 20% of the diameter of the original material, increased at central locations (2) and (8),

while decreasing at lateral positions (4, 7) and (6, 9).

The negligible difference in the particle size distribution below 0.025 mm suggests that the fine particles mobilized by the infiltration flow passed directly through the interface and were discharged into the silica sand No.1 layer. However, particles approximately 0.05 mm may have been unable to pass through the pores of the silica sand No.1, leading to deposition. At location (2), even particles approximately 0.04 mm showed an increased proportion. Because this location is farther from the boundary interface than in (8), it is possible that fewer fines were discharged, and the migrated particles remained within the ground. The mechanism by which the 0.05 mm particles fail to outflow into the silica sand No.1 layer warrants further investigation in conjunction with existing research findings.

CONCLUSIONS

In this study, a model experiment was conducted to investigate the effects of infiltration behavior and erosion phenomena in cases where a highly permeable layer existed beneath a surface layer composed of fine sand. The volumetric water content results confirmed that water infiltrated from the lower soil layer into the upper layer and reached near-surface saturation. In addition, upward infiltration combined with drainage from the slits induced soil particle movement in the upper layer, suggesting that the resultant water pressure during infiltration may have caused ground expansion and potential loosening.

These findings imply that, in long-term scenarios following embankment construction, internal erosion near the highly permeable layer should be considered a possible risk. However, no apparent loosening owing to particle movement was observed in terms of soil hardness. As for the particle size distribution, both similarities and differences were found in comparison with a previous study [4]. An increase in the mass fraction at approximately 0.106 mm particle size was observed, as in the previous study; however, because this size does not correspond to finer components within silica sand No.7, the possibility of erosion at the layer interface cannot be ruled out and warrants further investigation.

Fine-particle migration, which significantly changes the particle diameter by 20 %, is likely to affect permeability. The observed local decrease in permeability owing to clogging is consistent with previous findings and suggests a heightened risk of piping. Furthermore, the range of particle sizes capable of migration is within the ground-matched predictions based on prior knowledge. Among the fine particles that moved with the infiltration flow, the finer fractions likely escaped through the interface between the two layers, whereas slightly larger particles may have accumulated at the interface, leading to clogging.

The above phenomena were confirmed through model experiments. Therefore, in the future, it will be necessary to clarify the conditions under which similar phenomena occur in actual embankments and with real embankment materials, as well as their effects on the embankment, with reference to previous studies [4]. In actual embankments, there are long-term water level fluctuations, and the thickness of each geological layer at the bottom of the embankment may vary locally. Hence, there is a possibility that areas prone to phenomena similar to those observed in the model experiments exist. Furthermore, in real embankments, such phenomena may progress over a longer time scale than in the model experiments, making it necessary to consider cases in which sediment transport advances further than observed in the experiments.

POROSITY ASSESSMENT IN ONE-DIMENSIONAL PERMEATION GROUTING USING SUSPENSION-TYPE GROUT SOLUTION

Jemy C. Chua[1], Naoaki Suemasa[2], Takamitsu Sasaki[3] and Koichi Nagao[4]

ABSTRACT

Soil liquefaction, triggered by seismic activity, destabilizes loose and saturated ground leading to extensive damage. This research explores the application of permeation grouting as a mitigation technique for liquefaction. Grouting is a ground improvement technique that involves injecting grout solutions at low pressures into soil pores to enhance its properties. To promote sustainability, alternative materials to conventional cement-based grouts were proposed and demonstrated to be viable. Suspension-type grouts densify and solidify the ground, offering higher performance compared to solution-type grouts. However, a limitation of suspension-type grouts is the occurrence of clogging. As permeation progresses, porosity of the soil reduces, along with the performance of grouting. To evaluate the flow behavior and interaction of the grout to the soil, one-dimensional permeation tests using varying grout concentrations were conducted. The relationship between permeation pressure, permeation volume, and porosity of the soil were analyzed. Results demonstrated that densification happens as permeation volume and pressure increases. While beneficial for increasing liquefaction resistance, immediate densification impedes further grout permeation, reducing the improvement radius. Therefore, porosity assessment is critical in balancing densification and permeation volume. Numerical estimation using Kozeny-Carman equation was found to be feasible, with porosity estimations approaching the actual experimental results.

Keywords: Soil liquefaction, Permeation grouting, Suspension-type grout, Porosity assessment, Kozeny-Carman equation

INTRODUCTION

Amidst the continuous growth of cities and infrastructures, the field of geotechnical engineering becomes increasingly important as this serves as the foundation of every structure. Despite its apparent stability, the ground is composed of plates that are constantly in motion. When these plates collide, the immense force generated can lead to a sudden release of energy, resulting in an earthquake. The recent 2024 Noto Peninsula earthquake in Japan caused severe casualties and incurred several geotechnical-related disasters like slope failure and soil liquefaction.

Soil strength relies on intergranular contact forces (total stress). However, pore water pressure reduces this strength. Ground movement causes temporary excess pore water pressure, and when this equals or exceeds total stress, the soil liquefies, losing its load-bearing capacity. This liquefaction leads to significant ground consolidation, damaging infrastructure and impacting community safety and economic stability by blocking transportation.

Permeation grouting is one of many ground improvement methods that helps mitigate the risk of liquefaction. Grouting offers several advantages, like its simplicity, compact procedure, and minimal disturbance to the soil during improvement [1]. This makes it suitable for remediating existing foundations or to soil that cannot tolerate disturbance [2][3]. Grouting works by permeating a grout solution into the ground at low pressures. The solution consists of materials designed to improve the physical properties of the soil by means of densification and/or solidification. There are two types of solutions that are commonly used, solution-type and suspension-type. Compared to solution-type which uses liquid chemicals, suspension-type is a type of grout made with fine particles suspended in water. These particles are commonly composed of cement or pozzolans that solidify when activated, improving the properties of the soil its injected into. Suspension-type grouts offer higher versatility and generally develop greater strength due to particle densification, but estimating the quantity and area of improvement can be difficult, and particle clogging is a critical factor affecting performance [4].

Scope and Objective

Grouting is a three-dimensional ground improvement technique. As a first step for analyzing the permeation performance, one-dimensional permeation tests were conducted and analyzed. For the experiments, only one type of soil was used for all samples and were all in fully saturated condition prior to permeation. The study aims to assess the porosity changes of the soil throughout the permeation process using both experimental data and numerical analysis.

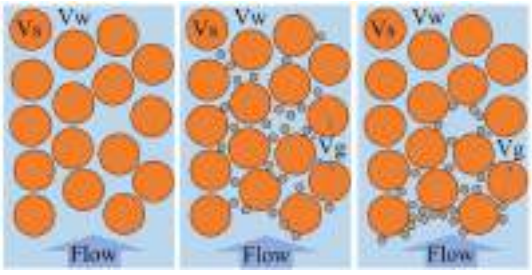
RESEARCH SIGNIFICANCE

Permeation grouting using suspension-type grouts has recently gained attention for its versatility and exceptional performance. However, the relationship between the grout material to its performance in grouting is not well backed. This study aims to establish a connection or understanding of the relationship between permeation pressure and changes in soil porosity based on both experimental and numerical modeling results. By doing so, prediction of grout performance concerning other types of material or soil may be plausible.

CLOGGING MECHANISM

Clogging is a major problem concerning the permeation of suspension-type grout. Clogging happens when the particles suspended in the grout accumulates into the voids of the soil to a point where either the void space has been fully filled, or the pore throat becomes obstructed. Figure 1 shows three scenarios dealing with permeation grouting. V_s, V_w, and V_g depict the volume occupied by the solid (soil), water, and grout respectively. Scenario (a) just shows the initial condition of the sample without any permeation. Scenario (b) shows the ideal grouting scenario, wherein the grout particles are evenly distributed throughout the voids of the soil sample. In contrast, scenario (c) shows the most realistic scenario that happens during permeation. The grout particles get trapped, or clogged in the direction of flow, hindering further permeation and resulting in uneven distribution of the grout particles within the voids of the soil. This also increases the flow resistance of the ground, thereby requiring increased permeation pressure to push grout particles deeper into the soil.

Clogging occurs erratically and it is difficult to pinpoint the exact locations. Several factors influence clogging, including soil type, relative density, pore throat size, particle size and shape, and many more. While difficult to pinpoint exactly, predictions can be made using external factors such as pressure and concentration or the amount of material injected into the pore spaces of the soil.



(a) (b) (c)

Fig.1 Grouting illustration. (a): Soil only (b): Ideal scenario; (c): Clogging scenario

EXPERIMENTAL SETUP AND MATERIALS

One-dimensional permeation tests were done to analyze the flow of the grout during permeation. This was achieved using the apparatus shown in Fig. 2. The model soil height was 100 cm with a diameter of 5 cm, divided into 10 segments. Silica sand #6 at a relative density of 60% was used as the soil medium. Several water pressure sensors were installed along the column, at the inlet, 5 cm, 15 cm, 25 cm, 45 cm, and 75 cm away from the inlet. These sensors record the pressure as permeation commenced. Smaller increments were considered near the bottom as a non-linear pressure profile was expected within the soil.

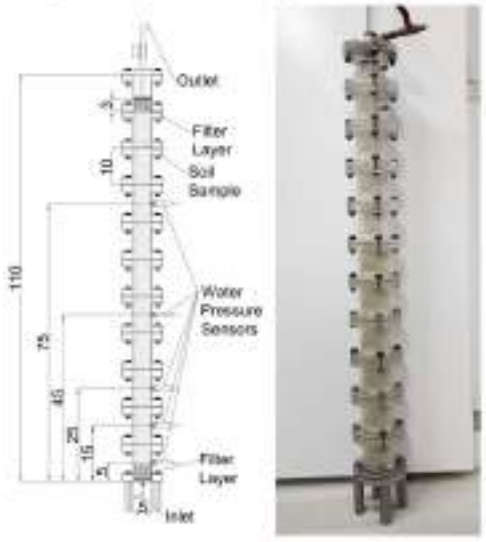


Fig.2 One-dimensional permeation apparatus (in cm)

Grouting is a very complex procedure in which several factors influence performance. The grout material used for the permeation tests were ground-granulated blast furnace slag (BS) and calcium carbonate ($CaCO_3$) in a 1:1 ratio, by weight. Varying concentrations were tested from 3%, 5%, and 7% powder-water ratio, also by weight. Permeation flowrate of 100 mL/min was deemed to be the optimal flow rate considering pressure developed and overall performance [1]. The permeation process was carried out until one of the following conditions was satisfied: (1) the pressure reached 400 kPa in the inlet ;(2) the pressure remained constant or (3) a sharp change in pressure was observed.

EXPERIMENTAL RESULTS

Permeation continued until one of the defined conditions was met. The amount of grout permeated as well as the grout retained within the soil column among the cases are summarized in Table 1. Despite having the most grout mass permeated, 7% concentration had a lower grout retention than 5% concentration. Grout retained means the amount of

grout estimated to be retained within the voids of the soil. In the case of 7%, a higher expelled grout amount was observed, likely caused by soil fracture, creating a path of lesser resistance for the grout to pass through. This fracture can be further speculated from the pressure profile in Fig 3, as there was a sharp decrease in pressure.

Table 1 Grout injected amount per concentration

Case	1	2	3
Grout concentration	3%	5%	7%
Grout volume (L)	12.5	9.0	6.5
Dry grout injected (g)	375.0	450.0	455.0
Dry grout retained (g)	280.5	378.3	312.2
Dry grout expelled (g)	54.00	28.32	111.6
Loss (g)	40.48	43.37	31.23

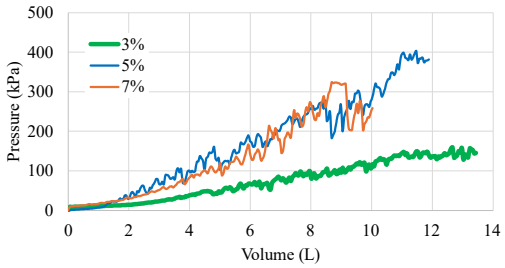

Fig.3 Pressure at the inlet

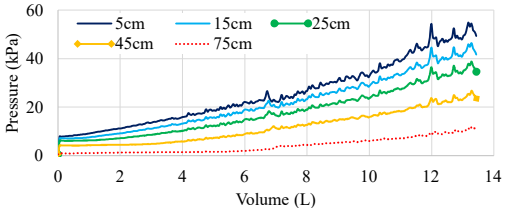
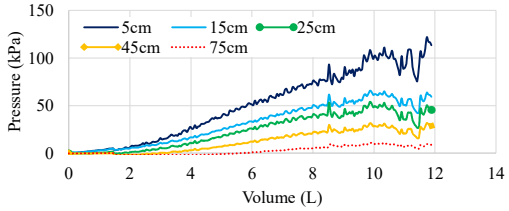
Pressure Profile

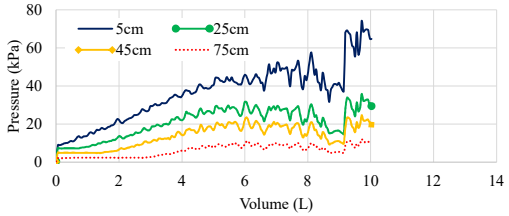
As the permeation progressed, the pressures gradually rose in response to the volume of grout injected. This rise in pressure can be attributed to the reduction in pore spaces within the soil, which decreased its overall permeability. To compensate, higher pressure was needed to maintain a stable permeation rate. Fig. 4 presents the results of the permeation pressure to the volume of grout injected with varying concentrations. In all cases, pressure was higher near the inlet and decreased with distance. Apart from this, an almost linear pressure profile can be observed at each location as the permeation progressed. The pressure fluctuated erratically due to the continuous clogging and unclogging of grout particles. As these particles accumulate at specific points, the force required to push them increases, causing a temporary rise in pressure. Once pressure reaches the threshold needed to break apart the clumped particles, the pressure is abruptly released, causing pressure fluctuations.



(a)



(b)



(c)

Fig.4 Permeation pressure to the volume injected with varying concentrations: (a) 3%; (b) 5%; (c) 7%.

Fracturing of soil usually happens during high pressure permeation. While less common and usually at a smaller size, fracturing can also occur during low pressure permeations. A sharp decrease in pressure that does not recover back to the previous pressure generally means fracture occurred that lead to a path of lesser resistance for the grout to permeated into. Fracturing or cracking results in an uneven grout distribution, and lesser grout retention. Correlating this change to the amount of grout expelled a fracture was highly likely to have happened during the permeation. While fracturing is unavoidable and unpredictable, it is possible to know the moment it happens. This detection allows for adjustments or consideration of its impact on the overall grouting process.

Grout Distribution and Porosity

Following the permeation process, grout particle concentrations were measured at 10 cm intervals within the soil. Each segment was washed with water, and sieved using a 75-micron sieve to allow the grout particles to pass through while retaining the sand. This process was repeated multiple times to maximize particle recovery. The resulting liquid was oven-dried, and the remaining powder was weighed to determine the final concentration. Fig. 5 compiles the grout retained in the soil per segment. For all cases, more grout retained in the part near the inlet and gradually lessens as the distance increases, albeit some uneven distributions.

Porosity is a fundamental parameter in permeation grouting, as it directly influences the effectiveness of grout flow and rate of soil densification. The initial porosity was computed to be 0.441, using the void ratio of silica sand #6 at a relative density of 60%. The post-permeation porosity of each segment was calculated and tallied in Table 2.

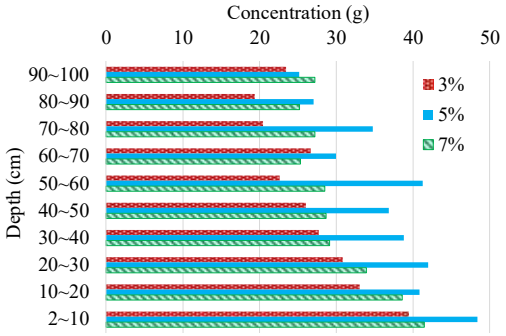


Fig.5 Grout retained per segment per case

Table 2 Post-permeation porosity of each case

Position (cm)	Porosity		
	3%	5%	7%
90~100	0.399	0.396	0.393
80~90	0.407	0.393	0.396
70~80	0.405	0.379	0.393
60~70	0.394	0.388	0.396
50~60	0.401	0.368	0.390
40~50	0.395	0.375	0.390
30~40	0.392	0.372	0.389
20~30	0.386	0.366	0.381
10~20	0.382	0.368	0.372
2~10	0.353	0.333	0.349

Correlating the porosity data with the pressure data, an inversely related relationship can be observed from Fig. 6. From here, it can be observed that the higher the change in pressure results in a higher change in porosity. This can mean that each parameter influences the other in a direct manner. With this, predictions of porosity, and ultimately grout retained, can be made just by using the pressure data during the permeation process.

NUMERICAL ANALYSIS OUTLINE

Given the potential relationship between grout concentration or the porosity of the soil to the permeation pressure, numerical analysis serves as a powerful tool for optimizing permeation performance. This reduces the need for extensive physical testing which enhances the efficiency of grouting techniques. Numerical analysis was attempted to estimate soil porosity from permeation pressure incorporating factors such as pressure, depth, time, permeability, and particle size.

Quadratic Regression

Five pressure sensors were used in the permeation experiment with varying distances from the inlet. These determine the pressure change in the location of the sensor as the permeation commenced. To obtain a pressure profile of the soil column during permeation, quadratic regression was used.

$$P = ax^2 + bx + c \quad (1)$$

Where P is the pressure, x is the depth or the distance from the inlet. One function was created from one set of pressure data (from five sensors) per unit time (1Hz). Each function was able to achieve an r-squared value of around 0.95, signifying a high level of accuracy.

Darcy-Weisbach Equation

The energy of water flow comes from total head loss due to the frictional resistance on particles surfaces on both the soil and the grout [5]. Clogging further increases the required energy to flow. There are several ways to predict permeability using equations [6,7], Darcy-Weisbach is one of the commonly known equations to calculate for permeability. From the regression, pressure at any point in the soil column, at any point in time, can be estimated. As such, permeability using Eq. (2) at any place and time can also be calculated.

$$q = Ki \quad (2.1)$$

Where q is the flowrate in m^3/s, K is the hydraulic conductivity in m/s, and i is the hydraulic gradient. By altering some parameters, Eq. 2.2 can be derived from Eq. 2.1. This way, instead of the hydraulic gradient, the pressure gradient can be used.

$$q = \frac{k}{\mu}\left(\frac{dP}{dx}\right)A \tag{2.2}$$

Where k is the intrinsic permeability in m^2, μ is the viscosity in $kPa \cdot s$, dP/dx is the pressure gradient in kPa/m, and A is the area in m^2. Hydraulic conductivity and intrinsic permeability are commonly misunderstood and mixed up. Hydraulic conductivity is a function of both the soil and the fluid flowing through it, while intrinsic permeability is just a function of the soil or porous substance, independent of the fluid. [8,9]

Kozeny-Carman Equation

The Kozeny-Carman equation is an equation that relates permeability to its porosity, grain size, and tortuosity [9], shown in Eq. (3). It is a semitheoretical and semiempirical formula that is used to predict the permeability [5].

$$k = \frac{\theta^3 D_g^2}{72 * \alpha\,(1-\theta)^2} \tag{3}$$

Where θ is the porosity, D_g is the particle size, and α is the tortuosity and sphericity factor.

ANALYSIS RESULTS AND DISCUSSION

As an initial attempt to estimate the porosity using pressure data, several assumptions were made, and some parameters were made constant. The soil medium was assumed to be fully uniform, using D_{15} as the particle size. Discharge velocity (or average velocity) was used instead of seepage velocity (or actual velocity). Tortuosity and sphericity factors were set to make the constant number in Eq (3) to a value of 200. The boundary conditions on porosity were set according to the maximum and minimum porosity recorded in the experiments conducted. Viscosity was taken from the viscosity of 5% concentration, and since it did not differ much from 3% and 7%, it was assumed constant.

Numerical modeling using the pressure profile data from the experiments, the porosity changes of the soil throughout the permeation process was estimated and shown in Fig. 7. In this figure, porosity can be assessed with respect to both time (or volume injected) and distance (permeation radius). The initial porosity of the soil was 0.441, but an empirical factor for the upper boundary was used in the model that corrected the max porosity from 0.441 to 0.410. This factor was to account for the fine fraction of the grout particles that occupied pore spaces but were either small enough, or light enough not to incur any permeation pressure. Due to this, minimal changes in porosity were estimated near the starting time and towards the upper portions of the soil column. As the permeation commenced and more grout volume was permeated, grout particles deposited into the voids and resulted in a reduction of porosity.

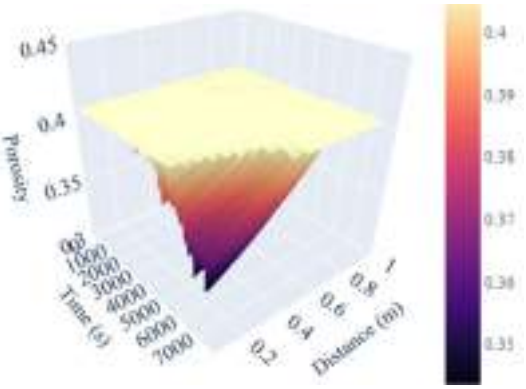

Fig.7 Porosity assessment of 3% concentration

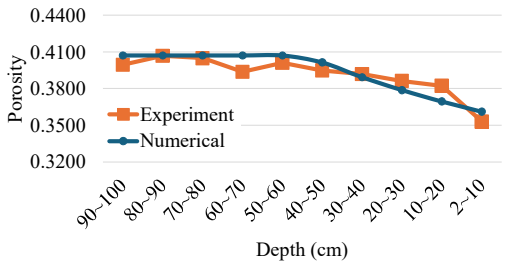
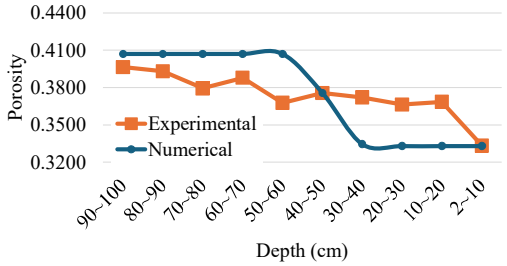
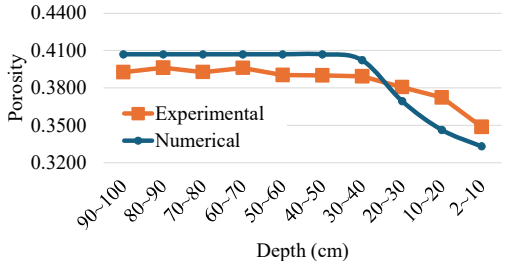
Post-permeation porosity estimated from using the model was compared with the experimental result and shown in Fig. 8. The estimated porosity was true to the assumption that the porosity was lowest near the inlet and gradually increases with distance. However, the slope of the estimation was steeper in some cases like in the 5% concentration (Fig. 8b.). Both 3% and 7% cases (Fig. 8a. and 8c.) had a better fit, reaching similar values with the experimental results. Although fracturing was suspected in the 7% case, since this occurred in the latter part of the permeation, the model was not significantly influenced. The flat line observed was due to the empirical factor and the upper boundary condition.



(a)



(b)



(c)

Fig.8 Numerical and experimental comparison for various concentrations: (a) 3%; (b) 5%; (c) 7%.

The challenge faced with this current model was the slope of the porosity change. From Eq. (3), one of the crucial factors was the particle size, D_g. In the analysis, it was assumed to be constant using the size of D_{15}. This was used because in assessing the groutability of the grout solution, D_{15} was the particle size fraction used [1]. Moreover, tortuosity increases with lowering porosity [11].

To improve the accuracy of the estimation, future improvements include altering the particle size and tortuosity factors into variable parameters that consider the changes during the permeation process. As a model primarily reliant on the obtained pressure profile during the permeation process, the empirical factor used to consider the fine fraction of the grout is planned to be improved by correlating the void space and pore throat size to the grout particle size to have more accurate boundary conditions. A sensitivity analysis or allowable error is also planned to evaluate the reliability of the model. Adjustments arising from the occurrence of fracturing are to be studied and applied to the model correspondingly.

Optimizing the model offers several advantages in permeation grouting. By knowing initial soil parameters like particle size from site investigation, the injected grout's composition (particle size and viscosity), and installing pressure sensors around the injection site, porosity changes during the grouting process can be predicted. This helps ensure proper coverage and allows for estimating the developed strength based on the grout concentration.

CONCLUSION

Several one-dimensional permeation experiments were conducted with different grout concentrations. With increasing grout concentration, clogging rate becomes faster and fluctuations in permeation pressure can be observed more frequently. But apart from this, all tests revealed that permeation pressure increases with permeated volume caused by the clogging of the grout particles. This establishes an inversely related relationship between permeation pressure and soil porosity. It was also observed that porosity change was greatest near the inlet and gradually lowers with distance.

An attempt to numerically analyze the clogging mechanism or the changes in soil porosity was made, and results signify that similar trend to the experimental results can be modeled. Despite there are some differences between the experimental values and the numerically estimated values, the outline and flow of the model was able to be validated.

Future plans to improve the accuracy of the model include altering some parameters to create a better fit and provide a more versatile model that can be used in a wider array of materials. Overall, conducting numerical analysis enables the estimation of porosity at any point in both time and distance during grouting.

NUMERICAL SIMULATION OF SCOURING AROUND CYLINDRICAL BRIDGE PIERS UNDER STEADY FLOW USING REEF3D

Shu Tsuyumine[1], Tatsuya Matsuda[1], and Naoto Naito[1]

[1] Department of Architecture and Civil Engineering, Toyohashi University of Technology, Japan

ABSTRACT

Scouring around bridge foundations installed within riverbeds can significantly affect structural safety, potentially causing pier overturning, settlement, or tilting owing to river-flow-induced scour and erosion. Understanding and accurately predicting the scouring behavior around a structure are essential for ensuring the stability of bridge foundations and preventing structural failures. In this study, the applicability of scouring assessment methods was evaluated through a reproduction analysis conducted using REEF3D, an open-source computational fluid dynamics and wave modeling framework. REEF3D facilitates high-resolution simulations of sediment transport and scour processes depending on flow conditions using optimized hydrodynamic modules. The results of the numerical simulation, which replicated a model test, successfully reproduced the general scouring tendencies around the pier, including the initiation of scouring from the front direction. However, the maximum scour depth was underestimated compared with the model test results. These findings indicate the need for the careful consideration of analytical conditions when numerically reproducing the sediment transport results obtained from model tests.

Keywords: REEF3D, Scour, Model Test, Numerical Simulation

INTRODUCTION

Severe flooding events cause significant scouring around river bridge piers, resulting in the settling and tilting of structures. Enomoto et al. [1] investigated the local scour around a bridge damaged by flooding and suggested that the widening of the bridge foundation during seismic retrofitting had increased the local scour depth. They highlighted the importance of considering changes in river flow conditions when assessing scour risk. Takebayashi et al. [2] examined the cause of bridge pier failure and attributed it to riverbed scouring around the pier, which was induced by flooding. At the bridge site, the fine-grained riverbed material caused rapid bed degradation. Their findings indicate that pier settlement could be prevented by implementing effective erosion protection around piers based on the expected bed lowering. Proactive countermeasures are necessary to prevent or mitigate damage to bridge structures because such failures disrupt transportation networks and negatively affect daily life. Understanding and accurately predicting the scour behavior around structures is essential for ensuring the stability of bridges, preventing structural damage, and supporting the safety and wellbeing of the public.

Bed level changes around hydraulic structures have been experimentally and numerically studied in consideration of their importance in disaster prevention. Matsuda et al. [3] conducted physical model experiments and numerical simulations using REEF3D (Kamath et al. [4], Ahmad et al. [5]) to elucidate the fundamental mechanisms of wave-induced scour around cylindrical structures. Numerical simulations were conducted and validated against physical model tests for a bare seabed and good reproducibility was obtained. When a monopile foundation was installed in both the numerical and physical tests, the flow velocity on the seabed in the offshore and inshore directions increased on the side of the foundation perpendicular to the direction of the wave motion. In the model test, scouring occurred at the same location and was attributed to the flow velocity. However, scouring occurred locally, underscoring the need for a detailed analysis of the associated factors. Kadono et al. [6] conducted model tests using a 1 / 40 scale cylindrical pier model and investigated the characteristics of local scour. Ishii et al. [7] developed a bed variation analysis method for reproducing three-dimensional sediment transport by solving three-dimensional motion equations and comprehensively evaluated the local scour on the upstream side of bridge piers.

This study aims to clarify the progression of scour around cylindrical structures induced by unidirectional flow, considering the characteristics of soil materials. To this end, the open-source computational fluid dynamics (CFD) system REEF3D was used in river environments to enhance the accuracy of scour simulations and tackle existing issues associated with numerical modeling.

Numerical simulations using REEF3D were conducted to analyze the sediment dynamics based on detailed flow features around a cylindrical structure and their effects on the riverbed. The sediment transport processes around the cylindrical structure

were evaluated by comparing the simulation results with the topographic changes observed in physical model tests.

RESEARCH SIGNIFICANCE

In this study, the numerical model REEF3D, which was developed to simulate the flow and riverbed changes around hydraulic structures, was used to perform a replicated analysis. The scour process was elucidated considering the bed conditions around cylindrical structures owing to its importance in the design of safe structures. In this simulation, flow-induced sediment transport phenomena were qualitatively evaluated based on hydraulic model experiments.

NUMERICAL SIMULATION METHOD

The REEF3D model is governed by the incompressible Reynolds-averaged Navier–Stokes (RANS) and continuity equations.

$$\frac{\partial u_i}{\partial x_i} = 0 \quad (1)$$

$$\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = -\frac{\partial P}{\partial x_i} + \frac{\partial}{\partial x_j}\left[\nu\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) - \overline{u_i u_j}\right] + g_i \quad (2)$$

Here, u, t, x, ν, ρ, P, and g denote the flow velocity, time, position on the x axis, kinematic viscosity, density of water, pressure, and gravity, respectively.

In CFD models, the fluid velocity is assumed to be sufficiently low such that the compressibility of water and air can be neglected. This assumption allows the simplification of the flow using the RANS and continuity equations. The turbulence model is the unsteady RANS with k-ω model.

REEF3D, which addresses two-phase flows, uses the level-set method to capture the air–water interface. In this method, the interface between the two phases is defined as the reference surface and the regions on either side of the interface are represented using a distance function.

The sediment transport model was used based on the flow field simulated using the hydrodynamic REEF3D model. Changes in the bed elevation are evaluated using the following Exner equation, which follows the conservation of sediment mass:

$$\frac{\partial z_b}{\partial t} + \frac{1}{(1-n)}\left[\frac{\partial q_{b,x}}{\partial x} + \frac{\partial q_{b,y}}{\partial y}\right] + E - D = 0. \quad (3)$$

Here, z denotes the bed elevation; $q_{b,x}$ and $q_{b,y}$ are the bedload transport rates in the x and y directions, respectively, as defined at the morphological time step; E is the entrainment rate from the bedload to the suspended load; and D is the settling rate from the suspended load back to the bed.

ANALYSIS MODEL

Figs. 1 and 2 present the side and plane views of the movable bed, respectively. In this analysis, a computational domain with a length of 0.75 m, width of 0.5 m, and height of 0.4 m was defined, and unidirectional flow was introduced from the left boundary of the domain. The hydraulic and soil conditions were set to match the experimental parameters [6]. The 50% diameter on the grain size diagram of the bed material is 0.11 mm and the grain size distribution is not considered. The mesh consists of 5 and 10 mm cubes.

To investigate the influence of the flow velocity on the scour depth, two flow conditions with a velocity V_1 = 0.107 m/s, corresponding to the experimental condition, and a doubled velocity V_2 = 0.214 m/s, were analyzed.

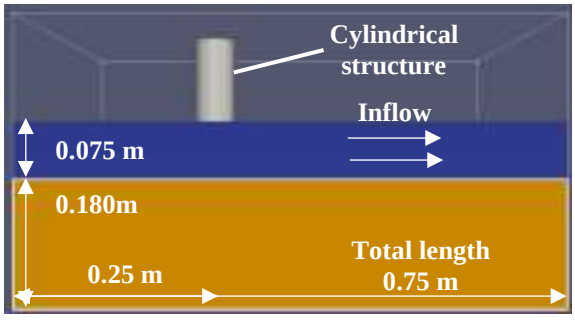

Fig. 1 Region of numerical analysis: side view

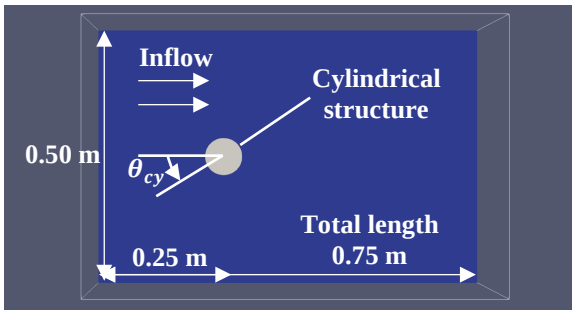

Fig. 2 Region of numerical analysis: plane view

Table 1 Conditions for numerical analysis

Cylinder diameter (m)	0.065
Bed elevation (m)	0.18
Water depth (m)	0.075
Flow velocity V_1 (m/s)	0.107
Flow velocity V_2 (m/s)	0.214
Particle size (mm)	0.11

RESULTS AND DISCUSSIONS

Bed surface profile

Figs. 3 to 5 present the bed surface profiles around the cylindrical structure at 1,800 s for both the model test and numerical analysis with 5 mm and 10 mm meshes. Fig. 6 presents the bed surface profile from the 5 mm mesh analysis with a doubled flow velocity. In all results, scour initiation occurs at approximately $\theta_{cy} = 45°$. However, while the model test reveals scour holes forming around the entire circumference of the cylinder, the numerical analysis under flow condition V_1 exhibits scour holes primarily in the range of $\theta_{cy} = 45°$ to $90°$, indicating a different scour pattern.

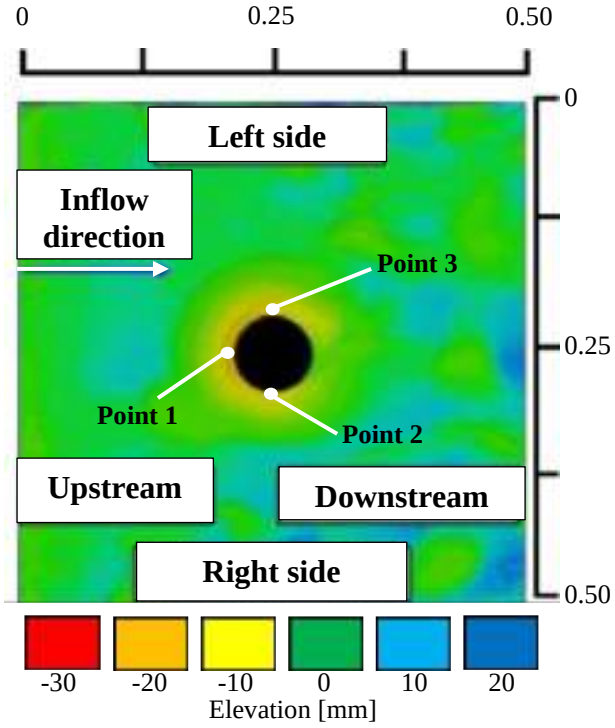

Fig. 3 Sand surface profile near the cylinder in the model test (adapted from [6])

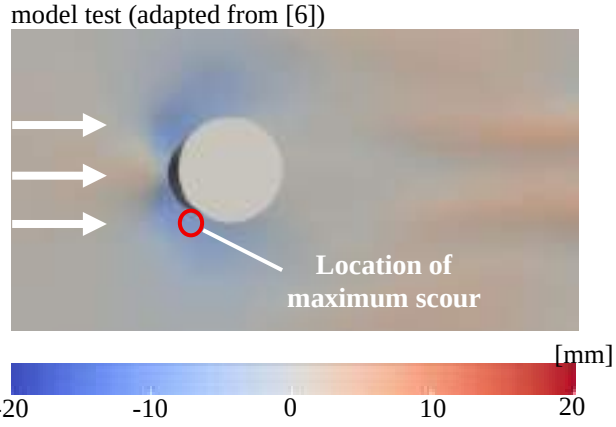

Fig. 4 Sand surface profile near the cylinder using a 10 mm mesh (V_1 = 0.107 m/s)

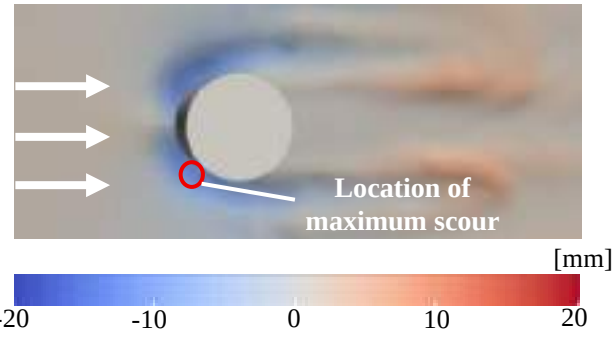

Fig. 5 Sand surface profile near the cylinder using a 5 mm mesh (V_1 = 0.107 m/s)

The analysis with a finer mesh size produced a sand surface profile that more closely matched the experimental results. As shown in Fig. 6, increasing the flow velocity results in the expansion of the scour hole toward the $\theta_{cy} = 0°$ region. Additionally, both sets of results indicate a tendency for sediment deposition around $\theta_{cy} = 180°$.

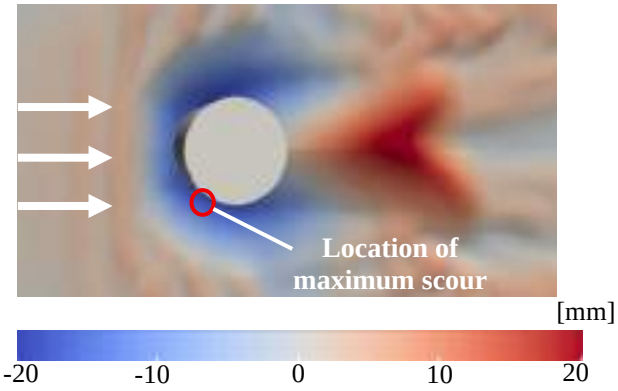

Fig. 6 Sand surface profile near the cylinder using a 5 mm mesh (V_2 = 0.214 m/s)

Maximum scour depth

Fig. 7 presents the scour depths at $\theta_{cy} = 0°$ and $\theta_{cy} = 45°$ for the 5 mm and 10 mm meshes. The maximum scour depth is approximately 6 mm for the 5 mm mesh and 12 mm for the 10 mm mesh. The results indicate that a finer mesh size led to a greater scour depth, suggesting that scour depth is dependent on mesh size. The maximum scour depths in Fig. 3 are 32, 27, and 26 mm at points 1, 2, and 3, respectively, indicating that the numerical results underestimate the experimental results.

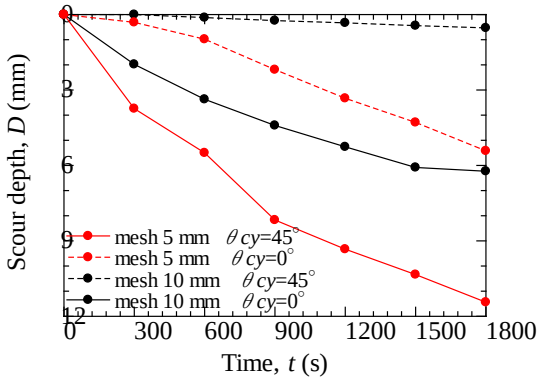

Fig. 7 Comparison of Scour Depth between 5 and 10 mm meshes

Fig. 8 presents the scour depths at $\theta_{cy} = 0°$ and $\theta_{cy} = 45°$ for V_1 and V_2. Under the flow condition V_2, the maximum scour depth increases to approximately 22 mm, which is approximately 2.7 times the depth obtained with the lower flow velocity. The scour depth at $\theta_{cy} = 0°$ obtained for V_2 is approximately 14 mm, which is approximately 7.0 times greater than that corresponding to condition V_1 (comparison at 800 s).

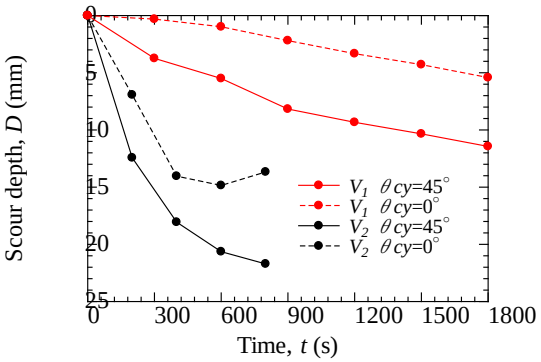

Fig. 8 Comparison of scour depths between V_1 and V_2

The reasons for the differences in scour depth observed in the numerical analysis results are discussed based on the flow conditions around the structures. A comparison of the streamline distributions in Figs. 9 and 10 suggests that in Fig. 9, the flow downstream of the cylinder remains horizontal with a limited downward motion, resulting in less scour. In contrast, the increased flow velocity in Fig. 10 induces downward flow, leading to a more pronounced scour and a scour pattern similar to that observed in the model test. Therefore, the analytical conditions must be carefully assigned when numerically reproducing the sediment transport results obtained from model tests.

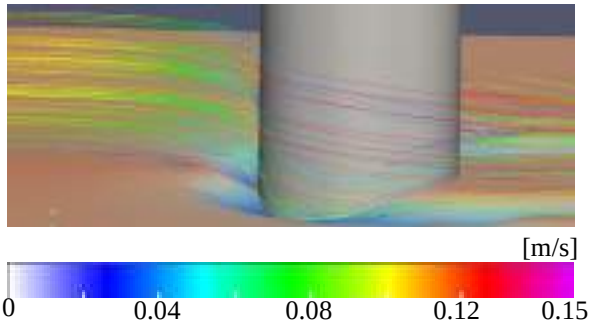

Fig. 9 Streamline distribution near the cylinder under V_1

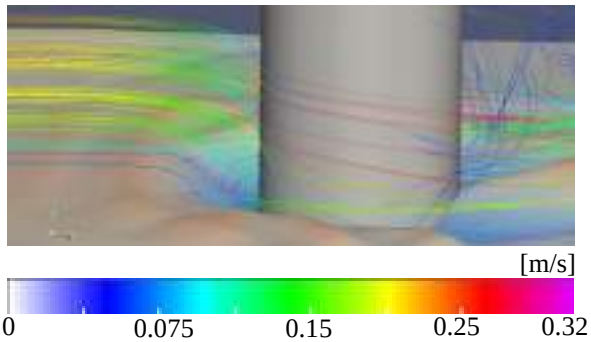

Fig. 10 Streamline distribution near the cylinder under V_2

CONCLUSIONS

The scour phenomenon around a cylindrical structure under unidirectional flow was analyzed using REEF3D to investigate the flow characteristics and sediment dynamics. The following conclusions were drawn.

- Scouring occurred at $\theta_{cy} = 45°$ both in the model test and numerical analysis. In the model test, scour holes were formed around the entire circumference of the cylinder, whereas they were primarily observed between $\theta_{cy} = 45°$ and $\theta_{cy} = 90°$ in the numerical analysis.
- Sediment deposition occurred near $\theta_{cy} = 180°$, which was similar to the experimental observations.
- The results indicated that a finer mesh size led to a greater scour depth, suggesting that scour depth is dependent on mesh size.
- The maximum scour depth in the model test was approximately 20 mm, whereas the numerical analysis underestimated this value by approximately 12 mm.
- When the flow velocity was doubled compared with the experimental condition, the scour depth at $\theta_{cy} = 0°$ increased by approximately 7.0 times. This increase allowed the numerical analysis to reproduce the scour pattern near $\theta_{cy} = 0°$. Additionally, downward flow in front of the cylinder was observed (comparison at

• 800 s).

These results highlight the need for careful consideration of the analytical conditions when numerically reproducing the sediment transport results obtained from model tests. Further investigations are required to improve the accuracy of the current reproduction and enhance scour prediction methodologies. Additionally, incorporating more complex turbulence models and refining sediment transport mechanisms could improve the numerical accuracy. Future studies will focus on optimizing the computational parameters and validating the model under various flow conditions to ensure better agreement with experiments. Furthermore, the effects of mesh size and other factors on analysis accuracy will be analyzed to improve the reproducibility of water flow and sediment transport.

Precision-Controlled Backfilling Methodology for Enhancing Positional Accuracy in Foundation Element Replacement

Haruka Kiyotomo [1], Yuji Taya [1], Masahiro Ueda [1], Tomio Tsuchiya [1] and Shinya Inazumi [2]

[1] Takenaka Corporation, Japan; [2] Shibaura Institute of Technology, Japan

ABSTRACT

The demand for removal of existing piles has increased significantly due to increased demolition and reconstruction activities in urban areas. Ensuring the quality of the backfilled area after pile removal is critical, as inadequate backfill can negatively affect the construction accuracy of new piles installed near these areas.

Currently, no established standardized method exists for achieving consistent backfill quality. This study proposes a novel construction method designed to ensure uniform unconfined compressive strength throughout the depth of backfilled areas. The proposed method involves the simultaneous penetration and injection of a specially prepared backfill material, combined with thorough mixing using a mixing auger. The auger, which has a diameter equal to or greater than that of the casing, incorporates mixing blades and a screw mechanism. Additionally, we developed a method for designing the backfill material mix, emphasizing the importance of preliminary laboratory mixing tests prior to actual construction.

The effectiveness of the proposed construction and mix design methods was validated through field implementation. The existing piles were successfully removed, and the resulting backfilled areas achieved the targeted uniform strength profiles. Subsequent measurements confirmed that the design accuracy of newly installed piles adjacent to these backfilled areas remained within acceptable control limits. In conclusion, the implemented method of pile removal and controlled backfilling demonstrated reliability and accuracy, significantly improving the quality of subsequent new pile construction.

Keywords: Pile removal; Controlled backfilling; Unconfined compressive strength; Mixing auger; Construction accuracy

INTRODUCTION

In recent years, the demand for removing existing piles has increased due to the demolition and reconstruction of buildings. After removing the existing piles, the holes are filled with backfilling material. There are no regulations for backfilling materials or methods, making it difficult to ensure the quality of the backfilled area. If the strength of the backfilled area cannot be controlled, problems will occur when constructing new piles near the backfilled area, such as poor vertical accuracy and eccentricity, which will reduce construction accuracy.

This paper presents a case study of an existing pile removed using the cutting casing and extraction method in clay ground. Following removal, the ground was backfilled through a process of penetrating and ejecting cement slurry mixed bentonite liquid (hereafter referred to as CB liquid) while simultaneously stirring with an auger. This auger, with a diameter equal to or greater than that of the cutting casing, was equipped with a mixing blade and screw mechanism to facilitate thorough mixing of the area. Furthermore, this study examines the construction accuracy of new piles subsequently installed at the same site.

RESEARCH SIGNIFICANCE

The purpose of this research is to develop a backfill material and construction method for use after removing existing piles that will not adversely affect the construction of new piles. Such materials and construction methods do not currently exist.If this goal is achieved, not only will the construction quality of new piles in building reconstruction work improve, but it will also be possible to prevent an increase in the construction period and cost of the entire new construction work.

METHODOLOGY

First, the site conditions and pile characteristics are described. The ground overview and specifications of both existing and new piles are illustrated in Fig. 1. The ground profile consisted of a buried soil layer (F layer), an alluvial sand layer (As layer), and an alluvial clay layer (Ac1 and Ac2 layers). The Ac2 layer exhibited an average N-value of 1 at depths ranging from -6.8 m to 17.9 m below the construction ground level (hereinafter referred to as GL), with an unconfined compressive strength of 50 kN/m^2 measured at GL-12.8 m. The removed existing piles were prefabricated prestressed concrete piles with a design length of 20 m and diameters of 350

mm and 400 mm, respectively. The pile heads were positioned at approximately GL-2 m. The newly installed piles had typical specifications including a length of 17 m, pile heads at GL-7.1 m, and a diameter of 1000 mm. The upper sections utilized high-strength SC piles, while the lower sections employed high-strength nodular PHC piles.

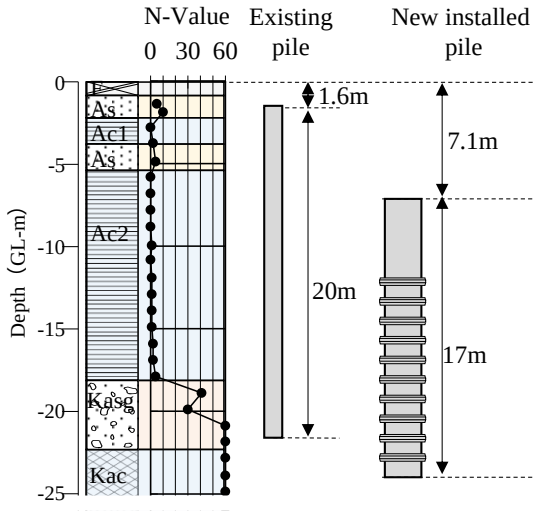

Fig. 1 Ground overview and pile specifications

Second, the pile extraction methodology and backfilling procedure are described. The operational sequence and cycle time for existing pile removal are illustrated in Fig. 2. Initially, the perimeter of each existing pile was separated from the surrounding soil using a cutting casing, after which the piles were extracted utilizing a wire-pull system. Subsequently, an auger head with a 2-m long screw was attached to the lead end. The CB liquid was then injected and mixed using an auger assembly comprising alternating 5-m mixing blades and 5-m screws. In accordance with deep mixing treatment protocols [1], the penetration, lifting, and rotation speeds of the auger were established at a minimum of 350 rotations per meter. Following CB liquid injection and auger advancement to the target depth, the auger was rotated and withdrawn in the conventional direction. Immediately post-construction, unconsolidated samples were collected from three distinct backfilled locations (designated No. 1 to 3), and their unconfined compressive strength was evaluated after a 28-day curing period. Additionally, a standard penetration test was performed at backfilled location No. 3 at 26 days post-construction.

The strength parameters for the backfilled sections were established as follows: While the original ground exhibited an unconfined compressive strength of 50 kN/m^2, the target unconfined compressive strength for the backfilled sections was specified at 100 kN/m^2, accounting for practical strength management constraints in field applications. Furthermore, considering the pile body/pile perimeter soil ratio [2], laboratory mixing tests were conducted using Ac2 layer clay prior to implementation. The resulting construction specifications are presented in Table 1. The CB liquid injection volume corresponded to 100% of the volume mixed by the auger.

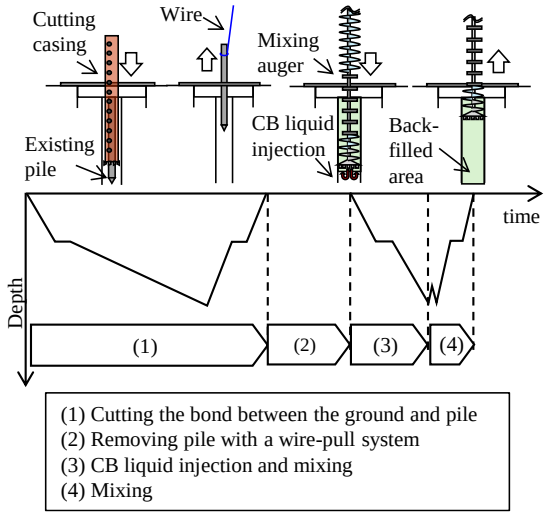

Fig. 2 Operational sequence and cycle time for pile extraction

Table 1. Construction specifications

Existing pile No.	Diameter (mm)	Outside diameter of cutting casing (mm)	Mixing auger diameter (mm)	The pile body/pile perimeter soil ratio	Water to cement ratio of CB liquid (%)
1	350	700	700	0.33	600
2 and 3	400	700	700	0.48	500

RESULTS

Fig. 3 illustrates the unconfined compressive strength profiles of unconsolidated samples from locations No. 1 to 3, alongside comparative data from undisturbed samples of the original ground. The backfilled zones exhibited generally uniform strength characteristics with depth, predominantly exceeding the target strength parameters. However, the sample from location No. 1 at GL-3m demonstrated values below the target threshold. This anomaly is attributed to the proximity of the sampling location to the upper boundary of the improvement zone, resulting in material heterogeneity and consequent inter-specimen variability. Significantly, all samples demonstrated strength values superior to those of the

original ground. Fig. 4 presents standard penetration test results from location No. 3 compared with corresponding values from the original ground. The original Ac2 layer exhibited N-values of approximately 1, whereas equivalent depths within backfilled section No. 3 yielded N-values ranging from 3 to 4.

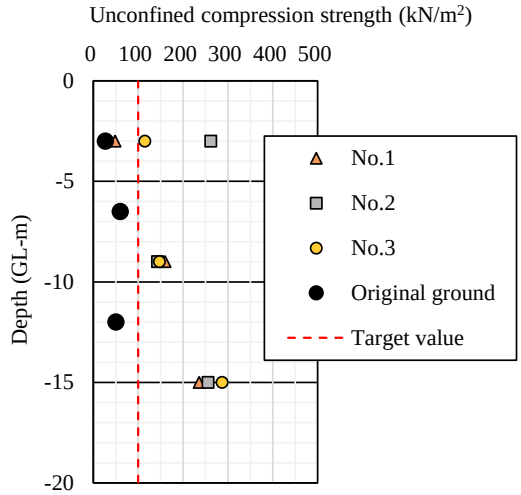

Fig. 3 Unconfined compressive strength profiles

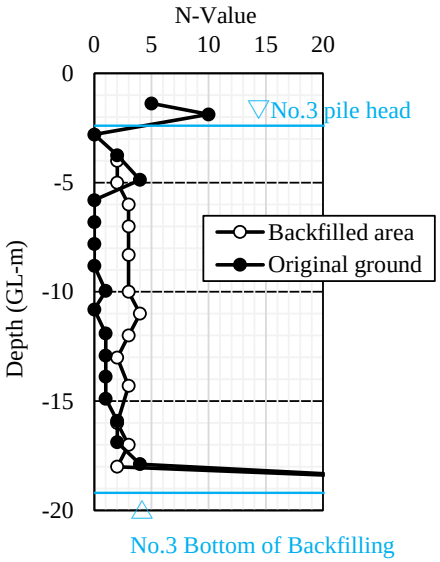

Fig. 4 Standard penetration test N-values

FINDINGS

This investigation examined how backfilled zones from extracted piles influenced the installation accuracy of new foundation elements. Positional measurements were conducted at sequential construction phases as illustrated in Fig. 5, utilizing a light wave transit to quantify the aboveground displacement of drilling rods, pile heads and guide rods. Measurements were recorded as coordinate deviations (x, y) from design specifications and subsequently converted to resultant vector magnitudes $\sqrt{(x^2 + y^2)}$ to determine eccentricity values. Following the classification framework established in [3], the spatial relationship between newly drilled pile locations and backfilled zones was categorized as: (a) non-overlapping with separation ≥ 1D (n = 36), (b) non-overlapping with separation < 1D (n = 4), and (c) partially overlapping (n = 5).

Fig. 6 presents the measured eccentricity values of aboveground pile sections across construction phases. Comparative analysis between categories (a) and (b) revealed similar mean eccentricity values, though category (b) exhibited greater statistical variance. Category (c) demonstrated the highest eccentricity values; however, these remained within acceptable tolerance limits (x, y ≤ 100 mm each), indicating that backfilled zones did not adversely affect construction viability of new foundation elements. Analysis of mean eccentricity progression through construction phases (1) to (4) revealed a systematic increase with advancing construction stages, underscoring the critical importance of achieving high drilling precision during the initial phase (1) rod drilling to ensure positional accuracy in subsequent operations.

To further analyze the influence of spatial relationships between backfilled zones and new pile positions, the overlap configuration in categories (b) and (c) was quantitatively assessed using an overlap ratio methodology (Fig. 7). This ratio was calculated as: Overlap ratio (%) = (overlap dimension) ÷ (diameter of new pile borehole) × 100.

For non-overlapping configurations, the negative separation distance between outer boundaries was substituted as the numerator term.

Fig. 8 illustrates the correlation between overlap ratio and eccentricity magnitude across construction phases. A consistent trend emerged wherein maximum eccentricity values occurred at approximately 5% overlap ratio across all construction phases. Continued data acquisition regarding this correlation is recommended to establish definitive statistical relationships and enhance predictive understanding.

CONCLUSIONS

This study demonstrated successful implementation of a controlled backfilling technique in cohesive soil conditions, achieving an unconfined compressive strength that predominantly exceeded the target value of 100 kN/m^2. The methodology established effective control over the geotechnical properties of backfilled zones following pile extraction.

Positional deviation measurements during construction of new foundation elements indicated that eccentricity values generally remained within established tolerance limits, confirming that backfilled zones did not adversely affect new pile installation. The investigation revealed that partial overlap configurations between newly drilled pile locations and previously backfilled zones exhibited comparatively higher eccentricity values, suggesting a potential correlation between overlap ratio and positional deviation. Future research will focus on expanding the experimental dataset to establish definitive statistical relationships between backfilled zone characteristics and installation precision of adjacent foundation elements.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the valuable contributions and technical support provided by the following personnel from Takenaka Corporation: Director Takahashi, Construction Division Manager Kato, and Engineers Enomoto, Sugai, Adachi, and Harada. Their expertise and assistance were instrumental in the successful implementation and evaluation of the methodologies presented in this study.

ABSTRACT

Soil liquefaction is a hazardous phenomenon triggered by earthquakes, which can result in widespread damage such as uneven settlement of structures and ground deformation, posing serious risks to people and property. One method to mitigate liquefaction is the chemical grouting technique. This approach involves displacing pore water in the soil with silica-based acidic solutions that form a gel over time that improves the strength and stability of the soil. However, the presence of alkaline components in the soil may react with the solution, potentially hindering gelation and emphasizing the importance of selecting appropriate injection materials. This study investigated the effects of varying injection flow rates on the gelation time of the solution by conducting one-dimensional injection tests using soil samples with high alkalinity. The temporal change of pH, gelation time, and the silica concentration at various distances from the injection port were measured. Results showed that while pH changes were not significantly influenced by flow rate, gelation time and silica concentration were affected. A slower injection flow rate resulted in faster gelation, which was attributed to the quantity of silica adsorbed from the chemical solution onto the soil particles. To increase the applicability of this method, a model equation involving the estimation of gelation time to the silica concentration is planned. The findings from the experiments conducted indicated that injection flow rate is a significant factor in the chemical grouting method.

Keywords: Soil liquefaction, Chemical grouting, Ground improvement, pH test of soil, Gelation time

INTRODUCTION

The 2024 Noto Peninsula earthquake caused devastating damage due to liquefaction in channels and marshlands. Liquefaction-induced damages have not been eliminated in recent years, and countermeasures against liquefaction are necessary in preparation for major earthquakes that are highly likely to occur within the next 30 years. One effective countermeasure is the chemical grouting method, in which grout solution is injected into the ground to replace pore water and chemicals to improve the properties of the ground. However, the effectiveness of this method is considerably affected by the alkaline content in the soil. As a result, it can be very difficult to achieve proper penetration and solidification, and sufficient improvement may not be achieved due to partial solidification or inadequate penetration.

Previous studies have shown that grouting effectiveness depends on factors such as silica concentration, soil properties, and chemical behavior. Higher silica content leads to greater strength [1], and unconfined compressive strength is influenced by particle adhesion, negative pore pressure, surface area, and internal friction angle [2]. Hayashi [3] found that grout strength variability is due to settling after injection, not dilution during flow. Endo [4] emphasized the need for multiple evaluation indicators in heterogeneous soils.

While such findings provide important insight into grouting performance under neutral or controlled conditions, few have focused on the interaction between high-alkaline field sands and grout permeation behavior. In particular, the influence of alkaline content on gel time and silica reaction dynamics remains poorly understood.

Therefore, the purpose of this study is to elucidate the permeation mechanism by conducting a one-dimensional injection test using a soil sample composed of field sand containing high amounts of alkaline and chemically inert silica sand. In addition, based on these results, this study aims to construct a reaction model for this method.

In this paper, one-dimensional injection tests were conducted on samples prepared using Souma sand and silica sand no. 6. Injection materials with different compositions were used, and the injection rate was varied. This paper presents the results of investigations on three aspects: (1) the temporal change in the pH of the chemical solution within the soil, (2) the variation in gel time (GT), defined as the time required for solidification, and (3) the change in silica concentration at different penetration distances.

EXPERIMENTAL METHOD

Understanding the influence of alkaline compounds present in the soil is crucial. To do this, two types of soil samples with different alkaline

contents were utilized. Silica sand No. 6 was used as the neutral or inert sand, with a calcium content of approximately 200 mg/kg, and Souma sand as the high-alkaline sand, having a calcium content of about 10,000 mg/kg. Souma sand contains calcium carbonate that originated from shells and corals, making the sand alkaline in nature. Four experiment cases were formulated, with one case focusing on the reaction of the chemical solution with little effect from the sand, and three cases focusing on the reaction of both the chemical solution and the sand. In Case 1, only silica sand No. 6 was used and in Cases 2 to 4, a mixture of Souma sand and silica sand No. 6 at a weight ratio of 1:8 was used, resulting in a high alkaline soil mix with a pH value of 7.9.

For the one-dimensional permeation test, a cylindrical mold with an inner diameter of 50 mm and a height of 1030 mm was used, shown in Fig.1. A soil column with a height of 920 mm at a relative density of 60% was prepared, with filter layers, composed of silica sand No. 4, placed at both the top and bottom of the specimen to ensure uniform flow and adequate drainage.

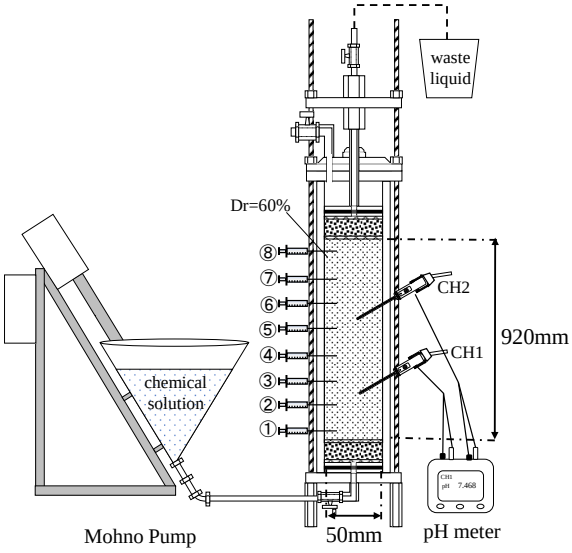

Fig.1 Injection device

To prepare the specimen for permeation, it was saturated with de-aired water from the bottom. After ensuring the sample was fully saturated, a constant flow rate pump was connected to the inlet to inject the chemical grout at a fixed flow rate. Case 1 and 2 followed a standard value of chemical permeation of 60 mL/min while Cases 3 and 4 used slower and faster flow rates of 30 mL/min and 120 mL/min, respectively to investigate the effect of varied flow. The grout compositions for each case are listed in Table 1 [5]. The injection solution was prepared by mixing Actor-MS, PR silica, and ASF silica-30, with all mixtures adjusted to achieve a silica concentration of 3.8%. Actor-MS is a mixed acid composed of sulfuric acid (H_2SO_4) and phosphoric acid (H_3PO_4). PR silica and ASF silica-30 are both mixtures of silicon dioxide or commonly known as silica (SiO_2) and sodium oxide (Na_2O) but differ in their silica form: ASF silica-30 exists in a colloidal form, while PR silica consists mainly of monomers to trimers.

Table 1 Chemical compounds and ratios

Case	Solution A			Solution B	
	MS(mL)	ASF(mL)	water(mL)	PR(mL)	water(mL)
1	9.958	7.323	151.300	49.930	181.500
2	8.004	7.905	197.628	49.407	237.055
3	8.100	8.000	233.900	50.000	200.000
4	8.100	8.000	233.900	50.000	200.000

From the grout mixtures formulated, the estimated pH values were 2.2, 3.5, and 4.0. The injection process was terminated when approximately 830 g of liquid (equivalent to the volume of the pore space) had been discharged from the specimen. This means that all the water initially present prior to the injection was replaced entirely by the chemical solution, assuming that no mixing occurred.

To monitor the penetration and reaction state of the chemical solution, pH glass composite electrodes for capillary tubes (MCD-45, Nihon Ash Co., Ltd.), shown in Fig.2 for Case1 and Fig.3 for Cases 2 to 4, were inserted at approximately 1/3 and 2/3 of the specimen height from the bottom (referred to as CH1 and CH2, respectively). In this way, the temporal change in pH inside the sample was measured. While cases 2 to 4 used a different pH meter, it was confirmed beforehand that both types had similar performance. Since the grout solution was acidic, the metal part of the 1st type (Case 1) was not ideal to be used for long-term so a glass-type pH meter was substituted.

Fig.2 Glass electrode (Case 1)

Fig.3 Glass electrode (Case 2 - 4)

Additionally, syringes were inserted at equal intervals along the height into the specimen to extract the chemical solution at the end of injection, allowing measurements of pH, GT, and silica concentration at different penetration distances. The extracted solution was transferred to a petri dish, and GT was measured

by gently rocking the dish back and forth using a small shaker device. The GT was defined as the point in time when the extracted solution stops flowing, indicating solidification. The pH and silica concentration of the extracted solution from the syringes after injection were immediately measured using a compact pH meter (LAQUA twin-pH-22B, HORIBA), shown in Fig.4, and using a silica pack test (WAK-SiO2, Kyoritsu Chemical-Check Lab., Corp.). In conducting the pack test for silica concentration measurement, appropriate dilutions were made to fall within the measurement range (5-50 mg/L).

Fig.4 Compact pH meter

EXPERIMENTAL RESULTS

Case 1 (Silica Sand No. 6)

Fig.5 shows the change in pH over time in Case 1. From this graph, it can be confirmed that the pH of silica sand No. 6 used in this experiment was about 6.6 when saturated with water. The sudden drop in pH value signifies the contact time of the grout solution to the pH meter. Since the solution was highly acidic, a drop in pH was expected. With a bottom-up flow direction, CH1, located nearer to the inlet was contacted first with the solution before CH2, hence the difference in time with the pH drops. After the injection finished, the pH of the soil sample full of the grout solution did not change significantly with time and remained constant. This may be because the acid in the chemical solution was not consumed by the neutralization reaction, and since the soil sample prepared was made with a chemically inert silica sand with minimal amounts of alkaline components.

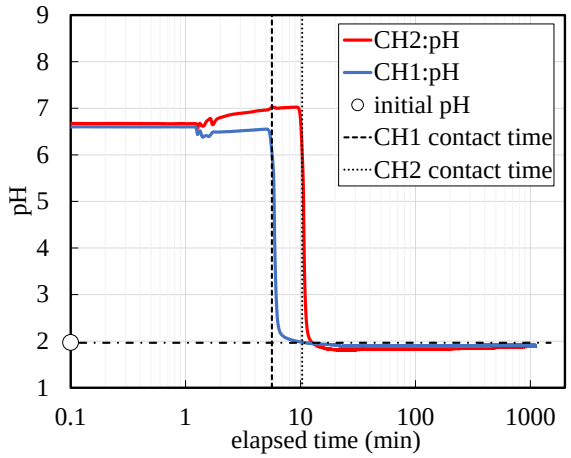

Fig.5 Temporal change in pH (Case 1)

Using the solution extracted from the syringes inserted at different penetration distances, the pH and the GT of the solution from each point were tested. Fig.6 shows the relationship between pH and GT with distance. As with the temporal change in pH, minimal changes in pH were observed within the soil column. GT, however, had a slight change with distance. Showing a slightly faster solidification time as the penetration distance increased. This might be caused by the small amount of calcium compounds in the sand that incurred a minor neutralization reaction that hastened the gelation. Given the minimal change in pH with both time and distance, paired with the slight changes in GT, it can be suggested that the reaction occurred in this case was mostly due to the chemicals present in the grout solution with little interference from the soil specimen made with silica sand No. 6.

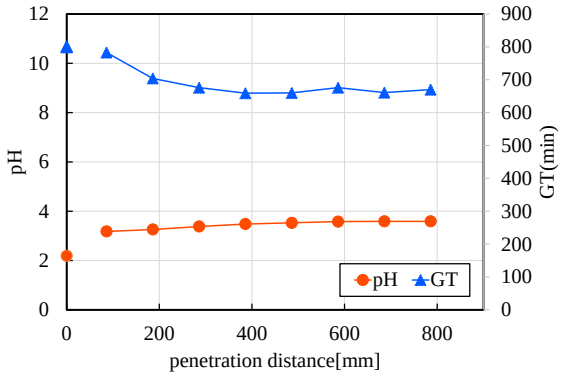

Fig.6 Relationship between pH and GT with distance

However, the actual situation of the ground in the real world is not always composed of chemically inert material that will provide similar results with this case. To understand the effect of alkaline compounds, present in the ground during chemical grout injection, a specimen with high alkalinity needs to be made and tested. Apart from this, the injection flow rate is also another crucial factor in this ground improvement method. A faster flow results to more turbulence within the voids and material contact time that may hasten the reaction of the grout material. As such, 3 additional cases (Case 2 to 4) were prepared using high alkalinity sand, and varying flow rates.

Case 2 to 4 Results (High-Alkaline Sand & Varying Flow Rates)

The setup and testing procedure were the same as Case 1, with only the soil composition and flow rate changed. For these three cases, all used the same high-alkaline sand mixture formulated. Case 2 followed the same flow rate as Case 1 at 60 mL/min, Case 3 used a slower injection rate of 30 mL/min, and Case 4 with a faster injection rate of 120 mL/min. The temporal changes in pH during and after the chemical injection are shown in Figs. 7 to 9. From

here, the initial pH of the soil was between 8 and 9, which was noticeably more alkaline than silica sand used in Case 1. The arrival times of the injected solution at CH1 and CH2 can be identified through the graphs as well. In Case 2, the injection solution reached CH1 and CH2 approximately 4 minutes and 9 minutes after the start of injection, respectively. In Case 3, the arrival times were approximately 10 minutes and 20 minutes, and in Case 4, they were approximately 2 minutes and 6 minutes, respectively.

As the solution approached the pH meter, a drop in pH was recorded similar to Case 1. A major difference compared to the previous case, however, was the extent of pH decrease. In Case 1, the readings reached the value of the initial pH of the grout solution, but in Cases 2 to 4, it was deviated from the initial pH of the grout solution. This further supported that silica sand had a low impact on the solution, while high-alkaline sand resulted in some changes in the solution.

The reaction between the alkaline compounds in the soil and the acid present in the solution is expressed by the following Eq. (1). The sulfuric acid present in the grout solution reacts with the calcium carbonate present in the Souma sand, and this creates calcium sulfate, water, and carbon dioxide. This acid-carbonate reaction caused a neutralization reaction that slowly raised the pH value of the solution.

$$H_2SO_4+CaCO_3 \rightarrow CaSO_4+H_2O+CO_2 \quad (1)$$

All cases underwent similar chemical reactions and suggested that the pH behavior after completion of the injection was independent of the injection flow rate. Furthermore, it was observed that in all cases, pH increased almost linearly with respect to the logarithm of time, regardless of measurement location.

Apart from differences in arrival time, there were no significant differences in the general shape of the curves among the cases. In all cases, CH1, located at the bottom of the specimen, maintained lower pH values than CH2 throughout the monitoring period. The low pH values at CH1 before the arrival of the solution are believed to be due to the alkaline components in the soil. Since area around CH1 had more acid compounds while the area around CH2 had less due to acid-base reactions occurring during injection. It can be incurred that the bottom area had the highest number of acidic compounds, that gradually lessens with distance. Although towards the end of the injection, it was observed that the pH values converged, as no fresh acid-rich grout were being injected anymore.

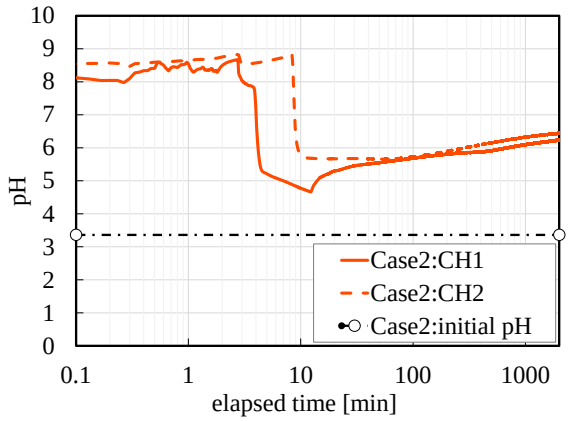

Fig.7 Temporal change in pH (Case 2; 60 mL/min)

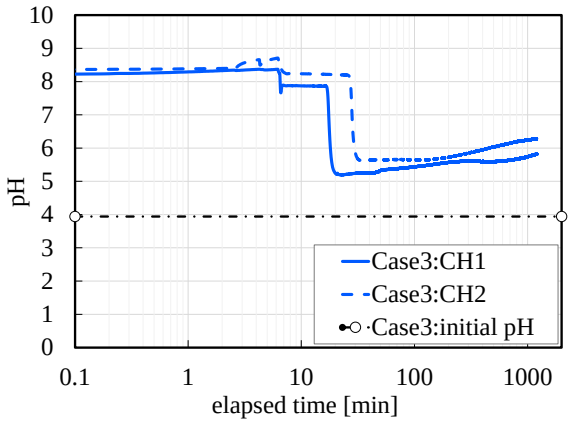

Fig.8 Temporal change in pH (Case 3; 30 mL/min)

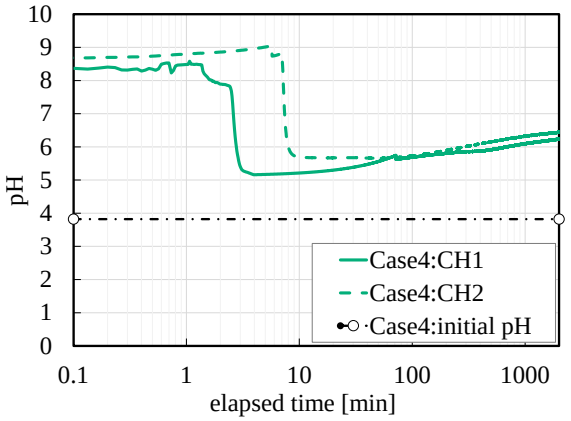

Fig.9 Temporal change in pH (Case 4; 120 mL/min)

As the pH was seen to converge after the injection was completed, solutions from different penetration distances along the specimen were taken using the syringes installed. Along with this, GT was also measured. Fig.10 shows the relationship between pH and gel time (GT) at various penetration distances for Cases 2 through 4. In Case 2, the initial pH of the grout solution was 3.36, the GT of the solution alone was 332 minutes. In Case 3, the initial pH was 3.94,

the GT of the solution alone was 700 minutes. In Case 4, the initial pH was 3.82, the GT of the solution alone was 710 minutes. Ideally, the same solution with Case 2 was planned to be used for Case 3 and 4. However, with the slow flow rate of Case 3, injection failed to complete due premature gelation. To counter this, the mixture was modified to have a longer GT to accommodate extended duration of injection.

From Fig.10, it can be seen that differences in injection flow rate have minimal impact on the pH variation with respect to penetration distance. However, when comparing the GT of the solution alone with that of the extracted solution, Case 3 exhibited a longer GT. This was particularly visible around 0 mm and 200 mm penetration distances. Case 4 with the highest injection flow rate experienced the fastest gelation. This can be related to the pH value seen on Fig.11. A faster flow rate tends to have lower pH values, and a slower flow rate tends to produce higher pH values. On top of that, a lower pH was observed to have a longer GT.

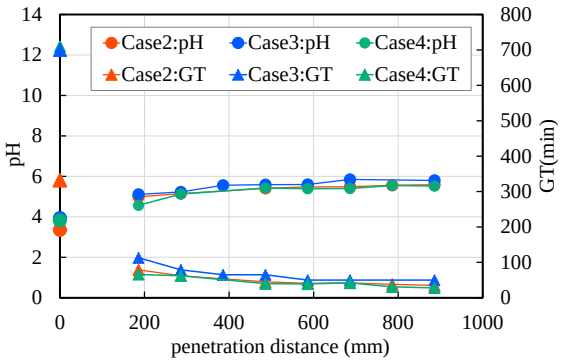

Fig.10 Relationship between pH and GT with distance (Case2-4)

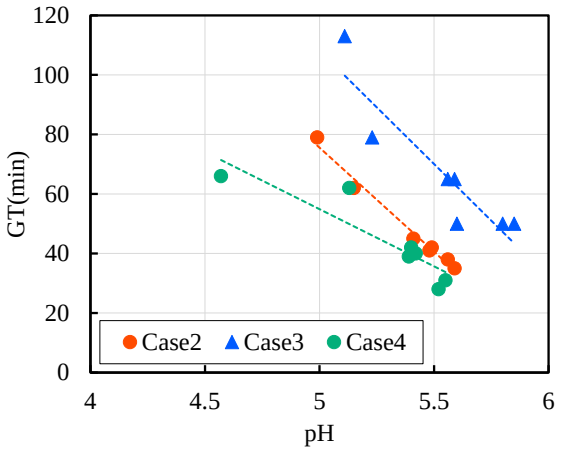

Fig. 11 Relationship between pH and GT

These changes in GT may be attributed to the injection time and the amount of silica present within the solution. With this, the change in the concentration of silica in the grout was also measured using a pack test. Pack tests are a simple and straightforward way of determining the amount of substance in a solution. A disadvantage of using this method is that only low concentration solutions can be tested. Since the grout solution had a high concentration of silica, it was diluted with distilled water until the acceptable range was reached. Maintaining the same dilution rate, the silica concentrations per penetration distance are illustrated in Fig.11. From all cases, the concentration decreases with distance regardless of flow rate, with the largest change occurring with Case 3.

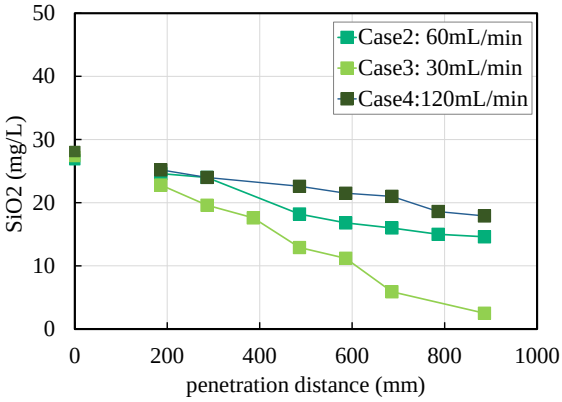

Fig.12 SiO_2 concentration with distance

These changes in GT and silica concentration were believed to be a result of three things, dilution, adsorption, and partial gelation. Since the specimen was prepared in a fully saturated condition, the injected highly concentrated silica grout solution tends to diffuse into the water in the void spaces. Though this might be minimal according to Endo [4].

On top of this, suspended silica particles might get adsorbed onto the sand particle surfaces due to rapid neutralization reactions. Since the grout solution was formulated to form a gel after some time to improve the properties of the soil, gelation occurs after the injection process. This gelation or the reaction of the grout to form a gel utilizes silica to form complex polymers.

Looking at the results obtained on Figs 10 and 11, the longer GT arising from the slow flowing Case 3 and the faster gelation from the fast-flowing Case 4 can be related to the amount of adsorbed silica. With a prolonged injection time in Case 3, it may have resulted in more silica compounds being adsorbed to the sand particles. This way, when the solution was extracted using the syringes at the end of the experiment, the solution contained less silica which extended the gelation. On the other hand, Case 4 with a faster completion time, there was less adsorption of the silica into the sand particles, resulting in higher silica concentration in the extracted solution, shortening the gelation time.

From the results, it can be incurred that adsorption may have been the greatest factor in affecting the silica amount compared to diffusion and gelation.

CONCLUSIONS

In this study, one-dimensional injection tests were conducted using both inert and alkali-rich sand to investigate the performance of chemical grouting in terms of pH, GT, and silica concentration.

Results showed that the neutralization rate did not change with the injection flow rate, but the solidification time and silica concentration were affected. A higher pH resulted in a faster gelation, and a slower flow rate contributed to higher pH values. Gelation was deemed to be affected by both pH and silica concentration. Even with the same pH value, GT was longer with lower silica concentration.

The soil medium plays a major role in the effectiveness of chemical grouting. Alkaline components in the soil react with the acid compounds in the grout. It was observed that three things affect the performance of the grout solution, diffusion, adsorption, and gelation. From the experiments conducted, adsorption of silica greatly influenced the gelation time of the solution.

To better understand how the silica content affects the gelation in a more detailed manner, future tests including the dissolution of the gelled solution and its analysis are planned.

INFLUENCE OF SEEPAGE AND SEISMIC DISASTERS ON THE FAILURE BEHAVIOR OF LARGE-SCALE EMBANKMENTS

Satoko Io[1], Kazuya Itoh[2] and Naoaki Suemasa[3]

[1,2,3] Graduate School of Integrative Science and Engineering, Tokyo City University, Japan

ABSTRACT

Japan frequently experiences natural disasters due to its geographic location. In addition to earthquakes, climate change has intensified torrential rainfall, increasing the need to understand compounded effects of these disasters. For instance, the 1995 Southern Hyogo Prefecture Earthquake caused approximately 700 locations, which soared to over 2,000 after subsequent rainfall. A similar situation was observed following the 2024 Noto Peninsula Earthquake, where record-breaking rainfall triggered additional slope failures in the already-affected areas. Furthermore, embankments with groundwater presence were found to be more susceptible to large-scale collapses. This study investigates the effects of seismic motion and groundwater on slope stability, identifies the critical groundwater levels that trigger collapses, and proposes countermeasures for compound disasters. A centrifuge vibration-seepage test was conducted using a shaking device and a groundwater level stabilization system to simulate a large-scale embankment. The effects of input acceleration and groundwater fluctuations on embankment stability were then analyzed. Results showed that the embankment remained stable when exposed to shaking alone but collapsed when the groundwater level rose, signifying that groundwater contributes a major part in the collapse mechanism. From the responses of accelerometers installed within the soil sample, the bottom area reacted differently from the upper portion of the slope, highlighting variations in behavior under stress. Moreover, higher input acceleration led to an increase in groundwater levels, further increasing the risk of failure. Although pore water pressure rose, no liquefaction was observed. These findings indicate that a rapid groundwater rise, induced by vibrations, amplified sliding forces and reduced slope stability.

Keywords: Groundwater, Slope stability, Centrifuge model experiments, Seismic motion, Slope collapse

INTRODUCTION

Japan is vulnerable to natural disasters because of its climate and topography. Recently, earthquakes, torrential rainfall caused by climate change have become increasingly frequent. A study of large-scale widening-type embankments where deformation shaped after the 1995 Southern Hyogo Prefecture Earthquake was observed revealed that embankments with greater fill height and steeper natural ground slopes, especially in the presence of groundwater, were more susceptible to deformation [1]. This indicates that groundwater conditions and embankment height significantly influence embankment deformation and the occurrence of sliding failures. During that earthquake, approximately 700 locations experienced slope failure, but this number increased to over 2,000 following subsequent rainfall [2]. A similar phenomenon was observed after the 2024 Noto Peninsula Earthquake, where record-breaking rainfall triggered additional slope failure in the affected areas. Again, embankments with the presence of groundwater were observed to be more susceptible to large-scale collapses [3].

These events underscore the importance of understanding the effects of compound disasters. This study aims to evaluate the combined impact of seismic motion and groundwater on embankments, with the objective of identifying the critical groundwater level that significantly increases the risk of slope failure. Furthermore, potential countermeasures are proposed based on these findings. In this study, a centrifugal model test was conducted to simulate groundwater seepage within an embankment, assuming a large-scale embankment constructed in a residential development area. In addition to forming a groundwater level within the embankment, a second test was performed using a shaking table to reproduce seismic motion, referred to as the groundwater seepage–shaking table test. The effects of vibration and water infiltration on the embankment, as well as the behavior of the model ground, were then analyzed and compared.

CENTRIFUGE MODEL EXPERIMENTAL PROCEDURES

In this study, a groundwater seepage test was conducted using a centrifuge-based embankment backwater level stabilization system to simulate the presence of groundwater within the model ground. In addition, a dynamic shaking table test was performed on the same model ground to reproduce seismic motion. Furthermore, a combined seepage-shaking test was carried out to investigate the effects of both groundwater infiltration and seismic loading on the embankment.

All the tests described here were conducted on the TCU Mark III Centrifuge owned by Tokyo City University [4]. As shown in Fig. 1, an acrylic model container was custom fabricated with a water supply tank, located on the right side, to generate seepage from the back of the embankment. There was also a drainage tank, located at the bottom, for water discharge. The acrylic container measured 448 mm in width and 298 mm in height and was constructed as a single integrated unit to prevent water leakage. Inside the container, a gentle slope with a 20-degree inclination was formed using MC nylon, representing the base ground. To simulate a rough boundary condition, silica sand No.7 was bonded to the base and the slope surface. The water supply tank at the rear of the slope was constructed using an acrylic cutoff plate with nine 3/16-inch diameter holes. Of these, only the upper three holes were used, while the remaining six (middle and lower rows) were sealed. A porous stone was installed on the front side and integrated with the base slope to prevent water leakage.

A total of five experimental cases were conducted, and schematic diagrams of the model ground are shown in Figs. 2 and 3. The red circles in Fig. 2 indicate the pore water pressure gauges, and the yellow squares in Fig. 3 represent the accelerometers. The model ground for all cases was composed of a mixture of Ao clay and silica sand No.7 at a dry weight ratio of 1:3. The mixture was adjusted to achieve a wet density of 1.78 g/cm³, a water content of 13.0%, and a degree of compaction of 95%. Finally, a model embankment with a slope angle of 30 degrees and slope height of 188 mm was made.

In this study, Case 1 was designed as a groundwater seepage test simulating the presence of groundwater within the embankment only, while Case 2 was a dynamic shaking table test that simulated seismic motion only using a shaking device. Cases 3 to 5 were conducted as combined seepage–shaking tests, incorporating both groundwater seepage and seismic loading.

Regarding the simulated groundwater level in the embankment, a centrifuge-based embankment backwater level stabilization system was used to maintain constant water levels at different heights from the embankment rear. In Case 1, the water level was set at 2/3 of the total height. For Case 3, it was adjusted to 1/4 height, while Case 4 had it at 1/2 height. Finally, in Case 5, the water level was again set at 2/3 of the total height. In Cases 1 and 3–5, four pore water pressure gauges were installed at the base of the model ground. After reaching the target centrifugal acceleration of 40G, compressed air was applied to the injection tank, and water was supplied to the supply tank via a rotary joint to initiate groundwater seepage into the embankment.

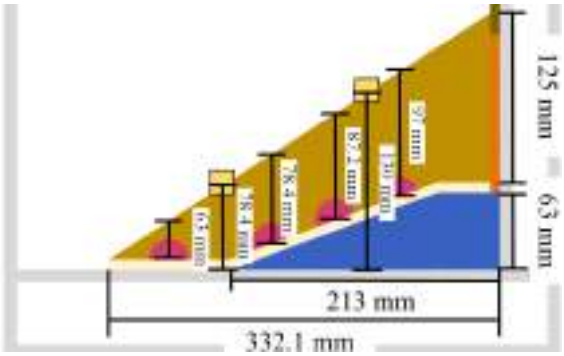

Fig.2 Model ground outline drawing

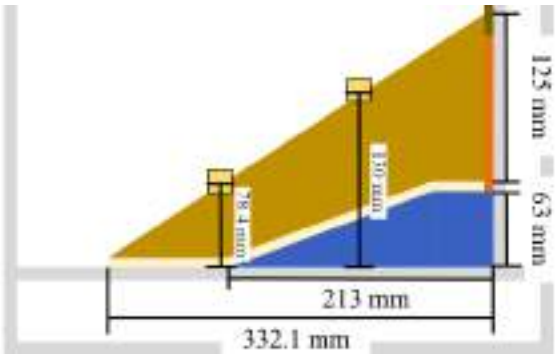

Fig3. Model ground outline drawing

As for the seismic loading, Table 1 summarizes the input acceleration and input duration for Case 2, which involved a sinusoidal wave. In Cases 3 to 5, the input acceleration was set to 300 gal and the input duration to 40 seconds. In Cases 2 and 3–5, two

Table 1. Sine wave input acceleration and input time (Prototype scale)

	Phase 1	Phase 2	Phase 3	Phase 4	Phase 5	Phase 6	Phase 7	Phase 8
Input acceleration (gal)	100	200	300	400	400	400	400	400
Input time (s)	40	40	40	40	40	80	80	160

accelerometers were installed on the model ground surface. After reaching the 40G centrifugal acceleration, the shaking was applied in phases at approximately 10-second intervals.

EXPERIMENTAL RESULTS

Behavior of the Model Ground During Testing

The conditions of the model ground after the completion of each test from Cases 1 to 5 are shown in Figs. 4-8. In Case 1, a small-scale failure occurred 180 seconds after the water was supplied. Progressive failure from the toe of the embankment was observed, as can be seen in Fig. 4. After the initiation of water supply, water infiltrated from the back of the model ground toward the toe of the slope, maintaining a level equivalent to that of the water surface in the supply tank. Once the infiltrated water reached the slope toe, the groundwater level near the toe rose to the slope surface. Subsequently, the rise in groundwater level extended to the middle section of the slope. After that, a local collapse occurred around the slope toe, forming a flow path for the water. As a result, progressive failure through a chain reaction occurred, and the embankment height on the back side decreased. Ultimately, gully erosion developed on the embankment surface as surface water runoff was observed. In Case 2, seismic motion was applied to the model ground in 8 phases as mentioned in Table 1. However, no noticeable deformation of the model ground was observed visually, and no significant changes occurred on the ground surface during the test, as seen in Fig. 5. In Case 3, a large deformation was observed during the first phase, where the back of the embankment settled due to the slope deforming towards the front. Similar deformation continued up to phase 6, with no substantial changes observed in the subsequent phases.

Fig4. Case1 Post-Experiment

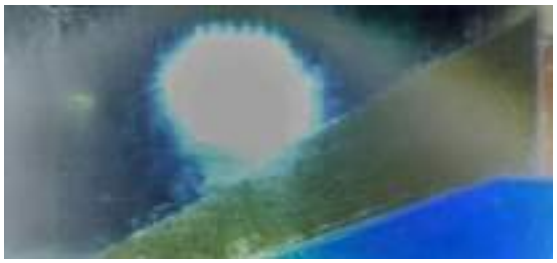

Fig5. Case2 Post-Experiment

Additionally, slope failure did not occur at the ground surface throughout all phases. In Case 4, the deformation pattern was similar to that in Case 3 during Phase 1, but the extent of the failure was greater than that in Case 3. The slope slid forward and continued with each phase. Cracks were observed to have developed across the entire ground surface during Phase 4. In Case 5, it was observed that embankment height settled during Phase 1, then a bulging-type failure around the middle of the slope occurred. During Phase 2, a large-scale slope failure occurred from the back of the model ground, that deformed downwards.

Groundwater Level in the Embankment

Trends of the groundwater level under the embankment for each case are shown in Figs 9-12. The peaks observed in Cases 3 to 5 correspond to the periods during which shaking was applied using the shaking table. The groundwater level is calculated from the pore water pressure recorded. Therefore, it

Fig6. Case3 Post-Experiment

Fig7. Case4 Post-Experiment

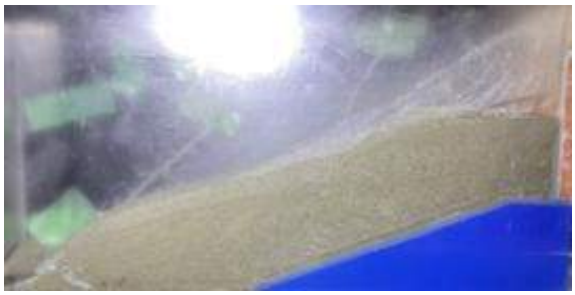

Fig8. Case5 Post-Experiment

should be noted that if the water pressure is not hydrostatic such as during shaking or with the dissipation of excess pore water pressure after shaking, the calculation result might slightly differ from the actual water level. In Case 1, the groundwater level began to decrease slightly around 7200 seconds after the onset of infiltration, which corresponds to the timing when the small-scale failure happened. Next, in Cases 3 through 5, it was confirmed that as the back water level increased and the groundwater level within the embankment also rose at all measurement points. Furthermore, it was observed that the application of seismic acceleration, in addition to seepage, caused the water level to rise at all measurement points. The influence of the seismic motion on slope failure was confirmed by comparing Case1, which included only groundwater seepage and Cases3~5, which are combining seepage and seismic motion. It was found that Cases 4 and 5 experienced failures at an earlier stage than Case 1. Moreover, although the back water level in Case 4 was lower than that in Case 1, the toe water level rose to the same height as in Case 1. Comparing Cases 1

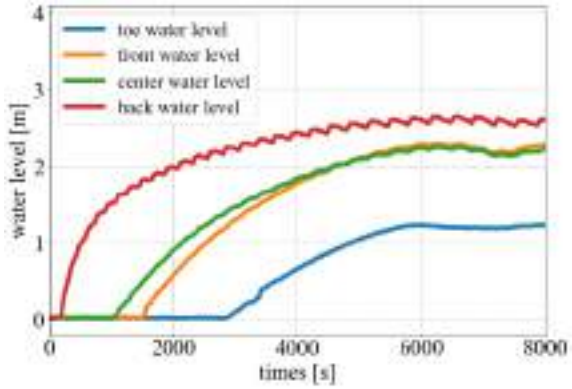

Fig9. Change in groundwater level under the embankment (Case1)

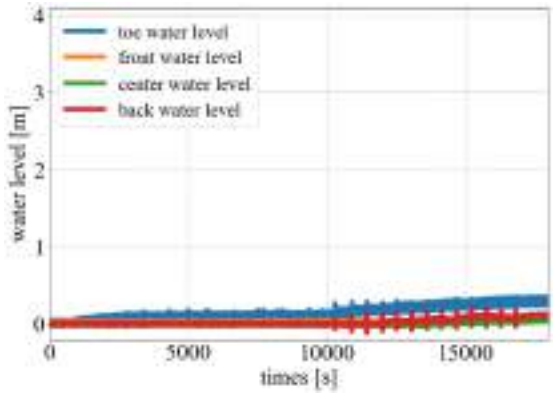

Fig10. Change in groundwater level within the embankment (Case3)

and 5, which had the same back water level, Case 5 has a higher groundwater level at toe of slope than Case 1. In Case3(backwater level : 1/4), the water level at all measurement points rose immediately after the seismic motion was applied, with a particularly remarkable increase in the water level at the toe.

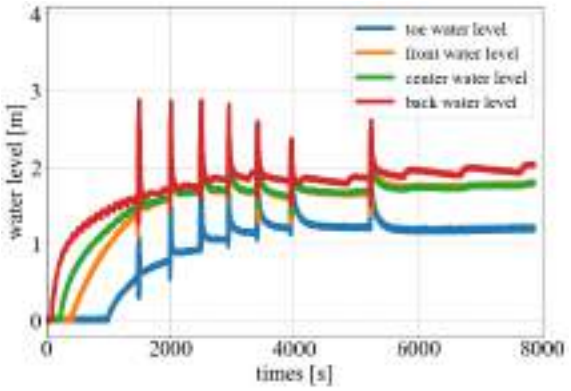

Fig11. Change in groundwater level within the embankment (Case4)

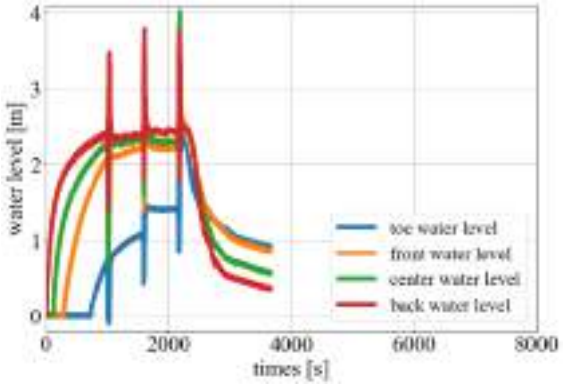

Fig12. Change in groundwater level within the embankment (Case5)

Cumulative Absolute Velocity at the Ground Surface

The cumulative absolute velocity (CAV) [5]for

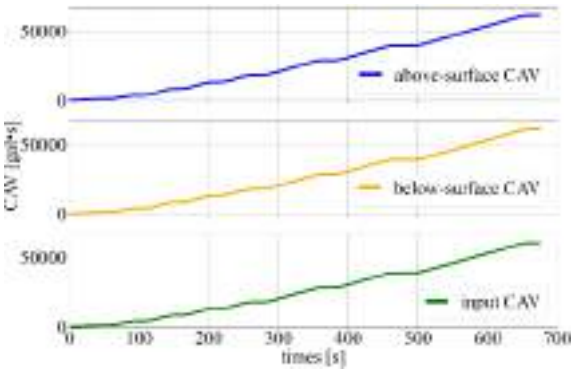

Fig13. CAV at Each Measurement Point (Case2)

each test case is shown in Figs. 13-16. These graphs represent the cumulative sum of the absolute values of acceleration over time, calculated by integrating

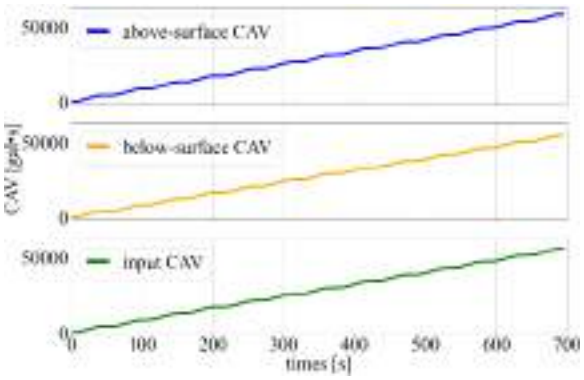

Fig14. CAV at Each Measurement Point (Case3)

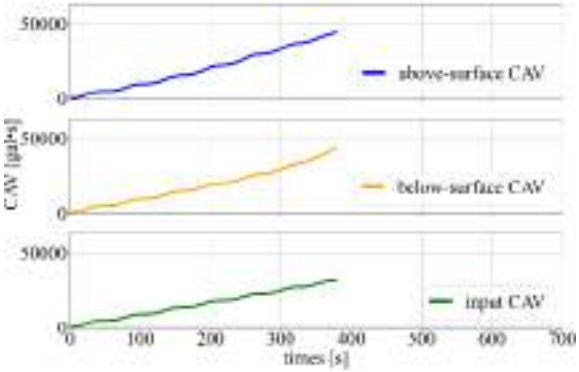

Fig15. CAV at Each Measurement Point (Case4)

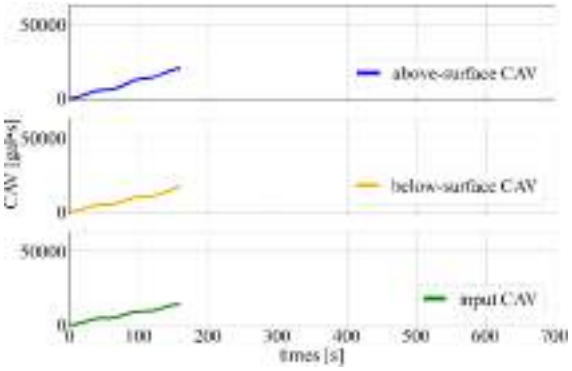

Fig16. CAV at Each Measurement Point (Case5)

the acceleration data. The time axis in each graph corresponds to the total duration of shaking during the test. From these graphs, it is evident that the final values of CAV differ depending on the test case. Although the extent of deformation varied among Cases 3 to 5, slope failure occurred in all three cases during Phase 1, and the CAV at the time of initial failure was approximately the same. However, Case 3 did not experience large-scale slope failure until Phase 13, whereas Cases 4 and 5 failed earlier, at Phase 7 and Phase 3, respectively. When comparing the CAV values, it was observed that Cases 4 and 5 failed with smaller CAV values than Cases 2 and 3. These results suggest that the presence and rise of groundwater within the embankment significantly contribute to the occurrence of slope failure.

Relationship Between CAV and Groundwater Level

Fig.17 summarizes the relationship between CAV and groundwater level for Case 1 and Cases 3 to 5. The plotted groundwater levels represent the average toe water level during the shaking period of each test. For Case 1, the groundwater level at the time of failure is plotted at CAV = 0, as no shaking was applied. From the figure, it can be seen that the final groundwater levels in Cases 3 and 4 are higher than that in Case 1. In addition, in all three cases (Cases 3 to 5), the toe water level increases with increasing CAV. In Cases 3 and 5, the groundwater level increases linearly with respect to CAV. In contrast, in Case 4, the rate of increase in groundwater level gradually decreases as CAV increases. These results indicate that the toe water level tends to rise with increasing CAV. However, the maximum CAV values differ among the cases. Furthermore, it was found that the higher the stabilized groundwater level, the greater the increase in both CAV and toe water level.

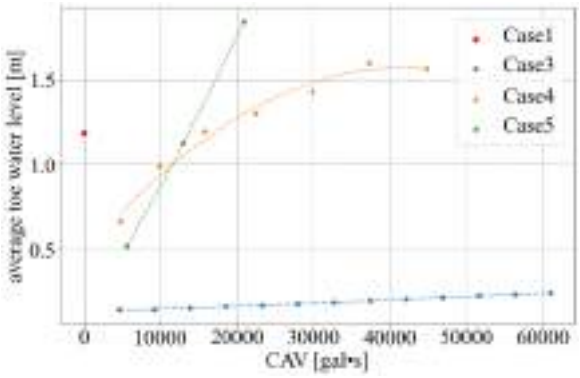

Fig17. Relationship Between CAV and Groundwater Level

CONCLUSION

In this study, a series of centrifugal model tests incorporating groundwater seepage and seismic shaking were conducted to investigate the behavior of embankments and model ground under conditions representative of large-scale residential embankments. A total of five test cases were performed. In Case 2, which involved only seismic loading, no slope failure

occurred even when the input acceleration was increased. In contrast, slope failure was observed in all other cases, including Case 1 (groundwater seepage only) and Cases 3-5 (combined seepage–shaking tests). Regarding groundwater level changes within the embankment, Cases 3-5 showed a more rapid rise in water level compared to Case 1. In particular, the water level at the toe of the slope, which critically affects slope stability, was observed to rise sharply after shaking. Analysis of the cumulative absolute velocity (CAV) at the ground surface revealed that the CAV at the time of slope failure did not necessarily match across cases. Moreover, the total CAV varied depending on the test case, and slope failure tended to occur earlier in cases with higher back water levels. These results suggest that the height of the groundwater level had a greater influence on slope failure than the magnitude of seismic motion. Finally, the relationship between CAV and groundwater level in Cases 3 to 5 showed that the groundwater level increased with increasing CAV. It was also confirmed that the higher the stabilized groundwater level, the greater the increase in both CAV and toe water level.

Future work will continue to explore seepage–shaking interactions under centrifugal conditions, focusing on identifying critical groundwater levels, understanding the combined effects of seismic motion and seepage, and evaluating their impact on slope behavior. In addition, countermeasures for sliding-type slope failures will be developed and their effectiveness assessed through further model testing.

VISUALIZATION OF PORE WATER FLOW IN GRANULAR MEDIA USING CYLINDRICAL TRANSPARENT PARTICLES

Shingo Hamano[1], Tatsuya Matsuda[1] and Naoto Naito[1]

[1]Architecture and Civil Engineering Department, Toyohashi University of Technology, Japan

ABSTRACT

Levee failures due to heavy rainfall are primarily caused by overtopping, scouring at the landside toe, and seepage failure. Understanding these mechanisms of soil-water interaction is essential to mitigate geo-disasters. However, conventional observation techniques struggle to capture internal erosion processes due to soil opacity. When the side walls of a model test tank are used to visualize seepage, its friction and confinement effects often lead to non-uniform flow behavior in the depth direction. This study introduces a saturated transparent soil model composed of cylindrical particles with a refractive index (~1.33) nearly identical to water, aiming to minimize boundary effects and other interferences in model testing, and to enable direct observation of pore water flow in the soil. Unlike conventional methods that rely on refractive index matching using viscous solutions (e.g., glycerin, silicone oil), this approach eliminates fluidity constraints, enhancing the accuracy of Particle Image Velocimetry (PIV) measurements. The model test results demonstrate that seepage can be quantitatively analyzed with high precision. The internal flow structure in soil was successfully visualized, revealing localized variations and confirming a proportional relationship between pore flow velocity and hydraulic gradient under low-gradient conditions. Additionally, the study identifies the critical hydraulic gradient, defined as the minimum gradient necessary to initiate particle mobilization within the soil matrix. These findings enhance understanding of sediment–fluid interactions during soil failure, contributing to a more advanced geotechnical framework for percolation-induced failure mechanisms.

Keywords: Transparent soil, Water, Particle image velocimetry, Seepage

INTRODUCTION

Many geotechnical disasters are related to an interaction between soil particles and water such as river levee failures caused by flooding [1], local scour around bridge piers [2], mound erosion of breakwaters caused by tsunamis [3], rainfall-induced slope failures [4], and submarine landslides triggered by earthquakes [5]. Accurate disaster prediction and reliable performance assessment of mitigation structures are essential to implement effective countermeasures against such events. Therefore, elaborate model tests have been conducted, and many studies on developing numerical methods for prediction and evaluation have been conducted using model test results as benchmarks [6-8].

One promising approach for obtaining highly accurate results is using transparent soil, which enables visualizing pore-scale flow [9–12] within the ground and three-dimensional particle behavior [13–16]. Previous visualization studies have significantly advanced the development and application of numerical models. However, these approaches often relied on viscous fluids to match the refractive index of solid particles, such as fused silica. Because the rheological properties of these fluids differ markedly from those of natural groundwater, they limit the accurate reproduction of soil–water interactions. Moreover, the use of viscous fluids hinders the simultaneous satisfaction of key dynamic similarity criteria—such as Froude and Reynolds similarity—which are essential for accurately modelling flow in scaled experiments. As a result, researchers have often faced a trade-off between achieving realistic flow behavior and maintaining optical clarity.

To overcome these limitations, we developed a transparent soil system composed of cylindrical particles fabricated from a novel material with a refractive index closely matching that of water. This design eliminates the need for viscous fluids, enabling direct observation of pore-scale flow under hydraulic conditions that more closely replicate natural soil–water interactions. Consequently, the proposed method achieves dynamic similarity while offering more accurate and detailed insights into soil transport processes than previous viscous-fluid-based approaches.

RESEARCH SIGNIFICANCE

This study proposes a new experimental method for visualizing pore-scale interactions between soil particles and water using a transparent soil material with a refractive index that matches that of water. Unlike many previous studies, no viscous fluid was used, which enables observations under realistic flow conditions. High-resolution measurements using laser sheet illumination and particle image velocimetry (PIV) enable the tracking of particle behavior not only near the transparent wall but also

within soil mass. The data obtained are valuable for validating advanced numerical models and contributing to the practical use of simulation tools in geotechnical engineering and disaster mitigation.

PARTICLE CHARACTERISTICS

Transparent cylindrical particles made of a fluoropolymer were used and their physical properties were analyzed through laboratory tests. A total of 100 particles were randomly sampled to measure their shapes. The particles had an average diameter of 2.89 mm and an average height of 3.17 mm. The specific gravity of the material was 2.06. Figs.1 and 2 show the transparent particles used in this study.

Fig.1 Transparent particles with a refractive index equivalent

(a) (b)

Fig.2 Transparent particles with a refractive index equivalent to that of water: (a) air and (b) water

Maximum and minimum void ratios

Maximum and minimum density tests were conducted to evaluate the packing characteristics of transparent particles. The maximum density test was performed in three cases, whereas the minimum density test was conducted in five cases. In addition to these tests, the minimum and maximum void ratios were calculated based on the maximum and minimum densities. The results indicated that the maximum dry density was 1,356 kg/m³, corresponding to the minimum void ratio of 0.342, while the minimum dry density was 1,281 kg/m³, corresponding to the maximum void ratio of 0.378.

Angle of repose

The angles of repose of transparent particles shown in Fig.3 were measured. Five tests were conducted based on the method proposed by Nakata et al. [17]. The average angle of repose, θ, was found to be 36.57°.

Fig. 3 Angle of repose

Coefficient of permeability

A constant-head permeability test was performed to determine the coefficient of permeability of transparent soil. Table 1 lists the test parameters. The specimens were cylindrical, 46 mm in diameter, and prepared under loose packing conditions. Based on the results of the density test under these conditions, the bulk density was 1,281 kg/m³. Seepage occurred in the vertically downward direction, and a hydraulic gradient of 1.27 was applied. The average hydraulic conductivity measured at a water temperature of 17.6 °C was 4.48 mm/s. After applying a temperature correction to standardize the value to 15 °C, the adjusted coefficient of permeability was 4.5 mm/s.

Table 1 Permeability test condition

Water temperature T (℃)	17.6
Water level difference ΔH (mm)	65
Flow volume Q (mL)	150
Cross-section area of sample A (mm^2)	1,662
Sample thickness L (mm)	51

Visualization experiment of vertical one-dimensional seepage flow

Experimental procedure

A transparent acrylic pipe with an inner diameter of 46 mm was used. Transparent particles were loosely packed inside the pipe to achieve a minimum dry density of 1,281 kg/m³ and a maximum void ratio of 0.378, as determined from the density tests.

A one-dimensional upward seepage flow was generated by adjusting the water-level difference. Water mixed with a tracer was circulated through the system to visualize the seepage behavior in transparent ground, and a laser beam was directed at the section filled with transparent particles. A schematic of the experimental apparatus is shown in Fig. 4. The particle size of the tracer is 50 μm. Both the pore-scale seepage flow and cross-sectional average flow velocity in the lower fluid-only region were measured.

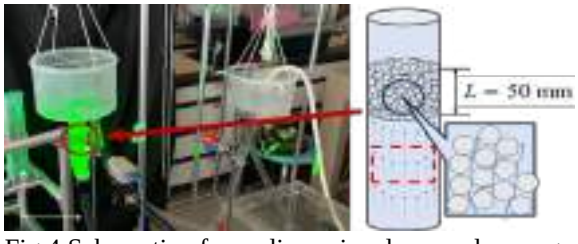

Fig.4 Schematic of one-dimensional upward seepage flow equipment

Fig.4 shows close-up images captured in regions where the movement of the tracers within the particle voids was observable. The recorded video was analyzed using PIV. Based on this analysis, the flow velocity distribution in the apparatus was obtained (Fig.5), and the pore-scale velocity field was evaluated (Fig.6).

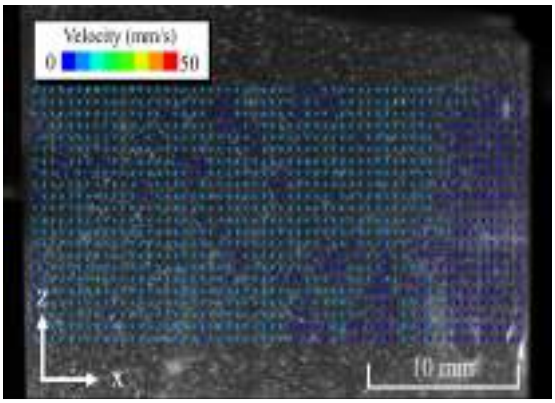

Fig.5 PIV analysis (visualization of flow velocity distribution in the equipment at a hydraulic gradient of i = 0.4)

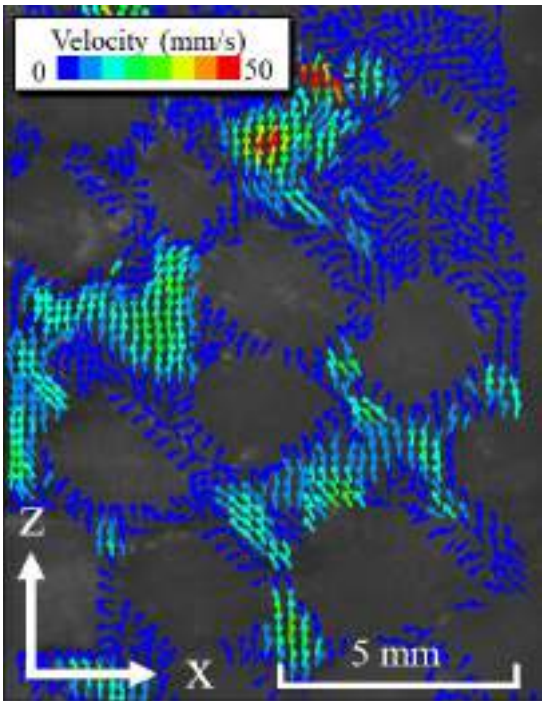

Fig.6 PIV analysis (visualization of pore-scale velocity at a hydraulic gradient of i = 0.4)

Experimental results and discussions

Fig. 7 illustrates the relationship between the hydraulic gradient (i) and the vertical pore velocity, as determined from PIV analysis. The vertical velocity was calculated as the average within the observation area. Although velocity generally increases with the hydraulic gradient, the relationship becomes increasingly nonlinear at higher values, suggesting a potential shift in flow behavior. Further analysis is required to clarify the nature of this change.

Fig. 8 shows the cumulative relative frequency distribution of pore velocity (v) for different hydraulic gradients (i), with dotted lines indicating the mean velocity for each gradient. Overall, the proportion of higher-velocity data points increases with the hydraulic gradient, indicating that larger gradients promote accelerated flow and expand the regions of faster movement.

However, for velocities above 20 mm/s, the number of occurrences is slightly greater at i = 0.6 than at i = 0.8, implying a possible redistribution of flow paths at higher gradients rather than a simple intensification of extreme velocities.

Fig. 9 presents the relationship between the hydraulic gradient (i) and pore velocity (v) as a relative frequency distribution. At i = 0.6, most data points correspond to velocities below 5 mm/s; however, the proportion of velocities exceeding 25 mm/s is slightly greater at i = 0.6 than at i = 0.8. In contrast, the distribution at i = 0.8 is relatively flat, lacking a distinct peak, which may suggest a reduction in localized high-velocity zones and a more uniform distribution of flow paths.

The focus shifts to the critical hydraulic gradient for further discussion. The critical hydraulic gradient in the vertical direction i_{cr} is calculated using

$$i_{cr} = G_s - 1/1 + e \quad (1)$$

where G_s and e represent the specific gravity of the soil particle and void ratio, respectively. The critical hydraulic gradient is defined as the minimum gradient necessary to initiate particle mobilization within the soil matrix.

In this study, the critical hydraulic gradient (i_{cr}) was determined to be 0.77. Considering the critical hydraulic gradient of the material, it is possible that a significant redistribution of the flow occurred in pore spaces outside the analyzed area at i = 0.8. Consequently, the proportion of velocities exceeding 20 mm/s was higher at i = 0.6 within the analyzed region, which indicates that a broader analysis domain is necessary for capturing flow behavior under high hydraulic gradients.

Although localized high-velocity zones diminished at i = 0.8, no noticeable changes in particle arrangement were detected within the analysis area. The tested material comprises uniformly sized particles without a fines fraction; thus, classical suffusion is unlikely. However, if the granular assembly is considered as a soil skeleton, the observed flow homogenization may indicate a potential for void formation or internal instability under sustained seepage conditions.

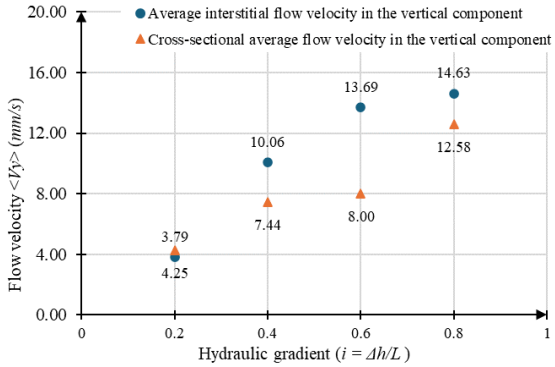

Fig.7 Cross-sectional average flow velocity and average interstitial flow velocity

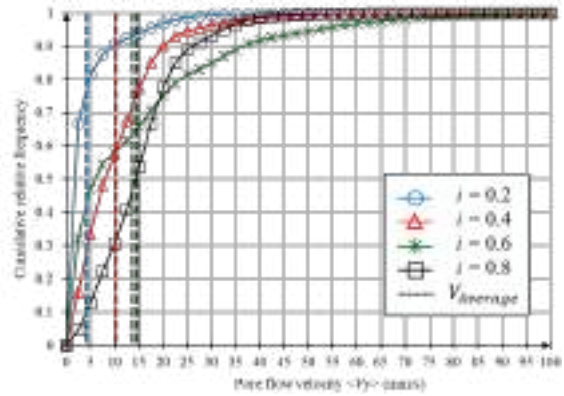

Fig.8 Cumulative frequency distribution of average interstitial flow velocity

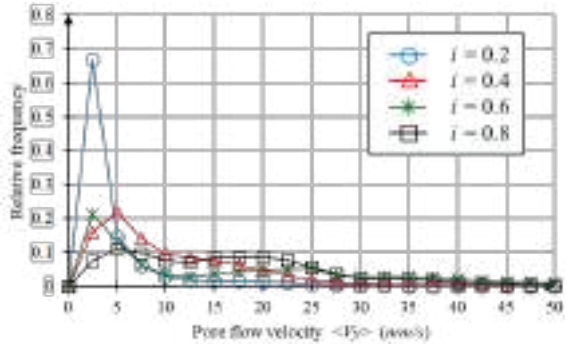

Fig.9 Relative frequency distribution of average interstitial flow velocity

CONCLUSIONS

This study employed a novel transparent soil material to visualize seepage flow, with physical properties closely matching those of natural soil. The results demonstrated a linear relationship between both the vertical mean flow velocity and the average pore velocity with the hydraulic gradient.

Notably, near the critical hydraulic gradient, a distinct flattening in the pore-scale velocity distribution was observed, suggesting a redistribution of flow paths under high-gradient conditions.

The present investigation was limited to scenarios in which soil particles remained fixed. Future research will focus on dynamic conditions that allow particle movement and rearrangement to more accurately replicate natural soil behavior. Additionally, efforts will be made to optimize imaging conditions for the transparent material and to further analyze its deformation and fracture characteristics.

GROUND IMPROVEMENT OPTIMIZATION USING DYNAMIC NUMERICAL ANALYSIS IN THE DEVELOPMENT OF THE BANYUWANGI AIRPORT IN INDONESIA

Christopher Tanjung[1], Andhika Sahadewa[1,2], Pebri Herry[1], Reza Ismaniar[1], and Aris Wibowo[1]

[1]Nur Straits Engineering, Indonesia
[2]Civil Engineering, Bandung Institute of Technology, Bandung, Indonesia

ABSTRACT

Banyuwangi Airport is located in Blimbingsari, East Java, Indonesia. Banyuwangi Airport was expected to be able to share heavy traffic load amongst nearby airports. Previously, the existing runway could only accommodate Boeing B737-500 as the largest airplane. It must be extended by 350 m to accommodate larger airplanes, such as Boeing B737-8MAX and B737-9MAX. Probabilistic Seismic Hazard Analysis (PSHA) results showed that Peak Base Acceleration of 500-year and 2,500-year return period were 0.24g and 0.39g, respectively. Soil investigations data on the extension location indicated shallow ground water table. The soil stratum was dominated by low plasticity sandy silt and silty sand. According to index properties and low to medium density, these soil types were prone to liquefaction. By evaluating the index properties and N value of Standard Penetration Test using NCEER 1997 method, liquefied layer depth varied from 6 m to 20 m from the ground surface. To optimize ground improvement design, dynamic analysis was performed using ground motion based on PSHA. This approach could reduce the predicted liquefied layer depth to 6 m to 17 m from the ground surface. Ground improvement must be selected and engineered by considering several critical aspects, including material availability, construction period, constructability, and cost. After considering several ground improvement alternatives, rigid inclusion was selected with column diameter of 42 cm with triangular grid spacing of 1.6 m. This study highlights that liquefaction evaluation using dynamic discrete element numerical analysis can optimize ground improvement cost by reducing ground improvement depth.

Keywords: Liquefaction, Numerical Analysis, Rigid Inclusion, Ground Improvement

INTRODUCTION

Blimbingsari Airport in Banyuwangi is projected to be a supporting airport for I Gusti Ngurah Rai Airport in Bali. The largest aircraft that Banyuwangi airport's runway can accommodate is B737-500 prior to 2019. Due to B737-900 or A320 aircraft usage increase for domestic flights, it was urgently required to upgrade the runway capacity by extending and widening the existing runway to accommodate larger aircraft models in the future. To achieve this goal, the runway must be extended by 350 m from 2,250 m to 2,600 m and widen by 15 m from 30 m to 45 m as shown in Fig. 1.

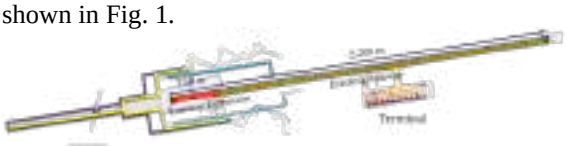

Fig. 1 Banyuwangi Airport Runway extension layout

Soil investigation on runway extension location indicated shallow ground water table with low to medium density coarse grain soil which was prone to liquefaction. Furthermore, Probabilistic Seismic Hazard Analysis (PSHA) results showed that Peak Base Acceleration of 500-year and 2,500-year return period were 0.24g and 0.39g which showed high risk of liquefaction occurrence in the runway extension area. Therefore, soil improvement was needed to prevent runway damages due to liquefaction. In this paper, ground improvement design using finite difference method and advantage of numerical analysis liquefaction over conventional liquefaction analysis is presented.

Liquefaction

Liquefaction is one of many geotechnical hazards in which loose and saturated granular soils undergo strength and stiffness degradation due to seismic load. When the soils lose all of its strength it will behave like a viscous fluid. Liquefaction occurs due to excess pore water pressure generated by cyclic loading which will reduce effective stress to nearly zero [1]. Susceptibility depends on soil density, saturation, and seismic intensity, with loose sands (D_r < 50%) and silty sands being most vulnerable.

On 28 September 2018 a Mw 7.4 earthquake struck Palu, capital city of Central Sulawesi, Indonesia. This earthquake triggered a series of tragic disasters and led to liquefaction events in many places. Following the earthquake, 11-m high tsunamis hit Palu Bay and surrounding coastal areas. The ground movements at these sites due to the earthquake were

associated with multiple mechanisms, including liquefaction, lateral spreading, landslide, and water channel breakage [2].

Liquefaction Evaluation

Cyclic stress ratio (CSR) and resistance (CRR) are the most common empirical method to assess liquefaction potential. CSR and CRR are often derived from Standard Penetration Test (SPT) or Cone Penetration Test (CPT) data. The NCEER National Center for Earthquake Engineering Research workshop established a simplified procedure to evaluate liquefaction potential, which compares CSR induced by cyclic load to CRR derived from the SPT [3]. CSR is calculated as:

$$\mathbf{CSR} = \mathbf{0.65}(\boldsymbol{a}_{\mathbf{max}}/\boldsymbol{g})(\boldsymbol{\sigma}_{\boldsymbol{vo}}/\boldsymbol{\sigma'}_{\boldsymbol{vo}})\boldsymbol{r}_{\boldsymbol{d}} \quad (1)$$

where a_{max} is peak horizontal ground surface acceleration, σ_{vo} and σ'_{vo} total and effective vertical overburden stress, and r_d is stress reduction coefficient. NCEER [3] developed CRR Curve which depends on fine content and N value of SPT (N-SPT).

Rigid Inclusion

Rigid inclusions are vertically stiff elements (e.g., cement-treated columns) installed to reinforce liquefiable soils by improving load transfer and reducing excess pore water pressure buildup during seismic events [4]. The primary mechanism involves stress redistribution, where the rigid inclusions carry structural loads to deeper, stable strata, thereby reducing shear stresses in the surrounding soil and minimizing liquefaction potential.

Rigid inclusion design emphasizes several parameters including column spacing, stiffness contrast between inclusions and native soil, and load transfer mechanisms.

Case histories, such as the 2011 Christchurch earthquakes, highlight the success of rigid inclusions in preventing foundation failures, though site-specific adaptations are critical for optimal results [5].

RESEARCH SIGNIFICANCE

Liquefaction has been one of most dangerous geotechnical hazards, but it is commonly analyzed by using conventional method. This method only considers soil fine content, N-SPT, and Peak Ground Acceleration (PGA). By using numerical analysis to simulate soil under dynamic loading, more soil parameters such as dynamic damping and dynamic stiffness will be considered. Therefore, more accurate soil behavior was analyzed which may affect liquefied layer depth. Ultimately this paper provides a new perspective of analyzing liquefaction potential using numerical method compared to conventional liquefaction analysis.

SOIL CONDITION

In the runway extension area, there were 3 available boreholes (Fig. 2). The N-SPT values were also obtained from these boreholes. The N-SPTs were obtained according to [6]. Four soil undisturbed sample units were retrieved from these holes. Daily well observation was performed to find that the ground water table was varying from 2.3 m to 3.4 m below the ground surface. The soil stratigraphy in the runway extension area was dominated by coarse grained soil which the upper layer consisted of loose to medium dense silty sand, with very loose sand (N-SPT = 1 to 2) was observed in DB-03. Upper layer depth is varied from 8 m to 15 m below the ground surface. The interpreted soil stratigraphy is shown in Fig. 3.

Based on laboratory test results, liquefaction potential was evaluated using methods proposed by [7], [8] as shown in Fig. 4. Both figures indicate high risks of liquefaction. Therefore, further analysis was required to determine liquefied soil depth.

Fig. 2 Soil Investigation Layout

LIQUEFACTION DEPTH ANALYSIS USING CONVETIONAL METHOD

To evaluate the liquefaction potential and mitigation depth, PGA with 500-year return period based on Indonesian seismic hazard map was used in this liquefaction analysis [9]. Indonesian seismic map in Fig. 5 shows that PGA with 500-year return period in Banyuwangi Airport location is 0.2g – 0.25g. Since the site class in runway extension area was classified as SD, the seismic load used in this analysis was 0.31g.

In order to evaluate liquefaction potential and mitigation depth, NCEER [3] method was used. Based on this method, liquefaction potential was identified from the ground surface until 20 m depth (Fig. 6). Thus, based on conventional analysis, soil improvement depth for liquefaction mitigation was 20 m from the ground surface.

LIQUEFACTION DEPTH ANALYSIS USING NUMERICAL METHOD BASED ON SEISMIC HAZARD ANALYSIS

In an attempt to optimize soil improvement depth, numerical dynamic analysis using FLAC 2D

was conducted [10]. In order to simulate seismic hazard more accurately, Probabilistic Seismic Hazard Analysis (PSHA) was performed to get synthetic ground motion and was used as input in FLAC.

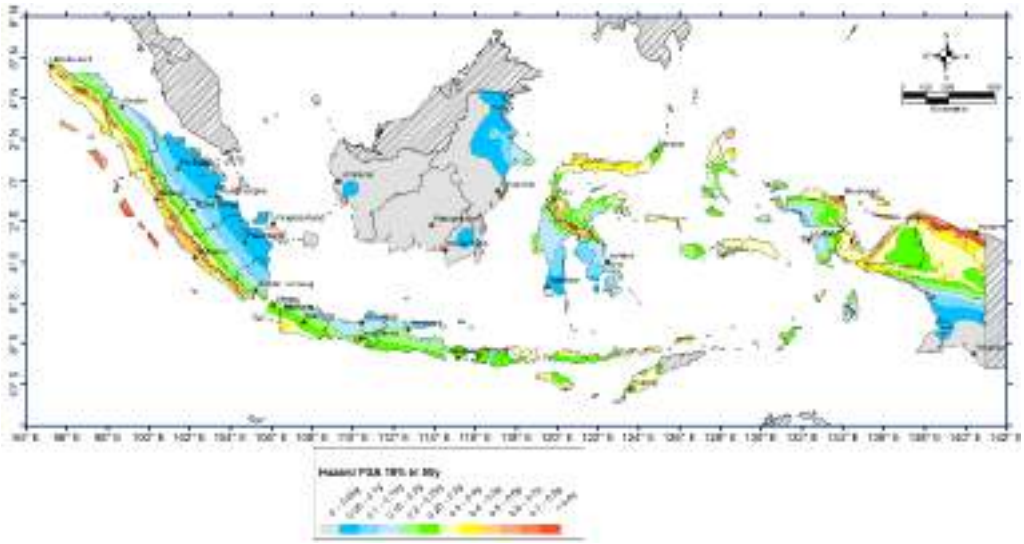

Fig. 5 Peak Ground Acceleration in Banyuwangi Airport

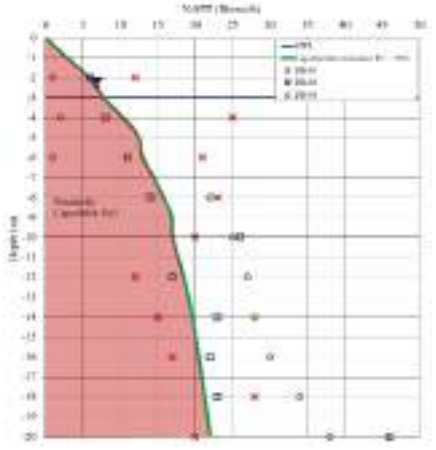

Fig. 6 Liquefaction analysis using NCEER (1997)

Dynamic analysis was conducted using free field boundary to prevent wave reflection. Soil constitutive model used in this analysis was Finn-Byrne model which is based on Mohr Coulomb model [10], [11]. The Finn-Byrne model can calculate pore pressure increase (R_u) in soil for simulating soil liquefaction. Table 1 shows geotechnical soil parameters for DB-01, including saturated unit weight (γ_{sat}), angle of internal friction for design (φ'_{Design}), shear wave velocity of soil, Poisson's ratio (v'), dynamic shear modulus (G_{Dyn}), dynamic bulk modulus (K_{Dyn}), and Finn-Byrne parameters (C_1 and C_2). The FLAC model is presented in Fig. 7.

Fig. 8 shows excess pore pressure ratio increase after the ground motion has subsided. Based on the analysis result, liquefied layer depth varied for each borehole. Liquefied layer depth was 17 m in DB-01, 10 m in DB-02, and 6 m in DB-03. These depths were less than those of NCEER analysis.

RIGID INCLUSION DESIGN

In order to prevent liquefaction during a seismic event, soil improvement using rigid inclusion was proposed. The rigid inclusion columns in this design were set to be 42 cm in diameter, 6 m to 17 m long, spacing on 1.2 m to 1.8 m in triangular pattern. A load transfer platform of 1-m thick made from granular soils was installed on rigid inclusion head.

The rigid inclusion model is presented in Fig. 9. Unit weight of the columns was set to be 22.43 kN/m^3, shear modulus of 5.2 x 10^9 kPa, bulk modulus of 6.91 x 10^9 kPa, The interface for normal and shear forces were both 1.38 x 10^{11} kPa. The maximum mesh size was 1 m. The corresponding analysis result is shown in Fig. 11. In order to determine the most optimum rigid inclusion spacing, the maximum R_u was plotted against Rigid Inclusion spacing to determine the maximum spacing which allows maximum R_u of 40%. Fig. 12 shows that using rigid inclusion with 1.6 m spacing, the predicted maximum R_u in all borehole was less than 40%.

Table 1 Geotechnical Parameter for DB-01

No.	Soil Layer	γ_{sat} (kN/m^3)	φ'_{Design} (°)	V_s (m/s)	v'	G_{Dyn} (Pa)	K_{Dyn} (Pa)	Finn - Byrne	
								C_1	C_2

CONCLUSIONS

Based on the conducted analysis, the following conclusions can be made.

a. Soil investigation results indicated that Banyuwangi Airport was prone to liquefaction
b. Conventional liquefaction analysis using 500-year return period PGA and NCEER method shows liquefied layer was 20 m depth.

c. PSHA and Dynamic analysis using FLAC 2D showed that the liquified layer depth could be reduced from 20 m to 17 m.
d. Rigid inclusion with 42 cm diameter and 1.6 m spacing could reduce R_u from 1.0 to 0.4 in this study.

EVALUATING THE VALIDITY OF MULTI-STAGE DIRECT SHEAR TESTING ACROSS DENSITY AND FINE CONTENT VARIATIONS IN SAND–CLAY MIXTURES

María José Toledo Arcic[1], Jens Engel[1]

[1]Faculty of Civil Engineering, University of Applied Sciences Dresden (HTWD), Germany

ABSTRACT

Multi-stage direct shear testing offers a time- and material-efficient alternative to conventional single-stage procedures. However, its applicability to sand–clay mixtures with varying densities and fines content remains underexplored. This study evaluates the validity of three multi-stage methods, (MSA) maintaining shear displacement, (MSB) full displacement reset, and (MSC) partial release by reverse shearing until near-zero shear stress, across a set of binary mixtures of sand and clay. Six mixtures with fines contents ranging from 10% to 75% were prepared and compacted to medium-dense to dense states using the standard Proctor method. For each mixture, single-stage and multi-stage direct shear tests were performed under normal stresses of 100, 200, and 400 kPa. Results show that all multi-stage methods yield comparable shear strength parameters to single-stage tests in fine-dominant mixtures and low-density states. In transitional and dense mixtures, however, MSB systematically overestimates the friction angle due to cumulative strain effects, while MSA tends to underestimate it, especially in strongly dilative mixtures, but compensates by higher apparent cohesion. MSC provides a balanced response, closely matching the single-stage reference across most cases. The results also confirm a clear behavioral shift from dilative to contractive with increasing fines content, particularly evident around the transitional zone (25–35 % fines content). This study demonstrates that multi-stage testing can be reliably applied to sand–clay mixtures if method selection considers both fines content and state. The findings provide practical guidance for geotechnical laboratories aiming to optimize resources without compromising accuracy in shear strength evaluation.

Keywords: Multi-Stage Direct Shear Tests, Sand–Clay Mixtures, Fines Content, Shear Strength Parameters

INTRODUCTION

Conventional direct shear testing requires two or three independent single-stage tests to determine the shear strength parameters of soils. While this approach is well established, it is both time- and material-intensive, particularly for granular or mixed soils, which require large specimen dimensions and specific sample preparation methods. As an alternative, multi-stage direct shear tests allow several shearing phases to be performed sequentially on the same specimen under controlled normal stress, reducing the overall testing time and material demand, and maximising the amount of shear strength information obtained from a single specimen [1].

Despite the advantages, multi-stage testing has not yet been standardised for all soil types. Most existing studies focus on coarse or fine-grained soils, with limited evaluation in mixed materials, particularly in sand–clay mixtures. In such mixtures, the mechanical behaviour varies significantly with the fines content and state, potentially affecting the validity of multi-stage methods.

The present study investigates whether multi-stage direct shear procedures can reliably determine peak shear strength in sand–clay mixtures with different fines contents. Three procedural variants are considered: one preserving shear displacement between shear phases, one with complete displacement reset, and one with partial release. The aim is to provide practical insight into the applicability of these methods by testing binary mixtures compacted to medium-dense and dense conditions.

In this study, the term *state* refers to the initial density condition, expressed as the Proctor compaction ratio D_{pr}, with values of approximately 90% and 100% corresponding to medium-dense and dense states, respectively.

RESEARCH SIGNIFICANCE

This study contributes to the ongoing evaluation of multi-stage direct shear methods by focusing on sand–clay mixtures. By isolating the effects of fines content and state, the research provides a clearer understanding of how multi-stage methods perform in mixed-grained soils. The findings support the development of practical guidelines for method selection, especially when the available sample quantity is not sufficient for several single-stage tests. Moreover, the study clarifies the conditions under which multi-stage methods provide reliable estimates of shear strength, especially in transitional and fine-dominant mixtures.

MATERIALS AND METHODS

Soil Mixtures

Six sand–clay mixtures (MIX 1 – MIX 6) were prepared with fines contents of 10 %, 25 %, 35 %, 45 %, 55%, and 75 %. The sand used in this study is a uniformly graded 0/2 mm sand (SE according to DIN 18196). Based on its narrow grain size distribution and negligible fines content, it is classified as SP (poorly graded sand) according to ASTM D2487 (USCS). The clay fraction consisted of a low-plasticity natural clay. The particle size distributions of the mixtures are shown in Fig. 1.

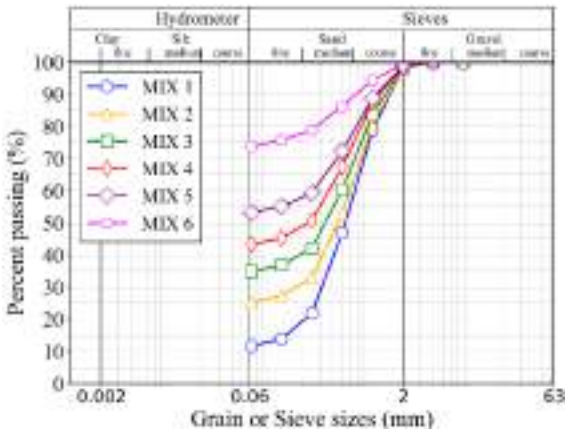

Fig.1 Grain size distribution of the tested mixtures

All materials were oven-dried and sieved prior to mixing. The physical properties of the individual soil fractions are summarised in Tables 1 and 2. These parameters were later used to assess the dominant fraction (coarse, transitional or fine) according to the revised soil classification system (RSCS) proposed by Park and Santamarina [2].

Table 1 Soil properties of tested sand

Fraction	G_S [-]	e_c^{max} [-]	e_c^{min} [-]
Sand	2.654	0.870	0.484

G_S: specific gravity of the solid particles; e_c^{max}: maximum void ratio, e_c^{min}: minimum void ratio.

Table 2 Soil properties of tested clay

Fraction	G_S [-]	LL [%]	$e_F^{(10kPa)}$ [-]	$e_F^{(1MPa)}$ [-]	$e_F^{(flow)}$ [-]
Clay	2.653	32.7	1.084	0.407	1.449

G_S: specific gravity of the solid particles; LL: liquid limit, $e_F{}^{(10\,kPa)}$: void ratio of fines in soft conditions, $e_F^{(1MPa)}$: void ratio of fines in stiff conditions, $e_F^{(flow)}$: void ratio of fines in flow conditions. $e_F^{(flow)} = \lambda \cdot e_F{}^{LL} = [2 \cdot log \cdot (LL - 25)] \cdot e_F{}^{LL} \approx 0.05 \cdot LL \cdot log(LL - 25)$, where $e_F{}^{LL}$: void ratio of fines at the liquid limit, and $\lambda = \geq 1.0$ [2].

Sample Preparation

Each mixture was compacted to a target state (D_{pr}) using its respective Proctor density as reference. The samples were prepared in a shear box with a cylindrical specimen cavity. The internal diameter of the cavity was 60 mm, corresponding to an effective area of 28.27 cm². The specimen height was 19.92 mm, resulting in a total specimen volume of approximately 56.3 cm³. Each mixture was compressed to approximately 90 %, 95 %, and 100 % of the maximum dry density determined from Standard Proctor tests (see Fig. 2). Static compaction was applied in three layers, resulting in a soil structure that differs from specimens compacted using the Proctor method. All specimens were compacted at the optimum water content determined from Standard Proctor tests, resulting in an initial degree of saturation between approximately 50 % and 80 %, depending on the target dry density. All specimens were then saturated prior to testing.

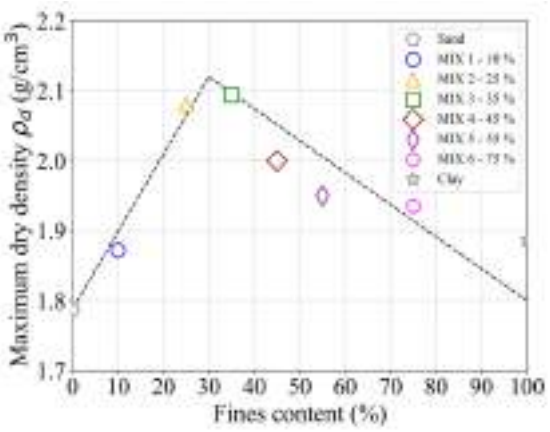

Fig.2 Maximum dry density of the tested mixtures

Shear Testing Methods

Direct shear tests were conducted under vertical normal stresses of 100 kPa, 200 kPa, and 400 kPa. Three multi-stage methods were applied, as illustrated in Fig. 3:

- MSA: No displacement reset; the shear displacement is preserved between phases.
- MSB: Full reset; the displacement is returned to zero before the next phase.
- MSC: Partial release; reverse shearing is applied until the shear stress reduces to <1 kPa.

For reference, conventional single-stage tests were also conducted on each mixture under the same stress levels. All tests were performed under drained conditions, with a horizontal displacement rate of 0.04 mm/min.

CLASSIFICATION OF THE MIXTURES ACCORDING TO RSCS

To determine the classification of the sand–clay mixtures, the threshold fines contents were calculated using the gravimetric–volumetric relationships proposed in the RSCS framework [2]. The theoretical fines fraction F_F is estimated as:

$$F_F = \frac{e_C}{1 + e_C + e_F} \quad (1)$$

Where e_C and e_F represent the void ratios of the coarse (sand) and fine (clay) fractions, respectively. For this study, the maximum and minimum void ratios of the sand were $e_C^{max} = 0.870$ and $e_C^{min} = 0.484$, while the clay void rations were $e_F^{(10kPa)} = 1.084$ (soft condition) and $e_F^{(1MPa)} = 0.407$ (stiff condition). All values were obtained from laboratory tests. Using these values, the lower threshold fines content (dense coarse + loose fines) is $F_{F,L} = 18.8$ % and the upper threshold (loose coarse + dense fines) is $F_{F,H} = 38.2$ %. This theoretical approach was used to assign the RSCS-based classification shown in Table 3.

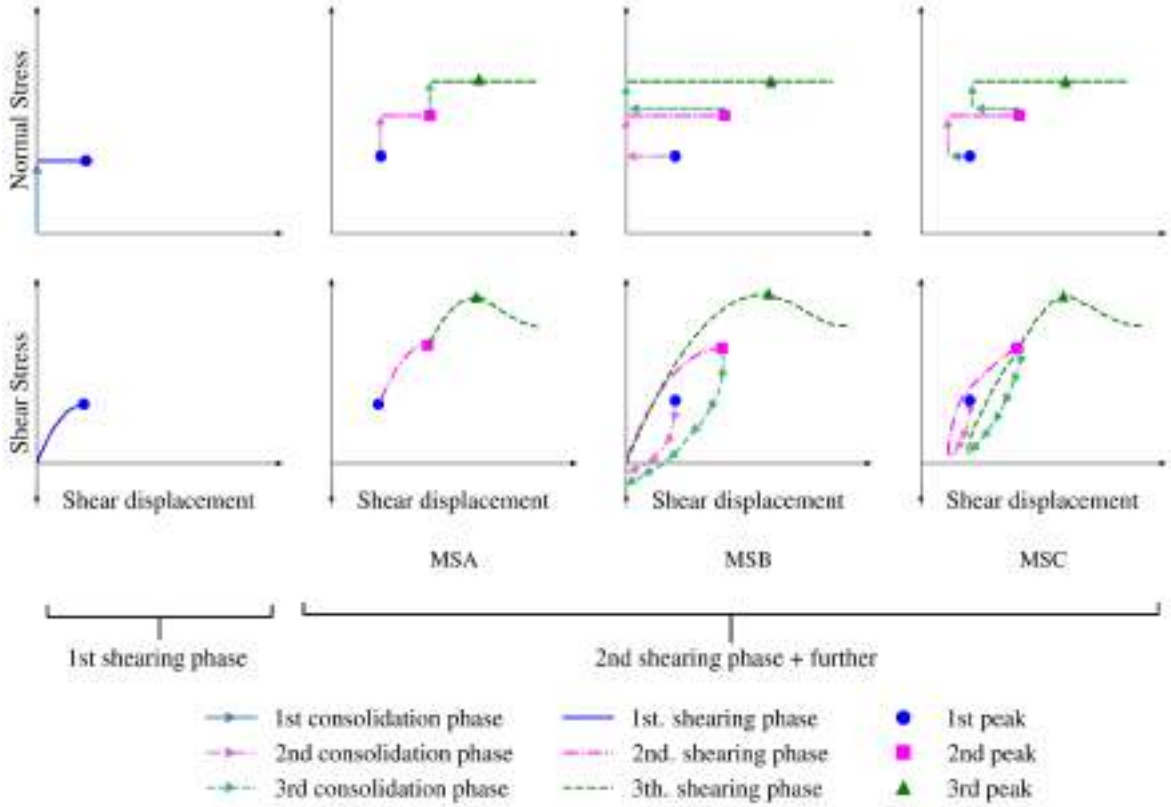

Fig.3 Schematic representation of the multi-stage direct shear methods used in this study (MSA, MSB, MSC)

Table 3 RSCS-based classification of the tested sand–clay mixtures

Mixture	Fines Content (%)	RSCS Classification
MIX 1	10	Coarse-dominant
MIX 2	25	Transitional
MIX 3	35	Transitional
MIX 4	45	Fine-dominant
MIX 5	55	Fine-dominant
MIX 6	75	Fine-dominant

RESULTS AND DISCUSSION

Influence of fines content on shear behaviour

Figure 4 shows the influence of fines content on the normalised peak shear strength τ_{peak}/σ'_N for direct shear tests conducted at $\sigma'_N \approx 100$ kPa. The results show two distinct trends depending on the

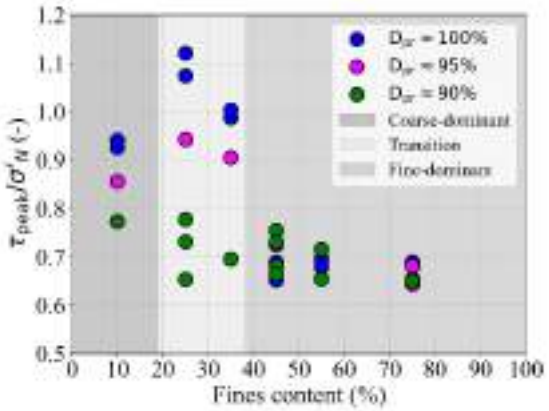

Fig.4 Normalised peak shear strength vs. fines

content at $\sigma'_N \approx 100$ kPa state of the specimens. In the dense state, the normalised shear strength increases with fines content up to approximately 25 %, reaching a maximum within the transitional zone. This behaviour is attributed to fines filling the voids between sand grains and participating in load transfer, reaching the peak of the cushioning effect, where both shear strength and dilatancy are maximised. Beyond this threshold, the shear strength decreases progressively, approaching the reference strength of the compacted fine-grained soil. This decline reflects the breakdown of the coarse grain skeleton, caused by excess fines interfering with interparticle contacts and weakening the load-bearing structure. This trend is consistent with the assumption that, in dense mixtures, fines initially enhance interparticle friction and restrict particle movement, until they become dominant and govern the overall mechanical response. In contrast, the medium-dense specimens ($D_{pr} \approx 90$ %) exhibit a continuous decrease in shear strength with increasing fines content. This supports the hypothesis that, in loosely to medium-dense packed sand–clay mixtures, fines do not contribute effectively to load transfer, unless they form a continuous matrix as in pure fine-grained soils. However, the fine-grained soil used in this study (LL = 32.7%) did not exhibit apparent cohesion under saturated conditions, even at $D_{pr} \approx 100$ %, indicating that no significant interparticle bonding was present. As a result, the resistance decreases progressively and tends to stabilise beyond the fines-dominant threshold.

Influence of fines content on Dilatancy

Figure 5 shows the evolution of the dilatancy angle ψ with increasing fines content for three states.

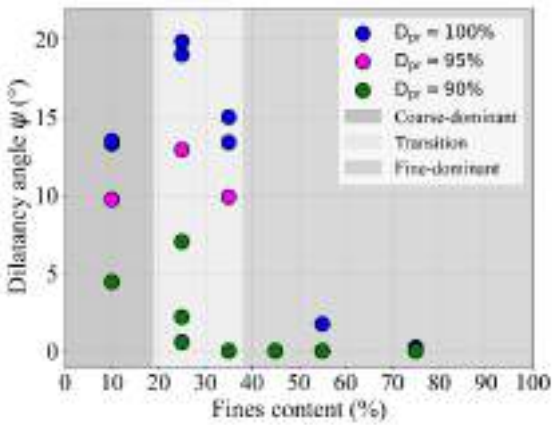

Fig.5 Dilatancy angle ψ vs. fines content at $\sigma'_N \approx 100$ kPa

In dense specimens ($D_{pr} \approx 100$ %), dilatancy peaks in the transitional mixtures (25-35% fines content), where interlocking is maximised and fines contribute to shear resistance without dominating the structure. As fines content increases beyond the range, the behaviour becomes increasingly contractive, leading to a sharp reduction in dilatancy angle. Specimens compacted to $D_{pr} \approx 90$ % show minimal dilatancy across all fines contents, indicating a contractive response consistent with loose packing. The intermediate state ($D_{pr} \approx 95$ %) exhibits a response closer to the dense condition, with a clear dilatancy peak around 30 % fines and a similar transition toward contractive behaviour at higher fines content. These results confirm that transitional mixtures exhibit the strongest dilative behaviour under dense conditions.

Influence of fines on the critical state angle of friction

To further understand the critical shear strength of the tested sand–clay mixtures, the critical state friction angle φ'_{cv} was determined for each mixture using all available data from multi-stage tests. As shown in Fig. 6, the critical state friction angle exhibits a non-monotonic trend: it decreases initially in coarse-dominant mixtures due to reduced interlocking, increases in the transitional zone as fines fill the voids, and then stabilises in fine-dominant mixtures where the clay matrix governs the shear resistance.

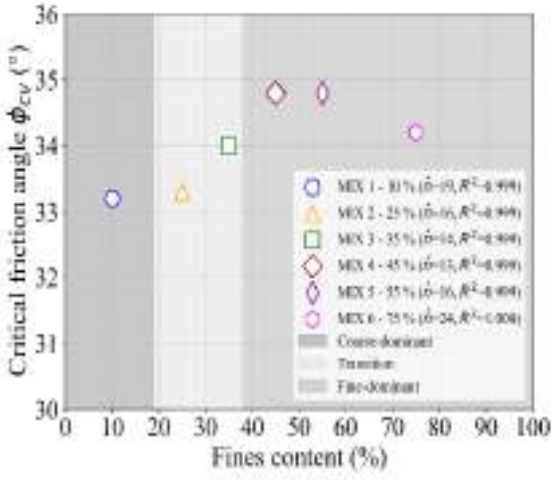

Fig.6 Critical state friction angle φ'_{cv} vs. fines content. The legend indicates the number of tests ($\hat{n}$) used for the determination of each angle

This evolution pattern aligns with the findings of previous studies [3–6], which reported similar behavior in binary mixtures of graded sands, and supports the soil classification scheme adopted in this work. The distinction between coarse-, transitional-, and fine-dominant mixtures based on fines content is thus further justified by their distinct mechanical

responses at critical state.

Influence of the multi-stage method

Beyond the intrinsic effects of fines content on shear behavior, the suitability of the testing method itself depends on the mechanical response of the soil. In particular, multi-stage and single-stage shear tests may yield different outcomes depending on the fines content, density, and structural behavior of the mixture. The analysis evaluates the consistency and capacity of each method to reproduce the reference shear resistance from single-stage tests.

Comparison of peak shear strength

To assess the effect of the testing method on the measured peak shear strength, the results from the last loading phase at $\sigma'_N \approx 400$ kPa were evaluated for all mixtures and methods. Figure 7 shows the relative deviation of the peak shear stress obtained from multi-stage methods (MSA, MSB, MSC) compared to the single-stage reference (SS), for $D_{pr} \approx 100$ % and $D_{pr} \approx 90$ %. The relative deviation is calculated as:

$$\text{RD}\ (\%) = \frac{\bar{\tau}_{p,\text{method}} - \bar{\tau}_{p,SS}}{\bar{\tau}_{p,SS}} \cdot 100 \qquad (1)$$

where $\bar{\tau}_{p,\text{method}}$ is the peak shear stress obtained with the corresponding multi-stage method, and $\bar{\tau}_{p,SS}$ is the peak value from the equivalent single-stage test.

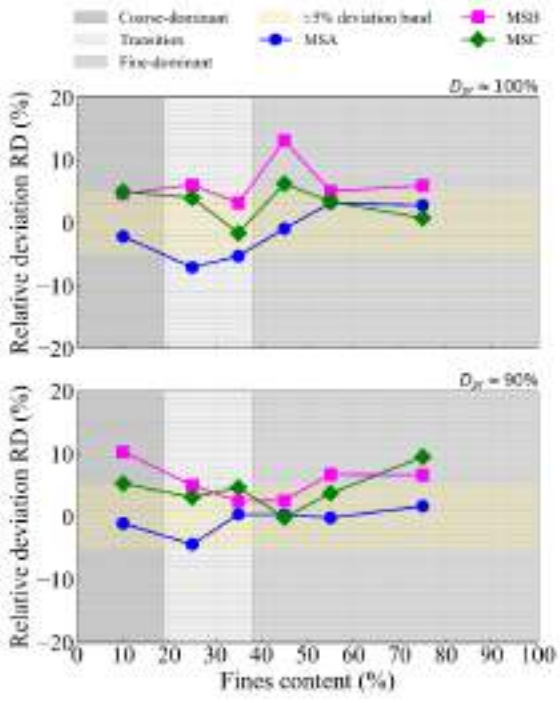

Fig.7 Relative deviation (RD) of peak shear strength from multi-stage vs. single-stage tests, for $D_{pr} \approx 100$ and $D_{pr} \approx 90\%$

In both states, method MSB consistently overestimates the peak shear strength across all mixtures, with relative deviations exceeding 5 % in most cases. In contrast, method MSA tends to underestimate the peak shear strength in transitional mixtures (25% - 35% fines), consistent with previous findings for a mixed-grained soil compacted to $\mathbf{D_{pr} \approx 97}$% [7]. The strongest under-estimation occurs at 25 % fines under dense conditions, where dilation and peak strength are most pronounced (see Fig. 5). In this case, the combination of transitional fines content and strong dilative behaviour appears to increase the sensitivity to accumulated disturbance in MSA. As shown in Fig. 8, this mixture also exhibits a marked loss of dilatancy with increasing stress. While this is partly due to barotropic effects, method MSA appears to further supress dilatancy and reduce the mobilised strength. In fine-dominant mixtures, MSA yields slightly higher strength values, with deviations below 5%. In the medium-dense state ($\mathbf{D_{pr} \approx 90}$ %), the underestimation in MSA is less pronounced or absent. In this state, MSC shows increasing deviation with fines content, while MSB continues to overestimate across all mixtures.

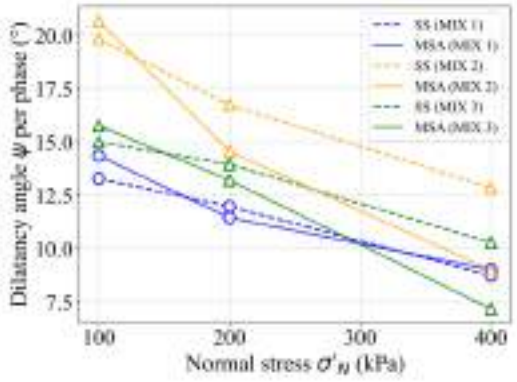

Fig.8 Evolution of dilatancy angle ψ' with increasing normal stress for single-stage (SS) and multi-stage (MSA) tests. Samples compacted to $\mathbf{D_{pr} \approx 100}$%

Comparison of shear strength parameters

The differences in effective friction angle (Δφ') and cohesion (Δc') between multi-stage and single-stage tests are shown in Figures 9 and 10. Values were obtained from shear stresses at failure under $\boldsymbol{\sigma'_N} =$ 100, 200 and 400 kPa. For Δφ', deviations range from -4° to +3° across methods and mixtures. Under $\mathbf{D_{pr} \approx 100}$ %, MSB shows the highest positive deviation at 45% fines, while MSA underestimates the angle, particularly in transitional mixtures (25–35 %). MSC yields positive deviations in fine-dominant mixtures, ranging from -0.2° to +1.6°, with larger differences observed at $\mathbf{D_{pr} \approx 90}$ %. For Δc', MSA shows increases above +10 kPa in mixtures under $\mathbf{D_{pr} \approx 100}$%, particularly for 10, 25 and 35% fines. This coincides with the underestimation of φ', which may be partially compensated by an apparent cohesion.

However, this cohesion could be influenced by device-related effects and boundary conditions. At $\mathbf{D_{pr}} \approx \mathbf{90}$ %, cohesion becomes negligible in both single-stage and multi-stage tests for these mixtures, and MSA yields consistent parameters. MSB shows negative Δc' values in transitional mixtures, while MSC remains close to the single-stage reference across all fines contents.

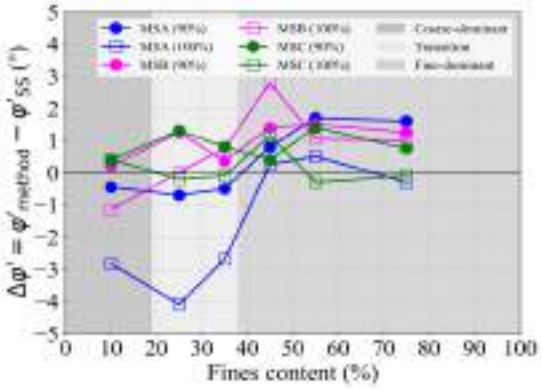

Fig.9 Difference in friction angle Δφ' between multi-stage and single-stage (SS) tests

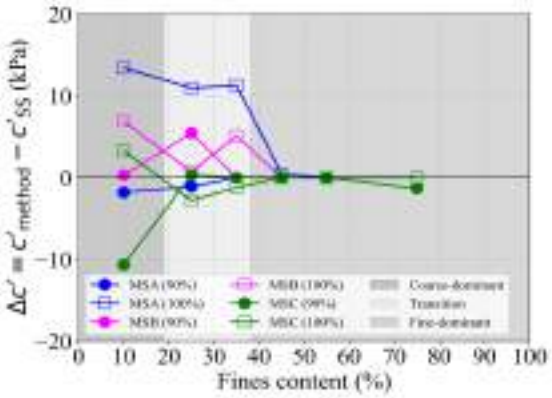

Fig.10 Difference in cohesion Δc' between multi-stage and single-stage (SS) tests

CONCLUSIONS

This study assessed the effect of three multi-stage direct shear methods (MSA, MSB, MSC) on the shear strength parameters of sand–clay mixtures with varying fines content and state. The main findings are:

- Method MSA understimates the friction angle in transitional mixtures (25, 35%) under dense conditions, but yields higher cohesion, partially compensating the reduced shear strength. In the medium-dense state, MSA aligns closely with single-stage results for all mixtures.
- MSB consistently overestimates the friction angle across all mixtures. At $\mathbf{D_{pr}} \approx 90$ %, it also overestimates cohesion in coarse and transitional mixtures, leading to increased shear strength. At $\mathbf{D_{pr}} \approx 100$ %, cohesion differences are smaller, but the friction angle remains higher than the reference, resulting in systematic overestimation of peak shear strength across all fines contents.
- Method MSC shows deviations under dense conditions but provides stable and reliable results at lower densities across all mixtures.
- Deviations in cohesion are more sensitive to the testing method than the friction angle, particularly in dense and transitional mixtures.
- For fine-grained dominated mixtures, all methods produce friction angles within ±2° of the single-stage reference under dense conditions.
- No single method is universally optimal. Its suitability depends at minimum on fines content and state, with additional influence from the soil's tendency toward dilation or contraction.

UNCONFINED COMPRESSIVE STRENGTH OF RIVER-DREDGED SOIL STABILIZED WITH ZEOLITE-BASED GEOPOLYMER

Jonathan R. Dungca[1], Roberto Gabriel A. Bas[2], Chris Anthony C. Elhig[2] and Dana Isabelle P. Villano[2]

[1]Faculty, De La Salle University, Philippines; [2] Student, De La Salle University, Philippines

ABSTRACT

This study explores the potential of zeolite-based geopolymers as stabilizers for river-dredged soil. Using a zeolite sourced in the Philippines and hydroxide and sodium metasilicate pentahydrate as alkali activators, this study investigated the increase in shear strength of the river-dredged sand with varying amounts of zeolite-based geopolymers. Unconfined compressive strength (UCS) tests reveal that higher zeolite concentrations generally improved the shear strength over varying curing periods. Specifically, a geopolymer concentration of 20% was determined to be ideal for curing periods of 7 to 28 days, whereas a 30% concentration exhibited superior UCS values and stability for periods exceeding 90 days. Scanning Electron Microscope (SEM) analysis also confirmed enhanced microstructural integrity with increased zeolite content. These findings indicate the increase in the unconfined compressive strength of dredged soil using zeolites as aluminosilicate precursors, thus producing a viable alternative for soil stabilization.

Keywords: Soil stabilization, Geopolymer, Zeolite, River-dredged soil, Unconfined compressive strength

INTRODUCTION

Geopolymers have emerged as a promising and sustainable alternative to traditional cementitious materials, particularly as a substitute for commercially available ordinary portland cement (OPC). Geopolymers, also known as alkali-activated materials (AAMs), have demonstrated the potential to reduce embodied carbon by nearly 80%, alongside a decreased impact on global warming and eutrophication (excessive plant and algal growth) (Almutairi et al., 2021). However, these benefits vary significantly depending on factors such as the aluminosilicate precursor, alkali activator, and the processes involved in the collection and processing of raw materials. The chemical composition of the aluminosilicates used is critical in developing effective and sustainable geopolymers. Therefore, further research into optimizing the combination of activators and precursors to enhance both performance and environmental sustainability is a valuable endeavor, particularly in soil stabilization, where the application of geopolymers has been relatively underexplored (Ayub & Khan, 2023).

Among the potential aluminosilicate precursors for geopolymers, zeolites—naturally occurring crystalline aluminosilicate materials with a porous molecular structure—stand out as promising candidates. Previous studies, such as those conducted by Villa et al. (2010) and Nikolov et al. (2017), have demonstrated the feasibility of using zeolites in geopolymerization and their effectiveness in various applications, including concrete, mortars, and plasters. However, due to the emerging nature of zeolite-based geopolymers, literature on their use, particularly for soil stabilization, remains limited. Given that zeolites are minimally processed natural materials, they produce fewer carbon dioxide emissions during mining and production compared to conventional soil stabilizers like OPC. Additionally, zeolites are considered "environmentally neutral," making them a promising alternative for environmentally friendly construction materials (Rożek, Król, & Mozgawa, 2019).

Dredged soil, commonly encountered at construction sites, is a type of loose particulate material comprising clay, silt, and sand. It results from natural erosion, weathering, or anthropogenic activities that disturb the environment. Typically treated as waste, dredged soil is often disposed of in the sea or on land, with disposal costs reaching up to 20% of the total dredging expenses (Chan, 2014). Furthermore, the dumping of dredged material can adversely affect neighboring flora and fauna (Cruz-Motta & Collins, 2004, as cited in Chan, 2014). Improving the properties of dredged soil through stabilization offers a promising area of research, as demonstrated in Dungca's 2019 study on soil dredged from a heavily silted river in Mindanao. This approach reduces the volume of material sent to dumping sites and landfills, thereby transforming a perceived liability into a valuable resource for environmental enhancement.

Thus, given the presence of naturally occurring zeolite deposits across various regions, the development of a zeolite-based geopolymer for the stabilization of dredged soil using the wet mixing

method emerges as an important and timely subject for investigation (Dignos, Gabejan, Olegario-Sanchez, & Mendoza, 2019).

The objective of this study was to develop a zeolite-based geopolymer as a stabilizer for dredged soil, utilizing solid activators, specifically sodium hydroxide and sodium metasilicate.

RESEARCH METHODOLOGY

Materials

Dredged Soil

The dredged soil was obtained from the Carmona River at the boundary of the cities of Biñan and Sta. Rosa, in the Philippines. This soil was oven-dried in batches before testing to ensure consistency in the results.

Zeolite

The natural zeolites were obtained from a zeolite mine located in Mangatarem, Pangasinan, Philippines. The study of Olegario and Pelicano in 2017 characterized this zeolite source in its structure, chemical composition, and adsorption characteristics, and they have found that the zeolite is mainly composed of heulandite with other crystalline mineral phases such as clinoptilolite, mordenite, and quartz. The have also observed that the zeolite has plate-like structures with rough surfaces and micro-pores. Table 1 shows the oxide composition of the zeolite from their study.

Table 1 Zeolite chemical composition (Olegario and Pelicano, 2017)

Compound	Oxide
SiO_2	73.20
AL_2O_3	10.72
Na_2O	0.99
CaO	3.84
Fe_2O3	4.05
TiO_2	0.45
MgO	4.34
K_2O	0.36

Alkali Activator

The alkali activator used consists of caustic soda (sodium hydroxide) and sodium silicate in dry powder form, wherein the solution form of the alkali activator mix for the geopolymerization process was achieved with the later addition of water.

Geopolymer Mixture

In creating the geopolymer paste, the dry alkali activator, consisting of powdered sodium hydroxide and powdered sodium silicate, was first mixed. The powdered zeolites were then added to the mixture. To achieve the desired 8M concentration of sodium hydroxide, an adequate measure of water was added, where specified liters per specified grams of sodium hydroxide was set. The resulting geopolymer mixtures were prepared for varying soil-to-geopolymer mix ratios.

Characterization of Geotechnical Properties of Dredged Soil

The index and mechanical properties of the dredged soil were examined per the ASTM standards using the following tests:

a) Particle Size Analysis (ASTM D422)
b) Specific Gravity (ASTM D854)
c) Atterberg Limits (ASTM D4318)
d) Standard Proctor Test (ASTM D698)
e) Unconfined Compressive Strength Test (ASTM D 2166)

Experimental Design

Geopolymer mixtures were operationally defined as the mix design between the alkali activator and precursor material to create the geopolymer paste. The sodium silicate to sodium hydroxide ratio was 1.5 (Villa et al., 2010), the sodium hydroxide concentration was 8M (Nikolov et al., 2017), and the alkali activator to zeolite precursor mass ratio was 0.6 (Villa et al., 2010).

The geopolymer-stabilized soil was defined to be the mix design between the dredged soil and the geopolymer paste in geopolymer percentages of 100%, 10%, 20%, and 30% similar to Dungca et al. (2019). Ambient curing was implemented in the resulting samples, with the results of the UCS tests recorded on the 7th, 14th, 28th, and 90th days. Note that this experimental design was based on the study of Villa et al. (2010).

Batches were assigned based on geopolymer percentages in the samples, namely 10%, 20%, 30%, and 100% respectively. Three UCS samples were tested for each batch per curing day.

Mix Design for Soil-Geopolymer Mix

The parameters to determine the required mass for each of the geopolymer mixtures were identified. These parameters are the specific gravity of the dredged soil, zeolites, sodium hydroxide, sodium

metasilicate pentahydrate, and water. The mass density (kg/m³) of the materials were then computed and shown in Table 2.

Table 2 Mix design Parameters

Material	Specific Gravity, Gs	Mass Density (Kg/m^3)
Dredged Soil	2.65	2650
Zeolites	2.20	2200
NaOH	2.13	2130
Na_2SiOH_3	1.75	1750
Water	1.00	1000

The volumes of the UCS molds were subsequently determined. The mass of each ingredient in the mix design was then proportionally determined from the ratio of the total batch volume to the respective unit volume per kilogram of each ingredient.

The alkali activator consisted of a mix of sodium silicate and sodium hydroxide. In calculating the formulation of sodium hydroxide, caustic soda powder was mixed with the amount of water required for the solution to reach the target molarity (8M). As sodium hydroxide has a molar mass of 40 grams, the target mass of caustic soda per 1 liter or 1000 grams of caustic soda solution was computed as eight times the molar mass, or 320 grams. On the other hand, a molarity of 6M was determined for the sodium metasilicate pentahydrate solution. As sodium metasilicate pentahydrate has a molar mass of 212.137 grams, the target mass of the pellets per 1 liter or 1000 grams of sodium silicate solution was computed as six times the molar mass, or 1270 grams. The mass of sodium silicate solution in 6M was then calculated as 1.5 times the mass of the sodium hydroxide in 8M, as based on Villa et al. (2010).

The geopolymer mix proportion was then calculated following the study of Villa et al. (2010). The mass ratio of the alkali activator (AA) to the zeolite precursor was computed as 0.6. The amount of sodium hydroxide presented in Table 3 was later determined as the combined mass of the caustic soda powder and water. Lastly, a moisture content of 18.99% was added to the mix for the dredged soil to achieve its ideal moisture content. The four soil-geopolymer batches were then differentiated based on the geopolymer percentages, namely 10%, 20%, 30%, and 100% based on Dungca et al. (2019).

Table 3 Mix Design Ratio

NaOH solution/Na2SiO3 solution	1.5
Alkali activator/Zeolite	0.6
NaOH pellets per water (kg/L)	0.32
Na2SiO3 pellets per water (kg/L)	1.27
OMC (%)	18.99%
NaOH solution/Na2SiO3 solution	1.5

Strength Tests

Unconfined Compression Test

The unconfined compression test was used to determine the shear strength of the geopolymer-stabilized soil sample. In this test, a cylindrical soil sample was axially loaded until failure occurred.

Specific percentages of the prepared zeolite-based geopolymer paste were thoroughly mixed with the dredged soil specimens at ideal moisture content. The resulting soil-geopolymer mixes were prepared through the following steps for the UCS test.

(1) The molds for the soil specimens were first prepared using PVC tube with a diameter of 50 mm (1.97 in) and a height of 100 mm (3.94 in). The height-to-diameter ratio was kept at 2;
(2) The soil-geopolymer mixes were then placed and compacted in the cylindrical PVC mold with 12 blows each for 5 layers;
(3) The sealed specimens were kept in ambient temperatures for specific curing periods (7 days, 14 days, 28 days, and 90 days).

After curing the specimens for the specified time per batch, the test specimens were then placed in the loading device for testing. Load was applied to the samples to produce an axial strain rate of 0.5% to 2% per minute. The value of UCS and the stress-strain curve of the soil-geopolymer mixes were obtained using the recorded load, deformation, and time values.

Microstructural Analysis

Scanning Electron Microscopy (SEM) was used to produce high-resolution images of the sample for better visualization of the microstructure of the geopolymer-stabilized soil. With this imaging technique, the morphology, size, and distribution of the individual phases or particles in the geopolymer matrix were closely examined. The information obtained from the SEM revealed critical information regarding the reactivity of the precursors and their implications in optimizing the formulation of the geopolymer.

Coefficient of Variation Analysis

Regression analyses were applied to determine the relationship between the dependent and independent variables. In this study, the dependent variables are the UCS values (kPa), while the

independent variables are the geopolymer concentration (%) and curing days. The choice of model order (linear regression for geopolymer concentration, and power regression for curing days) was made by examining the coefficient of determination (R^2) value. The models with the highest R^2 value were selected as the best fit for the data points.

To validate the data, the coefficient of variation (%) was obtained by dividing the standard deviation by the average of the UCS values obtained. These values were classified into their corresponding precision levels, which also translates to their degree of stability, where lower coefficients correspond to higher precision levels and stability, and higher coefficients correspond to lower precision levels and stability.

RESULTS AND DISCUSSION

Geotechnical Properties

The results obtained from conducting the following geotechnical tests on the dredged soil samples in accordance with their corresponding ASTM standards are summarized Table 4.

Table 4 Geotechnical properties of dredged soil samples

USCS Soil Classification	Poorly Graded Sand (SP)
Specific Gravity	2.65
Liquid Limit	N/A
Plasticity Index	N/A
Moisture Content	18.99%
Maximum Dry Unit weight	15.78 kPa
UCS	N/A

Grain Size Distribution Curve

The grain size distribution curve (GSDC) of the three samples of dredged soil is shown in Figure 1. Based on the figures presented below, Trials 1, 2, and 3 are observed to be composed mostly of sand with some gravel.

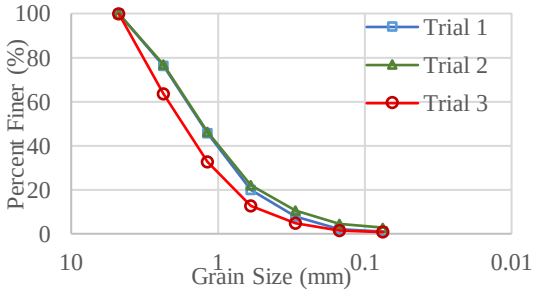

Fig.1 GSDC of the dredged samples

Compaction Behavior

Figure 2 presents the compaction curves of the dredged soil samples using the Standard Proctor Test. Three trials with at least six data points per trial were performed, and the optimum moisture content (OMC) and the corresponding maximum dry density (MDD) were calculated for each trial. The average values of the three trials, 18.99% for OMC and 15.78kN/m^3 for MDD, were used for the mix design and preparation of unconfined compression strength (UCS) samples of treated soils. The average OMC of 18.99% falls within the upper range for poorly graded sands, indicating a higher water content required for ideal compaction compared to well-graded soils. The MDD of 15.78 kN/m^3 aligns closely with typical values for similar soil classifications, reflecting the compaction ability and density achievable under standardized compaction conditions. Meanwhile, the coefficient of determination (r^2) values for each compaction curve ranged from 0.81 to 0.96 and are thus considered to have a very strong relationship between the moisture content and dry unit weight (Ridwan Aldila Melania Care et al., 2018). These values suggest reliable and consistent compaction behavior across the trials.

Table 5 indicates that the obtained OMC and MDD fall within the range typical for poorly graded sand, which is 12-21% and 15.71-18.85 kN/m^3 (Dungca et al., 2019), respectively. Generally, sandy soils have a steep compaction curve, indicating a more gradual increase in dry density with moisture content.

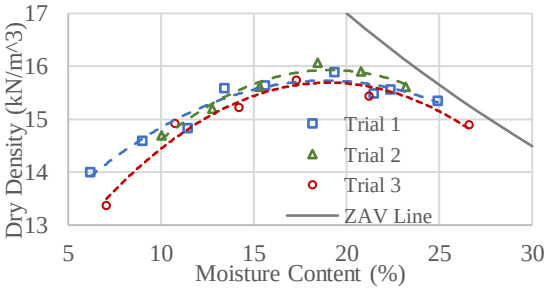

Fig. 2 Compaction curves of the dredged soils

Table 5 MDD and OMC of dredged soil.

Trial No.	OMC (%)	Max. Dry Density (kN/m^3)
1	18.86	15.73
2	19.08	15.93
3	19.04	15.69
Average	18.99	15.78

Scanning Electron Microscopy Results

The SEM micrographs in Figure 3 show the microstructural characteristics of the zeolite, dredged soil, and the soil-geopolymer samples cured in 28 days with varying geopolymer percentages. These

images provide insights into the interaction between the zeolite-based geopolymer binder and the poorly graded sand particles, and the resulting porosity.

The surface morphology of the zeolite indicates high surface area and significant porosity, which are characteristic of zeolitic materials. The jagged edges and uneven surface suggest good mechanical interlock potential, making zeolite an effective component in geopolymer formulations. The high porosity seen in the zeolite sample can contribute to enhanced reactivity and bonding when used as a binder in soil-geopolymer composites.

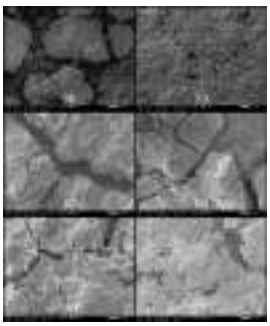

Fig.3 SEM photomicrographs of the (a) zeolite, (b) untreated dredged soil, (c) 10% geopolymer sample, (d) 20% geopolymer sample, (e) 30% geopolymer sample, and (f) 100% geopolymer samples at 1000x magnification.

The SEM photomicrograph of the untreated dredged soil reveals a more compact and less porous structure compared to the zeolite. The soil particles are more irregularly shaped and densely packed, with fewer voids and less apparent surface roughness. The texture suggests limited inherent binding capacity, as the particles do not exhibit significant interlocking features. This compactness and the presence of fewer pores indicate that untreated dredged soil alone may have lower mechanical strength and stability compared to geopolymer-stabilized samples.

The geopolymer-stabilized soil particles exhibit increased cohesion with the addition of higher concentrations of geopolymer, resulting in a general decrease in pore space. The untreated dredged soil photomicrographs suggest limited inherent binding capacity and lower mechanical strength, while the zeolite's high surface area and significant porosity serve to enhance reactivity and bonding in the geopolymer formulation, in alignment with the previously established theoretical framework. As the concentration of the geopolymer increased in the soil samples, improved bonding and integration of soil particles with the geopolymer binder were visible, leading to reduced porosity and enhanced structural integrity. These SEM observations validate the establishment of geopolymer emulsions in the soil, as no novel minerals were observed post-solidification. These findings demonstrate that the improved bonding effect of the geopolymer, particularly at increased concentrations, indeed enhances the mechanical characteristics of the original soil (Ayub & Khan, 2023).

Unconfined Compressive Strength Test Results

Figure 4 shows the relationship between consistency and UCS of soils, for samples cured at 7, 14, and 28 days, the soil mixed with 10% geopolymer concentration yielded UCS strength typically associated with very soft soil, with values ranging from 0 to 25 kPa. However, as geopolymer concentration is increased to 20% and 30%, the UCS strength noticeably improves, falling within the range of typical strength of medium soil (50-100 kPa).

Geopolymer Content	Days Cured			
	7	14	28	90
	UCS Value (kPa)			
100%	151.78	234.01	354.89	1211.57
10%	6.03	13.18	20.95	66.86
20%	51.90	54.60	76.62	143.20
30%	48.90	60.14	72.84	262.03

Fig. 4 UCS Results of zeolite-geopolymer treated soil.

Results showed that there is a significant difference among the UCS of samples with 10% geopolymer content in comparison to the samples with 20% geopolymer content across all curing day spans. Thus, the addition of geopolymer, from 10% to 20%, significantly increased the UCS of the samples.

For 7, 14, and 28 days of curing, the UCS value for the 20% geopolymer was found to be as high as the 30% geopolymer value. These observations indicate that the 20% geopolymer content represents the ideal content that produced the highest UCS value for the said curing span. Minute changes in the UCS values for samples cured at 7, 14, and 28 days were observed after reaching the ideal geopolymer content (20%).

Lastly, a significant increase in UCS from 20% to 30% geopolymer content was observed in samples

cured for 90 days. This extended curing period provided additional time for the geopolymer particles to geopolymerize and bind with the soil more fully; thus, for a curing span of 90 days, the ideal moisture content can be said to be 30%.

The difference in the ideal geopolymer content between samples with a curing span of 28 days and 90 days may be explained by the slow curing rate of Alkali-Activated cements (AAC) treated soil. The findings of Cristelo et al. (2011) established that with soil-AACs, the cementation process is slower and more gradual and durable; thus, the best strengths were achieved at 28–90 days of curing and beyond.

The stabilizing properties of the zeolite-based geopolymer were thus evidenced by the poorly graded sand developing a quantifiable unconfined compressive strength. These findings were also confirmed upon examination of the microstructure of the developed soil-geopolymer matrix as taken from the SEM results. Specifically, the increase in UCS from 10% to 20% geopolymer content can be attributed to the binding effect of zeolite-based geopolymers on the soil sample, densifying the fabric of treated soil and resulting in a more homogeneous and compact material (Sithole & Mashifana, 2020).

CONCLUSIONS

This study highlights the potential of zeolite-based geopolymers as an effective stabilizer for dredged soil. It was determined that with increasing geopolymer concentration, the dredged soil, classified as poorly graded sand, exhibited relatively consistent unconfined compressive strength values. Increased geopolymer concentrations resulted in corresponding increased UCS values.

For curing periods of 7 to 28 days, the most ideal geopolymer concentration was found to be 20%, as determined by samples with the highest UCS values and the lowest coefficients of variation. On the other hand, for curing periods longer than 90 days, the ideal geopolymer concentration was found to be 30%, which in turn had the highest UCS value and the lowest coefficient of variation.

A STUDY ON THE METHOD OF ESTIMATING THE BEARING CAPACITY OF TAPERED PILES

Takaki Asano[1], Naoaki Suemasa[2], Tsuyoshi Tanaka[3], Satoshi Shingai[4] and Yasutaka Sakamoto[5]

[1,2,3] Graduate School of Integrative Science and Engineering, Tokyo City University, Japan

ABSTRACT

In recent years, large-diameter steel pipe piles have been utilized to support larger structures, expedite construction timelines, and reduce costs. However, the bearing capacity of the pile may be insufficient. To address this issue, tapered piles were investigated. These piles feature a gradually decreasing diameter toward the tip, which is expected to enhance vertical bearing capacity regardless of the plug effect. This is because the shaft friction increases by pushing and expanding the ground during penetration. However, tapered piles are rarely employed in practice, and the quantitative evaluation of their pushing and expanding effects remains limited. The purpose of this study is to better understand the bearing capacity characteristics of tapered piles due to their pushing and expanding effects. To achieve this, small dynamic penetration tests, simulating the standard penetration test, were conducted using various tip geometries. The influence of these geometries on the relationship between the load value for each blow and the penetration depth was analyzed. The results showed that tapered piles exhibited greater tip resistance compared to ordinary straight pipes. Furthermore, when comparing with tapered piles, it was confirmed that the longer the tapered section, the easier it is to exert bearing capacity. This indicates that the tapered design had an effect the overall performance of the pile by pushing and expanding the surrounding ground during penetration, resulting in increased bearing capacity.

Keywords: Straight piles, Tapered piles, Plug Effect, Shaft friction

INTRODUCTION

In recent years, large-diameter steel pipe piles (hereinafter referred to as “straight piles”) have been used to increase the size of structures, shorten construction periods, and improve economy. Ordinary straight piles, with standard diameter, exhibit high vertical bearing capacity due to the plug effect of the tip during penetration. However, the larger diameter steel piles are less likely to cause plug effect at the pile tip, so the effect of increasing vertical bearing capacity cannot be expected to be sufficient. On the other hand, taper piles have a reduced diameter toward the tip, which is expected to have a higher vertical bearing capacity regardless of the degree of pile tip plug [1]. This can be attributed to the increased shaft friction due to the pushing and expanding of the ground during pile penetration.

Shingai [2] conducted impact loading tests to compare the performance of tapered and straight foundation piles. Table 1 shows the test piles used in the impact loading tests. Tapered piles were used with a taper angle of 2°. Vertical loading tests were also conducted on tapered piles and straight piles with the same pile length and diameter. Figure 1 shows the results of vertical loading tests on tapered and straight piles. The tapered piles required the same amount of hammer energy to drive as the straight piles, but the total resistance of tapered piles were higher. Therefore, it can be said that tapered piles tend to exhibit higher vertical bearing capacity than straight piles.

Table 1 Test piles used in impact loading tests

	Straight pile	Tapered pile
Pile length (m)	28.0	24.0
Pile diameter (mm)	2300	2300
Wall thickness (mm)	30.0	30.0
Tip diameter (mm)	2300	2021
Tapered part (mm)	0.00	4.00
Taper angle (°)	0.00	2.00

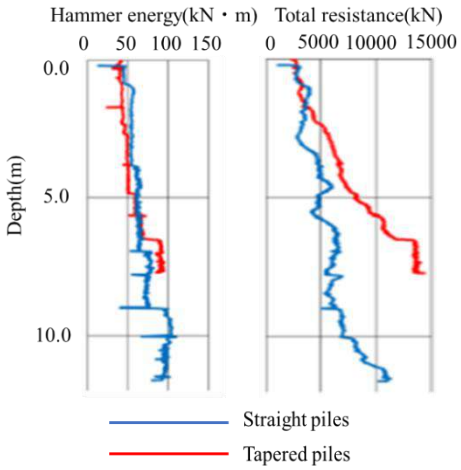

Fig.1 Results of vertical loading tests on piles

However, there are only a few cases of construction using tapered piles, and quantitative

evaluation based on the effect of pushing and expanding the ground has not yet been conducted. Therefore, the purpose of this study is to better understand the bearing capacity characteristics of tapered piles due to their pushing and expanding effects. In this report, small dynamic penetration tests simulating the standard penetration test were conducted using a reduced-size straight pipe (hereinafter referred to as "STP") and a tapered pipe with different shapes (hereinafter referred to as "TPP") to investigate how differences in the shape of the tip pipe and the taper length of the tapered pipe affect the relationship between the load value per blow and the penetration amount. The results of the small dynamic penetration test simulating the standard penetration test are reported.

TIP PIPES

To understand the difference between straight and tapered piles, two cases were done. Case 1 aimed to determine the effect to the difference in geometry between straight and tapered piles, while Case 2 aimed to understand how altering the length of the tapered section can affect the performance of the pile.

Case 1: Effect of Geometry

In this case, the effect of addition of the tapered section to the bearing capacity of the pile was investigated. The actual images of the STP and TPP used is shown in Fig 2. Apart from the tapering section, the effect of different wall thickness in STP and internal tip geometry of TPP were tested using small dynamic penetration tests.

Figure 3 shows the cross-section of the TPPs used, showcasing the difference in internal tip geometry. A more detailed specifications of each pile tested is tallied in Table 2. The diameter expansion ratio of the tip pipe was defined as the max diameter divided by the sum of the inner diameter and wall thickness of the tip. Here, the maximum diameter of the tip pipe was the same size in order to evaluate the same except for the difference in the shape of the tip pipe.

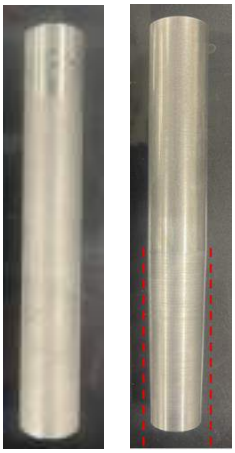

Fig.2 Tip pipe used in Case 1

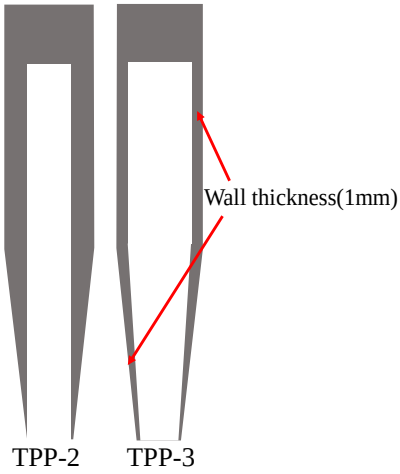

Fig.3 Shape of tip interior of the TPPs

Case 2: Effect of Tapered Length

For the second case, the aim was to understand how different taper length would affect the performance of the pile. Three types of TPPs were used, shown in Fig 4, and the specifications listed in Table 3. The taper ratio of the tip pipe was defined as the length of the tapered section divided by the max diameter. Like Case 1, small dynamic penetration

Table 2 Dimensions of each tip pipe (Case1)

Tip pipe	STP-1	STP-2	TPP-2	TPP-3
Straight section (mm)	178	178	103	103
Tapered section (mm)	-	-	75	75
Taper angle (°)	-	-	1.53	1.53
Max diameter (mm)	25	25	25	25
Inner section length (mm)	153	153	153	153
Inner diameter (mm)	23	15	19	19
Wall thickness (mm)	1.0	5.0	1.0	1.0
Diameter expansion ratio	1.04	1.25	1.25	1.25

Table 3 Dimensions of each tip pipe (Case2)

Tip pipe	TPP-1	TPP-2	TPP-4
Straight section (mm)	103	103	103
Tapered section (mm)	37.5	75	112.5
Taper angle (°)	11.3	5.71	3.81
Max diameter (mm)	25	25	25
Inner section length (mm)	115.5	153	190.5
Inner diameter (mm)	8.0	8.0	8.0
Wall thickness (mm)	1.0	1.0	1.0
Taper ratio	1.5	3.0	4.5

tests were conducted to observe the difference in bearing capacity each TPP achieved. For TPP-2, the same as in Case 1 was used.

TPP-1 TPP-2 TPP-4

Fig.4 TPP used in Case 2

EXPERIMENT OVERVIEW

The bearing capacity of each type of pile tested was quantified using small dynamic penetration tests. A stainless-steel tank with a diameter of 570 mm and a height of 890 mm was used to simulate the model ground, shown in Fig 5. The type of soil used for both Case 1 and Case 2 was kept constant using silica sand No. 7 with a relative density of about 85%. The soil sample was prepared by the air drop method using a hopper to ensure uniform density. Within the model ground, four PVC pipes were placed 300 mm from the ground surface to simulate the drilling of a standard penetration test, and penetration was made up to 300 mm from the bottom of the PVC pipes. Above the model ground, an apparatus simulating penetration test was placed, shown in Fig 6. A 5-kg weight was positioned at the top of the anvil section to be dropped at a height of 110 mm. This simulates one-tenth of the drop energy density of the standard penetration test done in real-scale. A 20-mm-thick cushioning material was placed between the weight and the anvil to prevent energy loss due to the rebounding of the weight. Two load cells, just below the anvil and the other attached to the tip of the rod, were used to measure the load value for each blow. An accelerometer attached to the anvil and a laser displacement meter fixed on top were used to measure the penetration speed and amount of penetration for each blow. The load measured at the tip of the rod is called the penetration resistance value, and the load measured just below the anvil is called the anvil load value.

EXPERIMENTAL RESULTS

Case 1: Effect of Geometry

Figure 7 shows the relationship between the number of blows and penetration depth. In penetration tests, the more blows it needs the higher the penetration resistance of the pile. Comparing the two STPs used, STP-2 had a higher number of blows up to a depth of 150 mm, and remained similar to STP-1 after. The increased number of blows at the beginning can be attributed to the increased wall thickness of the pile. At a depth of 150 mm, the tip was assumed to be plugged, resulting in almost similar blow counts thereafter. In TPP, it was confirmed that TPP-2 had a higher number of blows due to the difference in the tip interior shape. A structure that easily exhibits internal friction makes it harder to penetrate the ground. Between STP and TPP, TPP was observed to have a higher number of blows after 150 mm of penetration. This showed that the tapering of the pile tip caused some effect that increased the penetration resistance of the pile.

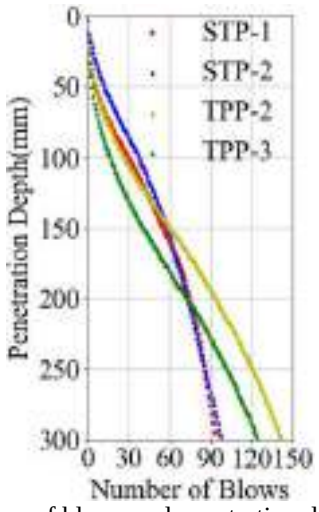

Fig.7 Number of blows and penetration depth

Apart from the number of blows, penetration velocity is also an important factor in pile driving. The slower the velocity, the stronger the resistance. Figure 8 and 9 shows the penetration velocity of the tip pipe at a penetration depth of 150 mm and 300 mm. The penetration velocity is the result obtained from the accelerometer integrated over time. Comparing STP and TPP, TPP had a slower velocity. This was true for both a depth of 150 mm and 300 mm, with more pronounced difference at the deeper depth. TPP-2 exhibited a lower velocity value due to the inner tip shape which creates a higher friction between time of penetration. With all piles having the same outer diameter, the difference in velocity can only be attributed to the geometric shape.

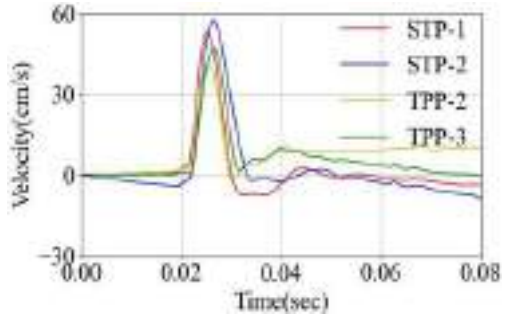

Fig.8 Penetration velocity of the tip pipe at a penetration depth of 150 mm

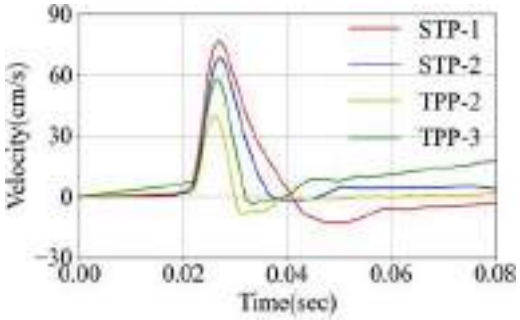

Fig.9 Penetration velocity of the tip pipe at a penetration depth of 300 mm

Figure 10 shows the relationship between the penetration depth of each end pipe and penetration resistance value. Here, the penetration resistance value in this graph is the maximum value per blow. Between the two STPs, STP-2 again had a higher value compared to STP-1 because of the thicker wall that created a higher surface area that touches the ground. At around 100 mm, a change in the slope of the graph can be observed that was assumed to be caused by the plugging of the tip. With the tip plugged, the penetration resistance value of the pipe did not vary significantly. This signifies that the wall thickness is not an important factor in deeper penetration depths.

For the two TPPs tested, both piles exhibited similar behavior until around 100 mm, the point where the tip was assumed to be plugged. After this, the straight geometry of TPP-2 had an advantage over TPP-3, developing higher penetration resistance.

Since the penetration resistance value of TPP is smaller up to a penetration depth of around 150 mm, it can be said that TPP has difficulty in providing bearing capacity when the penetration depth is small. However, with deeper penetrations, even with similar outer diameters and the same plugged condition, TPPs developed higher bearing capacity compared to STPs. This showed that a difference in geometry made an impact to the penetration resistance of the pile. Because of the tapering shape, the tapered pile penetrates the ground by pushing and expanding the ground, leading to a higher penetration resistance.

It has also been reported in A M. Rybnikov's[3] paper that for the same taper length, as the taper angle increases, the bearing capacity of the pile also increases. When comparing this with Case1 conducted in this experiment, the taper angle of the tapered pipe is small at 1.53°, so it is considered that increasing the taper angle would make it easier to exert bearing capacity.

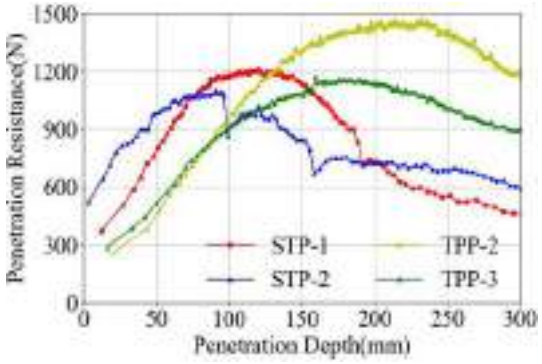

Fig.10 Depth of penetration for each end pipe and penetration resistance value

Case 2: Effect of Tapered Length

By varying the tip length and angle, its pushing and expanding effect to the developed bearing capacity can be understood. Figure 11 shows the relationship between the number of blows and depth penetration. From the three types with gradually longer tip length and lower taper angle, TPP-1, TPP-2, to TPP-3, in this order, all exhibited similar number of blows associated with the penetration depth. This meant that the number of blows is not significantly influenced by the length or the angle of the tapered section.

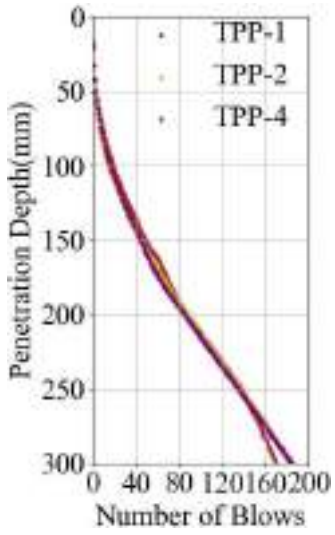

Fig.11 Number of blows and penetration depth

In terms of penetration velocity, the difference of the three types of TPPs were more pronounced. The velocity of the penetration was recorded at the point where the depth of the penetration was equal to the inner section length, shown in Fig.12. Between the three, TPP-4 exhibited the lowest velocity. It can be implied that a longer taper length with a lower taper angle results to a lower penetration velocity. This holds the same for a penetration depth of 300 mm, shown on Fig. 13.

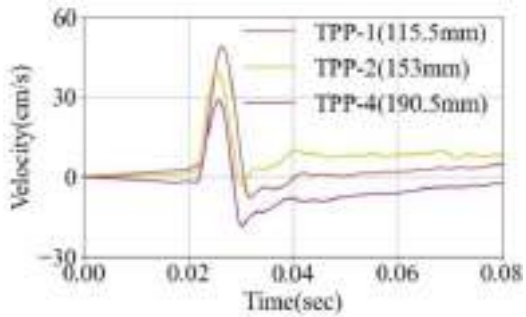

Fig.12 Penetration velocity when penetration depth reaches near the inner section length

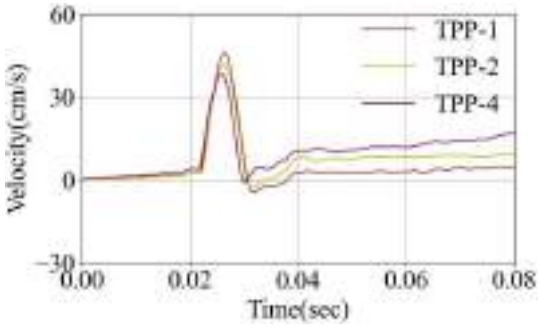

Fig.13 Penetration velocity of the tip pipe at a penetration depth of 300 mm

Figure 14 illustrates the relationship between the penetration depth of each end pipe and the penetration resistance value. As the penetration depth increases, the penetration resistance value gradually rises. When the depth reaches the inner section length, the length of the inner section, the tip is considered plugged that resulted to a shallower slope of the resistance curve. Up to a penetration depth of approximately 150 mm, a longer tapered section results in lower penetration resistance at the same depth. This is due to the difference in diameter of the penetrated portion, a longer tapered section will have a smaller average diameter. However, after a penetration depth of around 200 mm, the penetration resistance value of TPP-4 increases, suggesting that the influence of tip pipe diameter becomes less significant once the straight section of the piles was reached or the entire tapered section was buried. Instead, the rise in shaft friction, caused by pushing and expanding the surrounding ground, becomes more dominant. Additionally, a longer tapered section leads to a

deeper penetration depth before the resistance value peaks. This occurs because the straight section is reached later during penetration. However, the magnitude of the peak penetration resistance does not vary significantly with the length of the tapered section.

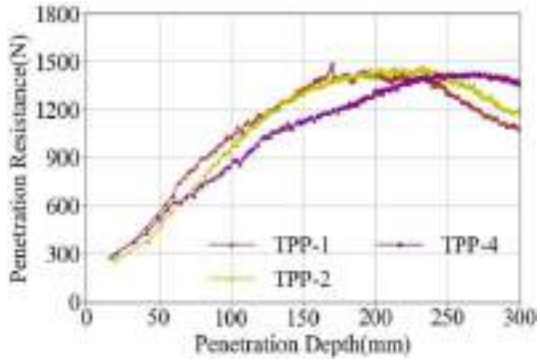

Fig.14 Depth of penetration for each end pipe and penetration resistance value

Figure 15 shows the relationship between the taper ratio and penetration resistance value. In here, two cases were compared, one being at a depth equal to the tapered length, and another one being at 300 mm deep, a depth where all tapered tips are buried inside the soil. From here, the penetration resistance value was greater with a larger taper ratio both when all penetration was made to the straight section and when all penetration was made only to the tapered section. Therefore, even when only the tapered section was penetrated, the vertical bearing capacity differed depending on the length of the tapered section, and it was confirmed that the longer the tapered section, the greater the vertical bearing capacity.

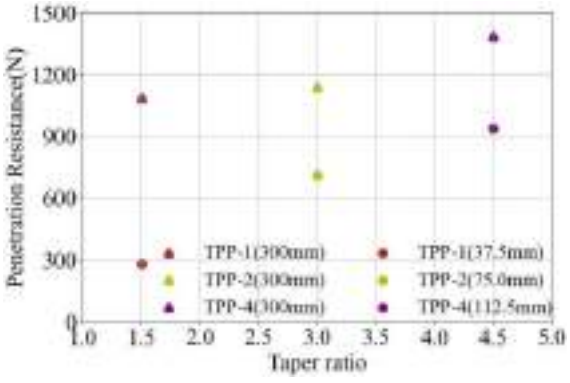

Fig.15 Taper ratio and penetration resistance of TPP

CONCLUSIONS

Overall, the experimental results for the two cases confirm that TPP has a higher penetration resistance value than STP at a deeper penetration depth. This confirms that a change in geometry in the tapered piles can increase vertical bearing capacity by pushing and expanding the surrounding ground during penetration. In addition, the following findings were obtained through experiments in two cases.

1) The thicker the wall thickness of the STP, the harder it is to penetrate up to a depth before the tip gets plugged. At a deeper depth than the inner section of the pipe, the thickness becomes insignificant.
2) A straight inner tip shape offered increased bearing capacity due to increased friction.
3) TPPs showed a higher bearing capacity compared to STPs in deep penetration depths of greater than the inner tip length, but struggled to provide similar bearing capacity to STPs in shallower depths.
4) From Case 2, a longer taper length and shallower taper angle experienced lower penetration velocity, but the peak penetration resistance value tended to be the same regardless of the geometry of the tapered tip at deep depths.

To further understand the mechanism and the effect of the tapering of the pipe tip, more experiments with varying soil types are planned in the future. Since the current model ground was made of silica sand No. 7 which has little cohesion, a case using cohesive soil is planned to be conducted which may increase the effect of the pushing and expanding of the ground that may lead to a further increase in bearing capacity. Furthermore, I would like to conduct a case where the taper angle of the tapered pipe is further increased based on A M. Rybnikov's paper and compare the bearing capacity.

ABSTRACT

This paper presents a relevant and timely study on the use of tin tailings, which are the solid waste material extracted from tin mineral processing at tin mine in the northern region of Thailand, as an alternative backfill material in Geosynthetic Reinforced Soil (GRS) abutments. By conducting a series of physical model tests under varying normal loads, including a test with a single-layered and double-layered geosynthetic reinforcement. The study provides practical insights into the pull-out behavior and deformation characteristics of the GRS composite system. The application of tailings characterized a mixture of various particle sizes with a maximum particle size of 4.75 mm, and a friction angle of 37° which demonstrates a promising approach to sustainable construction. The tailing mainly contains Silicon (Si) and other different proportions of elements without harmful chemical components. The paper aligns well with current engineering practices and sustainability goals by integrating waste utilization within the context of GRS design.

Keywords: Waste material, Tin mine, GRS, Pull-out behavior, Deformation

INTRODUCTION

In recent years, the trend of green and sustainable construction materials has witnessed a notable rise with regarding the concept of environmental issues, economic, and social [1-3]. Waste material is by-product in production processes and it is alternative choices for practical applications, including road construction, geosynthetic-reinforced transport infrastructure systems, pavement, embankments, load-bearing foundations, slopes, cement productions, agriculture, and backfilling in underground mining, etc. [4-8]. Currently, the selection of materials for construction work involves more than just strength. There are other critical factors to consider, such as cost-effectiveness, which include the price of materials, transportation to the site area, operational costs, safety concerns, healthy working conditions, and the use of environmentally friendly materials. Additionally, materials that emit low levels of carbon dioxide, have a long-life cycle, and can be reused with considered good options [9-13]. Thus, according to previous reasons, the waste materials from the mining industry are also seen as a beneficial choice for utilization [14-17].

This study highlights the waste materials from surface mining, particularly located near urban areas. These materials are considered alternatives for utilization and development to transportation infrastructure in northern region of Thailand. There are many alternative waste materials in this region, which include various types from mining operations, such as quarries, mineral extraction, coal mining, overburden excavation, sand mining, as well as kaolin mining. Emphasizing ore processing in mining, particularly regarding the waste materials extracted from Tin ore processing. These tailings are solid waste generated during the processing of tin ore. The tailings have been stockpiled over extensive surface areas and have remained unused since mining operations began as shown in Fig. 1.

Fig. 1 Location of Tin tailing, northern region of Thailand

Fig. 2 depicts the basic flowchart of extracted Tin mineral process. In general, the process to produce Tin production can be divided into 2 parts: the mining process and the extraction process. The mining process is the process of preparing raw material, which includes planning to remove overburden and

then using drilling and blast techniques to reduce the size by explosives that have high energy and create high shockwave after detonation. The drilling follows the mineral veins. The mining machines are used to dig and load raw material into the mine trucks, which are then hauled to the crusher plant that employs reduction steps. In this step, the raw material is reduced to small size and prepares for the following step. Finally, the production results in concentrated Tin production by using jig concentrators, electric, and magnetic separators. The tailings are delivered to waste stockpiles. To manage and optimize the natural resources, as well as the financial aspects and lifespan of mine. Firstly, low-grade raw materials can be blended with high-grade material using blending techniques.

Fig. 2 Basic flowchart of extracted Tin mineral process

Regarding utilization of the tailing from Tin mining in an engineering context, the Geosynthetic Reinforced Soil (GRS) structure consists of dense multiple layers of a densely compacted fill and closely spaced geosynthetic reinforcement, and a stable facing block with either frictional or mechanical connections. The GRS structure is widely used in practice due to its advantages, such as being easier to construct, more economical, requiring less over-excavation, more ductile, more flexible, and it can be quickly built times. Moreover, GRS technology has a lower environmental impact as it uses less CO_2 emitting materials in its life cycle, and the materials can contribute to road infrastructures as they can be used as gravel for example, once their life cycle has ended. GRS technique has been adopted in many engineering contexts, including retaining walls, embankment, load-bearing structure, bridge abutment, etc. This construction consists of densely compacted backfill with closely spaced geosynthetic materials. Additionally, the space between each layer of geosynthetic sheet is usually laid less than 300 mm [13, 18-21]. The calculation of bearing capacity for GRS composite is influenced by various internal factors, as shown in Eq. (1)

$$q_{ult} = (\sigma_c + 0.7^{(\frac{Sv}{6d_{max}})}\frac{Tf}{Sv})Kp + 2c\sqrt{Kp} \quad (1)$$

Where:

q_{ult} : Ultimate bearing capacity

σ_c : External confining stress due to the facing element

Sv : Vertical reinforcement spacing

d_{max} : Maximum particle size

T_f : Ultimate tensile strength of the geosynthetic reinforcement

K_p : Coefficient of passive earth pressure of the backfill

c : Cohesion of the backfill

However, according to current design guideline for GRS bridge abutments, the facing element is typically not treated as a structural component of the GRS abutment. Furthermore, the confining stress induced by the facing element is often disregarded, assuming a confining stress of 0. In addition, in this design, cohesion is also eliminated since it cannot be relied on for long-term strength as Eq. (2), Eq. (3) [19].

$$q_{ult} = (0.7^{(\frac{Sv}{6d_{max}})}\frac{Tf}{Sv})Kp \quad (2)$$

$$\sigma_c = \gamma_b d \tan\delta \quad (3)$$

Where:

γ_b : Unit weight of facing block

d : Depth of the facing block

δ : Friction angle between the geosynthetic reinforcement and facing element.

Therefore, a concept has been developed to study waste materials that impact the environment, are low in cost to manage, and can be suitably applied to local conditions by creating a physical model that simulates the real area for practical application. This paper was conducted on a series of physical models and investigates the characteristics of Tin tailing and reinforcement for geosynthetic reinforced soil abutment under vertical loading using the pull-out loading technique and focus on the above parameters.

RESEARCH SIGNIFICANCE

This study investigated alternative materials that focus on industrial processes. Additionally, the use of waste material was utilized in practical applications offer cost-effectiveness, CO_2 emissions. Especially, the compacted backfill layer of GRS abutment was constructed of a mixture of various particle size. Tin Tailing is the solid waste material that was selected for analyzing the feasibility study. The design is based on research and practices guideline.

MODEL TEST

Material And Preparation

Tin tailing backfill soil

The Tin tailing was selected as the backfill soil for GRS applications. This tailing was used to investigate in this experiment. The first five main chemical compositions consist of Silicon (Si), Magnesium (Mg), Aluminium (Al), Calcium (Ca), and Iron (Fe) as showed in Fig. 3. Tin tailing backfill appears in dark yellow color and contains with various particle sizes as depicted in a line graph of gradation backfill by sieve analysis (Fig. 4). The Tin tailing backfill was screened particles, which determined a maximum particle size of 4.75 mm. In addition, the uniformity and curvature coefficients are around 5.4 and 1, respectively. This waste material takes into accounts to the well-graded backfill specifications, following FHWA guidelines. The properties of the backfill were determined including specific gravity, cohesion, friction angle, min. and max. dry unit weight were depicted in Table 1

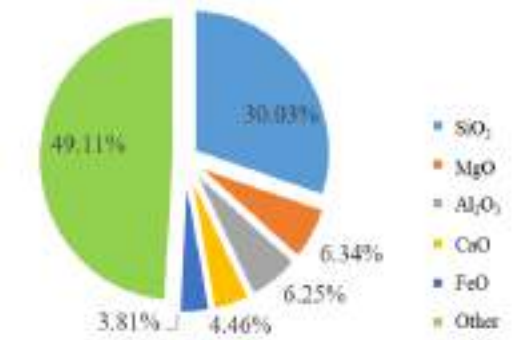

Fig. 3 Main Chemical compositions of Tin tailing

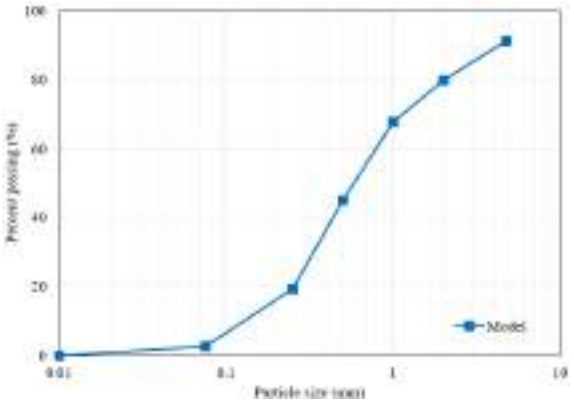

Fig. 4 Particle size gradation curve of Tin tailing

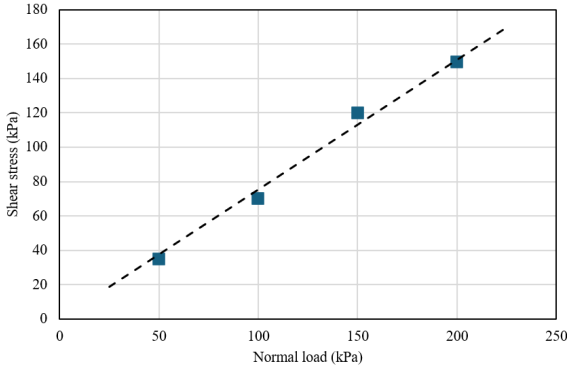

Fig. 5 The relationship between normal stress and shear stress at peak from direct shear test

Table 1 The properties of Tin backfill soil

Properties	Unit	Test Method	Tailing
Max. particle size	mm	Sieve analysis	4.75
Mean particle size	mm	Sieve analysis	0.61
Uniform coefficient	-	USCS	5.4
Curvature coefficient	-	USCS	1
Min. dry unit weight	g/cm^3	Relative Density	1.255
Max. dry unit weight	g/cm^3	Relative Density	1.600
SG	-	Water replacement	2.71
Cohesion	kPa	Direct shear test	0
Internal friction Angle	°	Direct shear test	37

Reinforcement

Fig. 6 shows the back color of Polyvinyl Chloride mesh (PVC) was selected as geosynthetic applications in function of reinforcement for this study, with an aperture size of 5 mm, 16 holes of 100 mm, and a thickness of 2 mm for each layer. The dimensions of the PVC sheet were 300 mm in width and 420 mm in length due to the factor of GRS design, typically expressed as a base-to-height ratio (B/H) of 0.7 [19, 22].

Fig. 6 Polyvinyl Chloride mesh

Test Plans

There are five different experiments that applied normal load at the top of model tests ranging from 0 kPa to 400 kPa. The experiments are focused on the pull-out loading characteristics and displacement of reinforcement. To ensure consistency, a compaction level is greater than 95% of maximum dry unit weight. Tests 1 to 4 were conducted with loads of 0, 100, 200 and 400 kPa. For Test 5 was conducted in the same manner as Test 3, but an additional double sheet of geosynthetic, as detailed in Table 2.

Table 2 Test plan

Test	Normal load (kPa)	Backfill
1	0	Tin tailing
2	100	Tin tailing
3	200	Tin tailing
4	400	Tin tailing
5	200*	Tin tailing

*Note: *: A double geosynthetic sheet.*

Model Test Setup

Fig. 7 shows the right-side view of the physical model, which consists of model box, backfill, geosynthetic reinforcement, digital dial gauge, hydraulic jack and load cell. The model box has the inside dimensions of 300 mm in width, 1000 mm in length, and 600 mm in height. The model was constructed with 4-side wood and 1-side transparent panel that allows to observe the interaction between backfill and geosynthetic during testing in a rigid frame. Furthermore, the top side is open to fill the backfill through this way. The rectangular outlet gap is 300 mm in length and 20 mm in width. A narrow gap of around 5 mm was left on top-bottom sides of geosynthetic sheet to prevent the friction between outlet wood and geosynthetic sheet during pull out by horizontal hydraulic jack. The geosynthetic sheet was allowed for lateral movement, as shown in Fig. 8.
A Geosynthetic sheet was placed in the middle height of model, which followed the FHWA guideline for bridge abutment. Moreover, a dense layer between the backfill and geosynthetic sheet is less than 300 mm.

The strip footing is a rigid plate that is placed as the beam seat in the prototype to receive the load of an integrated superstructure. However, in the experiment, a vertically distributed load was applied from the hydraulic jack and placed on the top of model at a setback distance of 40 mm behind reinforced soil. In addition, the size of the strip footing plate is 300 mm in width and 250 mm in length.

Fig. 7 Right-side view of the physical model

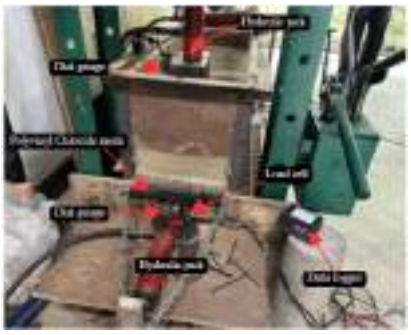

Fig. 8 A geosynthetic sheet in lateral movement

Loading Procedure

In this study, the vertical hydraulic jack was maintained and pressurized to apply normal pressure during testing. A distributed surcharge load applied to the model test, which applied an incremental pulling load of around 50 N per minute for the geosynthetic sheet until reaching maximum load. Throughout the performance test, the monitoring instruments displayed real-time data on screen, including vertical applied loading, vertical and lateral displacement and pull-out loading, as well as visual observation of the geosynthetic sheet and backfill soil through the transparent plexiglass.

RESULT AND DISCUSSION

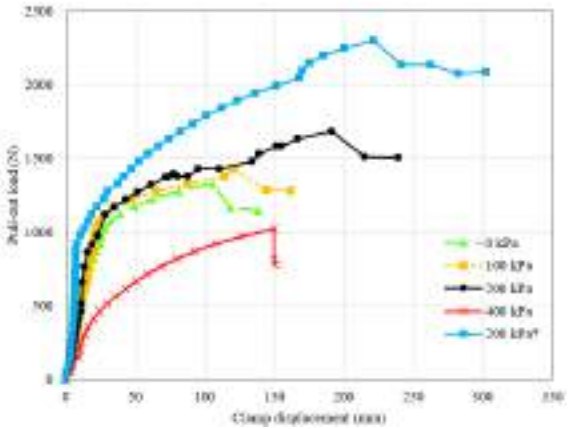
Pull-out Loading Characteristics

Fig. 9 shows pull-out loads and lateral displacement of model tests when the applied normal load on the strip footing ranged from 0 to 400 kPa at the top of the model. The GRS abutments are recommended to have a typical load at 200 kPa [23]. The graph demonstrates a steady line between pull-out load and displacement of geosynthetic, exhibiting elastic behavior characterized by a linear relationship according to Young's modulus. However, in the next

stage, the lateral displacement rapidly increases, exceeding the maximum load and reaching frictional resistance. Finally, the pull-out load sharply drops with increasing displacement, then becomes steady, following the same trend of all five model tests. Test 1 carried out without normal stress on the top of model test, the result of this case showed the lowest pull-out load due to only frictional resistance between backfill and geosynthetic sheet. Test 4, with a normal stress of 400 kPa, experienced a significant rupture of geosynthetic sheets at front of reinforced soil composite. In terms of GRS abutments under bridge service load, the behavior of pull-out loading exhibits a higher load with longer displacement. Moreover, the use of a double geosynthetic sheet occurred a higher load capacity compared to a single sheet.

Fig. 10 shows the influence of normal stress on pull-out loads, the results indicate that the normal load increased as pull-out load increased.

Visual observations between the geosynthetic layer and backfill through the transparent plexiglass demonstrated the minimal changing due to slow movement of reinforcement.



*Note: *: A double geosynthetic sheet.*

Fig. 9 Pull-out loads - displacement curve of geosynthetic sheet at different normal stress

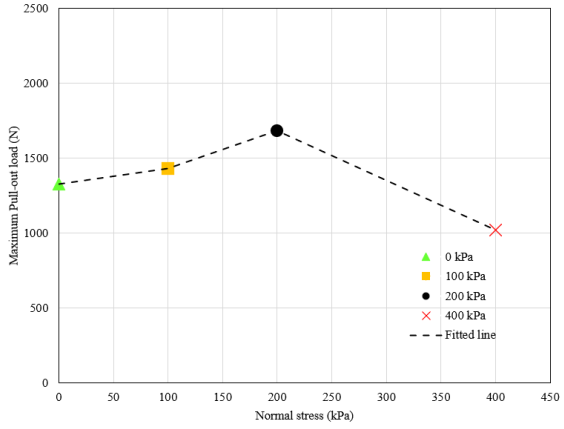


Fig. 10 Influence of normal stress on pull-out loads

CONCLUSIONS

The study compared and presented the analyses of five tests based on experimental results, highlighting the pull-out loading and deformation behavior.

The pull-out loading of GRS composite under varying normal stress on the top of model increased as the applied stress increased. In the case of an additional double sheet of geosynthetic, which increasing in the tensile strength of geosynthetic, resulted in higher pull-out load with achieved larger displacement. In comparison, the test under bridge service loads of 200 kPa to without loads, resulted in an increase of 1.2 times in pull-out load capacity. Additionally, the condition using a double geosynthetic sheet condition exhibited a significant enhancement of 1.7 times.

All experiments exhibited a similar trend in load characteristics when exceeding the frictional resistance at the interface between backfill and geosynthetic, followed by a decrease in load and then a stable value.

The failure behavior of the geosynthetic sheet resulted in a sharp rupture due to the application of an excessive normal load. The location of the rupture occurred at the front of the GRS composite.

SEISMIC BEHAVIOR OF STEEL STRIP REINFORCED SOIL WALLS WITH HIGH GROUNDWATER LEVEL

Akinobu Ogasawara[1], Makoto Kobayashi[1] and Kento Mori[1]

[1]Department of Civil Engineering, National Institute of Technology, Toyota College, Japan

ABSTRACT

It is known that reinforced soil walls, in which reinforcement materials composed of metals or polymers are installed in the soil, have high performance against earthquake. However, there have been reports of large deformations during earthquake, which has high groundwater level. In addition, in snowy cold areas, not only rainwater but also snowmelt water is expected to cause a rise in the groundwater level in the reinforced soil wall. Therefore, it is important to understand the seismic performance of reinforced soil walls under high groundwater level. In a previous study that verified the seismic performance of reinforced soil walls with multi-anchored reinforced soil wall subjected to seepage flow, it was reported that area between the anchor plates and facing panels, which called a reinforced area, behave as a single unit. On the other hand, the seismic deformation behavior of steel strip reinforced soil walls subjected to seepage flow has not been clarified. In this study, a series of centrifuge model tests were conducted to determine the seismic performance of steel strip reinforced soil walls subjected to seepage flow. As a result, the deformation behavior of the reinforced soil wall during the earthquake and the change in pore water pressure in the backfill soil confirmed that the reinforced area behaved as a single unit. This behavior also proved the high seismic performance of the steel strip reinforced soil wall.

Keywords: Centrifuge model test, Reinforced soil wall, Groundwater Level

INTRODUCTION

In general, the high seismic resistance of reinforced soil walls is known from past earthquake damage surveys. However, there have been reports of large deformations occurring when combined external forces such as high groundwater levels caused by poor drainage and earthquake motion are applied [1,2]. Furthermore, dynamic observations of full-scale reinforced soil walls constructed in snowy cold areas have reported that when back fill materials with freezing property are used, forward displacement occurs in winter due to cold air intrusion [3]. In snowy cold areas, the drainage layer installed behind the wall suppresses the increase in saturation within the backfill soil, thereby serving as an effective measure against frost heave. In recent years, drainage layers of appropriate thickness have been installed behind the wall in accordance with site conditions. However, some reinforced soil walls constructed in the past do not have drainage layers installed behind them. In the future, reinforced soil walls that have been in service for a long period of time are expected to have a higher groundwater level due to the reduced drainage function. In addition to these conditions, snowmelt as well as rainwater is expected to raise the groundwater level of reinforced soil walls in snowy cold areas. Reinforced soil walls in this condition can be subjected to significant deformation by complex external forces such as seismic motion.

From past damage cases, groundwater level is considered to be involved as a contributing factor in earthquake damage to reinforced soil walls. Therefore, there are several studies that have conducted centrifuge shaking table tests focusing on the degree of saturation of reinforced soil walls. In a study examining the influence of groundwater levels on the seismic performance of geogrid-reinforced soil walls, it has been reported that saturated conditions result in lower seismic performance compared to unsaturated conditions [4]. There are also studies that have examined the performance of geosynthetic reinforced soil walls subjected to the combined effects of earthquakes and rainfall through centrifuge shaking table tests. Similarly, it has been reported that the seismic performance of unsaturated reinforced soil walls is higher than that of saturated reinforced soil walls. Furthermore, it has been pointed out that the deformation and failure modes of reinforced soil walls differ between unsaturated and saturated conditions under seismic load [5]. However, steel strip reinforced soil walls using friction reinforcement assume that an adequate drainage environment is maintained to provide the prescribed frictional resistance. Consequently, there are many unknowns regarding the seismic deformation behavior of steel strip reinforced soil walls under conditions of high groundwater level or seepage flow. In this study, a series of centrifuge model tests were conducted to understand the seismic behavior of steel strip reinforced soil walls under high groundwater level conditions.

RESEARCH SIGNIFICANCE

In previous studies, centrifuge shaking table tests has been conducted to investigate the seismic deformation behavior of anchored reinforced soil walls under high groundwater level conditions. As a result, it has been noted that at seismic accelerations of about 2m/s^2, the reinforced area behaves as a single unit [6]. However, since the reinforcement effect differs between anchored reinforced soil walls and steel strip reinforced soil walls, it is important to clarify the mechanism of earthquake damage in order to evaluate the integrity of steel strip reinforced soil walls against earthquake motion under conditions of high groundwater level.

CENTRIFUGE MODEL TESTS

Figure 1 shows an overview of the model ground, and Table 1 shows the experimental conditions used in this study. The model ground is set at a scale of 1/50, and the shaking table tests are conducted in a centrifugal force field (50G), which is 50 times the acceleration of gravity. The reinforced soil wall model used in this study has a scale of 1/50, so the wall height converted to the actual scale is 8m.

As shown in Figure 1, the dimensions of the model ground are 120 mm high, with four rows of 30 mm wide by 30 mm high facing panels. Since the wide of the model soil tank is 60 mm, two rows of facing panels are placed in the depth direction. Phosphor bronze was used for the reinforcement model to match the extensional rigidity of the steel strip reinforcement. Four reinforcements are placed per facing panel, there are no connections or drainage installations between facing panels. Toyoura sand with a moisture content of w = 10% was used for backfilling and compacted to a specified relative density. In Experimental code D40SVR, the reinforcement on the upper sides of the facing panels, excluding the top panel, was removed, and a model ground was created. In the past, there have been cases of reinforcement connections breaking due to the frost heave of backfill materials in snowy cold areas [7]. If the reinforcement breaks at the connection, the seismic performance of the reinforced soil wall may be reduced. In order to closely observe the deformation behavior of reinforced soil walls and to conduct an examination of their failure mechanisms during earthquakes, it is also considered important to model conditions that may not occur in actual phenomena. To understand changes in the seismic performance of reinforced soil walls, this case reduces the number of reinforcements, simulating damage to the reinforcement. It is considered that data beneficial for design can be obtained by verifying the seismic deformation behavior under various external loading conditions. Also, pore water pressure gauges were installed in the model ground and measured at

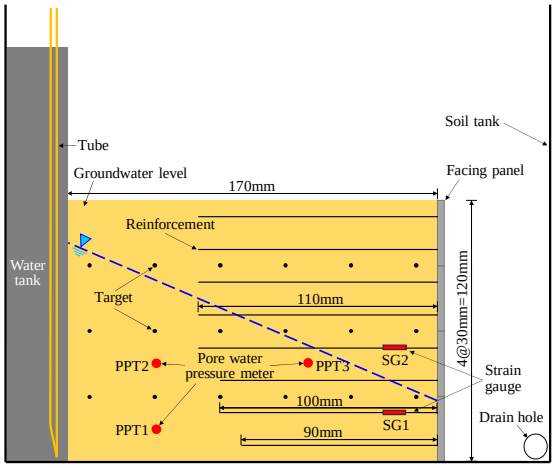

Fig.1 Overview of model ground

Table 1 Experimental conditions

Experimental code	Relative density D_r (%)	Moisture content w (%)	Rise in water level

three locations, two outside and one inside the reinforced area. In addition, strain gauges are affixed near the back of the walls of the first and second stages.

In the seepage experiments, a fluid (methylcellulose solution) with viscosity 50 times greater than that of water was used, considering the time-scaling law of seepage phenomena in centrifugal force fields. It has been reported that using such viscous fluids is highly effective in reproducing seepage phenomena in centrifuge model tests [8]. The viscous fluid is supplied to the water tank behind the model ground during its rotation. This experiment is started only after the centrifugal acceleration reaches 50G. The groundwater level within the reinforced soil wall is raised so that the water level in the tank reaches 100 mm. Since the seepage velocity is not fast, it is difficult to precisely control the rate at which the water level in the water tank rises. However, the

a) After shaking b) During shaking c) After shaking

Fig.3 Deformation conditions of the model ground in D40SVR

seepage behavior of the model ground is observed using a high-speed camera installed outside the apparatus, and the average rate of water level rise in the water tank is controlled to approximately 4mm/min. After confirming that the groundwater level reached the state shown in Figure 1, the shaking table test was conducted. The shaking conditions consisted of a vibration frequency of 1.0Hz and 20cycles with an acceleration amplitude of 2m/s^2, corresponding to a level I earthquake motion.

EXPERIMENTAL RESULTS AND CONSIDERATIONS

Figure 2 shows the safety factor before earthquake for pullout of the reinforcement under each test condition and the relationship between the wall inclination before and after shaking. The safety factor was calculated by referring to the design and construction manual for steel strip reinforced soil walls [9]. Since the reinforcement material used does not have ribs, the friction coefficient is assumed to be constant in the safety factor calculation process. This shows that even when the groundwater level of the backfill soil is high, the safety factor exceeds 1.0. In cases where the groundwater level has risen, the safety factor has decreased. In particular, when the amount of reinforcement installed is small, the safety factor is lowest. Furthermore, it was confirmed that the increase in wall inclination before and after shaking increased as the safety factor before earthquake factor decreased. This is thought to be due to a decrease in pullout resistance caused by a reduction in effective stress due to seepage flow.

Figure 3 shows an example of a model ground in D40SVR. This was filmed with a high-speed camera and shows the situation immediately before and after the shaking was applied. After starting shaking, it was confirmed that deformation of the reinforced soil wall gradually occurred. Furthermore, considering that the safety factor before earthquake was low in this case, it can be inferred that the displacement of the wall surface was the greatest.

Figure 4-6 shows the deformation behavior before and after shaking in each experimental code.

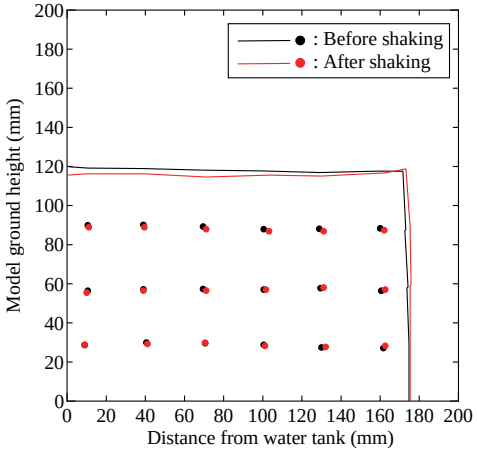

Fig.4 Deformation behavior of D40

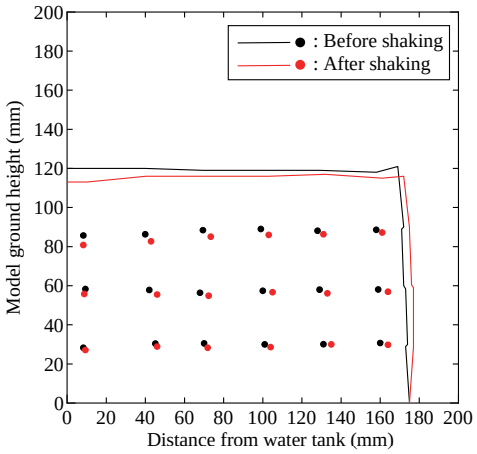

Fig.5 Deformation behavior of D40SV

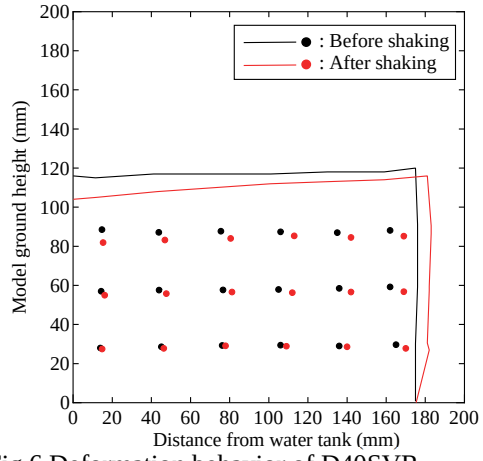

Fig.6 Deformation behavior of D40SVR

Focusing on the results of D40 in Figure 4, it can be confirmed that the amount of deformation of the wall surface is small. In this case, the groundwater level within the reinforced soil wall was not raised before applying shaking. Therefore, it is considered that deformation was minimized because the pullout resistance of the reinforced soil wall was secured. Next, by comparing the results of D40 and D40SV, it can be seen that D40SV, with its raised groundwater level, caused greater deformation of the wall. This is due to a decrease in the safety factor before earthquake caused by an increase in the groundwater level. As mentioned above, it is believed that the reduction in effective stress due to seepage flow caused a decrease in pullout resistance, resulting in pullout. Deformation observation results for D40SVR confirmed that it exhibited the greatest deformation among the three cases. This shows that the seismic resistance of reinforced soil walls changes as the number of reinforcements decreases. Furthermore, focusing on the displacement of the target point when the groundwater level rises, it can be confirmed that the deformation behavior differs between the reinforcement area and the non-reinforcement are. This behavior is examined based on the measurement results of the pore water pressure meter installed in the model ground.

Figure 7-8 shows the time variation of the excess pore water pressure ratio during shaking in D40SV and D40SVR. The shaking start time is set to 0.3 seconds. As shown in Figure 7, the excess pore water pressure ratio is negative in PPT2 outside the reinforced area and positive in PPT3 within the reinforced area. Therefore, it is considered that the reinforced area and the back ground did not integrate and deformation progressed. In other words, it is considered that the reinforced section integrated during the earthquake and exhibited deformation behavior. Despite the high groundwater level, no significant deformation of the wall surface occurred, as the reinforced areas showed integrated deformation behavior. However, as shown in Figure 8, the excess pore water pressure ratio is positive both inside and outside the reinforced area in D40SVR. This is thought to be because the reinforced areas did not integrate and exhibited deformation behavior. This is because the overall pullout resistance of the reinforced soil wall has decreased due to the reduction in the amount of reinforcement installed. The reinforced areas did not integrate and exhibited deformation behavior, resulting in the largest displacement in this case.

From the above, it was found that when the safety factor of the reinforced soil wall and the pullout resistance of the reinforcement are ensured, the reinforced area may exhibit integrated deformation behavior. This behavior demonstrates that reinforced soil walls have high seismic performance.

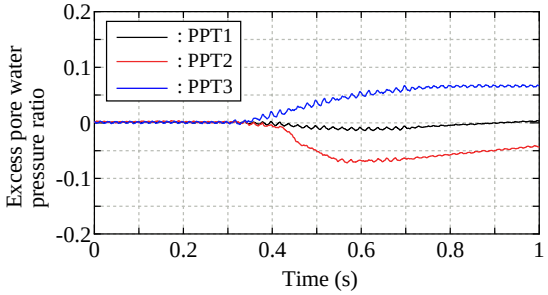

Fig.7 Time variation of excess pore water pressure ratio of D40SV

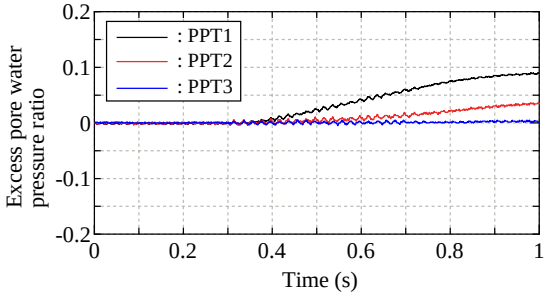

Fig.8 Time variation of excess pore water pressure ratio of D40SVR

CONCLUSIONS

The conclusions drawn from a series of centrifugal model tests on steel strip reinforced soil walls are as follows.

(1) Under conditions where the safety factor of reinforced soil walls was sufficient, no significant deformation due to rising groundwater levels was observed.
(2) The seismic performance of reinforced soil walls varies depending on the reduction in the safety factor.
(3) The deformation behavior of the reinforced soil wall during the earthquake confirmed that the reinforced area behaved as a single unit. This behavior also proved the high seismic performance of the steel strip reinforced soil wall.

THREE-DIMENSIONAL SIMULATION ANALYSIS OF OPEN-ENDED STEEL PIPE PILE BY USING FINITE ELEMENT METHOD

Kiyoka Kono[1], Koji Watanabe[1], Shihchun Lin[2] and Shuichi Kamei[2]

[1]Department of Civil Engineering, Aichi Institute of Technology, Japan; [2]Jibanshikenjo Co., Ltd., Japan

ABSTRACT

The static load test (SLT) is highly reliable for evaluating vertical bearing characteristics, but it incurs significant expenses and extended construction time. Conversely, the rapid load test (RLT) offers advantages in terms of cost and construction time; however, it includes the impact of dynamic resistance and inertial forces of piles and ground (dynamic effects) in its data. Therefore, to accurately assess the RLT result as static vertical bearing characteristics, it is essential to remove the effect, but there are still many unresolved aspects of the mechanism of the dynamic effect, and it cannot be completely removed. In this study, both full-scale SLT and RLT for the same open-ended steel pipe test pile were carried out to compare and investigate using these vertical bearing characteristics. Therefore, as the first step, a simulation analysis using elasto-plastic FEM in the full-scale SLT and SLT results was conducted, and examined the validity of the parameter evaluation and modeling method based on the existing evaluation equations. As a result, highly reproducible results were obtained by parameter evaluation using the evaluation formula described in "Technical Standards and Commentaries for Port and Harbour Facilities" in Japan and applying the following two points: (1) joint elements simulating the shaft friction behavior obtained by the full-scale SLT, (2) consideration of soilplug effect. Therefore, it is concluded that the parameter evaluation and the modeling method are suitable for the simulation analysis of SLT.

Keywords: Static Load Test, Steel Pipe Pile, Vertical Bearing Characteristic, Elasto-plastic FEM

INTRODUCTION

The rapid load test (RLT) offers advantages in terms of cost and construction time; however, it includes the impact of dynamic resistance and inertial forces of piles and ground (dynamic effects) in its data [1,2]. Therefore, to accurately assess the RLT result as static vertical bearing characteristics, it is essential to remove the effect. But there are still many unresolved aspects of the mechanism of the dynamic effect, and it cannot be completely removed. Many previous studies have reported the numerical analyses limited to RLT [3-5]. On the other hand, few studies have analyzed SLT and RLT using the same model, and this study aims to quantitatively evaluate the dynamic effects by constructing an analytical model that treats both tests in a unified manner. In this study, both full-scale static compressive load test (SLT) and RLT for the same open-ended steel pipe test piles were carried out to compare and investigate using these vertical bearing characteristics. Therefore, as the first step, a simulation analysis using elasto-plastic FEM in the full-scale SLT and SLT results was conducted, and examined the validity of the parameter evaluation and modeling method based on the existing evaluation equations.

A flow chart of the study procedure is shown in Fig.1. In Step.2 and Step.3, determine the parameters to reproduce the SLT and RLT. This allows us to confirm that stress and deformation conditions of ground and pile, which cannot be confirmed during the test, and the mechanism of the dynamic effect is examined by comparing these parameters.

RESEARCH SIGNIFICANCE

SLT is highly reliable for evaluating vertical bearing characteristics, because it's carried out under the same loading conditions as actual piles. However, the test equipment requires not only force application devices and measurement devices, but also large-scale reaction systems, which incurs significant expenses and extended construction time. Conversely, RLT applies a load of short duration by free-falling a weight onto the pile head, and offers advantages in term of cost and construction time because it doesn't

Fig.1 A flow chart of the study

require reaction systems in the test equipment. However, because the data includes the impact of dynamic effects, it is essential to remove these effects to accurately evaluate the RLT results as static vertical bearing characteristics.

If the mechanism of the dynamic effect is clarified and the results obtained by RLT can be accurately analyzed as static vertical bearing characteristics, it will be possible to carry out load tests and evaluate vertical bearing characteristics more rationally.

FULL-SCALE SLT

Test overview

In this study, a full-scale SLT was carried out. The test pile was an open-ended steel pipe pile (SPP) of SS400 material with a pile diameter D=318.5mm, wall thickness t=6.9mm, cross-sectional area A=0.0068mm^2, pile length L=11.8m, embedment length L_d=11.0m. The pile was installed using the drop hammer method. The results of the ground investigation, pile driving depth and measurement items and locations are shown in Fig.2, and the locations of Standard penetration test (SPT) carried out at the just points and the test pile arrangement are shown in Fig.3. The measurement items were vertical displacement at the pile head (4 points), load at the pile head, and strain in each cross-section (Pile head: 4 directions, Others: 2 directions).

Load test method

The loading method was the actual live load method using reaction piles, and loading was done in stages of 5-cycles. The planned maximum load for this test was calculated using the evaluation formula for the ultimate bearing capacity of SPP in the specifications for highway bridges construction [6]. Since the calculated ultimate bearing capacity of the test pile is R_u=751kN, the planned maximum load for the loading test is 800kN. The final loading load was set at 1040kN, which was sufficient to verify the pile's ultimate bearing capacity and other vertical bearing characteristic values that should be confirmed by loading tests, and loading was carried out at a pitch of 80kN.

SIMULATION ANALYSIS

Simulation Analysis Overview

In this study, a three-dimensional elasto-plastic FEM was performed using MIDAS's FEA-NX.

By comparing the vertical bearing characteristics obtained from the load test results with those from the analysis results, the reliability of the analysis results was confirmed, and the analytical model and ground parameters were evaluated. The analytical model and

9_Clay	126455	128.25	5.00	2.50	0.45
10_Sand	394171	10.00	35.36	17.68	0.35
11_Sand	401869	10.00	35.52	17.76	0.35

boundary conditions are shown in Fig.4. The analytical model was modeled over a quarter of the area, considering the symmetry of the test pile and the surrounding ground. And the ground of the analytical model was extended vertically in order to eliminate the influence of reflected waves when performing the simulation analysis of the RLT. Since the analytical model used in the simulation analysis of SLT and RLT should be same, the analytical model was also extended to include the extended ground in this study. The parameters of the extended ground were the same as "11_sand", since the boring test was conducted only up to 15.45 m. The loading method was based on full-scale SLT, with 80kN applied to the pile head in stages until a maximum of 960kN was reached. Table 1 lists the geotechnical parameters that were set. Among the ground parameters, deformation modulus (E) and internal friction angle (ϕ) were calculated in accordance with Technical Standards and Commentaries for Port and Harbour Facilities in Japan (Port) [7]. The dilatancy angle (ψ), which expresses the volume change, is half the value of the internal friction angle. Cohesion (c) was determined by Terzaghi and Peck formula using the uniaxial compression strength (q_u) obtained from the uniaxial compression test. The equations used as the evaluation of parameters are shown in Equation (1) through Equation (5).

$$\text{Sand: } G = 14100N^{0.68} \quad (1)$$

$$\text{Clay: } G = 170q_u \quad (2)$$

$$E = 2G(1+\nu) \quad (3)$$

$$\phi = 25 + 3.2\sqrt{\frac{100N}{70+\sigma_v'}} \quad (4)$$

$$c = q_u/2 \quad (5)$$

where, G: Shear modulus (kN/m^2), N: N-value (-), ν: Poisson's ratio (-) σ_v': Effective overburden pressure (kN/m^2)

The constitutive laws were Mohr-Coulomb law for ground and elasticity for SPP.

Assignment of Joint Elements

To simulation the shaft friction behavior between the SPP and ground, joint elements were set at the pile circumference. The parameters consisted of normal stiffness (K_n), shear stiffness (K_t), cohesion (c), and internal friction angle (ϕ). The equations used are shown in Equation (6) through Equation (9).

$$K_n = R \times G_{\text{soil}} \times \frac{2(1-\nu_{\text{joint}})/(1-2\nu_{\text{joint}})}{t_v} \quad (6)$$

$$K_t = R \times G_{\text{soil}}/t_w \quad (7)$$

$$c_{\text{joint}} = R \times c_{\text{soil}} \quad (8)$$

$$\phi_{\text{joint}} = R \times \phi_{\text{soil}} \quad (9)$$

where, R: Strength reduction factor (-), G_{soil}: Shear modulus of soil (kN/m^2), ν_{joint}: Poisson's ratio of joint element (-), t_v: Virtual thickness (m), c_{joint}: Cohesion of joint (kN/m^2), c_{soil}: Cohesion of soil (kN/m^2), ϕ_{joint}: Internal friction angle of joint (°), ϕ_{soil}: Internal friction angle of soil (°)

The strength reduction factor was set as 0.6 for sand and 0.5 for clay, all of virtual thickness were set at 0.01m based on [8].

Consideration of Soilplug

Since SPP in this study are open-ended, soilplug formed by soil that has penetrated into the pile body during driving were modeled. The soilplug set to 6.50m, the length obtained from the full-scale SLT, as shown in Fig.4. In addition, the inner shaft friction

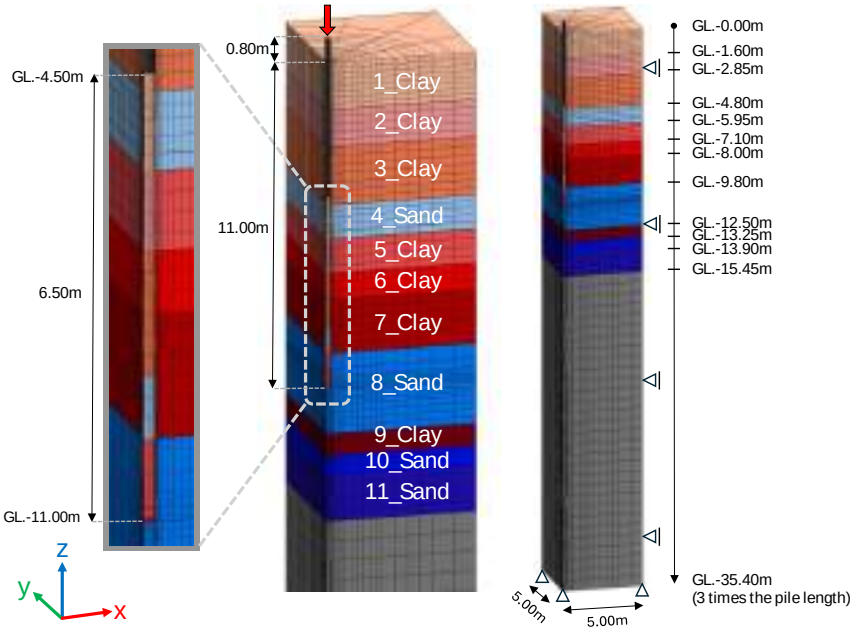

Fig.4 Analytical model and Boundary conditions

occurring at the boundary between the soilplug and SPP was also modeled, with parameters set according to the previously described parameter setting method.

RESULTS OF ANALYSIS

The axial force - displacement relationships obtained from the analysis are shown in Fig.5, Fig. 6 and Fig.7. This was calculated by multiplying the SPP strain obtained from the analysis by the elastic modulus and cross-sectional area of the steel. The axial force-displacement relationship obtained by full-scale SLT is also shown in these figures. The axial force-displacement relationship at the pile head (L1) shown in Fig.5 indicates that the behavior in the elastic range was almost identical. Furthermore, in addition to the elastic range, the behavior up to a displacement level of 11.7 mm (at 800kN loading) was consistent, confirming that the behavior partially reproduced that of the plastic range.

L2 is shown in Fig.6. Similarly, L2 shows high reproducibility in behavior up to a partially plastic zone. From this, it can be said that the parameter evaluation method for joint elements in the L1-L2 section was appropriate.

As shown in Fig.7, at the pile tip (L3), the behavior from the initial stiffness to the displacement level of 8 mm (at 800kN loading) showed good consistency and the values of ultimate bearing capacity are also generally consistent.

As mentioned previously, good consistency was obtained in the tip behavior up to 800kN loading. Therefore, a contour diagram of the vertical stress distribution at 800kN loading is shown in Fig.8. It shows that the load applied at the pile head is transmitted reliably to the ground at the pile tip. Also shows that the areas of concentrated stress at the pile tip are in the form of stress bulbs. In this case, stress transfer was observed to a depth of 3.2*D* and a horizontal region of 1.7*D*.

Based on these results, the modeling method in this study is appropriate for simulating SLT, and this modeling method can be applied to the simulation analysis of RLT.

CONCLUSIONS

In this study, as an analytical investigation, we performed a replication analysis using elasto-plastic FEM on full-scale SLT and SLT results to examine the validity of parameter evaluations and modeling methods based on the existing evaluation equations. The findings of this study are as follows.

1) The axial force-displacement relationship at the pile head (L1) indicates that the behavior in the elastic range was almost identical, furthermore the behavior partially reproduced that of the plastic range.
2) L2 shows high reproducibility in behavior up to a partially plastic range. From this, it can be said that the parameter evaluation method for joint elements in the L1-L2 section was appropriate.
3) In L3, the behavior from the initial stiffness to the displacement level of 8 mm (at 800kN loading) showed good consistency and the values of ultimate bearing capacity are also generally consistent.
4) The contour diagram of vertical stress at 800kN

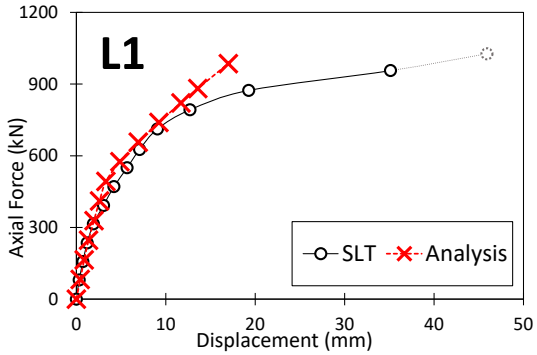

Fig.5 Axial force – displacement (L1)

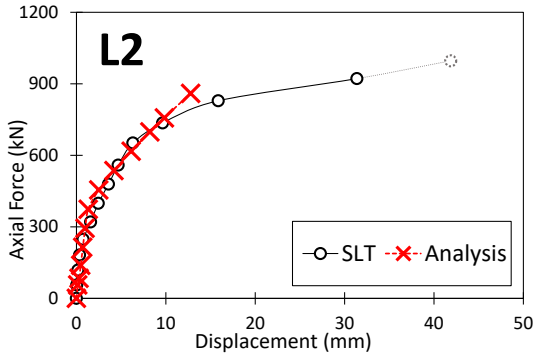

Fig.6 Axial force – displacement (L2)

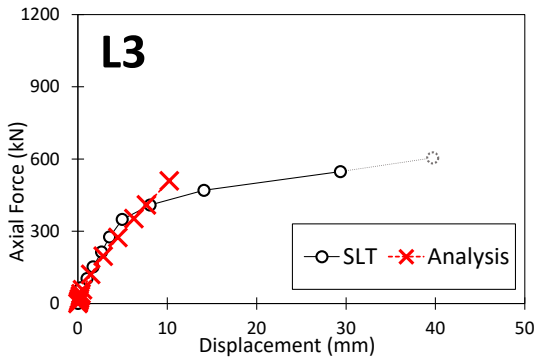

Fig.7 Axial force – displacement (L3)

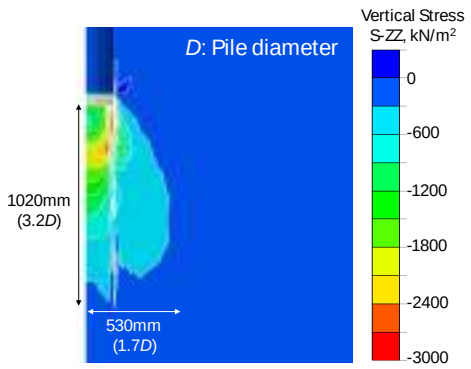

Fig.8 Contour diagram of the vertical stress distribution at 800kN loading

shows reliable load transfer from the pile head to ground at the tip, forming pressure bulb. The stress was transmitted to a depth of 3.2*D* and a width of 1.7*D*.

5) These results show that the modeling method used in this study is suitable for simulating SLT and can also be applied to RLT analysis**.**

DYNAMIC RESPONSE OF UNDISTURBED SOFT CLAY SOIL WITH SOIL DISTURBANCE EFFECT UNDER CYCLIC LOADING

Angelo B. Edora[1], Taiju Ichizono[1] and Kentaro Nakai[1]

[1]Department of Civil Engineering, Nagoya University, Japan

ABSTRACT

In Japan, accelerated subsidence damage was observed immediately after the Chuetsu Offshore Earthquake (2007) and the 2011 off the Pacific coast of Tohoku Earthquake, which occurred in soft clayey soil layers. Many studies have been conducted to understand such a phenomenon in soft clay soils. Most of these studies utilized artificially prepared reconstituted clay samples, and shear tests were conducted under isotropic stress conditions. Nakai et al. (2017) conducted numerical assessments of road embankments and river levees, where they found that soft clay loses its stiffness under seismic loading, in which such phenomenon is defined as "soil disturbance". To fill the gap, this study aims to conduct undrained cyclic triaxial tests under both isotropic and anisotropic conditions using undisturbed and artificially remolded clay samples to determine the effect of the "soil disturbance" phenomenon in the dynamic behavior and properties of clayey ground. Based on the results of experiments, the undisturbed soil specimen shows a subtle decrease in the peak shear strength as the number of cycles increases. In addition, a drastic decrease in the peak shear strength of soil specimens was observed under anisotropic conditions in a significantly lower number of cycles. Such an effect of soil disturbance (reduction in shear strength) was not observed in the reconstituted samples. Therefore, the impact of soil disturbances that occur when soft clay is subjected to cyclic loading can be summarized as (1) a decrease in initial stiffness and (2) a decrease in peak shear strength, which are more pronounced under anisotropic conditions.

Keywords: Soil disturbance, Anisotropic stress conditions, Undisturbed soft clay, Cyclic loading

INTRODUCTION

In Japan and many regions of the world, the frequent occurrence of earthquakes results in different seismic damage, such as liquefaction, building collapse, and subsidence. Although liquefaction damage in sandy ground is the primary cause of seismic damage, structural collapse, due to loss of bearing capacity and settlement damage during and after earthquakes, has been observed in soft clay soils. One prominent example was the 1985 Mexico City earthquake, where structures collapsed due to loss of bearing capacity. Additionally, following the 1957 Guerrero earthquake, [1] noted in 1973 that multiple foundation points of a particular building in Mexico City were continuously settling. These two examples are similar in a way that they are both situated on soft clay ground.

Soft clay soils are characterized by three main characteristics, which are: high water content, high void ratio, and high sensitivity ratio. Sensitivity ratio refers to the ratio of the peak shear strength of the undisturbed clay sample and the strength of the fully remolded clay sample from the same specimens with unchanged water content. Many studies [2-6] attempted to understand the dynamic properties of soft clay soils by determining the effects of confining pressure, cyclic frequency, stress ratio and overconsolidation ratio on its cyclic behavior and concluded that the mean effective stress also decreases in clayey soils. Undrained cyclic triaxial tests were performed on undisturbed soft clay specimens in certain studies [7,8]. They discovered that reconstituted samples had a higher cyclic shear resistance than undisturbed specimens. However, most of these studies are limited to remolded soft clay specimens under isotropic stress conditions. To better understand the dynamic behavior of soft clay soils, [9] and [10] conducted seismic assessments of road embankments and river levees located on naturally deposited soft clay soil. In their numerical analysis, they found that there is a gradual loss of stiffness in cohesive soils due to cyclic loading (earthquake load), which they described as "soil disturbance."

In-situ soil conditions are seldom isotropic, which suggests that it is essential to consider such "soil disturbance" phenomenon under anisotropic stress conditions. Anisotropy is the directional dependence of soil's mechanical properties – soil properties such as strength, stiffness, and permeability vary depending on the direction in which they are measured. This is an essential consideration in geotechnical engineering, most especially when dealing with naturally deposited soils, as they are subjected to various stress histories [11].

The main objective of this research is to deepen the understanding of the "soil disturbance" phenomenon by determining the effect of loading under anisotropic stress on undisturbed and reconstituted soft clay soil. In defining "soil

disturbance", cyclic and subsequent monotonic shear tests were conducted on undisturbed and reconstituted specimens under isotropic conditions. On the other hand, cyclic and subsequent monotonic shear tests were conducted at K_0 = 0.6 to determine the effect of anisotropy in the "soil disturbance" phenomenon.

RESEARCH SIGNIFICANCE

Most studies on seismic damage have focused on the liquefaction of sandy ground. However, earthquake damage can also manifest in clay soil, specifically under soft conditions. Many studies attempted to describe the dynamic behavior of soft clays however, these studies were limited to reconstituted specimens [2-6], insufficient description of such phenomenon [7-8], and numerical simulations of undisturbed soft clay [9-10]. To bridge the research gap, this study obtained the necessary experimental facts to confirm the results of previous numerical assessments and to further define the "soil disturbance" phenomenon by considering the effect of anisotropy in the dynamic behavior of undisturbed soft clay.

MATERIALS AND METHODS

Soil Specimen Information

This study's soil specimen, which was minimally to undisturbed, was extracted from Kaizu City in Gifu Prefecture, Japan. The geological cross-section of the area reveals a thick deposit of clay at depths ranging from 8.5 m to 36.5 m. Specifically, the researchers utilized the soft clay layers extracted from 17.5 m to 30 m, which had an 80 to 85% liquid limit and a compression index of 0.21 to 0.23, both of which were relatively higher compared to other layers.

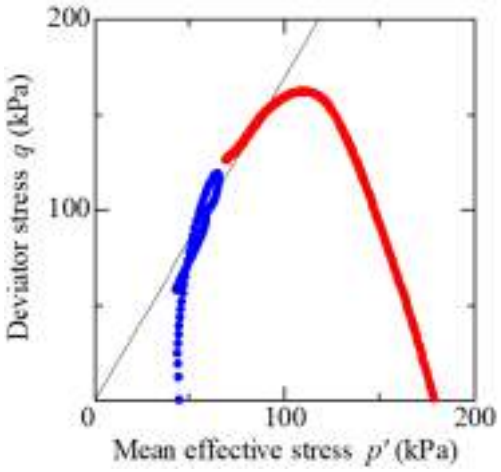

Fig. 1 Rewinding and Bowing Behavior of Soft Clay

On the other hand, the figures above exhibit the undrained monotonic shear test under isotropic conditions. Figure 1 shows the strain softening and the "rewinding and bowing" behavior of the *q-p'* graph of the soil specimen at different overburden pressures. Such characteristics are inherent to soft clay soils.

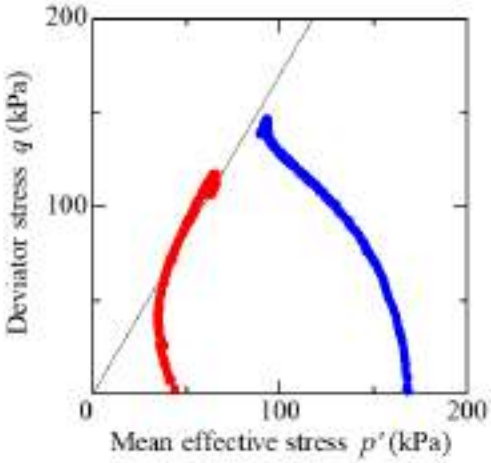

Fig. 2 Monotonic Shear Test of Reconstituted Normally Consolidated and Overconsolidated Clay

Reconstituted samples are prepared using the trimmings of undisturbed samples during sample preparation. The moisture content of the soil trimmings was increased to about 150% to 200% of its liquid limit, then mixed thoroughly using a drum mixer. Using a consolidation chamber, a pre-consolidation pressure of 150 kPa was applied for 4 days to remove air voids.

Figure 2 shows the graph of the monotonic shear test of reconstituted normally consolidated and overconsolidated soft clay. It can be observed that the peak shear strength of normally consolidated and overconsolidated specimens has minimal to no reduction, which indicates the absence of strain softening behavior of undisturbed specimens.

Experimental Procedures

The researchers conducted a series of isotropic and anisotropic consolidated-undrained monotonic triaxial tests per JGS 0523 and JGS 0525 to determine the initial and subsequent monotonic shear behavior of soft clay after applying cyclic loading. Additionally, cyclic shear tests based on JGS 0541 were also conducted to determine the dynamic response of soft clay. As for specimen preparation, the researchers found that performing stepwise loading/pressure application while maintaining a 10 kPa difference between cell pressure and back pressure is the most effective way of saturating the soil specimen. The overburden pressure used in the experiment was 180 kPa, which is based on the soil report of the site. The horizontal effective stress applied on the sample was calculated using the Eq. 1.

$$\sigma'_H = K_0 \sigma'_V \quad (1)$$

The experiments consisted of two stress conditions which were identified based on two K_0 values which are K_0 = 1.0 (isotropic) and K_0 = 0.6 (anisotropic). The K_0 value for anisotropic condition was set based on Jaky formula for normally consolidated clays [12]. Table 1 summarizes the shear tests conducted under isotropic and anisotropic conditions.

Table 1 Stress Conditions of Experiments

Spec. Type	K_0	σ'_V (kPa)	σ'_H (kPa)	q (kPa)	p' (kPa)
UDS	1.0	180	180	0	180
UDS	0.6	180	108	72	132
REC	1.0	180	180	0	180

RESULTS AND DISCUSSIONS

Undisturbed Cyclic Shear Test at K_0 = 1.0

The cyclic shear tests at K_0 = 1.0 were conducted with a stress amplitude of 72 kPa and a period of 20 seconds. This configuration was constant for all cyclic shear tests and subsequent monotonic shear tests in this study. Figure 3 shows that axial strain was developed on both the compression and extension sides, even in clay. Ultimately, the specimen fails at the extension side, which results in necking the specimen after 1295 cycles. The failure at the extension side is because naturally deposited soils are weaker against extension than in compression under isotropic conditions.

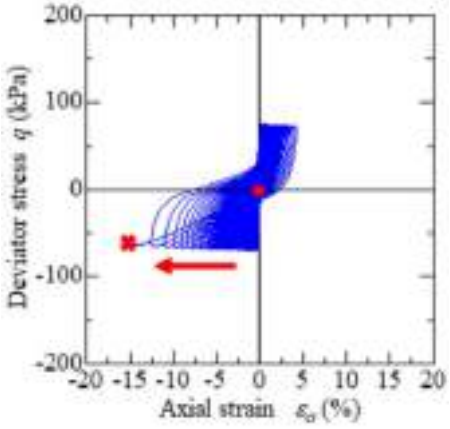

Fig. 3 Graph of q- ε_a of Cyclic Shear Test on Undisturbed Specimen at K_0 = 1.0

Furthermore, it is noticeable that there is a constant reduction in the mean effective stress, p', during cyclic loading (Fig. 4). At failure, p' is reduced to 20 kPa. This proves that even in natural clay, p' is also reduced under cyclic loading.

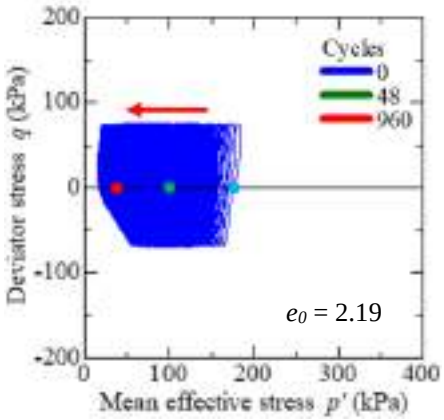

Fig. 4 Graph of q-p' of Cyclic Shear Test on Undisturbed Specimen at K_0 = 1.0

Subsequent Monotonic Shear Test after Cyclic Loading at K_0 = 1.0 of Undisturbed Soft Clay

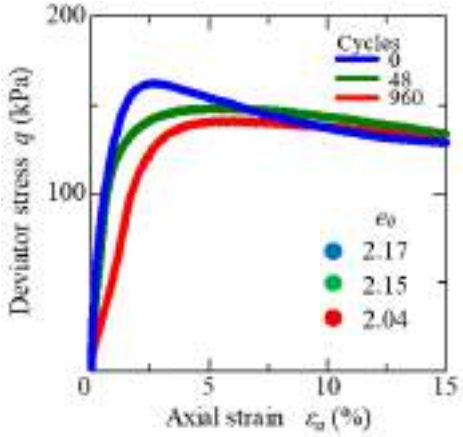

Fig. 5 Graph of q-ε_a of Subsequent Monotonic Shear Test on Undisturbed Specimen at K_0 = 1.0

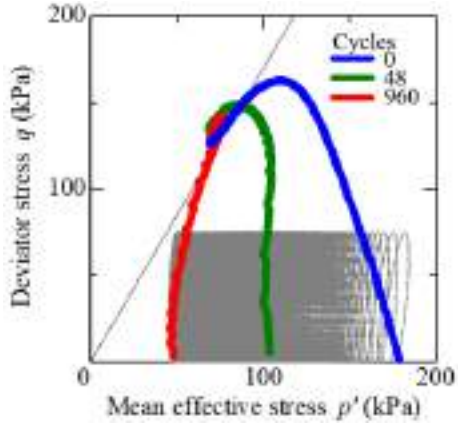

Fig. 6 Graph of q-p' of Subsequent Monotonic Shear Test on Undisturbed Specimen at K_0 = 1.0

Subsequent monotonic shear tests were also conducted at different numbers of cycles (0, 48, and 960). This is to determine the effect of cyclic loading (disturbance) on the peak shear strength, q_{max}, of the undisturbed soft clay soil. After 960 cycles, there is a 13% reduction in the peak shear strength of the sample, which emphasizes that there is only a subtle decrease in the peak shear strength after many cycles in isotropic conditions (Fig. 5 and 6).

Undisturbed Cyclic Shear Test at K_0 = 0.6

During B-value calculation and anisotropic consolidation, the mean effective stress was adjusted to 132 kPa to apply stress-induced anisotropy in the specimen. Then, the cyclic shear test was conducted based on JGS 0541. The results reveal that the axial strain propagates towards the compression side only, unlike in isotropic conditions, and eventually fails after 134 cycles (Fig. 7).

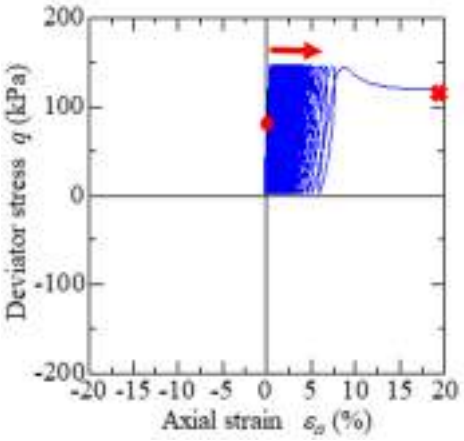

Fig. 7 Graph of q- ε_a of Cyclic Shear Test on Undisturbed Specimen at K_0 = 0.6

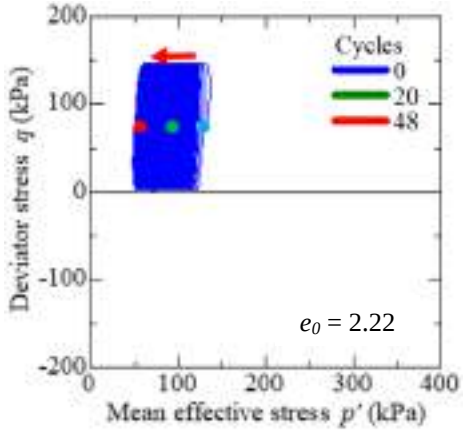

Fig. 8 Graph of q-p' of Cyclic Shear Test on Undisturbed Specimen at K_0 = 0.6

Additionally, Fig. 8 shows that the mean effective stress, p', continuously diminishes as the cyclic loading progresses. At failure, the recorded p' was 50 kPa.

Subsequent Monotonic Shear Test after Cyclic Loading at K_0 = 0.6 of Undisturbed Soft Clay

Subsequent monotonic shear tests were also conducted at different numbers of cycles (0, 20, and 48) based on the number of cycles at failure. This is to determine the effect of cyclic loading (disturbance) on the peak shear strength, q_{max}, of the undisturbed soft clay soil. The results reveal a 43% reduction in the peak shear strength after 48 cycles. It can be observed that there is a drastic decrease in the peak shear strength at a significantly lower number of cycles compared to isotropic conditions (Fig. 9 and 10).

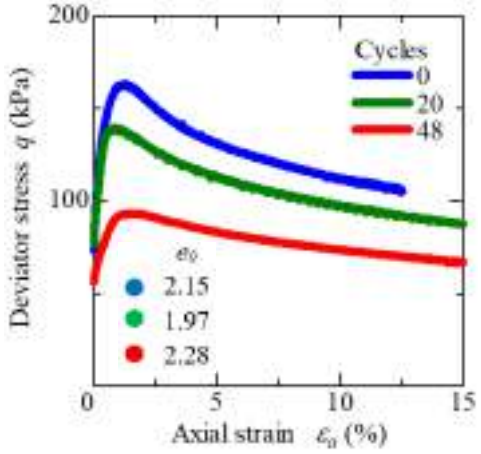

Fig. 9 Graph of q-ε_a of Subsequent Monotonic Shear Test on Undisturbed Specimen at K_0 = 0.6

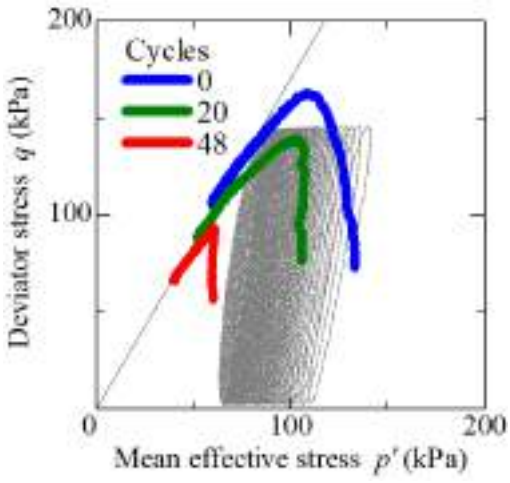

Fig. 10 Graph of q-p' of Subsequent Monotonic Shear Test on Undisturbed Specimen at K_0 = 1.0

Considering the results of cyclic and subsequent monotonic shear tests under isotropic (K_0 = 1.0) and anisotropic (K_0 = 0.6) conditions, it can be observed

that the mean effective stress, *p'*, and peak shear strength, q_{max}, were reduced after the application of cyclic loading. This can be attributed to the "disturbance" phenomenon brought by the application of cyclic loading. It can also be noticed that the reduction in q_{max} was greater under anisotropic (K_0 = 0.6) conditions at a significantly smaller number of cycles. From here, it can be deduced that the effect of "soil disturbance" is more pronounced at anisotropic conditions.

Reconstituted Cyclic Shear Test at K_0 = 1.0

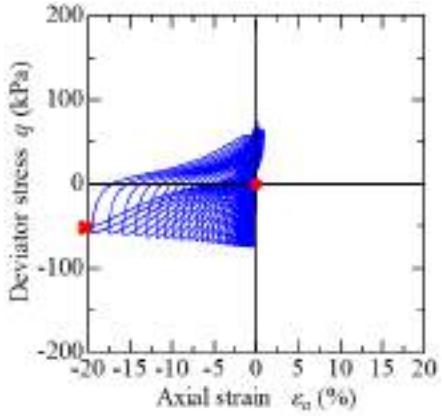

Fig. 11 Graph of q-ε_a of Cyclic Shear Test on Reconstituted Specimen at K_0 = 1.0

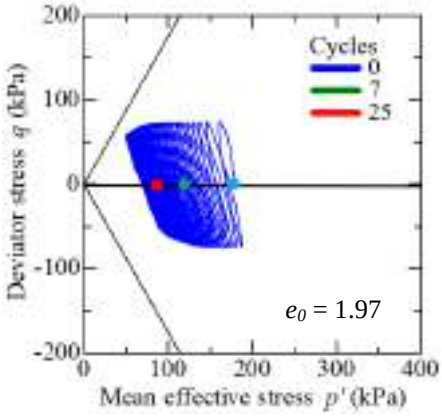

Fig. 12 Graph of *q-p'* of Cyclic Shear Test on Reconstituted Specimen at K_0 = 1.0

An isotropic cyclic shear test of reconstituted samples was conducted using the same amplitude (72 kPa) and period (20 seconds) as the undisturbed samples. This is to determine the difference between the cyclic behavior of undisturbed and reconstituted samples under the same stress conditions. Based on the results of the test, axial strain propagated initially in both compression and extension sides. However, the graph abruptly propagated towards the extension side after several cycles. This was followed by the failure of the specimen after 39 cycles (Fig. 11).

Furthermore, there was also a constant reduction in the mean effective stress of the reconstituted sample, similarly in undisturbed specimens. The mean effective stress, *p'*, at failure was about 60 kPa (Fig. 12).

Subsequent Monotonic Shear Test after Cyclic Loading at K_0 = 1.0 of Undisturbed Soft Clay

Subsequent monotonic shear tests at different numbers of cycles (0, 7, and 25) under isotropic conditions were conducted for reconstituted samples. The number of cycles was based on the number of cycles at failure. Based on the results of the experiment, there is no strain softening behavior present (Fig. 13). It is also important to take note that even after 25 cycles, the peak shear strength of the reconstituted specimen is almost equal to samples that have no cyclic loading history (Fig. 14).

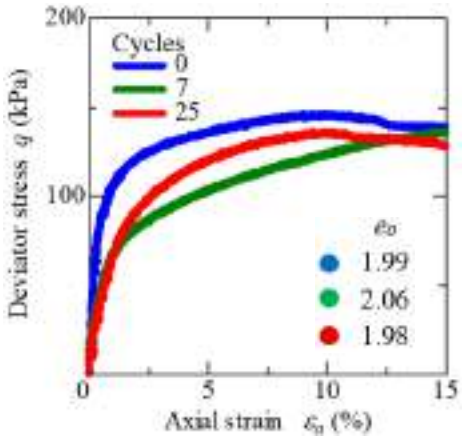

Fig. 13 Graph of q-ε_a of Subsequent Monotonic Shear Test on Reconstituted Specimen at K_0 = 1.0

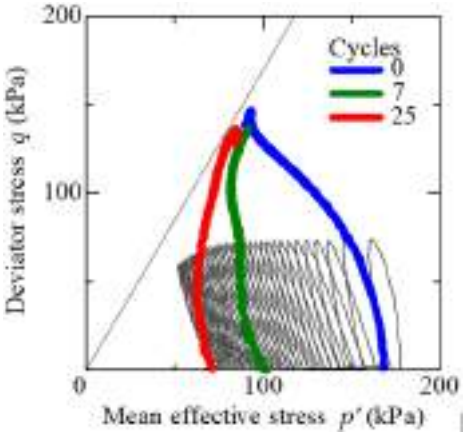

Fig. 14 Graph of *q-p'* of Subsequent Monotonic Shear Test on Reconstituted Specimen at K_0 = 1.0

Considering the results of cyclic and subsequent monotonic shear tests on undisturbed and reconstituted soft clay under isotropic conditions, it

can be observed that there is a reduction in the mean effective stress, *p'*, of the reconstituted specimen during cyclic loading. This suggests that the reduction of *p'* is not exclusively caused by cyclic loading (soil disturbance). On the other hand, the reduction in peak shear strength can only be distinguished in undisturbed soft clay specimens. It is also essential to take note that the number of cycles to failure of reconstituted specimens was significantly lower than that of undisturbed specimens. This behavior of reconstituted samples can be attributed to the lack of aging effect, which is present in undisturbed soft clay. Aging effect refers to the time-dependent increase in stiffness and strength of soil after deposition or seismic loading history. This behavior is more noticeable in fine-grained soils.

CONCLUSIONS

Based on the results of the experiments, the following conclusions can be drawn:

Physical properties of the specimen extracted from Kaizu City, Gifu Prefecture, Japan, showed that the soil specimen contains high moisture content and is mainly composed of fine-grained particles. In addition, the monotonic shear tests of the specimens exhibited strain softening in q- ε_a graph and "rewinding and bowing" behavior in q-p' graph. These characteristics proved that the soil specimen used in the experiments is indeed soft clay soil.

From the results of cyclic and subsequent monotonic shear tests on undisturbed and reconstituted soil, "soil disturbance" can be defined as the destruction of soil structure formed during deposition, loss of initial stiffness, and reduction of peak shear strength. The number of cycles to failure of the reconstituted specimen is also significantly lower than the undisturbed specimen which can be attributed to the lack of aging effect.

From the results of cyclic and subsequent monotonic shear tests under isotropic (K_0 = 1.0) and anisotropic (K_0 = 0.6) stress conditions, there is a greater reduction in peak shear strength of the specimen under anisotropic conditions at a lower number of cycles. Therefore, it can be concluded that anisotropy amplifies the effect of soil disturbance in soft clay soils.

From the geotechnical engineering perspective, it is essential to consider the anisotropic conditions of the actual ground because it may lead to overestimation of the cyclic shear resistance.

ACKNOWLEDGMENTS

The authors would like to express their deepest gratitude to the Japan International Cooperation Agency (JICA) and Geotechnical Engineering Laboratory of Nagoya University for providing the necessary resources to complete this research.

ABSTRACT

Soil improvement is a critical challenge in geotechnical engineering, especially for weak soils like dredged sediments. This study proposes an alternative stabilization method using hydraulic cement (HC), partially replaced with steel slag (SS), and enhanced with bamboo biochar in both soaked and dry forms. Various tests, including unconfined compressive strength (UCS), free-free resonance (FFR), X-ray diffraction (XRD), and scanning electron microscopy (SEM), were conducted to evaluate mechanical and microstructural behavior. Results indicated that the mixture with 25% steel slag substitution achieved a 7-day UCS of 900.71 kPa, exceeding the standard subbase requirement of 689 kPa. The inclusion of both kinds of biochar significantly enhanced early-stage strength development, with certain combinations reaching UCS values of 769.04 kPa and 645.51 kPa after only 3 days of curing, whereas the mixture without biochar exhibited a lower UCS of just 559.27 kPa. XRD and SEM analyses confirmed the formation of calcium silicate hydrate (CSH) and Ettringite, validating the chemical stabilization mechanism. Moreover, wave velocity data from FFR tests showed a strong correlation with UCS, supporting the use of non-destructive evaluation methods and enabling predictive modeling. This approach promotes sustainability through reduced cement usage and the beneficial reuse of industrial by-products and natural agricultural waste. The findings demonstrate potential for integrating these materials into geo-environmental soil stabilization practices, in alignment with circular economy principles and the Sustainable Development Goals (SDGs).

Keywords: soil improvement, steel slag, biochar, unconfined compressive strength, sustainable geotechnics

1. INTRODUCTION

Construction on weak or soft ground is often unavoidable in rapidly urbanizing countries like Thailand, where soft clay layers dominate the subsoil profile in many regions. Such soils pose challenges including excessive settlement and low bearing capacity, especially in projects such as road embankments and earth dams. To address these issues, soil improvement techniques are essential. These techniques are generally categorized into densification, reinforcement, drainage, and cementation [1]. Among problematic soils, fine-grained sediments dredged from canals and reservoirs are particularly difficult to manage. These sediments have high moisture content and low strength, making them unsuitable for direct use in construction. However, their continuous accumulation creates disposal and environmental issues. Prior studies have demonstrated that stabilization using ordinary Portland cement (OPC), combined with industrial by-products such as fly ash or slag, can improve strength and durability [2-8].

In response to environmental concerns and carbon reduction goals, hydraulic cement (HC) incorporating industrial waste has gained attention as a more sustainable alternative to OPC [9-10]. Additionally, biochar, which is a porous and carbon-rich material derived from biomass, has shown promise in enhancing soil properties while sequestering atmospheric CO_2. Despite growing interest, few studies have investigated the combined effects of HC, steel slag (SS), and biochar on the early strength and stiffness development of stabilized sediments.

Therefore, this study aims to evaluate the performance of dredged sediment stabilized using HC partially replaced with SS, along with either soaked or dry bamboo biochar. The study assesses unconfined compressive strength (UCS), wave velocities (V_p, V_s), and microstructural development using XRD and SEM. The goal is to promote the sustainable reuse of industrial and agricultural wastes in geotechnical applications, contributing to geo-environmental engineering and the Sustainable Development Goals (SDGs).

2. RESEARCH SIGNIFICANCE

The increasing generation of industrial, agricultural, and underutilized natural wastes, such as dredged sediments, poses a growing environmental challenge. This study proposes a sustainable approach for stabilizing such materials using HC partially replaced with steel slag and enhanced with bamboo

biochar. It uniquely examines the combined effects of these materials, including comparisons of soaked and dry biochar. Free–free resonance (FFR) testing is applied to develop correlations between UCS and wave velocities, offering a non-destructive method for strength assessment. This approach supports the SDGs and advances geo-environmental engineering.

3. MATERIALS

3.1 Dredged sediment from drainage canal

The sediment used in this study was collected from a drainage canal in Phetchaburi province, approximately 176 km southwest of Bangkok. Sediment accumulation in canal significantly affects water management efficiency, as illustrated in Fig. 1. To address this, the Royal Irrigation Department conducts annual dredging operations. In 2022, approximately 478,000 m³ of sediment was dredged at a total cost of USD 367,126.

After six months of air drying, the natural water content of the sediment decreased from 117% to 5%. The sediment was classified as silty sand (SM) under the USCS, and A-4 (0) under AASHTO, indicating suitability for low to medium construction applications [11]. It had a specific gravity of 2.67, with 46.29% of particles passing through the No. 200 sieve as illustrated in Fig. 2. The particle size distribution consisted of 0.71% gravel, 51.94% sand, 28.79% silt, and 17.50% clay.

From the standard Proctor test, the optimum moisture content (OMC) was 14.32%, and the maximum dry density was 17.26 kN/m³. The UCS of the untreated sample remolded at the OMC was measured at 49.03 kPa. Previous XRF analysis revealed that this sediment primarily consists of SiO_2 (79.61%), Al_2O_3 (10.33%), and Fe_2O_3 (3.80%) [12].

Fig. 1 Drainage canal in Phetchaburi province

3.2 Steel slag

Steel slag, a by-product from electric arc furnace (EAF) steelmaking, is generated in Thailand at approximately 500,000 to 600,000 tons annually [13], posing a significant challenge for disposal and reuse. In this study, slag was sourced from Siam Machinery and Equipment Co., Ltd. in Ayutthaya province, approximately 82 km north of Bangkok.

The steel slag used in this study was dark gray in colour and initially in lump form. Approximately 300 kg of the material was ground and thoroughly homogenised to ensure consistency across all experiments. The processed slag was sieved through a No. 10 sieve, resulting in a mixture that retained some residual steel particles. No intentional removal of these metallic inclusions was carried out, in order to reflect the use of steel slag in its typical industrial form. This may have implications for long-term environmental performance, including the potential generation of metal-rich leachate from the steel particles. Notably, the inclusion of biochar in the mix may offer additional benefits by adsorbing or immobilising such contaminants, thus contributing to the overall environmental safety of the amended soil. Particle size analysis showed that 16.44% of the slag passed through the No. 200 sieve, as illustrated in Fig. 2. The slag was used as a partial replacement for hydraulic cement in selected mix designs.

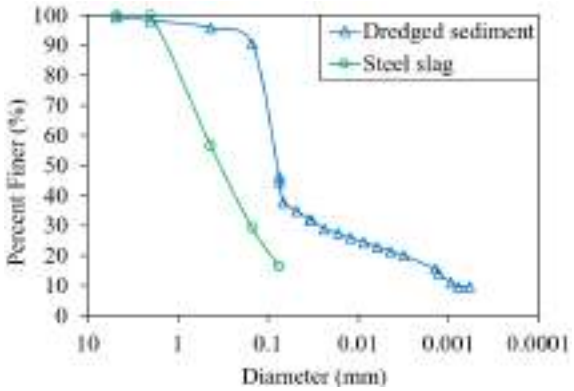

Fig. 2 Grain size distribution curve

3.3 Biochar

Biochar is a carbon-rich material produced through pyrolysis, a thermal decomposition of biomass in an oxygen-limited environment. Unlike combustion, this process stabilizes carbon into a solid form, making biochar effective for carbon sequestration and reducing greenhouse gas emissions [14-15]. The improvement in water retention of biochar-amended soil has been reported, which provides favorable effects for nature-based soil cover system in geotechnical engineering application [16].

In this study, bamboo biochar produced by Thai Carbon Co., Ltd., located in Nakhon Pathom province (55.2 km from Bangkok), using an industrial scale pyrolysis (US EPA approved technology) was utilized. The obtained sample was in fine black powder form. The manufacturer's datasheet indicates

its high specific surface area of 223 m^2/g with the pH of 9.60 indicating its alkalinity. Both dry and water-soaked biochar were incorporated into the mixtures to assess their influence on the mechanical behavior and strength development of the stabilized sediment.

4. METHODOLOGY

4.1 Specimen Preparation and UCS Test

Based on prior research [12], dredged sediment was stabilized using a base binder of hydraulic cement at 250 kg/m^3 (mass of cement by volume of soil), with a constant soil's moisture content of 17.0%. SS was used as a partial or full replacement for HC at 25% and 100%, respectively. Bamboo biochar was added at 2.68% by weight of dry soil in either dry or soaked form. Seven mix designs (Mix 0-Mix 6) are summarized in Table 1.

Table 1 Mix proportions and symbols

Symbol	Cement content (% of 250 kg/m^3)		Biochar (% by weight)	
	HC	SS	Dry	Soaked
Mix 0	100	0	0	0
Mix 1	75	25	0	0
Mix 2	0	100	0	0
Mix 3	75	25	0	2.68
Mix 4	0	100	0	2.68
Mix 5	75	25	2.68	0
Mix 6	0	100	2.68	0

Each mix was blended using a Hobart-type mechanical mixer and molded into cylindrical specimens (ϕ = 5.0 cm, h = 10.0 cm) following the method for making and curing non-compacted stabilized soil specimens (JSF T821-1988) [17] as suggested by [4]. Specimens were demolded after 24 hours and cured in plastic sealed for 3 and 7 days.

Unconfined compression tests were conducted on triplicate specimens using a universal testing machine (UTM) at a strain rate of 0.01 min^{-1}, following ASTM D2166 [18]. The maximum strength was recorded either at the peak load or at 15% axial strain, whichever occurred first.

4.2 Free-free resonance (FFR) Test

The FFR method, a non-destructive testing technique, was applied to evaluate compressional (V_p) and shear (V_s) wave velocities in the same UCS specimens. Each specimen was excited with an impact at one end, and the response was detected by an accelerometer at the opposite end.

The fundamental resonance frequency (f) was determined, and wave velocities were calculated using the relationships:

$$V_p = f_L \lambda = 2 f_L L \quad (1)$$

$$V_s = f_T \lambda = 2 f_T L \quad (2)$$

where L is the specimen length, f_L and f_T are the longitudinal and torsional resonance frequencies, respectively.

5. RESULTS AND DISCUSSIONS

5.1 Unconfined Compressive Strength (UCS)

The UCS results of all mixtures after 3 and 7 days are shown in Fig. 3. The findings indicate that both SS and bamboo biochar influence strength development. Although the UCS of Mix-1 (75% HC and 25% SS) at 7 days was lower than that of Mix-0 (100% HC), it represented the highest strength among all mixtures incorporating SS, reaching 900.71 kPa and exceeding the subbase requirement of 689 kPa [19]. Notably, Mix-3, which included 75% HC, 25% SS, and soaked biochar, exhibited the highest early strength, with a 3-day UCS of 769.04 kPa, equivalent to approximately 94% of its 7-day value (820.16 kPa). This 3-day strength exceeded that of both Mix-0 and Mix-1, highlighting the positive contribution of soaked biochar to early strength development.

In contrast, Mix-4, which consisted of 100% SS and soaked biochar, yielded the lowest UCS among all mixtures, reaching only around 104.38 kPa at 7 days. This result suggests that the combination of SS and biochar alone lacks sufficient binding potential to effectively stabilize the soil. Nevertheless, the UCS of Mix-4 was still slightly higher than that of untreated soil, indicating a marginal improvement in strength despite the absence of HC.

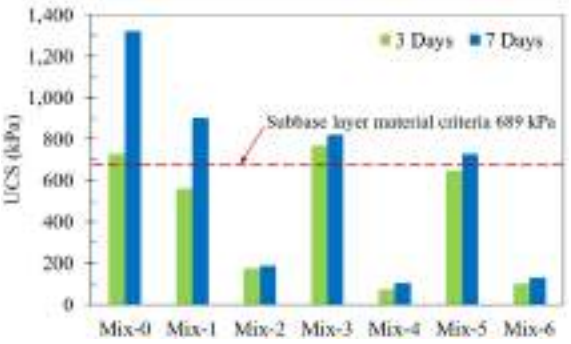

Fig. 3 UCS of stabilized sediment

Mix-3 exhibited a reduced water content after curing (13.97%) as illustrated in Fig. 4, likely due to moisture uptake and gradual release from soaked biochar. This contributed to more effective hydration and matrix densification. Comparing Mix-3 and Mix-5 (same binder, different biochar condition), soaked biochar led to higher UCS, indicating its superior contribution to early strength. Overall, the combination of HC, SS, and soaked biochar enhanced

UCS, particularly at early ages, likely through improved hydration and filler effects from the porous structure of biochar.

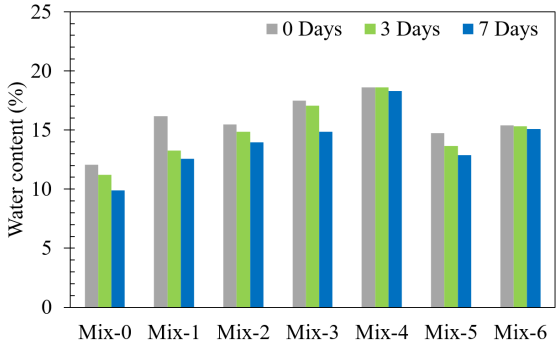

Fig. 4 Water content of stabilized sediment

5.2 Compression and Shear Wave Velocity

FFR test results for all mixtures are presented in Fig. 5 and Fig. 6. Both compressional (V_p) and shear (V_s) wave velocities increased with curing time and showed similar trends to the UCS results.

Mix-1, composed of 75% HC and 25% SS, exhibited the highest wave velocities after 7 days (V_p = 1,151.32 m/s, V_s = 657.90 m/s), indicating superior stiffness and well-developed internal structure. Mix-3, which additionally incorporated soaked biochar, also demonstrated relatively high wave velocities (V_p = 1129.74 m/s, V_s = 593.44 m/s), reflecting its notable early strength performance and enhanced material continuity.

In contrast, Mix-4, comprising 75% SS and soaked biochar without cement, recorded the lowest velocities (V_p = 203.02 m/s, V_s = 124.45 m/s), consistent with its poor mechanical properties. Overall, mixtures containing soaked biochar tended to show improved wave propagation characteristics compared to those with dry biochar or without biochar, especially when combined with a hydraulic binder.

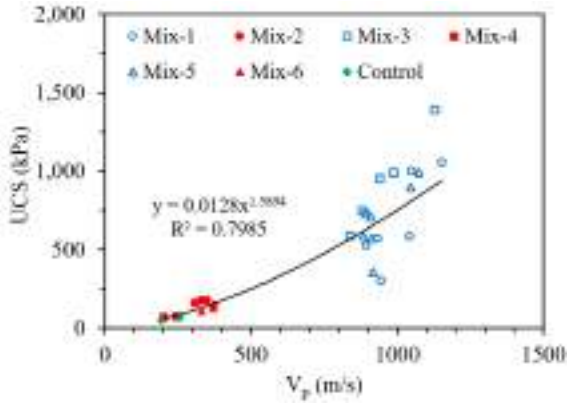

Fig. 5 UCS versus V_p

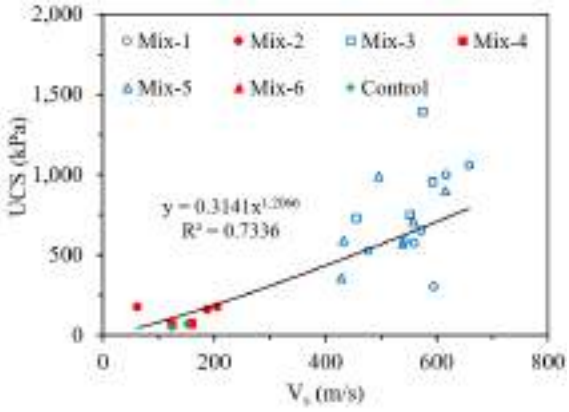

Fig. 6 UCS versus V_s

This can be attributed to improved particle bonding and water retention, which enhance matrix stiffness. Empirical equations were developed to predict UCS from wave velocities, as follows:

$$UCS = 0.0128V_p^{1.5894} \quad (R^2 = 0.7985) \quad (3)$$

$$UCS = 0.3141V_s^{1.2066} \quad (R^2 = 0.7336) \quad (4)$$

These correlations indicate that FFR testing provides a promising non-destructive approach for estimating strength development in stabilized dredged sediments.

5.3 X-ray diffraction analysis

The mineralogical composition of stabilized sediment was investigated using X-ray diffraction, and the results are presented in Fig. 7. The diffraction patterns indicated that quartz (PDF 05-0490) was the dominant mineral in the untreated dredged sediment. Secondary minerals identified included montmorillonite (PDF 03-0010), illite (PDF 43-0686), and kaolinite (PDF 05-0143), which correspond with the soil classification results.

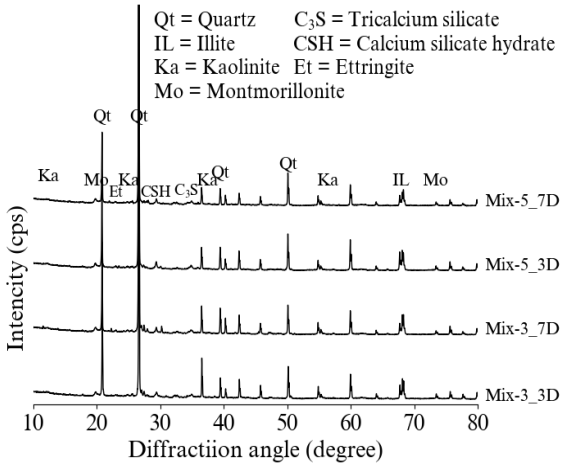

Fig. 7 XRD pattern of Mix-3 and Mix-5

In addition, characteristic peaks corresponding to hydration products, namely calcium silicate hydrate (CSH, PDF 00-012-0739) and ettringite (PDF 04-013-3691), were observed in the treated mixtures. Notably, the ettringite peak in Mix-3 was more pronounced than in Mix-5, consistent with its higher unconfined compressive strength (UCS). These findings confirm that chemical reactions occurred during the curing process and contributed to the observed strength development.

5.4 Scanning electron micrographs

Microstructural analysis was performed using scanning electron microscopy (SEM) on fractured surfaces of selected specimens. Fig. 8 shows the SEM micrograph of Mix-3 after 7 days of curing. The image reveals a substantial presence of rod-shaped ettringite crystals, one of the key hydration products in cement-treated soils.

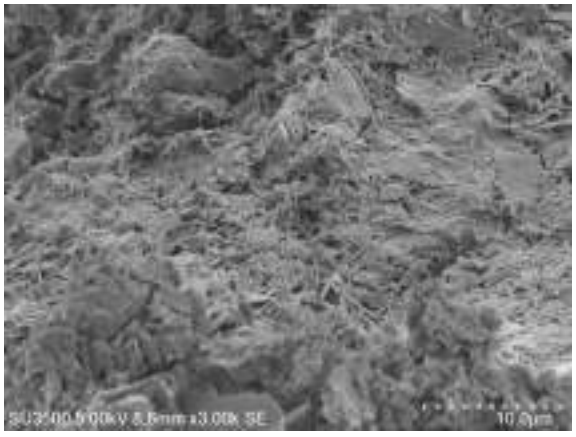

Fig. 8 SEM micrograph of Mix-3 at 7 days curing

These needle-like formations are known to contribute to strength development by filling voids and bridging soil particles, thus enhancing matrix integrity. The presence of ettringite observed here is consistent with the XRD results (Section 5.3), which also confirmed distinct peaks for ettringite in Mix-3. The agreement between SEM and XRD findings validates the occurrence of hydration reactions in the treated soils, supporting the mechanical performance results observed in the UCS and FFR tests.

6. CONCLUSIONS

This study investigated the stabilization of dredged sediment from drainage canals using hydraulic cement partially replaced with steel slag and enhanced with bamboo biochar. The main findings are summarized as follows:

1. Partial replacement of hydraulic cement with steel slag (up to 25%) improved the mechanical performance of the stabilized sediment. Mix-1 achieving a 7-day UCS of 900.71 kPa exceeding 689 kPa, meeting subbase material standards.

2. The addition of a biochar, particularly in the soaked condition, significantly accelerated early strength development. Mix-3 and Mix-5 reached UCS values of 769.04 kPa and 645.51 kPa, respectively, at 3 days, outperforming mixes without biochar in early-age strength.

3. A clear correlation was observed between UCS and wave velocities (V_p and V_s), reflecting increased material stiffness. This relationship supports the development of predictive equations and highlights the potential of FFR testing for non-destructive strength estimation in stabilized soils.

4. XRD and SEM analyses confirmed the formation of key hydration products, notably CSH and ettringite. Their presence validated the hydration mechanisms responsible for strength development.

5. In addition to enhancing strength, hydraulic cement may help reduce environmental risks. Its alkalinity promotes heavy metal precipitation, while hydration products like CSH and ettringite can immobilize contaminants [20]. Although leachability or chemical composition analysis of steel slag were not assessed in this study, the addition of biochar with high sorptive capacity may further limit pollutant mobility. Further research is recommended to assess long-term performance.

Overall, the combination of hydraulic cement, steel slag, and bamboo biochar a promising and sustainable solution for reusing dredged sediments in civil engineering applications. This approach not only improves geotechnical performance but also promotes circular use of industrial and natural by-products, aligning with low-carbon geo-environmental engineering practices and SDGs.

7. ACKNOWLEDGMENTS

The authors gratefully acknowledge the Faculty of Engineering, Kasetsart University, for its financial support and provision of laboratory facilities throughout this study. Special appreciation is also extended to the Royal Irrigation Department, Ministry of Agriculture and Cooperatives, Siam Machinery and Equipment Co., Ltd., Green Ground Solutions Co., Ltd and Thai Carbon Co., Ltd. for their generous support in supplying essential materials. Their valuable contributions were instrumental in accomplishing the research objectives. Assistance from Mr. Chalantorn Thiansri and Mr. Pannathorn Sukkul in sample preparation and performing experiments are thanked for.

ABSTRACT

Dispersive soils are prone to structural collapse and erosion when exposed to water, often leading to turbidity, sedimentation, and reduced reservoir life when improperly managed in flood retention pond construction. This research aimed to investigate the dispersive characteristics of soils excavated from a flood retention pond in Prachin Buri province, Thailand. Laboratory tests included physical dispersion tests such as the crumb test, double hydrometer test, and pinhole test, and chemical analyses such as the sodium adsorption ratio (SAR) and the percentage of sodium (%Na) relative to total dissolved salts. Mineralogical analysis using X-ray diffraction (XRD) was also performed. Field observations and tests were conducted in parallel and compared with actual water quality data. The findings suggested that soil dispersivity is strongly related to sodium content and mineralogy, particularly the presence of montmorillonite. A practical solution is proposed for managing dispersive soils during excavation, including proper separation and stockpile zoning to reduce dispersion risks, thereby promoting the sustainable use of excavated soil in construction projects.

Keywords: Dispersive Soils, Flood Retention Ponds, Soil Erosion, Water Turbidity, Soil Management

INTRODUCTION

Flood retention ponds are vital to Thailand's water management, helping reduce floods and support sustainability [1], [2]. Excavation from these ponds produces large volumes of soil, which can be reused in roads, embankments, or dams [1]. However, some soils are dispersive, making them prone to internal erosion and piping [3]. If not properly identified, they may compromise structural integrity and cause turbidity, environmental harm, and safety concerns [4].

In the Prachin Buri project, signs of erosion, slumping, and shallow channels were observed in stockpiled soils, indicating dispersive behavior [1]. These traits were not detected by standard classification methods [3], [5]. Improper zoning also led to mixing of dispersive and non-dispersive soils, complicating reuse and revealing a gap in routine soil assessment practices [6].

Dispersive soils can degrade earth structures through internal erosion, leading to turbidity, siltation, and water quality loss [4], [7], [8]. In rural areas, this increases maintenance needs and risks for flood control systems. Early identification is crucial for long-term safety and sustainability [2]. Although dispersive soils are well documented globally [3], geotechnical investigations in Thailand rarely include specific tests. Common methods, such as Atterberg limits or grain size distribution, cannot reliably detect dispersive behavior [5]. Proper evaluation requires tests like the crumb test, pinhole test, double hydrometer test, and chemical indices such as SAR and %Na [9], which are often omitted.

This research supports Thailand's Bio-Circular-Green (BCG) Economy Model, which promotes sustainability through bio-based resources , material efficiency , and eco-friendly technologies [2], [10]. Identifying and managing dispersive soils enables more sustainable reuse of excavated materials, reduces environmental risks, and enhances infrastructure resilience. By applying geotechnical and chemical indicators, this study contributes to better resource use and reduced construction waste key goals of the BCG strategy.

The study investigates the dispersivity of soils from flood retention projects in Prachin Buri using laboratory tests and field observations. A zoning approach is proposed to manage dispersive soils for safe reuse. Recommendations include compaction and lime treatment to improve stability. The findings support practical guidelines and align with Thailand's BCG Economy Model [2], [10].

RESEARCH SIGNIFICANCE

This study addresses the often-overlooked challenge of managing dispersive soils excavated from flood retention ponds, which can pose long-term environmental risks if mishandled. Focusing on a project in Prachin Buri Province, Thailand, the research links soil dispersivity with erosion and turbidity, and proposes a practical zoning strategy developed through field surveys and laboratory

testing to minimize environmental impacts during soil disposal. The findings offer practical guidance for dam engineers, irrigation planners, and project managers in implementing appropriate soil management strategies for safer and more resilient infrastructure development. resilient infrastructure.

MATERIALS AND METHODS

Study Area

Following the work of Thiamthong and Nontananandh [11], this study was conducted at five water resource development projects in Prachin Buri Province, Thailand an area with extensive flood retention initiatives under national water management plans. The province was selected for its representative geology, frequent use of flood retention ponds in rural infrastructure, and the variety of excavation and stockpiling practices observed in recent RID projects. These factors make it a suitable location for evaluating the dispersive characteristics of excavated soils. The selected sites include the Talad Mai Flood Retention Project, Sapa Khon Public Pond Dredging Project, Saphan Hin Pumping Station Project, Noen Na-ngam Flood Retention Project, and Wang Takhian Flood Retention Project all under the Prachin Buri Agricultural Research and Development Center. Conducted between 2021 and 2023, these projects differ in excavation volume, stockpiling methods, and field conditions, which are expected to influence the geotechnical behavior of the soils [6]. Table 1 summarizes key project characteristics, including excavation volumes, stockpile height, and compaction status.

Table 1. Excavation volume, stockpile height, and compaction status

Project Name	Excavation Volume (x 10^4 m^3)	Stockpile Height (m)	Compaction
Taladmai	12.50	4.00	Yes
Sappakhon	3.15	1.00	No
Saphanhin	2.37	1.00	Partial
Noennangam	10.61	1.00	No
Wangtakhian	50.00	2.00	No

Soil and Water Sampling and Field Observation

Disturbed soil samples were collected from stockpiles at five study sites following RID's soil sampling guideline [9]. Test pits were excavated at depths of 1.0 and 1.5–2.0 meters using a crawler-mounted backhoe. the sampling depths were selected based on typical excavation depths during pond construction and preliminary field observations of soil dispersivity with depth. Approximately 20 kilograms of soil were collected per sample for laboratory testing and sealed in moisture-retaining containers. Water samples were collected from each reservoir surface using standard grab methods in line with MWA standards, which are modified from WHO guidelines [12-13]. Turbidity was measured in the laboratory using portable meters under ISO 7027.

Laboratory Testing

The collected soil samples were tested to determine their basic physical properties and dispersive potential. Geotechnical properties were evaluated through grain size analysis using the combined sieve and hydrometer method (ASTM D422-72) [14], liquid limit (ASTM D423-72) [15], plastic limit (ASTM D424-71) [16], and classification based on the Unified Soil Classification System (USCS) per ASTM D2487-17 [17].

To assess dispersivity, three physical tests were conducted: the Crumb Test and Pinhole Test following Royal Irrigation Department (RID) standards, and the Double Hydrometer Test per ASTM D4221-99. Chemical indices, including Percent Sodium (%Na) and Sodium Adsorption Ratio (SAR), were also analyzed to understand soil sodicity and its correlation with dispersive behavior [9].

To support the physical and chemical results, selected samples underwent X-ray Diffraction (XRD) to identify dominant clay minerals such as montmorillonite, kaolinite, and illite, which influence deflocculation and erosion resistance in fine-grained soils. The mineralogical data helped interpret the test results and clarify the relationship between clay composition and observed dispersivity [18].

RESULTS AND DISCUSSION

Soil Classification and Field Observations from Excavated Samples

Soil samples from eleven locations across five flood retention projects in Prachin Buri Province were analyzed to assess basic geotechnical properties and field behavior. Table 2 summarizes the results, including grain size distribution, plasticity indices, USCS classification, and field observations such as erosion and water clarity.

Among the eleven samples, four were classified as CL or CH, indicating moderate to high plasticity clays. The remaining samples were SM or ML, corresponding to silty sand and low-plasticity silt. Liquid Limit (LL) values for the clayey soils ranged from 44.05% to 52.46%, and Plasticity Index (PI) values from 21.45% to 24.86%, reflecting moderate to high plasticity.

Field observations showed that erosion, dust, and turbid water were mostly associated with CH and CL soils. For example, Sample 1 (Talad Mai) and Sample

3 (Sapa Khon) exhibited turbid water and surface erosion. In contrast, most SM and ML samples, especially those from greater depths, were linked to clearer water.

Plasticity behavior was further interpreted using the LL–PI chart (Figure 1), which relates plasticity to erosion categories [19]. Samples 1 to 4, though classified as CL and CH, were in the highest erosion resistance zone, indicating that high plasticity alone does not imply erosion susceptibility. This contrasts with field observations of turbidity and erosion. The discrepancy suggests that Atterberg limits alone are insufficient to predict dispersive or erosive behavior and should be combined with physical, chemical, and mineralogical indicators.

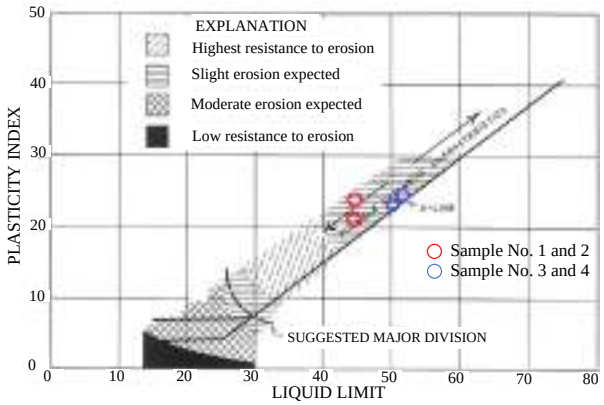

Fig.1 Correlation between plasticity index and liquid limit for evaluating erosion categories (Gibbs 1962)[19]

Physical Dispersion Test

Three physical tests, namely the Crumb Test, Double Hydrometer Test, and Pinhole Test, were used to assess the dispersive potential of the soil samples. The results are presented in Table 3.

The Crumb Test evaluates soil dispersion based on turbidity observed after immersion in distilled water. According to ASTM D6572, Grade 1 indicates no dispersion, while Grade 4 denotes immediate and strong dispersion. Samples 1, 2, 9, and 10 were rated as Grade 4, indicating high dispersivity. Conversely, Samples 3, 4, 6, 7, 8, and 11 were rated as Grade 1, reflecting non-dispersive behavior.

The Double Hydrometer Test quantifies dispersion as a percentage. According to ASTM D4221, values below 33% are considered non-dispersive, values between 34–67% are intermediate, and values above 68% are classified as highly dispersive. Sample 2 (76%) were classified as highly dispersive. Samples 1, 7, 9, and 10 fell within the intermediate dispersive range (34–67%).

The Pinhole Test assesses soil behavior under a hydraulic head. According to ASTM D4647-06, ND1 indicates non-dispersive behavior, while D1 and D2 denote dispersive behavior. Most samples were classified as ND1, which corresponds well with their Crumb Test and hydrometer results. However, Sample 10 exhibited D1 behavior, confirming its highly dispersive nature.

Chemical Dispersion Test

Chemical tests were conducted to evaluate dispersivity based on sodicity and salinity indicators, including Percent Sodium (%Na) and Sodium Adsorption Ratio (SAR). Table 4 presents the results.

Samples 1, 2, and 9 exhibited high %Na values of 86%, 82%, and 73%, respectively. According to RID guidelines[9], soils with %Na exceeding 60% are considered chemically dispersive, particularly when combined with low salinity. The corresponding SAR values for these samples were 5.0, 4.2, and 3.7, all exceeding the RID-defined threshold of 2.0 for dispersion behavior.

By contrast, Samples 5 through 8 exhibited low %Na (0-33%) and SAR values below 0.4, indicating low sodicity and a low risk of dispersion. Sample 11, with moderate values (SAR = 0.65, %Na = 42%), was categorized as intermediate dispersive.

Based on the Sherard classification diagram[2] (Figure 2), Samples 1, 2, 3, 4, 9and10 were categorized as Zone A (dispersive); Samples 5-8 were classified as Zone B (non-dispersive); and Sample 11 as Zone C (intermediate dispersive). These chemical findings correlate well with both the physical test results and field observations.

Water Turbidity Assessment

Field observations were conducted after the construction phase and revealed signs of surface erosion, airborne dust, and runoff-induced washout at multiple locations. Additionally, visual inspection of adjacent reservoir water indicated persistent turbidity at the Talad Mai,Noen Na-ngam, and Wang Takhian sites, whereas water at the Sapa Khon and Saphan Hin sites appeared visibly clear. These observations suggested that the soils at the more turbid locations may exhibit dispersive characteristics.

Water turbidity in the excavated areas was evaluated both visually and using Nephelometric Turbidity Units (NTU). Table 5 summarizes the results of turbidity values measured in NTU and visual observations of water clarity at each site.

The highest turbidity was recorded at Wang Takhian (19.63 NTU), followed by Talad Mai (9.99 NTU) and Noen Na-ngam (6.55 NTU). These value exceeded the WHO guideline for drinking water (5 NTU) [13], although this reference is used here only

Table 2 Basic geotechnical properties and field observations of soil sample

No.	Project	Depth (m)	%Passing No.4	%Passing No.200	LL (%)	PI (%)	USCS	Pits	Dust	Surface Erosion	Water Clarity
1	Talad Mai	1.0	100	73.05	44.13	24.86	CL	No	Yes	Yes	Turbid
2		2.0	100	94.11	44.05	21.45	CL				
3	Sapa Khon	1.0	100	90.41	52.46	24.77	CH	No	Yes	No	Clear

9	Wang Takhian	1.0	98.29	50.01	NP	NP	ML	Yes	Yes	Yes	Turbid
10		1.0	88.49	23.95	NP	NP	SM				
11		2.0	83.01	35.94	NP	NP	SM				

Note : NP = Non-Plastic. 'Turbid' indicates visibly cloudy water observed during field investigation

as a benchmark. In contrast, Sapa Khon and SaphanHin exhibited clearer water, with turbidity levels of 5.52 and 2.95 NTU, respectively. These results are consistent with laboratory data, affirming that dispersive soils contribute to increased turbidity due to clay deflocculation and colloid release

XRD Analysis Test

The mineralogical composition of soil samples was analyzed using X-ray Diffraction (XRD) to support interpretation of dispersive behavior. Figure 2 shows diffraction profiles from four sites: Sapa Khon (1.0 m), Noen Na-ngam (1.0 m), Wang Takhian (1.0 m), and Wang Takhian (2.0 m).

Quartz (Qt) was the dominant mineral in all samples, with a major peak at $2\theta \approx 26.6°$, matching ICDD PDF No. 01-085-0799. As a non-clay silicate with no cation exchange capacity, quartz is not associated with dispersion.

Kaolinite (Ka), a non-dispersive clay mineral, appeared in several samples with peaks at $2\theta \approx 12.4°$ and 24.9° (PDF No. 00-014-0164). Its presence, especially in Samples 1, 2, and 3, suggests stable soil with low swelling potential and minimal dispersivity.

Montmorillonite (Mo) was identified in Sample 4 (Wang Takhian, 1.0 m), with a basal reflection at $2\theta \approx 5.8°–6.2°$ (PDF No. 00-029-1498). As a smectite clay with high cation exchange capacity and strong sodium affinity, montmorillonite is a key indicator of dispersivity. This aligns with Sample 4 Crumb Grade 4, D1 pinhole classification, and high SAR, suggest moderate dispersion under field conditions.

Illite (I), a non-expanding clay, was also found in Sample 4, with peaks near $2\theta \approx 8.8°$ and 19.8° (PDF No. 00-026-0911). With moderate plasticity, illite may contribute to intermediate dispersivity, particularly when combined with high sodium content, as observed in Sample 4 (SAR 3.7, D1 classification).

Minor amounts of calcite (C) were detected, with a peak near $2\theta \approx 29.4°$ (PDF No. 01-072-1937). Calcite, however, is not directly linked to dispersivity.

Implications and Recommendations for Excavation and Soil Stockpile Management

This study emphasizes the importance of early excavation planning, particularly in setting safe depths that avoid dispersive soil layers. Overlooking these horizons can lead to long-term issues, including persistent turbidity and environmental risks from exposed stockpiles. Where deep excavation into dispersive strata is unavoidable, careful planning of stockpile and reuse zones is essential to minimize impacts. Environmentally responsible soil management can draw from past water resource projects in the area. This includes assessing site-specific soil properties and dispersion potential before excavation. Excavation and placement should comply with the Ministerial Regulation on Soil Erosion Prevention for Excavation and Landfilling, B.E. 2543 (2000). Sustainable stockpile management should follow these key guidelines:

First, a preliminary subsurface investigation should be conducted at 1–2 points per site to identify soil boundaries. Soil zoning must designate suitable areas for stockpiling different soil types. Representative samples should be collected every2,000 m^3 of excavated soil per RID standards. In areas with potential dispersive soils, at least five physical and chemical tests should be conducted. If three or more confirm dispersivity, the soil is

classified as dispersive. Appropriate treatments, such as lime stabilization or alum solution, should then be applied to mitigate erosion and dispersion [20].

Second, if excavation into dispersive layers is unavoidable, physical barriers like geomembranes should be installed to isolate dispersive soils and prevent exposure to surface water, thereby reducing turbidity and downstream sedimentation.

Third, if dispersive soil must be stockpiled, piles should be covered with materials such as geotextile, mulch, or temporary grassing to reduce surface erosion and colloid dispersion from rainfall or runoff.

These recommendations promote sustainable, compliant excavation and management of dispersive soil. Zoning, testing, and treatment reduce risks to the environment and improve infrastructure resilience.

CONCLUSIONS

This study examined the dispersive characteristics of soils from five flood retention projects in Prachin Buri Province through physical, chemical, mineralogical, and field assessments. Soils with high Crumb Test grades, dispersion rates above 68%, Pinhole classifications of D1 or D2, SAR values over 2, and %Na above 60% consistently showed dispersive behavior, surface erosion, and water turbidity. XRD analysis confirmed montmorillonite, highlighting the role of clay mineralogy in soil instability. These results emphasize the importance of early identification of dispersive soils to prevent long-term environmental and structural issues.

To manage such risks, the study recommends subsurface investigations, zoning by dispersivity, and chemical stabilization where appropriate. Stockpiled dispersive soils should be protected to limit erosion and colloidal loss. These practices follow RID guidelines and support the sustainable reuse of excavated soils in water projects.

For future outlook, further investigation on chemical stabilization techniques for dispersive soils found in flood retention areas, as well as long-term monitoring of water quality impacts, will be proposed. These findings would support site-specific design guidelines, enabling safe reuse of dispersive soils in infrastructure. Integrated approaches can reduce environmental impacts, lower maintenance costs, and support Thailand's Bio-Circular-Green (BCG) Economy Model by promoting sustainable soil use.

ACKNOWLEDGMENTS

The authors express their sincere gratitude to the Faculty of Engineering, Kasetsart University, for their generous research funding. They also acknowledge the Soil Science Division, Royal Irrigation Department, for their invaluable assistance in conducting dispersive soil testing. Additionally, the Metropolitan Waterworks Authority is acknowledged for its kind support in conducting water sample testing, which significantly contributed to the successful completion of this study.

Abstract

Identifying subsurface information (e.g., loosened rock mass and moisture content) is extremely important for slope disaster prevention in mountainous areas. However, estimating the distribution of loosened rock mass in subsurface layers has been difficult, and practical methods have not yet been established. Electromagnetic exploration is one of the methods for investigating subsurface structures, and recently, drone-based electromagnetic exploration method has been utilized. In this study, we investigated vertical resistivity profile patterns acquired using drone-based electromagnetic exploration method in a mountainous area in the southwestern Shikoku region of Japan, adjacent to the Kanagi landslide. Resistivity distributions were measured during both dry and wet terms. The difference in resistivity between the terms was examined in both ridge and valley terrains. As a result, a clear decrease in resistivity was observed in some ridge areas. Furthermore, the decrease suggests the possibility of estimating the depth of the loosened layer, which is one of the important factors in landslide occurrence. This indicates that the drone-based electromagnetic exploration method has the potential to contribute to slope disaster prevention.

Keywords: Loosened rock mass slope, Geophysical exploration, Resistivity, Drone

1. INTRODUCTION

In mountainous regions, at the loosened slopes due to gravitational deformation, deep-seated landslides or slope failures can be triggered by earthquakes or heavy rainfall [1]. To mitigate the disasters caused by such landslides and failures, it is essential to understand subsurface conditions such as loosened rock mass and moisture content to estimate the risk of disasters. There are several methods to estimate the looseness of the slopes. Geophysical method is one of the means to estimate the subsurface structure. To acquire the regional resistivity as looseness related information, airborne electromagnetic measurements have been used. Although measurement via helicopter has been commonly used, recently, the drone-based electromagnetic exploration method [2] is also used as one of the most efficient geophysical techniques for assessing the condition of rock mass. Several cases of applying the drone-based electromagnetic exploration method in the field of disaster prevention have been reported [3]. However, a practical method for evaluating subsurface looseness for the purpose of slope disaster prevention has not yet been established. In this study, slope resistivity surveys were conducted using the drone-based electromagnetic exploration method in mountainous terrain in the upstream basin of the Sakihama River in Muroto City. In this area, previous studies have reported that the bedrock slopes are deformed due to flexural toppling [4]. The presence of such loosened zones had been identified by topographic features and helicopter-based exploration method [5].

In this study, based on the data acquired, we analyze the relationship between zones with resistivity changes from the dry term to the wet term and the loosened rock mass. By identifying locations and depths where significant decreases in resistivity are observed during the rainy and dry terms, we propose a method to estimate loosened rock mass based on the rate of change in resistivity, thereby clarifying the relationship with areas where loosened bedrock is likely to be significant.

2. RESEARCH SIGNIFICANCE

The drone-based electromagnetic exploration method is considered one of the most efficient geophysical exploration techniques. In this study, we focused on changes in resistivity from the dry to the wet term to examine the relationship with loosened rock mass. If this method, which allows safe and efficient large-area surveys, can estimate the locations and depths of rock mass loosening, it will contribute to the development of effective slope disaster prevention strategies.

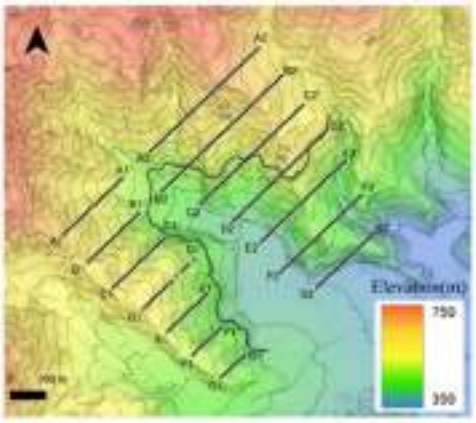

Fig.2 Locations of survey lines with elevation

3. STUDY AREA

The study area is in the upstream basin of the Sakihama River in Muroto City, Kochi Prefecture, in southwestern Japan (latitude 33°27′30″ to 33°29′00″ N, longitude 134°06′50″ to 134°11′00″ E) (Fig. 1). The bedrock in this area consists of sandstone, shale, alternating sandstone–mudstone layers, belonging to the Paleogene Muroto Peninsula Group in the Outer Zone of southwest Japan [6]. The geological strata generally strike northeast–southwest or north-northeast–south-southwest, and dip steeply to the northwest at angles between 60° and 90° [7]. A large-scale slope failure known as the Kanagi-kuzure occurred in the 1707 Hoei Nankai earthquake and heavy rainfall in 1746 [8], or possibly a rain-induced event that occurred several hundred years before 1707.

4. RESISTIVITY SURVEY

Fig. 2 shows 14 survey lines. In this study, the resistivity was acquired by the D-GREATEM system [2] (Fig. 3). The total precipitation for the 30 days prior to each survey date was 945.5 mm during the dry term and 245.0 mm during the wet term. Previous studies have shown that resistivity tends to decrease when saturation increases due to rainfall [9-10]. The average air temperatures on the survey dates were 21.0°C (dry term) and 25.6°C (wet term). Based on previous studies [11], this temperature difference is considered small and unlikely to affect resistivity measurements.

5. RESULTS OF THE RESISTIVITY SURVEY

The resistivity for each depth was calculated from the measured data using the method proposed by Jomori et al. [2]. Resistivity was estimated at 10 m intervals along the survey line, and at each point, it

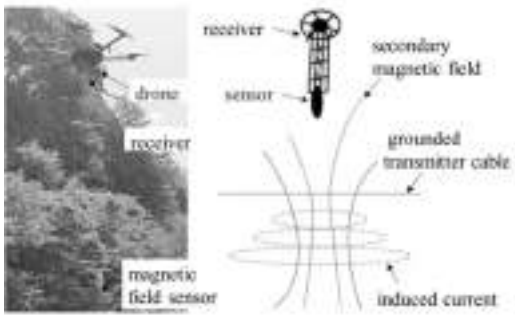

Fig.3 Schematic of exploration method (D-GREATEM)

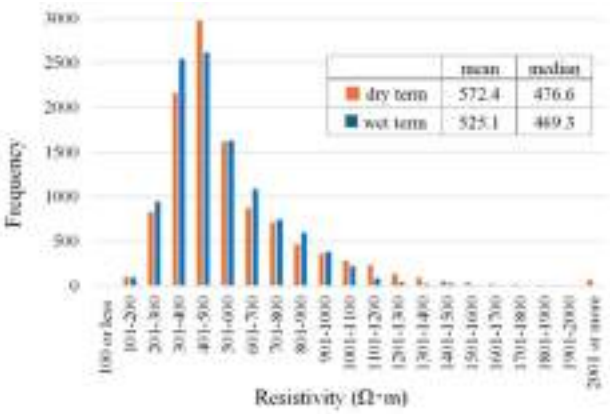

Fig.4 Frequency of resistivity: dry/wet terms

was estimated vertically at 5 m intervals. Resistivity was calculated from the depth at which sensitivity was obtained to the ground surface, and the maximum depth was 175 m.

Fig. 4 shows a histogram of resistivity distributions measured along 14 survey lines during the dry and wet terms. The observed resistivity values ranged from 100 to several thousand Ω·m, which are within the typical range for bedrock materials [12]. According to the histogram, resistivity values exceeding 1,700 Ω·m were present only in the dry term and were absent in the wet term. In the wet term,

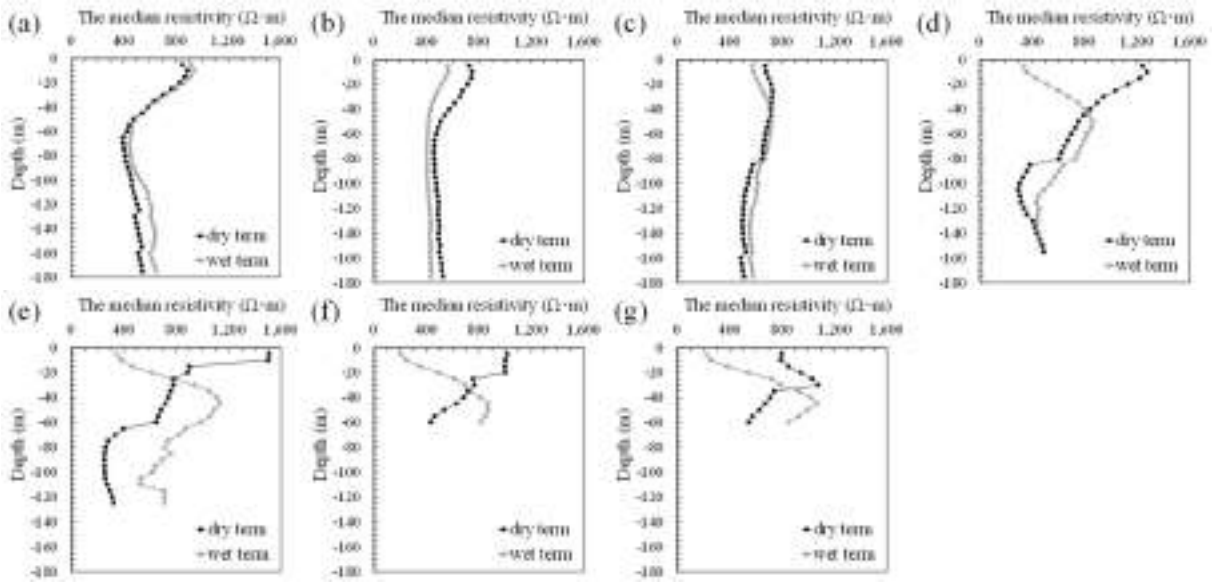

Fig.5 Median resistivity values by depth along survey lines. Shown depths indicate effective data limits per profile. *(a) A1–A1' survey line; (b) B1–B1'; (c) C1–C1'; (d) D1–D1'; (e) E1–E1'; (f) F1–F1'; (g) G1–G1'.*

the mean and median of the resistivity values are lower than those in dry term. These indicate that resistivity values decreased in the wet term compared to the dry term.

Fig. 5 shows plots of median resistivity values by depth for each survey line. Data of the 14 survey lines, those of acquired on the survey lines from A1-A1' to G1-G1' on the west side were used (Fig. 5). This is because those survey lines were installed along single or a few ridges and valleys and were considered uitable for capturing the effects of the terrain. Two distinct patterns of resistivity change were identified. In survey lines A1-A1' (Fig. 5a), B1-B1' (Fig. 5b), and C1-C1' (Fig. 5c), there was little difference in resistivity between the dry and wet terms. However, in survey lines D1-D1' (Fig. 5d), E1-E1' (Fig. 5e), F1-F1' (Fig. 5f), and G1-G1' (Fig. 5g), decrease in resistivity from the dry to wet term was observed down to a depth of approximately 40 m. In the unsaturated zone of bedrock slopes, resistivity increases with higher porosity and lower saturation. In addition, an increase in saturation due to water accumulation leads to a decrease in resistivity [12]. This indicates that the resistivity reduction observed in the D1-D1' to G1-G1' survey lines likely reflect rainwater infiltration into typical toppling-induced loosened zones in the bedrock of the study area. At greater depths along the D1-D1' to G1-G1' survey lines, there are areas where resistivity is higher in the wet term than in the dry term. Such a trend has also been reported in previous studies [9], where it was interpreted that infiltration of rainwater from above caused downward movement of air. To verify this, detailed investigations such as borehole surveys are required, which were not conducted in this study.

Table 1 Number of Measurement Points and Resistivity Change Rate α by Depth

Depth (m)	Total points	α (resistivity change rate)			
		Quartiles			Robust Z = -2
		Q1	Median (Q2)	Q3	
5	381	0.006	-0.398	-0.695	-1.438
20	378	-0.054	-0.300	-0.501	-0.963
35	366	0.103	-0.017	-0.313	-0.634

6. ANALYSIS AND RESULTS

6.1. Resistivity Change Rate

To evaluate the degree of resistivity reduction at each location, the resistivity change rate α was calculated at each survey point using Equation (1). ρ1 is the dry resistivity and ρ2 is the wet resistivity.

$$\alpha = (\rho 2 - \rho 1) / \rho 2 \quad (1)$$

Table 1 summarizes the calculated resistivity change rate (α) by depth, showing quartiles and values with a robust Z-score of -2. Although the robust Z-score [13] is typically used for outlier detection, in this study it is applied to identify locations with significant decreases in resistivity — areas where well-developed looseness may be of concern. A significant decline is defined as a robust Z-score less than −2. These results indicate that the resistivity reduction is greater near the surface, suggesting a stronger influence from rainfall at

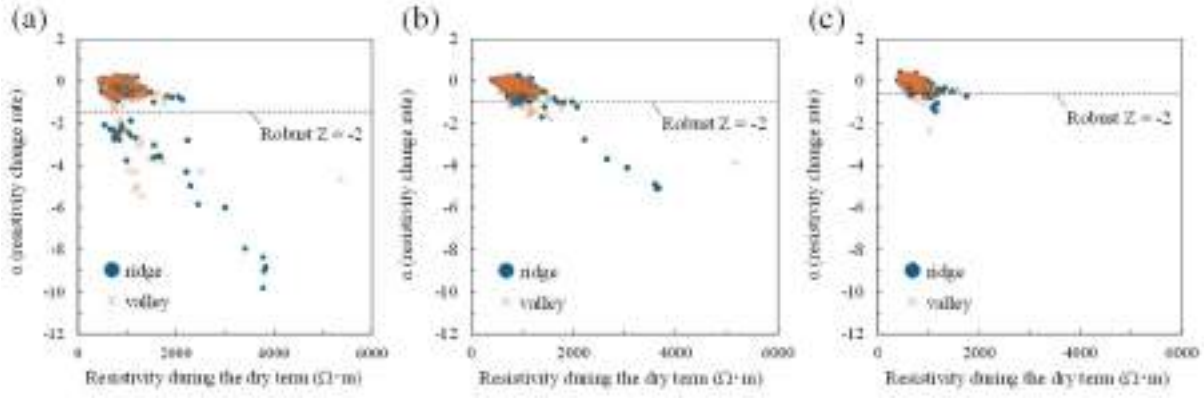

Fig. 6 Relationship between α (resistivity change rate) and dry- term resistivity, classified by terrain type (*a): Depth = 5 m; (b): Depth = 20 m; (c): Depth = 35 m*

shallower depths. As depth increases, the decrease in resistivity becomes more gradual, indicating the infiltration behavior of rainwater. These findings indicate that differences in subsurface conditions within a relatively shallow range, down to approximately 35 m in depth, were successfully captured using the drone-based airborne exploration method.

6.2. Topography-Based Analysis

To analyze the influence of local topography on the resistivity change rate α described in the previous section, each measurement point was classified as either a ridge or a valley based on plan curvature. Plan curvature (Kp) was calculated using the Equation (2) [14-15]. A 10-m resolution digital elevation model (DEM) was analyzed using the GIS software ILWIS 3.3.

$$K_p = -\frac{d_y{}^2 d_{xx} - 2d_x d_y d_{xy} + d_x{}^2 d_{yy}}{(d_x{}^2 + d_y{}^2)^{\frac{3}{2}}} \qquad (2)$$

Each measurement point was classified as a ridge when Kp > 0 and as a valley when Kp < 0 [16]. Fig. 6 shows a plot with the resistivity change rate α on the vertical axis and the dry-term resistivity on the horizontal axis, with data points classified as either ridges or valleys. Measurement points with a robust Z-score less than −2 — indicating potentially well-developed looseness — were found predominantly in ridge areas. This tendency was particularly evident at shallow depths. In addition, at ridge points, greater resistivity changes were observed at locations with higher dry-term resistivity.

7. DISCUSSION

Fig. 7 shows a red relief image map. The slopes where survey lines A1-A1' to G1-G1' are located lie near the remnants of the Kanagi landslide. Gentle

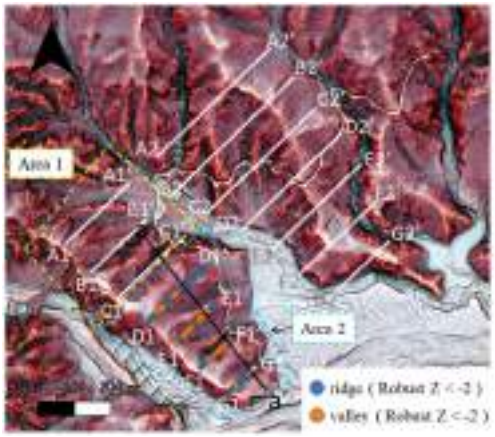

Fig.7 Points where robust Z-score < −2

slopes are also observed near some of the mountain summits in this area. Although the slopes lie along the same main ridgeline, the A1–A1' to C1–C1' and D1–D1' to G1–G1' sections show differences in ridge shape and valley development. In the area from A1–A1' to C1–C1', the valleys are more developed than in the surrounding region, resulting in a tendency toward narrow ridges (hereafter referred to as Area 1). The relationship between ground permeability and topography has shown that areas with more developed valleys tend to have lower permeability [17]. This is consistent with the observation that there was little difference in resistivity between the dry and wet terms in A1–A1' (Fig. 5a), B1–B1' (Fig. 5b), and C1–C1' (Fig. 5c), suggesting limited water infiltration. On the other hand, in the area from D1–D1' to G1–G1', valleys are few, and rounded ridges along with gentle upper slopes are distributed (hereafter referred to as Area 2). Such characteristics observed in Area 2 are consistent with those typically found in bedrock with relatively high permeability coefficients [20]. This is consistent with the significant decrease in resistivity observed in D1–D1' (Fig. 5d), E1–E1' (Fig. 5e), F1–F1' (Fig. 5f), and G1–G1' (Fig. 5g), suggesting the possibility of deep rainwater infiltration. Furthermore, the tendency for

resistivity decrease near the surface gradually diminishes with depth is consistent with the formation process of toppling-type looseness. These findings show that the patterns of resistivity decrease clearly reflect the near-surface bedrock permeability inferred from topographic features (Fig. 5).

Measurement points showing a significant decrease in resistivity (robust Z-score less than −2) were concentrated on the slopes in Area 2 (Fig. 7). The slopes in this area feature rounded ridges and gentle upper slopes, indicating terrain where gravitational deformation is suspected to be well developed. In particular, the slope where the D1–D1' survey line is located is convex-shaped, with gentle upper slopes and step-like features, suggesting deep-seated deformation possibly caused by deep-seated gravitational slope deformation [18-19]. At the outcrop along the forest road on this slope, loosened bedrock with openings was visually observed (Fig. 8). It is considered that the data showing a significant decrease in resistivity (robust Z-score less than −2) successfully identified slopes where deep-seated looseness is suspected. On the other hand, some measurement points classified as valleys based on plan curvature (Kp) are also located on the same convex-shaped slope. This is likely because the classification is based on elevation data (DEM) calculated over a fixed area, which reflects local terrain features. This issue may be improved by adjusting the analysis window size used in calculating plan curvature (Kp). In addition, measurement points classified as ridges based on plan curvature (Kp) showed a correlation between high dry-term resistivity and resistivity decrease rate, particularly at shallow depths (Fig. 6a, b). These findings suggest the possibility of estimating significant rock mass loosening using only dry-term resistivity data; however, this remains a subject for future investigation.

Next, regarding the estimation of the development depth of loosened bedrock: accurately determining the depth of looseness at each site requires detailed investigations such as borehole surveys. However, it is reasonable to consider that the depth at which resistivity decreased due to water infiltration lies at least within the extent of the loosened zone. Fig. 9 shows an elevation profile along the a–a′ cross section (Fig. 7), along with the resistivity decrease zones obtained from D1–D1' (Fig. 5d), E1–E1' (Fig. 5e), F1–F1' (Fig. 5f), and G1–G1' (Fig. 5g). The resistivity decrease zone along the D1–D1' survey line falls within the elevation range between the ridge crest (535.7 m) and the valley bottom to the west (490.9 m). In the case of a ridge with no lateral confinement where tilting of the geological strata is progressing, this depth range can be reasonably considered to correspond to the distribution of loosened zones. The ridge where the E1–E1' survey line is located also lacks lateral confinement on the

Fig.8 Outcrops along the D1 survey line forest road

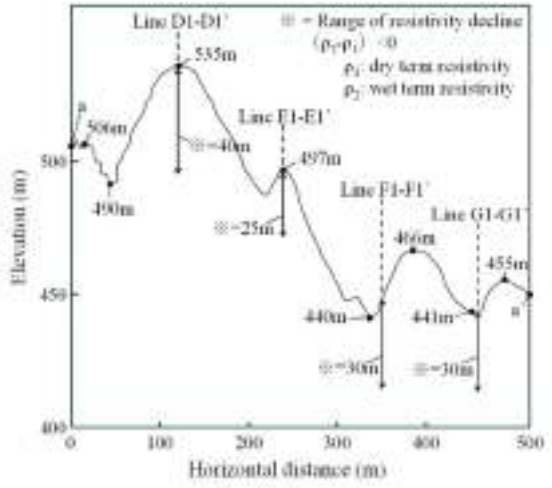

Fig.9 Elevation & resistivity drop (a–a' section)

eastern valley side. Considering the steep dip of the geological strata across the area (to the northwest), it is likely that looseness has developed to greater depths. Since the airborne exploration method provides average resistivity values over a given area, interpretation becomes difficult when the survey line crosses both ridges and valleys. This applies to the F1–F1' and G1–G1' survey lines. A method for estimating the depth of loosened bedrock caused by toppling has been proposed by Ueno [20]. In addition to empirical knowledge from past disasters, the depth can be inferred from borehole investigations and on-site observations of rock mass displacement and tilt direction. Although this method offers a certain level of accuracy, empirical rules can vary widely, and on-site investigations require considerable time and effort. On the other hand, the interpretation combining low-resistivity zones detected by drone-based airborne electromagnetic surveys with topographic conditions enables rapid and wide-area investigations. This approach may prove useful as preliminary information in the early stages of disaster prevention planning.

8. CONCLUSION

In this study, we analyzed resistivity data obtained from mountain slopes using drone-based

electromagnetic exploration method in relation to terrain features and derived the following findings.

- The patterns of resistivity decrease in the near-surface zone (up to ~35 m depth) obtained from the drone-based electromagnetic exploration method showed clear differences between valley and ridge terrains.
- Under wet conditions, robust Z-score < −2 areas were concentrated on gently sloping, rounded ridges where loosened bedrock is topographically suspected. In some cases, the resistivity reduction depth matched the ridge–valley elevation difference, suggesting the method's utility in estimating loosened bedrock depth.

IMAGE-BASED ESTIMATION OF SOIL PARTICLE SIZE AS A SUPPLEMENT TO SIEVE ANALYSIS

Jose Manuel U. Subido[1], Erica Elice S. Uy[1], Joenel G. Galupino[1]

[1] Department of Civil Engineering, De La Salle University, Philippines

ABSTRACT

Particle size distribution is an important parameter influencing soil behavior. This parameter is identified using a combination of tests such as the sieve and hydrometer analyses to identify the potential characteristics and behavior of a soil sample. This study investigates the use of image processing techniques as a supplementary tool to traditional methods, enabling the rapid and detailed generation of particle size distribution curves. Twenty different soil samples were collected and prepared for imaging following controlled conditions. Only particles retained up to a No. 40 (0.420 mm) sieve were considered in the study. Camera and measurement calibrations, thresholding, and edge detection were performed to extract particle dimensions. Particle boundaries were identified to estimate particle sizes using pixel to real-world measurement conversions. At least one of the dimensions taken from the particle is expected to be of greater value than a reference value from the sieve openings where it was retained to ensure that there is an accurate result in the particle size estimation. The test results showed a close correlation between the estimated particle size distribution and sieve analysis using the maximum Feret diameter. However, there is an observable decline in accuracy when the particle size decreases. The proposed method has potential to capture particle size and be further studied for use in the development of particle size distribution curves, confirming its viability as a supplementary technique.

Keywords: Particle Size Distribution, Image Processing, Camera Calibration, Sieve Analysis, Feret Diameter

INTRODUCTION

Soil is a heterogeneous material composed of minerals, organic matter, and void spaces, serving as the fundamental support for all engineered structures [1]. In geotechnical engineering, the assessment of soil physical properties is essential for the safe and efficient design of foundations, embankments, and other infrastructures. Among these properties, grain size distribution significantly influences the strength, permeability, and compressibility of soil [2,3]. The conventional laboratory methods used to determine particle size distribution are the sieve and hydrometer analyses [4,5]. However, these methods require extensive sample preparation and are limited in capturing finer details such as particle shape [6].

Recent advancements have explored how image processing can be a complementary technique for estimating particle size distribution. While a standard sieve analysis makes use of mass relations, image-based techniques use individual grain geometry to compute the percent finer needed to construct the particle-size distribution curve [6-8]. These non-contact techniques have shown potential in advancing the body of knowledge on soil characterization using images.

Studies have integrated different preprocessing techniques which can improve the focus of the image towards the soil particles within the images used for particle size analysis [9,10]. Moreover, these studies also considered the use of different cameras with different capacities. However, these studies were limited to certain setups and the identification of a laboratory setup for image-based analysis of particle size [6-8]. Moreover, a common limitation within these studies is the lack of proper calibration procedures that can ensure accurate transformation of pixel-based measurements into real-world dimensions [6-10]. Calibration processes are performed to ensure that images acquired were without distortion and with proper scaling of measurements from pixel to real-world dimensions. Proper calibration corrects image distortion and ensures reliable scaling, as shown in Figure 1, where camera intrinsic and extrinsic parameters define the transformation from world coordinates to 2D image space [11,12].

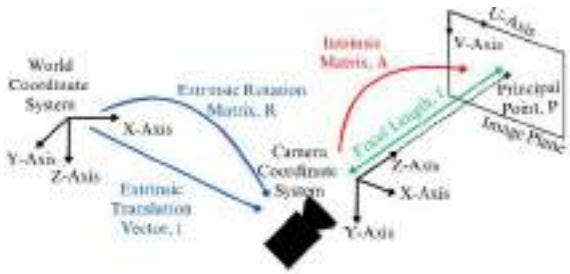

Fig. 1 Transformation of 3D to 2D system by images [12]

In this study, particle size measurements for individual particles were measured following a standard calibration procedure. Two dimensions were measured for each particle based on the bounding rectangle that was measured in the software. These dimensions were converted to real-world measurements and compared to sieve openings to identify if the estimated particle size matches the results of a sieve analysis.

RESEARCH SIGNIFICANCE

Particle size distribution is an important indicator for various characteristics of soil. The study highlights a significant advancement in soil particle size assessment by integrating image processing techniques as a supplementary tool to traditional methods. By providing a faster and detailed estimation of particle size distribution, this approach enhances the efficiency of geotechnical investigations while maintaining alignment with standard practices. The method can support preliminary site assessments and improve decision-making in construction planning and risk management.

METHODOLOGY

The methodology is composed of five phases: sample preparation, setup preparation and calibration, image acquisition, image processing, and image analysis.

Sample Preparation

A soil sample was collected from Santa Rosa, Laguna. The sample was oven-dried and clustered into particle size groups according to sieve sizes. The particles were grouped based on the sieves where they were retained. The particle groups used in the study are shown in Table 1.

Table 1 Particle Clusters (PC) for Particle Size Analysis

PC (Sieve No.)	Particle Size Bounds (mm)
No. 4	> 4.750
No. 8	2.360 – 4.750
No. 10	2.000 – 2.360
No. 16	1.180 – 2.000
No. 30	0.600 – 1.180
No. 40	0.425 – 0.600

Setup Preparation and Calibration

A mirrorless camera was used to estimate the particle size of the sample. The lighting conditions used in the study follows the schematic diagram of the image acquisition setup shown in Figure 2. The position of the camera was determined through calibration of parameters that can be identified from the camera's field of view [13-15].

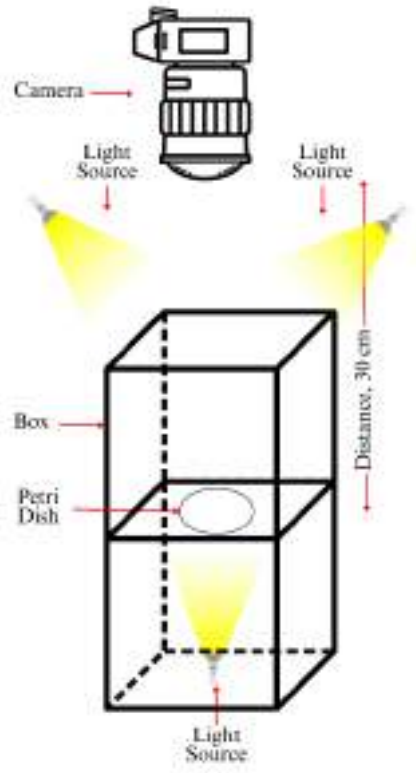

Fig. 2 Schematic Diagram of Image Acquisition Setup

In this study, calibration was performed through a 2-dimensional calibration for distortion, and a measurement calibration using NI LabVIEW 2020. The distance of the camera from the soil sample surface was determined through the 2D calibration [13]. A calibration grid, as shown in Figure 3, was used to convert the projected three-dimensional world points captured by an image to two-dimensional sensor coordinates. The grid is composed of dots with a radius of 2 mm and center-to-center distances of 1 cm. Ten images of the grid were acquired, at varying angles. In each trial of acquiring images of the grid, the set of images were collectively used to perform camera calibration [14]. However, if the calibration grid is not completely seen by the camera's field of view, the distance of the camera from the surface was adjusted accordingly. The grid images were only accepted if a large portion of the dots were identified by the program, which can be signified by having a distortion of less than 1% [15]. Once all images had a resulting distortion less than the threshold, the recorded intrinsic and extrinsic parameters were recorded. It was identified that the camera should be positioned 30 cm away from the sample to meet the threshold values. Shown in Figure 3 is the sample image of the grid after calibration. Each image was

captured with a resolution of 2784x1856 pixels.

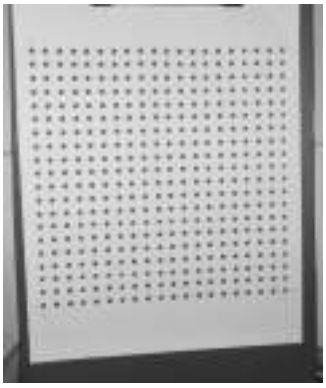

Fig. 3 Grayscale Calibrated Image of Grid

The next phase involved converting pixel data into real-world measurements using sieves and a ruler as reference objects, due to their known dimensions. A measurement calibration program was developed to determine x- and y-axis scaling factors, which convert pixel values into actual sizes [14,15]. These factors were validated by comparing program-measured values with known dimensions of sieve openings and ruler markings. The measured x and y-values in pixel measure were plotted against the actual values, as shown in Figure 4. From there, the slope of the best-fit line, where the y-intercept was set to 0, was identified. The reciprocal values were taken as the multiplying factor to convert pixel data to real-world measurements across both axes. The factors for the x-direction and y-direction are 0.1232 mm/pixel and 0.1269 mm/pixel, respectively.

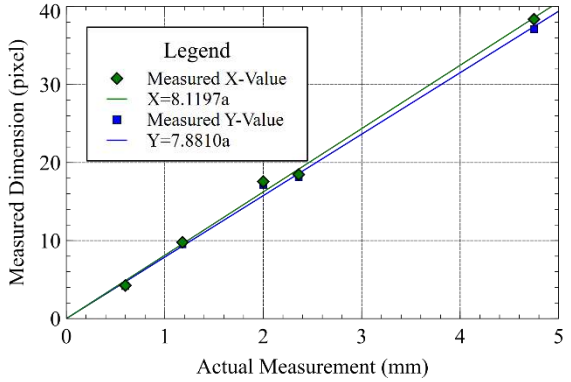

Fig. 4 Calibration Plot for Dimension Measurements

Image Acquisition

The camera was configured with an aperture of f/16, a shutter speed of 1/80 second, ISO 1600, and no flash. Once the samples were separated into groups, each cluster was placed on the petri dish in such a way that majority of the particles were loosely positioned so that the individual particle measurements were evaluated by the proposed program. To prevent reflection of light from affecting the particle size recorded, a thick piece of paper was used below the petri dish. Images were taken until 60 individual particles for each cluster group can be extracted using the particle size analysis program. Figure 5 presents the sample configuration for the particles within the petri dish, showing non-overlapping and overlapping particles.

Fig. 5 Raw Image of Particles Retained in No. 10 Sieve

Image Processing

Each acquired image underwent image processing to reduce noise and ensure accurate extraction of particle characteristics. The region of interest (ROI) was isolated using a combination of masking and thresholding techniques. A circular mask was used to create a focus on the petri dish, with the center set using pixel data references and the edge was based on the real-world diameter of the petri dish. Thresholding was then applied to isolate soil particles from the background. The optimal threshold values were determined through an analysis of the gray level histogram, revealing that gray levels below 120 reflect the particle pixels. Shown in Figure 6 are the applied masking and thresholding into a sample image.

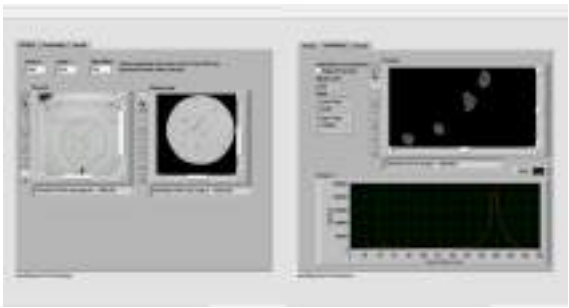

Fig. 6 ROI Extraction by Masking and Thresholding

The data gathered from images for particle size estimation focused only on particles that were loosely placed in the petri dish. In the analysis of particle size, the area was defined as the total number of pixels that were bound by the edge of the particle being analyzed.

This serves as the frequency for a certain particle. Both dimensions from its bounding rectangle were considered as its particle size following the same convention as the sieve sizes. The larger dimension yielded the maximum particle size by image analysis, whereas the smaller dimension yielded the minimum particle size by image analysis. These values serve as the maximum and minimum Feret diameters recorded in the program developed. For each particle, these parameters were extracted from LabVIEW using the IMAQ Particle Analysis VI. An example of feature extraction for the particle size estimation is shown in Figure 7.

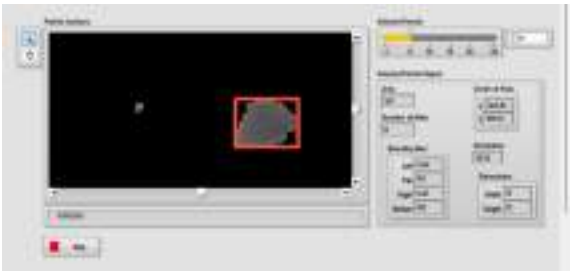

Fig. 7 Particle Size Analysis using NI LabVIEW 2020

Image Analysis

For each particle analyzed, the recorded dimensions were converted into real-world measurements and cross-validated with the group of soil particles to identify if the particle is retained on the sieve for that specific particle group. The particle size and area in real-world measurements are computed using the following equations:

$$PS_i = Max(W_i/x_{SF}, H_i/y_{SF}) \quad (1)$$

$$PS_i = Min(W_i/x_{SF}, H_i/y_{SF}) \quad (2)$$

$$A_i = A_{p,i} \times x_{SF} \times y_{SF} \quad (3)$$

where PS_i = particle size of particle i (mm); A_i = area of particle i (mm^2); W_i and H_i = width and height of particle i (pixel), $A_{p,i}$ = area of particle i (pixel); x_{SF} and y_{SF} = scaling factors for x- and y-axis (mm/pixel).

RESULTS AND DISCUSSION

The particle size was estimated based on the recorded dimensions of the bounding rectangle for each particle. The validation of values taken from the individual particle size characteristics was conducted by comparing the measured dimensions with the size of the sieves where the particles were retained. Only individual particles were considered in the study, with sample processed images shown in Figure 8. On the other hand, packed particles were not considered in the computations since dimensions measured by the program were the combined measurements from the packed particles. Including these particle measurements would introduce errors since these measurements are larger than the measurement intervals for each particle group considered. Instances of packed particles are shown in Figures 9 and 10.

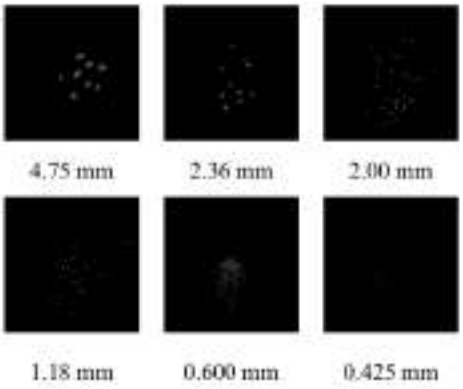

Fig. 8 Processed Images for Each Particle Size Group

Fig. 9 Excluded Packed Particles from Particles Retained in No. 10 Sieve

Fig. 10 Excluded Packed Particles from Particles Retained in No. 10 Sieve

To validate the accuracy of the estimation of particle size, two parameters were considered. Since particles were grouped based on the particle retained metric, each particle had to fall within the specified size intervals listed in Table 1. The first parameter involved calculating the cumulative area of particles that fell within these intervals and comparing it to the total area of all detected particles. The second parameter is taken by identifying the cumulative number of particles within the same intervals and comparing it to the total particle count. For both methods, the ratio of valid particles (by area or by

count) to the overall total was used to determine the percentage accuracy of the program. Table 2 presents the results based on the maximum Feret diameter of the particle (larger dimension of the particle's bounding rectangle) while Table 3 provides the results based on the minimum Feret diameter of the particle (smaller dimension of the particle's bounding rectangle). For both tables, the range of estimated particle sizes was also provided.

Table 2 Validation Metrics for Particle Size Estimation considering Maximum Feret Diameter

PC	%Accuracy by Area	%Accuracy by # of Particles	Range (mm)
No. 4	99.24%	98.33%	4.69 – 10.28
No. 8	85.14%	88.33%	2.03 – 5.42
No. 10	71.07%	71.67%	1.90 – 2.79
No. 16	95.68%	93.33%	1.11 – 2.03
No. 30	77.55%	85.00%	0.49 – 1.52
No. 40	69.58%	66.67%	0.25 – 0.63
Overall	94.53%	83.89%	0.25 – 10.28

Table 3 Validation Metrics for Particle Size Estimation considering Minimum Feret Diameter

PC	%Accuracy by Area	%Accuracy by # of Particles	Range (mm)
No. 4	96.02%	93.33%	4.44 – 8.13
No. 8	91.26%	86.67%	1.97 – 4.80
No. 10	29.88%	35.00%	1.48 – 2.41
No. 16	80.14%	68.33%	0.86 – 1.90
No. 30	85.99%	71.67%	0.37 – 1.11
No. 40	21.52%	16.67%	0.13 – 0.62
Overall	88.95%	61.94%	0.13 – 8.13

The results from Tables 2 and 3 highlighted that a difference exists in the accuracy of estimating particle size based on which dimension is used. When using the minimum dimension, accuracy by area and number of particles significantly decreased for particles retained on the No. 10 and No. 40 sieves. On the other hand, the accuracy by area for the particle cluster retained on No. 30 sieve increased despite fewer particles being correctly estimated, indicating that these particles had higher individual areas. The overall range of values indicated that the minimum particle size estimated by the developed program is 0.13 mm, which is also equivalent to the measure of 1 pixel along either the x- or y-axis, as taken from the measurement calibration. While this indicates that estimation is possible up to this degree, it is observed that the estimation accuracy becomes lesser for the smaller particle clusters (No. 30 and No. 40).

A previous study investigated the use of the minor diameter of particles, assuming these particles have an ellipsoidal shape [16]. In this context, the minor diameter is appropriate because it aligns with the concept of percent passing, where the proportion of particles smaller than the sieve opening is compared to the total number of particles in the sample. In contrast, this study focused on retained particles, where the particles were clustered by the sieve where each particle did not pass through. In a sieve analysis, retention occurs when at least one dimension of the particle is larger than the sieve opening, preventing it from passing through. An illustration of this concept is presented in Figure 11, highlighting that the maximum dimension (Feret diameter) is the more suitable metric for the analysis of results in the current context. This approach is more aligned to the physical behavior of particles being retained in a sieve analysis.

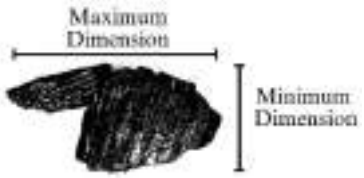

Fig. 11 Particle Size Dimension Considerations

The validation metrics indicate that the accuracy by area is consistently higher than the accuracy by number of particles in estimating particle size. Using the maximum Feret diameter, the program achieved an accuracy of 94.53% by area, compared to 83.89% by count, corresponding to 302 correctly classified particles out of 360. Conversely, when using the minimum Feret diameter, the accuracy dropped to 88.95% by area and 61.94% by count, with only 223 out of 360 particles correctly classified. In conjunction with other studies, an area-based validation is suggested in image analysis, as particle area has been shown to correlate more strongly with particle mass based of the density of these particles [16]. The recorded accuracy by area considering the maximum Feret diameter suggested that the potential of the program to identify particle sizes through the concept employed. In this study, the particle sizes considered were particles classified as gravel or sand. To improve the capacity of the proposed technique, recalibration can be conducted to improve the pixel-to-mm scaling factor.

CONCLUSION

Particle size was estimated using image processing. The developed program was able to identify particle sizes by making use of the bounding rectangle for each individual particle identified. The particle size for each particle is estimated accurately if the dimensions correspond to interval of the size between sieves where the particle was retained. Only individual particles were considered, since packed particles caused inaccurate measurements. The developed program achieved an accuracy of 94.53% by area and 83.89% by particle count using the maximum Feret diameter, whereas the minimum

Feret diameter produced an 88.95% accuracy by area and 61.94% by count. These findings indicate that the maximum Feret diameter is a more appropriate metric for particle size estimation by sieve-based classification. The study also highlighted that while the program could estimate particle sizes as small as 0.13 mm (equivalent to one pixel), accuracy decreased for finer particle groups (e.g., No. 30 and No. 40). Overall, this methodology shows potential for wider applications in particle size estimation. Future studies can extend the capacity of this method to cover three-dimensional analysis, which would consider volumetric measurements, potentially yielding closer results to a sieve analysis. Moreover, studies may also investigate analyzing how particle shape characteristics can be extracted and used as a supplement to identify the mechanical properties of soil.

ABSTRACT

This study investigates the effects of compaction effort, moisture content, and soil type on the Maximum Dry Density (MDD) of silty sand, which plays a crucial role in the stability of geotechnical structures. A full factorial experimental design (3×3×3) was employed, encompassing three types of silty sand: natural (SM-N), cement-modified (SM-C), and plastic-modified (SM-P). Each soil type was subjected to three levels of compactive effort (0.5×, 1.0×, and 1.5× of Modified Proctor energy) and three moisture conditions (2% below, at, and 2% above the Optimum Moisture Content). In total, 27 laboratory tests were conducted in accordance with ASTM D1557. The results revealed that MDD increased with higher compactive effort and reached a maximum at the Optimum Moisture Content. SM-P exhibited the highest MDD due to enhanced interparticle bonding, while SM-N presented the lowest. Excessive moisture or compactive effort beyond optimal conditions led to reductions in density, particularly in modified soils. Analysis of variance (ANOVA) confirmed that all main factors and their interactions had statistically significant effects on MDD. A second-order polynomial regression model was developed with a coefficient of determination (R^2) of 0.968, demonstrating strong predictive capability. These findings contribute to the development of improved compaction strategies for infrastructure projects involving modified soils.

Keywords: Factorial Experimental Design, Soil Compaction, Maximum Dry Density, Optimum Moisture Content

INTRODUCTION

Soil compaction plays a critical role in geotechnical engineering, influencing the stability and load-bearing capacity of infrastructure projects such as roads, foundations, and embankments. Optimal compaction ensures long-term performance and minimizes settlement. Maximum Dry Density (MDD), a key measure of compaction quality, depends on soil type, compaction effort, and moisture content.

Several real-world cases highlight the importance of soil compaction in construction projects. For instance, the failure of highway embankments in flood-prone regions has often been attributed to improper soil compaction, leading to excessive settlement and loss of structural integrity [1]. Similarly, foundation failures in expansive soils have demonstrated how inadequate control of moisture content during compaction can result in differential settlement, causing cracks in buildings and road pavements [2]. These cases emphasize the need for a systematic approach to soil compaction analysis.

Different soil types exhibit varying compaction behaviors. Natural silty sand (SM-N) generally has lower dry density due to its loose particle arrangement and high void ratio, whereas chemically modified soils like cement-modified silty sand (SM-C) and plastic-modified silty sand (SM-P) show improved compaction due to enhanced particle cohesion and reduced void space. Prior studies have demonstrated that soil modification techniques significantly improve dry density and long-term stability under loading conditions. [3]

Controlling Optimum Moisture Content (OMC) is crucial for achieving maximum dry density. Excess moisture beyond OMC can cause saturation effects, reducing particle interlocking and compaction efficiency. A study on highway subgrades exposed to varying moisture conditions found that roads compacted under excessive moisture levels (OMC+2%) showed accelerated degradation, requiring frequent maintenance and repair. [4]

This study utilizes a full factorial experimental design (3×3×3) to systematically evaluate the effects of soil type, compaction effort, and moisture content on MDD. By employing statistical techniques such as Analysis of Variance (ANOVA) and interaction effect analysis, the research aims to provide insights into the optimal conditions for soil compaction. The findings will contribute to geotechnical design guidelines, aiding engineers in optimizing soil treatment methodologies for infrastructure development.

RESEARCH SIGNIFICANCE

Soil compaction is a critical factor in geotechnical engineering, influencing the stability and durability of infrastructure. Maximum Dry Density (MDD) is a

fundamental parameter for assessing compaction efficiency, yet its optimization remains complex due to variations in soil type, compaction effort, and moisture content. This study employs a full factorial experimental design (3×3×3) to systematically examine the combined effects of these parameters, offering a quantitative approach to soil compaction assessment. Advanced statistical analyses, including ANOVA and interaction effect evaluation, provide a robust framework for interpreting MDD behavior, particularly in modified soils such as plastic-modified silty sand (SM-P) and cement-modified silty sand (SM-C). Unlike conventional studies that focus on isolated variables, this research integrates a multi-factorial approach, enabling a comprehensive understanding of compaction mechanisms under diverse conditions. The findings contribute to refining geotechnical practices, supporting engineering applications in embankments, road subgrades, and foundation systems by offering predictive insights and optimized compaction strategies.

LITERATURE REVIEW

Several studies have investigated the effect of compaction parameters on MDD and OMC for various soil types. According to [5], compaction energy significantly influences soil structure and density, particularly in fine-grained soils. Their findings highlight a threshold beyond which excessive compaction may lead to particle degradation. Cement-treated soils, due to pozzolanic reactions, often require careful control of moisture during compaction [6]. Meanwhile, plastic-modified soils have shown inconsistent responses due to hydrophobic properties and fiber alignment issues, which can affect pore structure and air void content [7]. In Southeast Asia, the challenge of optimizing soil compaction for rapidly constructed infrastructure, especially on modified soils, requires more localized and statistically structured studies. A factorial design approach as adopted in this study provides comprehensive insights into multivariable interactions [8].

MATERIALS AND METHODS

1. Experimental Materials

1.1 Soil Types and Modification Methods

This study utilizes three different types of silty sand (SM), categorized based on their modification techniques:

- SM-N (Natural silty sand): Unmodified soil collected from a construction site, primarily consisting of sand with small fractions of silt and clay.

- SM-C (Cement-modified silty sand): Prepared by blending natural silty sand with 5 % Portland cement by weight, enhancing particle cohesion and reducing void spaces.

- SM-P (Plastic-modified silty sand): Combined with 3 % synthetic polymer additive by weight, increasing elasticity and improving soil workability for compaction.

To ensure consistency, all samples were air-dried and passed through a 4.75-mm sieve before testing.

Table 1 Physical and Chemical Properties of Tested Soils

Soil Type	Modification Method	Grain Size Distribution (%)	Plasticity Index
SM-N	No modification	Sand: 65%, Silt: 30%, Clay: 5%	Non-plastic
SM-C	5% Portland cement	Sand: 60%, Silt: 30%, Clay: 10%	Low plasticity
SM-P	3% synthetic polymer	Sand: 62%, Silt: 28%, Clay: 10%	Medium plasticity

1.2 Moisture Content and Soil Preparation

Moisture content is a critical factor influencing soil compaction efficiency. Each soil type was mixed to achieve target moisture levels based on the Optimum Moisture Content (OMC) determined from standard Proctor tests.

1.3 Compaction Testing Methodology

This study employs the Modified Proctor Test (ASTM D1557), which is widely recognized for its standardization in soil compaction analysis. This test is designed to determine the effect of compaction energy on soil density under controlled conditions.

The compaction procedure was conducted using a Standard Proctor Mold, which has a 4-inch diameter and a 4.58-inch height, ensuring consistency across all experimental trials. Each soil sample was compacted in three successive layers, with each layer subjected to a specific compaction effort. The applied compaction efforts were categorized as follows: low effort (0.5× Modified Proctor), medium effort (1.0× Modified Proctor), and high effort (1.5× Modified Proctor).

2. Experimental Design and Procedures

2.1 Research Hypotheses

The compaction characteristics of soil are influenced by various factors, including compaction

effort, soil type, and moisture content. This study is structured around the following hypotheses, which serve as the basis for the factorial experimental design.

Primary Hypotheses

- H1: Increasing compaction effort enhances MDD by reducing voids and improving particle interlock.
- H2: Soil types (SM-N, SM-C, SM-P) exhibit significantly different MDD values under the same conditions due to differences in cohesion, porosity, and stabilization.
- H3: Moisture content near the Optimum Moisture Content (OMC) facilitates efficient compaction and higher MDD.
- H4: Excessive moisture beyond OMC (e.g., OMC+2%) reduces MDD due to pore water pressure and loss of particle interlock.
- H5: Excessive compaction effort (e.g., 1.5× Modified Proctor) may disturb soil structure, lowering MDD, especially in modified soils.

These hypotheses form the foundation for the experimental framework, wherein soil type, compaction effort, and moisture content are systematically varied to evaluate their individual and interactive effects on MDD. The factorial analysis enables a comprehensive assessment of soil compaction behavior, contributing to the optimization of geotechnical practices.

2.2 Factorial Design Setup

A full factorial experimental design (3×3×3) was employed to systematically assess the effects of soil type, compaction effort, and moisture content on Maximum Dry Density (MDD) is presented in Table 2. The study involved:

- Independent variables:
- Soil Type: SM-N, SM-C, SM-P
- Compaction Effort: 0.5×, 1.0×, 1.5× Modified Proctor
- Moisture Content: OMC−2%, OMC, OMC+2%
- Dependent variable: Maximum Dry Density (MDD), measured in g/cm³.

A total of 27 experimental runs (3 × 3 × 3 = 27 combinations) were conducted to ensure comprehensive analysis of individual and interaction effects, as presented in Table 2.

Table 2 A total of 27 experimental runs

Soil Type	SM-C	SM-N	SM-P	3
Compaction Effort	0.5	1	1.5	3
Moisture Content	OMC	OMC +2%	OMC -2%	3
Factor Experimental				27

2.3 Compaction Testing Procedure

Soil samples were prepared at three target moisture levels (OMC−2%, OMC, and OMC+2%) and compacted in a standard Proctor mold. Each sample was placed in three layers and subjected to compaction efforts of 0.5×, 1.0×, and 1.5× Modified Proctor. After compaction, bulk density and moisture content were measured, and Maximum Dry Density (MDD) was calculated from dry mass and volume. The results are summarized in Table 3.

Table 3 Results of Compaction Testing（MDD in g/cm³)

Factor	MDD (g/cm³)		
Compaction Effort	0.5	1	1.5
Moisture/ Type		SM-C	
OMC	1.44	1.52	1.6
OMC+2%	1.52	1.6	1.65
OMC-2%	1.42	1.436	1.58
Moisture/ Type		SM-N	
OMC	1.6	1.67	1.72
OMC+2%	1.68	1.76	1.81
OMC-2%	1.51	1.58	1.62
Moisture/ Type		SM-P	
OMC	1.618	1.735	1.738
OMC+2%	1.668	1.738	1.788
OMC-2%	1.558	1.627	1.678

2.4 Statistical Analysis

To quantify the influence of independent variables on Maximum Dry Density (MDD), a series of statistical techniques were employed using Minitab 16. The primary objective was to evaluate both individual and interactive effects of Soil Type, Compaction Effort, and Moisture Content using factorial analysis. The statistical methods applied in this study are outlined as follows:

Table 4 Analysis of Variance

Source	P-Value	Significance
Soil Type	0.000	Significant
Compaction Effort	0.000	Significant
Moisture Content	0.000	Significant
Soil Type × Compaction Effort	0.000	Significant
Soil Type × Moisture Content	0.005	Significant

Source	P-Value	Significance
Compaction Effort × Moisture Content	0.000	Significant
Soil Type × Compaction Effort × Moisture Content	0.002	Significant

From Table 4, the analysis confirmed that soil type, compaction effort, and moisture content all significantly affect Maximum Dry Density (MDD) ($P < 0.05$).

- Soil Type (H2): SM-C and SM-P achieved higher MDD than SM-N, demonstrating the benefits of soil modification.

- Compaction Effort (H1): Increasing effort improved MDD, but excessive energy caused slight declines in modified soils.

- Moisture Content (H3–H4): OMC produced the highest MDD, while OMC−2% and OMC+2% reduced density due to poor lubrication or saturation effects.

Interaction Effects

1) Soil Type × Compaction Effort : The impact of compaction varies across soil types ($P = 0.000$, $P < 0.05$).

2) Soil Type × Moisture Content – Moisture's influence on MDD depends on soil composition ($P = 0.000$, $P < 0.05$).

3) Compaction Effort × Moisture Content – The effectiveness of moisture levels is contingent on compaction intensity ($P = 0.000$, $P < 0.05$).

4) Three-Way Interaction : Soil Type, Compaction Effort, and Moisture Content interact non-linearly, with each factor dynamically influencing the others ($P = 0.000$, $P < 0.05$).

Main Effects Analysis

1) Soil Type: SM-C and SM-P exhibited higher MDD than SM-N, confirming the benefits of soil modification.

2) Compaction Effort: MDD increased with greater energy input (0.5×, 1.0×, and 1.5× Modified Proctor) due to better particle rearrangement.

3) Moisture Content: OMC resulted in peak MDD, while OMC+2% caused density reductions due to excess void space filling with water, hindering particle interlocking.

The main effects plot for Maximum Dry Density (MDD) revealed distinct trends across the three studied factors: soil type, compaction effort, and moisture content, as shown in Figure 1 and the interaction plots provide deeper insights into the combined effects of soil type, compaction effort, and moisture content on Maximum Dry Density (MDD), as illustrated in Figure 2.

Soil Type × Compaction Effort: SM-P showed the most pronounced improvement in MDD with increasing compaction effort, while SM-N consistently had the lowest MDD across all levels.

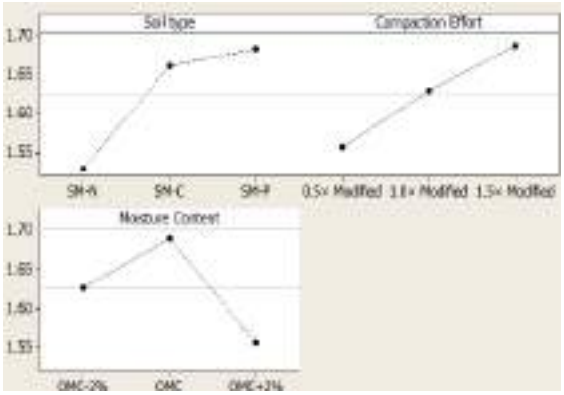

Fig.1 Main Effects Analysis on MDD (g/cm³)

This indicates that the benefits of increased compaction are more effective in modified soils, particularly those with plastic additives. Soil Type × Moisture Content: All soil types exhibited peak MDD values near OMC, with significant reductions at OMC+2%. SM-P again showed the best performance under optimal moisture, aligning with its enhanced particle cohesion and compaction compatibility. Compaction Effort × Moisture Content: The best results occurred under 1.5× Modified Proctor and OMC, validating that the synergy of optimal moisture and high compaction produces the highest MDD. However, MDD declined at OMC+2%, regardless of compaction effort, supporting H5 regarding the saturation effect.

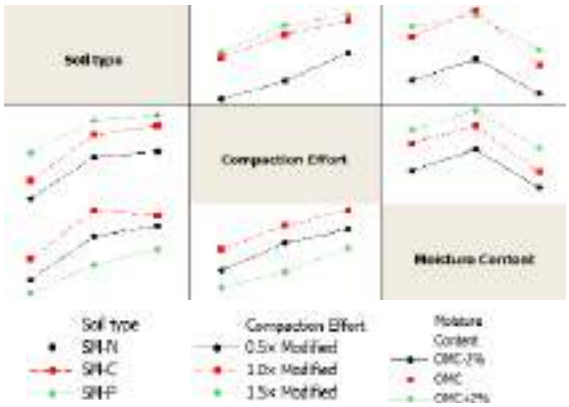

Fig.2 Interaction Plots Analysis on MDD (g/cm³)

RESULTS AND DISCUSSION

The results confirm both theoretical expectations and hypotheses developed in this study. The following conclusions can be drawn.

Soil modification, particularly with plastic additives (SM-P), significantly enhances MDD by improving soil structure and compactability. The superior performance of SM-P under optimal moisture aligns with Maher & Ho [7], who reported improved density in fiber-reinforced soils due to enhanced interparticle bonding. SM-C's moderate results agree with Consoli et al. [6], indicating moisture sensitivity in cement-treated soils.

Optimizing moisture content is crucial, as deviations from OMC reduce MDD, especially at higher water levels due to saturation effects.

Response Optimizer analysis identified SM-P soil compacted at 1.5× Modified Proctor under OMC as the optimal condition for achieving maximum MDD. These findings were further analyzed using a polynomial regression model, as described below.

Polynomial Regression Approach for Soil Compaction Analysis. The experimental results suggested that Maximum Dry Density (MDD) does not respond linearly to changes in compaction effort and moisture content, particularly in modified soils such as cement-modified silty sand (SM-C) and plastic-modified silty sand (SM-P). To model this nonlinear behavior, a second-degree polynomial regression model was developed.

The model was built using the full experimental dataset comprising 27 combinations of soil type (SM-N, SM-C, SM-P), compaction effort (0.5×, 1.0×, 1.5× Modified Proctor), and moisture content (OMC − 2%, OMC, OMC + 2%). Soil types were encoded using One-Hot Encoding, with SM-P as the baseline category, resulting in two binary variables. The complete predictive equation is as follows:

$$\begin{aligned}\mathrm{MDD}_{\mathrm{predict}} = {} & -2.9816 + 1.5378 \cdot \mathrm{Effort} + 0.6733 \cdot \mathrm{Moisture} \\ & - 2.1660 \cdot \mathrm{SoilType}_{\mathrm{SM-C}} + 0.6389 \\ & \cdot \mathrm{SoilType}_{\mathrm{SM-N}} - 0.1302 \cdot \mathrm{Effort}^2 \\ & - 0.0996 \cdot (\mathrm{Effort} \cdot \mathrm{Moisture}) + 0.5454 \\ & \cdot (\mathrm{Effort} \cdot \mathrm{SoilType}_{\mathrm{SM-C}}) - 0.2079 \\ & \cdot (\mathrm{Effort} \cdot \mathrm{SoilType}_{\mathrm{SM-N}}) - 0.0247 \\ & \cdot \mathrm{Moisture}^2 - 0.0251 \cdot (\mathrm{Moisture} \\ & \cdot \mathrm{SoilType}_{\mathrm{SM-C}}) - 0.0007 \cdot (\mathrm{Moisture} \\ & \cdot \mathrm{SoilType}_{\mathrm{SM-N}}) + 0.6057 \\ & \cdot (\mathrm{SoilType}_{\mathrm{SM-C}} \cdot \mathrm{SoilType}_{\mathrm{SM-N}}) \\ & - 0.0266 \cdot (\mathrm{SoilType}_{\mathrm{SM-C}})^2 + 0.1115 \\ & \cdot (\mathrm{SoilType}_{\mathrm{SM-N}})^2\end{aligned}$$

To effectively quantify the nonlinear response of Maximum Dry Density (MDD) to compaction effort and moisture content, a second-degree polynomial regression model was developed using 27 experimental test cases. The model incorporated linear, quadratic, and interaction terms, achieving a high predictive accuracy (R^2 = 0.968). The full regression equation accounts for compaction effort, moisture levels, and soil type (SM-P as the baseline). Residual plots confirmed the absence of bias and overfitting, with error metrics validating model reliability (MAE = 0.0150 g/cm³, RMSE = 0.0188 g/cm³). These findings highlight the model's robustness and applicability for field-based MDD estimations, reducing reliance on repeated laboratory tests. Results align with previous studies on mechanical soil compaction. [9] identified increased bulk density due to heavy equipment, consistent with higher MDD observed in SM-P. [10] reported machinery-induced compaction effects comparable to the trends found in SM-N and SM-P. [11] highlighted pore space reduction at higher moisture levels, which correlates with the MDD decline at OMC+2% in SM-C are presented in Table 5.

Table 5 Optimum compaction conditions for each soil type

Soil Type	Best Compaction Effort	Best Moisture Condition	MDD (g/cm³)
SM-N	1.5×Modified	OMC	1.81
SM-C	1.5×Modified	OMC+2%	1.65
SM-P	1.5×Modified	OMC	1.788

This study was conducted under controlled laboratory conditions, which do not fully represent field variability. Differences in compaction equipment, operator technique, weather conditions, and subsoil properties were not considered. Field calibration is therefore recommended before applying these results to large-scale projects. Future work should include field validation of the regression model, integration of machine learning for broader predictive capability, and testing with alternative soil stabilizers such as fly ash or biochar under diverse climatic conditions.

LIMITATIONS AND FUTURE WORK

The experiments were performed under controlled laboratory conditions, which do not fully represent field variability. Differences in equipment, operator technique, weather conditions, and subsoil properties were not addressed. Field calibration is therefore necessary before applying these results in practice. Factors such as equipment type, operator technique, weather, and subsoil variability were not accounted for in this investigation. While the results offer valuable insights into the behavior of modified silty sands under varying moisture and compaction levels, the findings should be interpreted with caution when applied to large-scale construction projects. Future research should focus on validating the proposed regression models through field compaction trials using in-situ equipment. Additionally, the influence of real-time environmental factors and different soil depths should be evaluated to enhance model reliability. Integration with machine learning techniques may also improve prediction accuracy and adaptability for broader geotechnical applications.

CONCLUSIONS

This study examined the effects of compaction effort, moisture content, and soil type on the maximum dry density (MDD) of silty sand soils. Experimental results revealed that MDD increased with compaction effort up to an optimum level, beyond which excessive effort slightly reduced density in modified soils due to structural disruption. Moisture content close to the optimum moisture content (OMC) yielded the highest MDD. Excess moisture led to reduced density, validating the importance of proper moisture control. Among the tested soils, natural silty sand (SM-N) showed the highest MDD, while cement-modified (SM-C) and plastic-modified (SM-P) soils responded differently due to their internal bonding and elasticity. Statistical analysis confirmed significant interaction effects between soil type, moisture, and compaction effort. A second-degree polynomial regression model was developed, achieving high predictive accuracy (R^2 = 0.968, MAE = 0.0150, RMSE = 0.0188), demonstrating its utility for practical prediction of MDD in design and field control. This model offers an efficient alternative to repeated laboratory testing and supports tailored compaction strategies for different soil types. Further field validation is recommended to enhance its applicability under real-world conditions.

CENTRIFUGE MODEL TEST AND NUMERICAL ANALYSIS ON EVALUATION OF VERTICAL BEARING CHARACTERISTICS FOR SOIL-CEMENT COMPOSITE PILE

Shohei Koga[1], Koji Watanabe[2] and Nobuaki Tsuchiya[1]

[1]Obayashi Corporation, Japan; [2]Aichi Institute of Technology, Japan

ABSTRACT

The method for soil-cement composite pile construction was developed that uses a compact mechanical agitator for pile foundations of lightweight structures. The construction machine is a mechanical agitator with an attached vibration mechanism and improved drilling capacity. The purpose of this study is to apply soil-cement composite piles, which have been conventionally designed as temporary structures, to permanent structures. Since the strength of soil cement is 1000~5000kN/m2 and its stiffness is lower than that of concrete piles and precast piles, it is necessary to evaluate the failure mechanism of the pile body. Therefore, centrifuge model tests and numerical analysis such as an elasto-plastic FEM focusing on the failure mechanism at the pile tip were carried out to evaluate the vertical bearing characteristics of soil-cement composite piles. According to this study, it can be said that the end bearing capacity can be related to the shape of the pile tip. In addition, modelling and parameter evaluation methods were developed to simulate the results of centrifuge model experiments by numerical analysis using elasto-plastic FEM.

Keywords: Soil-cement composite pile, Vertical bearing characteristic, Centrifuge model test, Numerical analysis

INTRODUCTION

There are several pile construction methods with relatively small construction machinery that are suitable for construction in narrow urban spaces and areas with low overhead clearance. The Top-drive Boring Hole (TBH) method, which has a machine height of 4.5m, is often used. However, there are many cases where even these construction machines are interfered by architectural Limitations and existing structures. In particular, near railway tracks or on rail platforms, piles are currently constructed after temporary construction to ensure construction spaces. The Boring Hole (BH) pile method can handle narrow spaces and low overhead clearances better than the TBH method. However, because the BH pile method is a direct circulation method, mud cakes easily form on the hole walls, and slim tends to accumulate at the pile tip. These lower the bearing capacity of the piles, so subsidence of the pile is more likely to occur. Such challenges related to the construction method, bearing capacity and settlement need to be resolve for pile construction in narrow urban spaces.

Furthermore, noise and industrial waste need to be considered with regard to their effects on the surrounding environment. Therefore, a method for H-section steel pile construction combined with soil-cement composite pile was developed that uses a compact mechanical agitator for pile foundations of lightweight structures [1]. The construction machine is a mechanical agitator (i.e. e-column construction method) with an attached vibrating mechanism and improved drilling capacity. This e-column construction machine as shown in Fig.1 can be used to realize pile construction in narrow spaces where construction is usually difficult. This method is characterized by having no need to drill up to a fixed depth as in the pre-boring pile construction method. Instead, soil is agitated along with the cement milk at the original position. Therefore, the construction sludge for pile is greatly reduced.

Fig.1. Construction machine of soil-cement composite pile

Although the soil-cement composite piles are generally designed as temporary structures [2], the

purpose of this study is to design the soil-cement composite piles as the permanent foundation structures. Where, the vertical bearing characteristics of soil-cement composite piles are largely dependent on the failure of the adhesion between the soil-cement and H-section steel pile and the compressive failure of the soil-cement at the pile tip. The relationship between the shape of the pile tip and bearing capacity has been studied with regard to the tip protected pile in which a precast pile is inserted into soil-cement [3], but it is not clear whether the results of previous studies can be applied to this construction method in which H-shaped steel is built into the soil cement. Therefore, in this study, centrifuge model tests were carried out to evaluate the effects of pile tip shapes which is diameter of soil-cement or distance of pile tip on the vertical bearing characteristics of the piles. In addition, a numerical analysis was carried out and discussed to simulate the experimental results.

CENTRIFUGE MODEL VERTICAL LOADING TEST

Fig.2 shows the schematic view of centrifuge model test and model pile. And Table 1 lists the model specifications. In these tests, in order to focus on the failure mechanism of the pile tip due to the shape of the pile tip, normalized separation *L/D* was used as a parameter. Specifically, four types *L/D* were prepared as *L/D* = 0.25, 0.5, 1.0, and 1.5. Where, *L* (mm) is the separation from the H section steel pile tip to the soil cement tip and *D* (mm) is the pile diameter.

Moreover, to investigate the influence of ground strength on the failure mechanism of the pile tip, two type model grounds were prepared such that the relative density of the D_r was 80%. The D_r =80% ground was created using compaction by vibrators. Silica sand No. 7 (Specific gravity of soil, G_s=2.626) was used in preparing the model ground.

In addition, for investigation the influence of soil-cement strength on the failure mechanism of the pile tip, two type soil-cement were prepared. The soil-cement mix was designed to have unconfined compressive strength (or UCS for short) of 1,500kN/m^2. On the day of the test, a uniaxial compression test was carried out to confirm that the UCS of the two types of soil-cement was close to the target value.

As the model scale ratio is 1:30, a centrifuge acceleration of 30G was used in the vertical loading tests. The pile models were constructed using miniature H-section steel shape of H-10×10×0.33×0.5 (mm) and soil-cement, the pile diameter was constructed as 20 mm. In order to increase the axial force reaching the pile tip and to reduce the adhesion resistance between the H-section steel pile and soil-cement, silicone grease was applied to the blue shaded area in Fig.2. The measurement items were displacement and load at the pile head, and strain of the H-section steel. The strain gauges are attached both side of the web section at the pile head and the pile tip.

Two model piles were constructed in a rigid soil container with a specified layer thickness and target relative density. The specimens were mounted on a centrifuge and subjected to centrifugal acceleration up to 30G, vertical loading tests were carried out. The loading method was a displacement-controlled

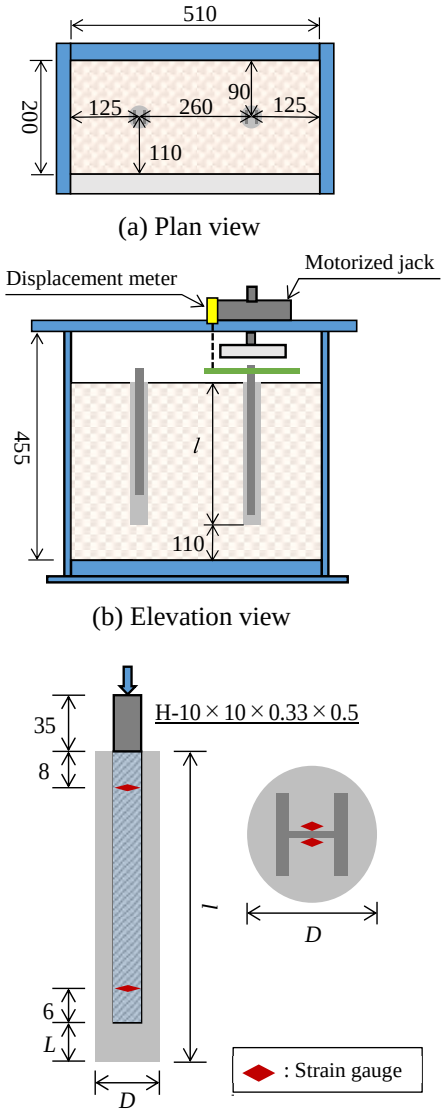

Fig.2. Schematic view of centrifuge model test and model pile (Unit: mm)

Case 4	200	20	30	1.50	1,500	80

method, and the electric jack set at the top of the rigid soil container was used to load the model pile heads at a loading rate of 0.03 mm/sec. The centrifuge model tests were carried out using a beam-type centrifuge model test equipment owned by the Aichi Institute of Technology. The specifications of the test equipment and its overview are shown in Table 2 and Fig.3.

NUMERICAL ANALYSIS

In order to simulate the results of the centrifuge model test, numerical analysis such as an elasto-plastic FEM focusing on the failure mechanism at the pile tip were carried out. In this analysis, the H-section steel pile were modeled as elastic, and the soil-cement and model ground were modeled as elasto-plastic using Mohr-Coulomb's fracture method. Fig.4 shows the schematic view of analytical model, and Table 3 lists the input parameters for the model ground, soil-cement, and H-section steel pile. Where, two types of deformation modulus were used, one calculated from triaxial compression test results (Case x-A) and the other calculated from N-values (Case x-B). In Case x-A, the confining pressure was calculated based on the soil cover at the pile tip shown in Table 1(6,000 mm on the actual scale), and the deformation modulus used in the analysis was determined from the relationship between the deformation modulus and the confining pressure resulting from the triaxial compression test. On the other hand, in Case 1-x-B, the internal friction angle obtained from the triaxial compression test was used to determine the deformation modulus for the analysis by calculating the N value using Equations (1) and (2) shown in [4].

$$\phi = 1.85\left(\frac{N}{\sigma_v'/100}\right)^{0.6} + 26 \quad (1)$$

$$E_d = \rho_{gE} E_N / \gamma_{gE} \quad (2)$$

Where, ϕ :Internal friction angle of sand(°), N : SPT(Standard Penetration Test) N value, σ_v' :Effective overburden pressure of appropriate depth at the soil investigation(kN/m^2), E_d : Design deformation modulus used in the calculation of coefficient of subgrade reaction for foundations(kN/m^2), ρ_{gE} : Modified coefficient of ground for deformation modulus (ρ_{gE} =1.0), E_N : Tested value of deformation modulus obtained from SPT(kN/m^2), γ_{gE} : Coefficient of soil investigation for deformation modulus (γ_{gE} =1.4).

The coefficient of earth pressure at rest was calculated from the internal friction angle using Jaky's equation. Then, the Poisson's ratio of the soil was calculated using the coefficient of earth pressure at rest.

In addition, joint elements were added at the boundary between the soil and the pile and between the soil-cement and the H-section steel pile, respectively. Table 4 shows the input constants for the joint elements. The purpose of the joint elements is to simulate the slip between soil and pile and between soil-cement and H-section steel pile. Shear modulus was determined using the relationships between shaft friction and local pile displacement from the centrifuge model test results. Then, normal modulus was determined as 100 times the shear modulus.

RESULTS OF CENTRIFUGE MODEL VERTICAL LOADING TEST AND NUMERICAL ANALYSIS

This section describes the results of centrifuge vertical loading tests and the numerical analysis. The test results are shown converted to full-scale.

Fig.4 shows the relationships load and displacement at pile head. In Case 1, the measured values show acute gradient changes around 15mm

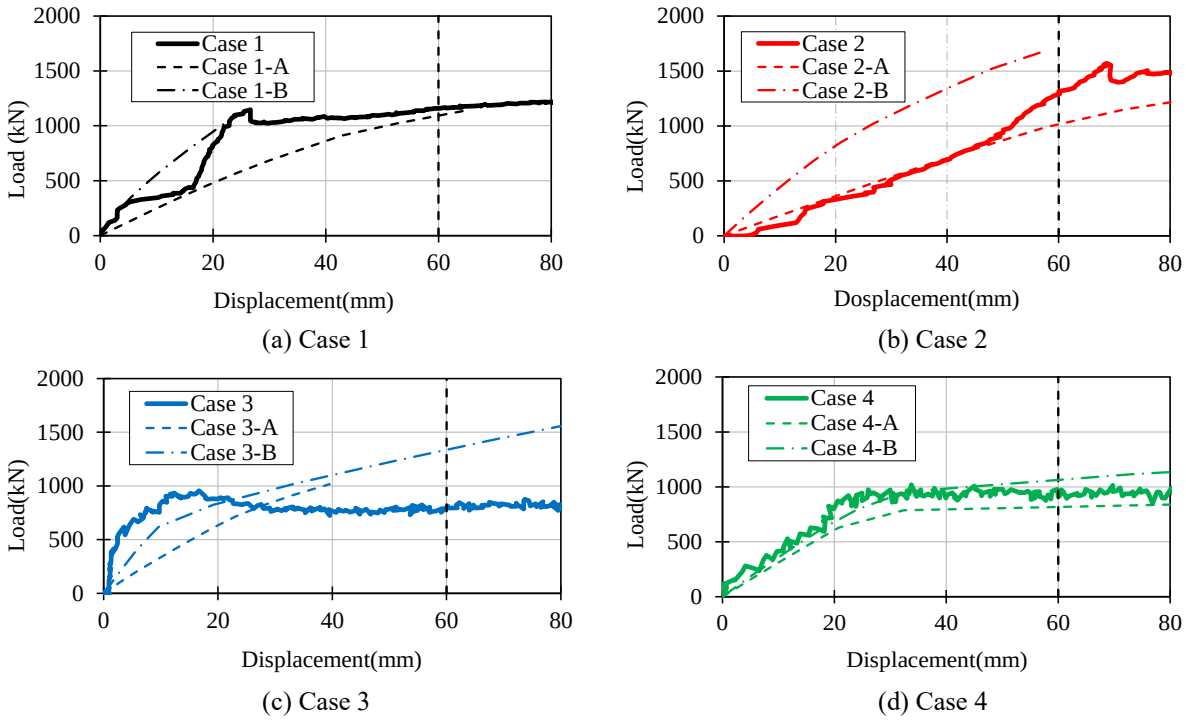

Fig.4. Relationships between load and displacement at pile head

and 25mm of pile head displacement. This is surmised to be due to the breakdown of the adhesion between the soil cement and the H-section steel pile. After that, the state of residual is shown to be in the range of 1,000kN to 1,200kN. As in Case 1, Case 3 and Case 4 show a change in gradient and shift to a residual condition at a pile head displacement of about 15 to 25mm. It can be seen that Case 3 is in a residual state at about 800kN and Case 4 is in a residual state at about 900 to 1000kN. However, in Case 2, the gradient change can be seen at a pile head displacement of about 70mm. After that, it shows that it is in a residual state at about 1500kN. Comparing the maximum load of different pile tip shapes, Case 2 with normalized separation L/D=0.5 has the highest maximum load. In other words, the most effective vertical bearing capacity is obtained when the normalized separation L/D=0.5.

In Case 1, if the measured values at the beginning of loading and about 20 mm displacement are loosely connected, it can be seen that Case1-B shows a close behavior to the measured values. However, in the region of about 60mm pile head displacement, Case1-A shows a behavior close to the measured value. Although the gradient change in Case 4 cannot be observed as in Case 1, Case 4-B behaves close to the measured value in the initial stage of loading as in Case 1. And Case 4-A shows behavior similar to the measured value as the pile head displacement increases. In Case 2, the measured loads are larger than in Case 2-B until the pile head displacement is 20mm. However, after the pile head displacement of 30mm, the measured load is smaller than that of Case2-A. In Case 3, Case 3-A shows behavior close to the measured values until the pile head displacement of 50mm. After that, the measured values show behavior between Case 3-A and Case 3-B.

Fig.5 shows the relationships end bearing capacity and displacement at pile tip. Fig.5 shows a different trend from Fig.4. In Case 1, it can be seen that Case 1-A shows behavior close to the measured values from the initial stage of loading. On the other hand, Case 2-A, as in Fig.4, shows a behavior similar to that of the measured values. However, in Case 3, the measured values show behavior between Case 3-A and Case 3-B until the pile tip displacement is about 15mm. After that, Case3-B shows a behavior close to the measured value. In Case 4, Case 4-B shows behavior close to the measured value until the pile tip displacement is about 20mm, but then the end bearing capacity increases and the maximum value is close to Case 4-A. Furthermore, the measured values of Case 2, Case 3, and Case 4 show a change in gradient around 1,500kN/m^2, leading to a state of residual. Considering that the uniaxial compressive strength of the soil cement is 1,500kN/m^2, it can be assumed that a compressive failure of the soil cement at the pile tip has occurred. However, Case 1 shows residual state at 800 to 1000kN, which means that the UCS of the soil-cement in Case 1 may be smaller than the design

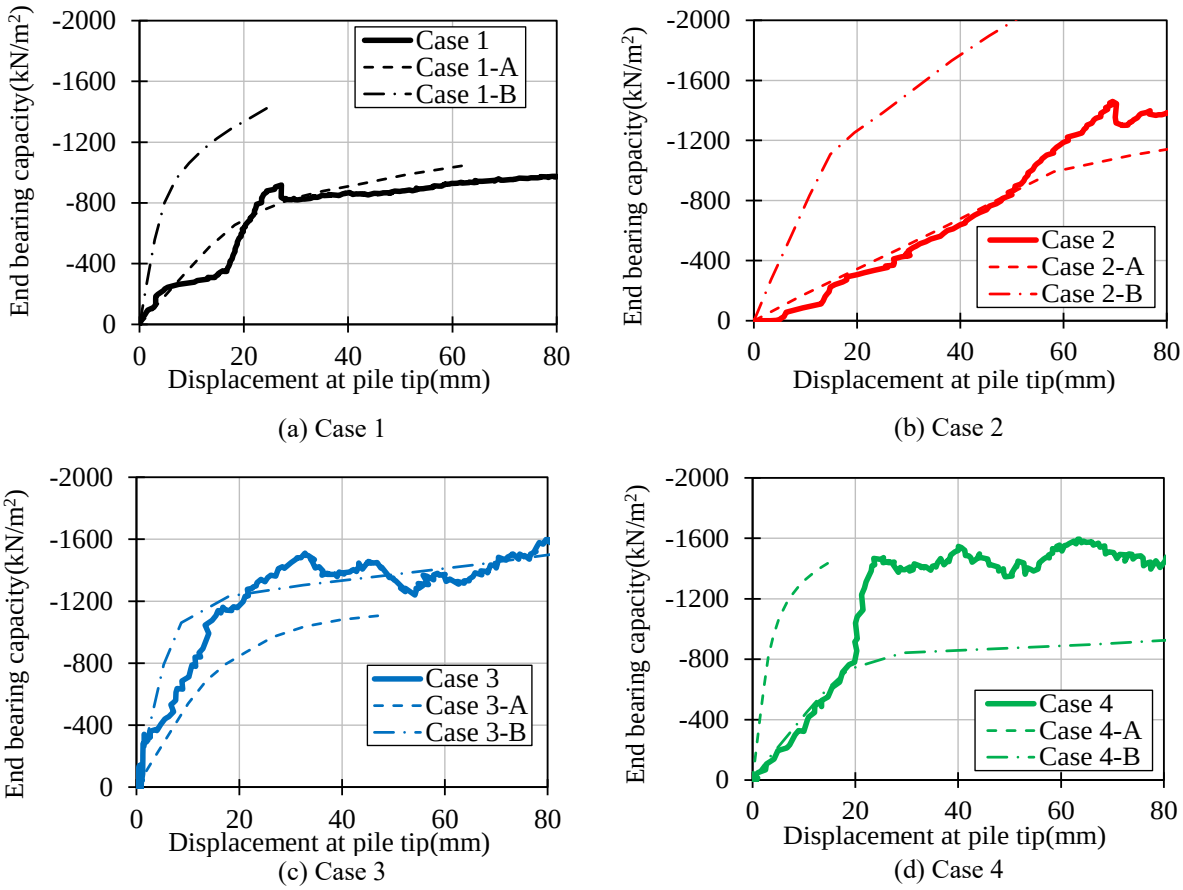

Fig.5. Relationships between end bearing capacity and displacement at pile tip

strength. Comparing the maximum end bearing capacity for different pile tip shapes, Case 2, Case 3 and Case 4 with normalized separation *L/D* = 0.5 to 1.5 show the end bearing capacity about the UCS of soil-cement, which is larger than that of Case 1. In other words, it can be seen that the most effective vertical bearing capacity is obtained at normalized separation *L/D* = about 0.5 to 1.5.

CONCLUSION

In this study, centrifuge model test focusing on the vertical bearing characteristics of the pile tip of soil-cement composite piles was carried out. Furthermore, numerical analysis using elasto-plastic FEM was carried out with the purpose of simulating the test results, and the following findings were obtained:

1) In the relationships between load and displacement at pile head, the gradient change can be observed in Case 1, Case 3, and Case 4 at pile head displacements of 15 to 25 mm.
2) In many cases, the analytical results of Case x-B show behavior close to the measured values in the relationship between load and displacement at pile head.
3) In many cases, the analytical results of Case x-B show behavior similar to the measured values in the relationship between the end bearing capacity and displacement at pile tip.
4) The test results of Case 2, Case 3 and Case 4 show a gradient change in the end bearing capacity near the UCS of the soil-cement. This suggests that the soil-cement at the pile tip has been failed in compression.
5) Focusing on the maximum load and end bearing capacity in the centrifuge model tests, it can be seen that Case 2 with normalized separation *L/D* = 0.5 shows the largest values for both maximum load and end bearing capacity, thus indicating that it has the most effective vertical bearing capacity.

BEARING CAPACITY AND BEHAVIOUR OF SHALLOW FOUNDATIONS SUBJECTED TO CYCLIC LOADINGS: A STUDY IN 1G

ABSTRACT

The design of geotechnical structures is based on the use of safety factors (partial factors), which have a direct impact on the quantities of material used and therefore on the carbon footprint of these structures, as well as on their construction costs and timescales. These partial factors guarantee the robustness and durability of geotechnical structures by limiting displacements to levels compatible with the requirements for their proper functioning. Although largely proven by experience, the French method for designing shallow foundations (as well as other international methods) is still conservative, either because of a lack of knowledge, or because of a simplistic choice not to exploit all the information obtained from geotechnical surveys and test campaigns on deep foundations. These shortcomings and choices are limitations that need to be overcome in order to improve the way in which the displacements and permissible loads of deep foundations are estimated. The aim of this communication is to study the load-bearing capacity and behaviour of shallow foundations subjected to complex loadings. After clearly stating the problem and describing the experimental approach, results of the experimental campaign based on tests performed at 1g and on a reduced scale are presented in detail. It was observed that some combination of actions will not affect the stability of the foundations, even after millions of cycles, and that the stability of the foundations under cyclic loadings is due to both the mean stress applied under the foundation, but also the amplitude, in a concomitant manner.

Keywords: Shallow Foundations, Laboratory Testing, 1g Testing, Small Scale

INTRODUCTION

The current approach of rapid construction combined with minimizing settlement risks often rely on deep foundations, which imposes significant environmental and societal costs. Given today's global pressures—economic, technical, and environmental—continuing to use shallow foundations could lead to overall project cost savings of 5% to 20% and a substantial decrease in environmental impact associated with foundation construction.

This highlights the ongoing need for a dependable method to design the bearing capacity of shallow foundations using cost-effective soil investigation techniques—an enduring goal of geotechnical engineering. Research on this topic dates back to the early 20th century. Notably, [1] discusses how foundation shape affects bearing capacity, referencing earlier experimental work by [2] in Finland, [3] in Germany, [4] in the U.S., and [5] in the U.K. These studies, conducted in laboratory using reconstituted sand masses and footings no wider than 0.3 meters, preceded [6] who introduced the first general equation for calculating the bearing capacity of soils beneath a continuous footing under a centered vertical load.

Further studies were carried out to validate the parameters of this equation proposed by [6] but also to extend the field of application of this formula by [7] in Canada, [8-9] in Belgium and [10-11-12] in France.

At the same time, tests were carried out to establish the direct pressumeter direct method [13].

During the past 15 years, complimentary works were also conducted to study the behavior of shallow foundation resting on unsaturated soils [14] and also to compare different methods and there reliability, trying to assess the impact of the choice of soil investigation [15].

However, and even if some test campaigns were carried out during the last 30 years to assess the behavior of shallow foundations submitted to combined loadings [16], there is still room for improvement in the actual design methods, as the experimental data are still relatively scarce ([17-18] for example), and because the static case is the only one taken into account, even if it has been established that fatigue caused by cyclic loadings can result in the failure of the soil under the foundation [18].

Therefore, collaboration has been initiated between France and Japan in order to better apprehend the behavior of shallow foundations under complex loadings as well as to optimize the existing design methods.

RESEARCH SIGNIFICANCE

This ongoing research aims to further document the behavior of shallow foundations under complex loading, including – but not exclusively – cyclic loadings, through the acquisition of experimental data achieved in laboratory on reconstituted soil masses.

The extensive use of actual reconnaissance tests (albeit at a reduced scale) [19-20] will allow for a direct transposition of the results to the practionners.

Indeed, diagrams of stability will be drawn that will at terms lead to the improvement of the existing design methods, whether based on laboratory parameters or in situ parameters.

EXPERIMENTAL SETTINGS

Reference Soils

The soils used for this study are two clean sands called sand n°6 (from Japan) and HN32 (from France), with zero fine content, and which are relatively uniform. The grain size distributions of both sands are very similar (Fig. 1). The coefficient of uniformity C_u are also very close, being equal to 1.67 for sand n°6 and 1.64 for HN32.

All the reconstituted sand masses were compacted, having in mind a target relative density of 80%. The peak friction angles for both sands are very close at this relative density, being equal to 42° and 39° respectively.

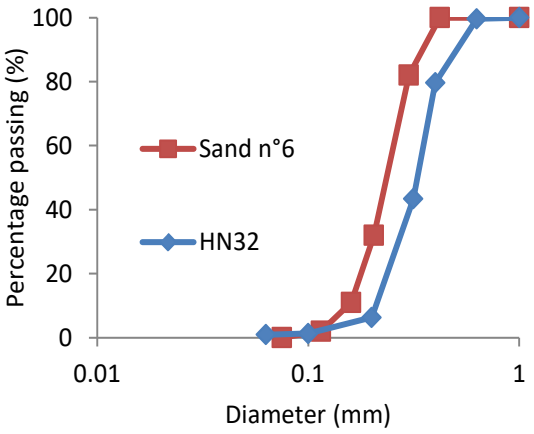

Fig.1 Grain size distributions of the sands

Soil Masses Reconstitution

Whether in Japan or in France, the soil masses were reconstituted following the sand process.

The containers dimensions were chosen to allow for at least two tests (three in France) to be carried out without any interference between the tests or with the tank' sides.

Nine layers or sands, 5cm thick, were tamped down, each at a target relative density of 80%, as stated before.

Foundations and Loading Systems

The foundations consist of square stainless-steel plates measuring 100 mm in width and 25 mm in thickness. A ball joint was used to ensure the transmission of the load to a constant point of load application.

The loading systems are very close, with only few differences: in Japan, a big diameter triaxial apparatus was used for applied the load through an electric motor, while in France a reaction frame (Fig. 2) was used, on which a hydraulic simple effect jack piloted with an advanced pressure and volume controller was used.

In all cases, a load cell and four displacement sensors were used, to follow the reaction of the foundation during the tests.

Testing Procedures

Different types of loading were applied to the foundations: a load-step loading, which is the most common way to carry tests on real scale foundations [21] and displacement controlled loadings were also performed. Both types of test gave comparable results, whether in Japan or in France.

Fig.2 Dedicated loading frame

RESULTS AND DISCUSSION

Compaction Quality Controls

It was important to assess the compaction quality, and repeatability and reproductibility of the soil masses creation, inorder to validate the results achieved during this research carried out in the form of a parametric study.

Dynamic Cone Penetrometer Tests (DCPT) were carried out on each of the tanks for this purpose.

The results of six tests carried out in Tank 3 show a good repeatability (Fig. 3).

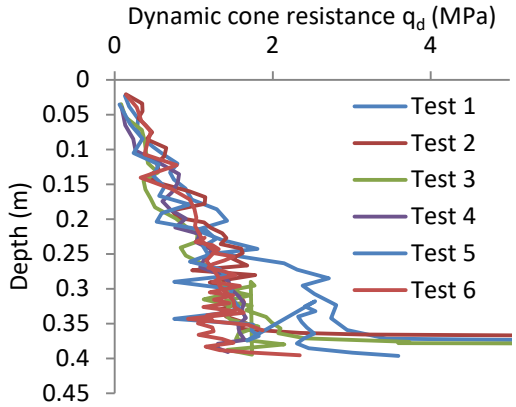

Fig.3 DCPT results in Tank 3 carried out on HN32

They allow concluding on the homogeneity of the soil mass, especially on the first 25 cm of depth, which will be the most impacted by the loadings

Figure 4 shows the average relative density achieved in Tanks 2 to 5, filled with HN32.

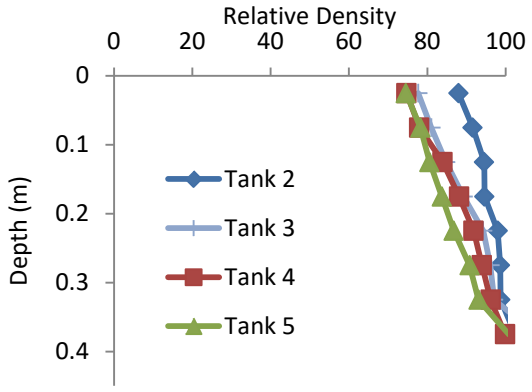

Fig.4 Relative density profiles in various tanks

It can be seen that Tank 2 seems a little bit denser than the following tanks, allowing to conclude that after a learning phase for the creation of sand masses, homogeneity is now ensured. The relative density was calculated using a correlation adapted from [22]. The target relative density of 80% is achieved in the tank for depths lower than 25 cm, ensuring testing conditions in accordance with the objectives.

Monotonic Loadings

In order to carry out a parametric study on the influence of the mean stress and of the amplitude of the cyclic loading on the behavior of a shallow foundations, monotonic loadings had to be carried out, to assess the monotonic bearing capacity (Fig. 5).

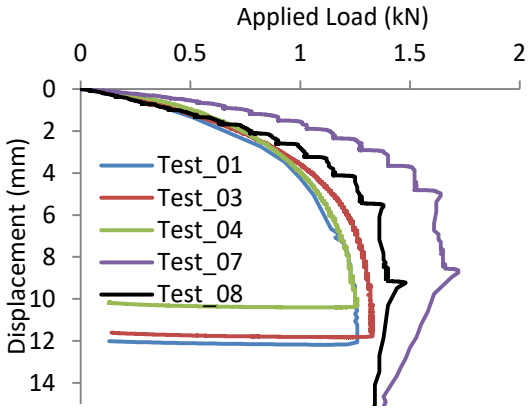

Fig.5 Results of monotonic loadings

The chosen criterion for failure is the well accepted criteria of a B/10 displacement induced by the load. The bearing capacity of the foundations is therefore defined as the load inducing a displacement of 10 mm, in our case.

The monotonic loadings performed on the HN32 sand gave an average bearing capacity of 1.25 kN (Fig. 3), in good accordance with the results achieved in Japan on Sand n°6. This value will thereafter be defined as the maximum vertical load applicable on the foundation, monotonally ($V_{mon;\ max}$).

Monotonic loadings performed load step by load step or displacement controlled gave very similar results, too.

Cyclic Loadings

Having ensured that the results achieved in Japan were very comparable to those achieved in France, it was decided to pursue the study by carrying out tests in parallels.

For this study, the main objective was to assess the importance of the cyclic mean stress ($V_{cyc;\ mean}$) and of the demi-amplitude DV_{cyc} on the behavior of the foundation.

The tested configurations are presented in Fig. 6.

From the first tests carried out, it can be seen that there is a clear impact of the ratio between the amplitude of the cycles, the mean stress and the

number of cycles leading to failure.

In particular, for a ratio maintained constant of (DV_{cyc} / $V_{mon;\ max}$) / ($V_{cyc;\ mean}$ / $V_{mon;\ max}$) (in this case 0,5), the number of cycles leading to failure decreases exponentially with the mean cyclic stress (Fig. 7). A complementary test carried in France confirms this conclusion.

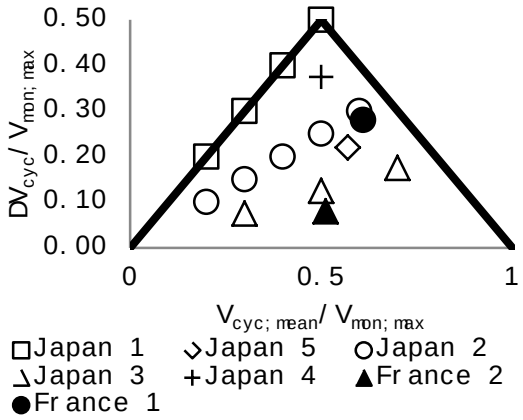

Fig.6 Cyclic loading configurations tested included in stability diagram

However, the patterns appear less clear, but this may be due to the very low values of the demi amplitude and of the cyclic mean stress in some cases, for which the stability is ensured for any given number of cycles, and on the other side to the complete unloading of the foundation (see Serie Japan 1 for example, on Fig. 6) which is an extreme case that causes higher displacements.

Furthermore, for a constant value of the ratio ($V_{cyc;\ mean}$ / $V_{mon;\ max}$), there is also a clear influence of the amplitude of the cycles on the number of cycles leading to the failure. This can be seen very easily on Fig. 8, for two values of ($V_{cyc;\ mean}$ / $V_{mon;\ max}$). The two series seems very close, with very similar patterns.

Finally, for a constant value of DV_{cyc} / $V_{mon;\ max}$, it appears that there is also an influence of the mean stress on the number of cycles leading to failure (Fig. 9). However the relation does not seems so simple and more tests will need to be done to draw any conclusion.

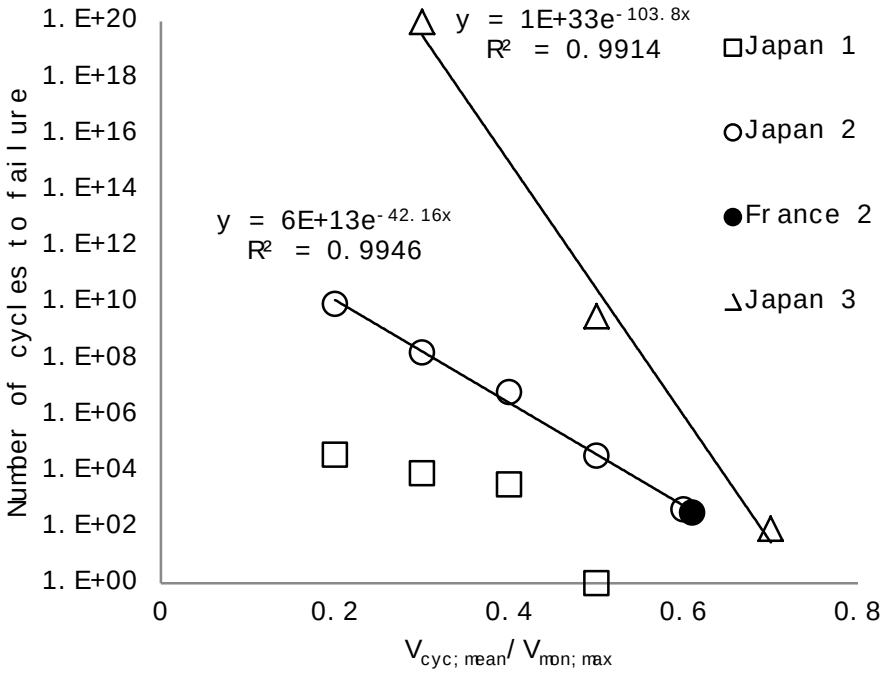

Fig.7 Relationship between the number of cycles leading to failure and the ratio $V_{cyc;\ mean}$ / $V_{mon;\ max}$

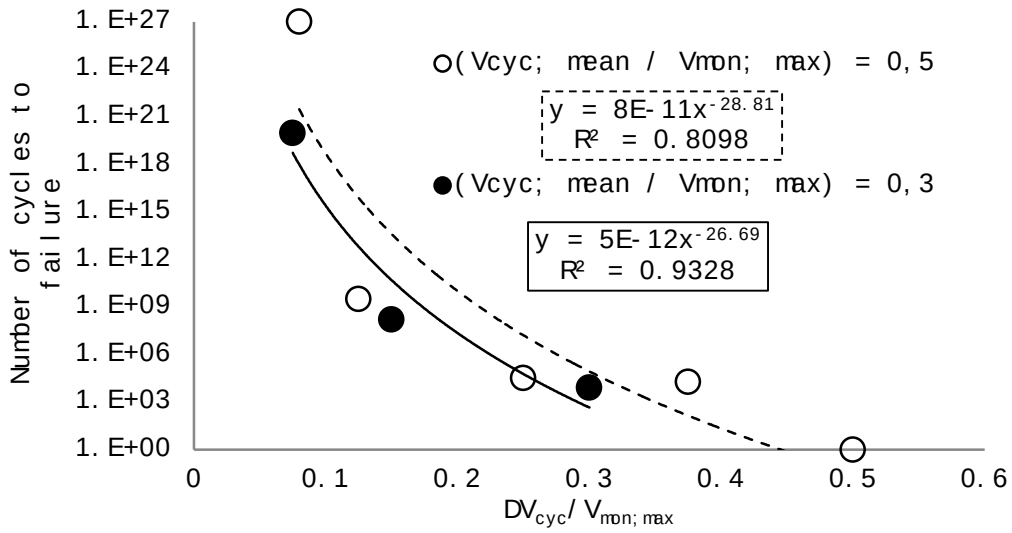

Fig.8 Relationship between the number of cycles leading to failure and the ratio DV_{cyc} / $V_{mon;\ max}$, for two values of mean stress

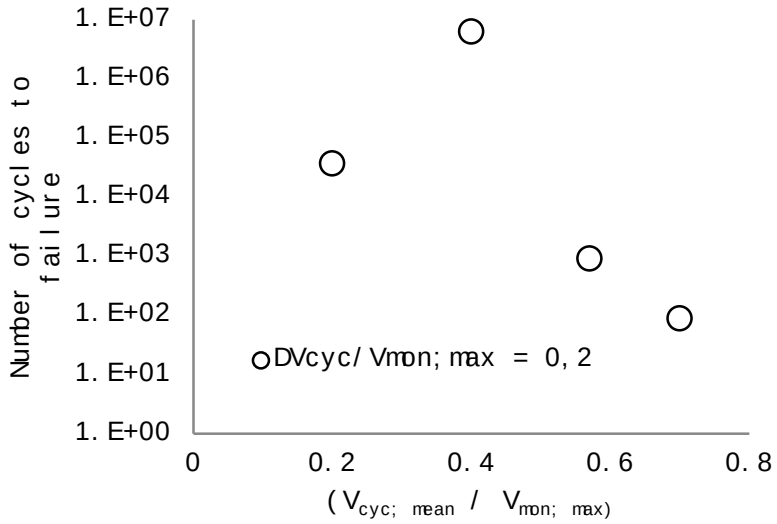

Fig.9 Relationship between the number of cycles leading to failure and the ratio $V_{cyc:\ mean}$ / $V_{mon;\ max}$

CONCLUSIONS

This communication presents the preliminary results of an experimental work on the behavior of shallow foundations under cyclic loadings. After presenting the soundness of the experimental procedures and protocols, results of centered cyclic vertical loading on footing are presented.

It can be concluded that the stability of the foundations under this kind of solicitation is due to both the mean stress applied under the foundation, but also the amplitude, in a concomitant manner.

Some combination of actions will not affect the stability of the foundations, even after millions of cycles, but it is still difficult to draw definitive conclusions. A major factor influencing the results might also be the soil density.

In the light of these results, it is important to continue this study, which in time will allow for the performance of more complex tests and to propose design approaches based on displacement that take into account the nature of the soil and its condition, as well the nature of the loadings in terms of amplitude and duration of application.

ACKNOWLEDGMENTS

The authors would like to acknowledge the constant support of the Université Gustave Eiffel, the RTRI and the Chuo University, allowing for very constant exchanges and periods dedicated to experimental works in the facilities of the different partners.

LANDFILL MINING IN BRAZIL: SOME CHALLENGING ASPECTS FOR APPLICATION

Thiago Villas Bôas Zanon[1] and Maria Eugênia Gimenez Boscov[1]

[1]Polytechnic School, University of São Paulo, Brazil

ABSTRACT

Several international research report landfill mining (LFM) cases with different levels of investigations, most involving conceptual analyses or pilot feasibility studies, with a limited number of full-scale studies. To assess the recovery of materials from LFM process, these materials are typically divided into: (i) combustible fraction, (ii) inert fraction, (iii) soil-like materials and (iv) remaining fractions. In most studies, soils and similar materials are the predominant fraction, followed by combustible fraction; literature mainly addresses the use of these groups of materials. This article discusses some challenging aspects of Brazilian situation regarding LFM. There are few Brazilian studies about LFM, all conceptual analyses. Historically municipal solid waste (MSW) in Brazil is mostly disposed of on land and there is low recovery of MSW, allowing to infer that there are significant quantities of landfilled materials with recovery potential. However, field studies (pilot, large and full-scale) are recommended for future research to investigate key questions involving excavation technologies, technological routes for material recovery, and assessment of economic viability. Assessment of local variables that are not present in LFM cases reported in the literature are important, such as high rainfall, high organic matter content, higher and steep landfill slopes, limited operation time along the year due to rainfall regime, and higher generation of leachate.

Keywords: Municipal solid waste, Landfill, Mining, Energy recovery, Resource recovery.

INTRODUCTION

There is a global consensus that the current economic model, known as Linear Economy, should transit to Circular Economy, one of whose principles is to avoid wasting resources, e.g., disposing of waste without prior recovery [1].

Globally 19% of municipal solid waste (MSW) is recycled, 13% is used for energy, 30% is landfilled, and 38% is dumped [2]. Therefore, more than half of MSW is sent for final disposal on land.

Materials disposed of in landfills may be recovered by landfill mining (LFM), a technique in which waste is excavated, sorted, separated and subsequently used as a resource, eliminating potential sources of subsoil contamination, assisting in recovering land value, and reducing greenhouse gas emissions [3-5]. Mined materials that are eventually not used can be again landfilled, however the goal is to minimize or even eliminate the need for returning materials to the landfill [6]. Mining allows to release part of the volume previously occupied by waste disposed, extending landfill operation and thus applying the concept of a “perpetual” landfill, or freeing up areas for alternative uses [5,6]. Therefore, LFM is a technique that avoids impacting new areas for expansion or construction of new landfill and reduces the exploitation of natural resources which causes scarcity of raw materials, and can thus be another valuable activity in the transition to a circular economy [7].

Although LFM has been the subject of an increasing number of studies in recent years, it is not a recent technique, since there are reports of its being used in Israel in the 1950s [3].

This article aims to assess whether there are conditions for carrying out LFM in Brazil, comparing conditions of reported international experiences with those found in Brazil.

RESEARCH SIGNIFICANCE

This study aims to assess the state of the art of Landfill Mining, discuss the main variables involved, investigate the incipient situation of LFM in Brazil, and prospect the development of LFM applications, based on international experience and on the consideration of local particularities. This article thus intends to contribute with ideas for the development of research necessary to enhance LFM in Brazil, pointing out issues that need more detailed studies. The final objective is to promote the circularity in waste management, present alternatives for landfill disposal, and suggest means of recovering dumpsites.

LANDFILL MINING STATE OF ART

Most LFM studies involve conceptual analyses or feasibility of specific pilot projects, with a limited number of large and full-scale studies [4,8,9]. The number of studies has grown in recent decades [4].

The mining process of waste disposal sites involves not only the extraction of the landfilled materials, but also the separation of the materials into groups (or fractions) with properties of interest. LFM feasibility is highly dependent on the correct selection

of processes and equipment [4].

To extract waste to be mined, two methods are found in literature: drilling and excavation, both using conventional equipment [4,8,9]. Drilling is performed using drilling equipment and is used in pilot projects of scientific nature, allowing great depths to be reached but reducing the size of the mined material, and having high operational costs; excavation is performed using hydraulic excavators or similar, is used in large or full-scale projects, has low operational costs, but does not reach great depths.

Following extraction, materials must be separated and screened for efficient material recovery. Pre-drying is recommended to improve sorting (separation) processes and for end-use of mined materials [8-12].

Sorting equipment is always necessary to separate mined materials into different groups due to MSW is composed of many different constituents. To select the sorting equipment, it is necessary to identify and quantify the materials to be mined and groups or subgroups into which materials can be divided. Such division typically is based on the potential uses as resources [4,9,13]: (i) combustible fraction (paper, cardboard, textiles, wood, foams, plastics, leather and rubber); (ii) inert fraction (stones, ceramics, glass and metals); (iii) soil-like materials; and (iv) remaining fractions.

Combustible fraction includes materials with high calorific potential that can be used as fuel (in biomass industrial boilers, clinker production furnaces, in pyrolysis, gasification or incineration). Here the main critical parameters are calorific value, moisture content, metals, ash content and chlorine content. Many components of landfilled waste are potentially but not effectively recyclable. Only ferrous and non-ferrous metals have effectively the possibility of being recycled, while other materials which are conceptually recyclable (mainly paper, cardboard and plastics) do not have the minimum necessary quality due to the presence of impregnated contaminants (for example, organic matter and soil), which makes them attractive to use as fuels; even though, prior treatments could be necessary, such as separation, cleaning and drying [8,9].

Soil-like materials involve soils and materials with a granulometry similar to soils (such as partially or fully decomposed organic matter) and can be used at final disposal sites as waste cover or in other applications as construction material. Soil present in mined material mainly originates from waste landfill daily, intermediate and final covers, and is used in large quantities during landfill operations. Composting is also a possibility for this fraction, but evaluation of the percentage of remaining organic matter and concentration of metals is necessary, since these constituents can limit or make composting unfeasible, even in non-food crops [4].

The composition of material mined from MSW landfill varies significantly among different landfills, depending on original waste composition, waste age, location, climate and hydrological conditions [4,8]. Original waste composition of MSW varies according to population income level [2], whereas composition of disposed waste varies depending on prior treatments before final disposal. Table 1 presents waste compositions and ranges of values found in two review papers that present cases on landfill mining in different countries. Percentage of combustible fraction in both studies is in the same order of magnitude in both studies, while soil-like-materials are relatively close.

Table 1 Percentage of material recovered in different LFM cases

Fractions	Krook et al. [9]	Jain et al. [4]
Soil-like material	50% to 60%	48.6%
Combustible fraction	20% to 30%	24.5%
Inert fraction	10%	21.3%
Others	-	5.6%

Time factor, represented by waste age, is a key variable of mined materials composition over time, since degradation processes of organic-putrescible materials (mainly food remains, wood, paper and cardboard) occur, reducing the participation of this fraction. Thus, over time, soil-like materials fraction increases, combustible fraction decreases, and the inert fraction remains constant [4,5]. This occurs because the combustible mass degrades over time and converts to soil-like materials fraction, while the inert materials remain constant. There are also changes in characteristics, such as reduction of materials size in waste mass [5,14,15]. Granulometry is an information of interest, since one of the most conventional processes for separating MSW is sieving, allowing the separation of smaller fractions (soil and food waste) from larger fractions, which generally have a higher calorific value.

Since most of mined waste composition is soil-like materials, as shown in Table 1, the first process recurrently applied after waste extraction is granulometric separation. This fraction is distinguished from the others mainly by size, therefore sieving sets soil-like materials apart. For screening, trommels or vibrating screens are mainly used, with no standard size for screen openings (screen sizes between 1 and 40 mm are described in the literature), which impairs the comparison of percentage soil-like materials fraction among different LFM studies [4,8,9]. The grain diameter for coarse sands, the thickest fraction of soils, is defined as 4.8 mm in geotechnics. Many mining studies use much larger opening sizes, probably due to the mined soils forming clods and being agglutinated.

To separate the other groups and subgroups of

materials, the following equipment is also found in mining studies: crushers, ferrous metal separators, non-ferrous metal separators, air separation technologies and conveyor equipment [4,8,9].

Krook et al. [9] conducted an extensive literature review on landfill mining, covering the main trends, objectives, topics and findings in 39 research articles published during the period 1988-2008, whose geographical distribution is shown in Fig. 1. The main topics of the articles are presented in Fig 2. Jain et al. [4] found 108 publications related to LFM distributed in different regions as seen in Fig 3. In both review papers there are no publications from Latin America, Caribbean, and Sub-Saharan Africa.

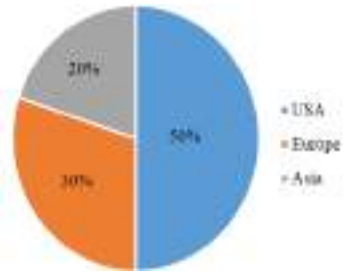

Fig.1 Krook et al. [9] geographical distribution of LFM cases

Fig.2 Krook et al. [9] categorization of 39 reviewed papers regarding main topics

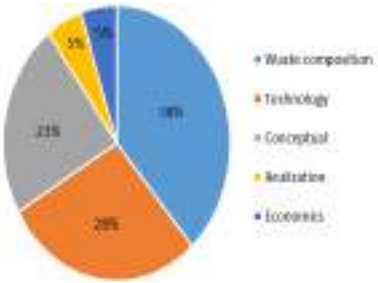

Fig.3 Jain et al. [4] geographical distribution of LFM cases

One of the fundamental topics to be evaluated in LFM is economic viability. There are articles in the literature that explore this topic, addressing the need for generating gains and revenues - avoided post-closure costs of the landfill, externalities, added value due to landfill space gain, land value, materials sales (including rare materials) - to fund activities related to LFM (extraction, separation, transportation, heat treatment and final disposal of materials) [16-19]. Esguerra et al. [16] conducted a review of studies that assessed LFM economic potential, selecting 15 that met certain criteria (full article in English, quantitative analysis, among others). These studies mostly comprised an economic analysis focused on decision-making about a specific landfill and concluded that mining has low economic potential; only 2 proved to be profitable [16]. However, the authors call attention to the need for expanding scenarios and improving scientific prospective analyses.

STATE OF THE ART OF LFM IN BRAZIL

There are few studies on the application of landfill mining in Brazil [5,13], and no cases of pilot, large and full-scale application have been identified.

Regarding recovery potential, data analyses from tropical landfills, comparing new waste and mined waste aged 4 to 6 years, show that there is a tendency for components with high calorific potential to concentrate along the disposal time, and at the same time there is a reduction in the moisture content (from 100% on a dry basis to 20% to 60%). These are indications that 4 to 6 years are sufficient for most microbial processes to occur, conditions that can favor LFM and energy recovery from waste due to the moisture reduction [5]. This expected behavior can be observed in Fig. 4, where after 0.5 years the higher calorific value (HCV) reaches a high-level range; HCV remains in the range of 23 to 27 MJ/dry kg for circa 2.5 years (investigated time). Kasam et al. [20] studied the effect of age on MSW composition collected in an Indonesian landfill. However, samples from 0 to 2 years were collected from a well-managed part of the landfill, whereas samples older than 3 years were collected from an open dumping site, what makes the comparison more difficult.

In a landfill located near the city of São Paulo, waste aged between 10 and 16 years was sampled with the aim of evaluating combustible fraction. The study concluded that the fraction with diameter higher than 40 mm, which corresponded to 27% of the mined materials, had potential for energy recovery (due to the high presence of plastics and paper), presenting average calorific value that would meet the criteria for refuse derived fuel according to the applicable state legislation [13].

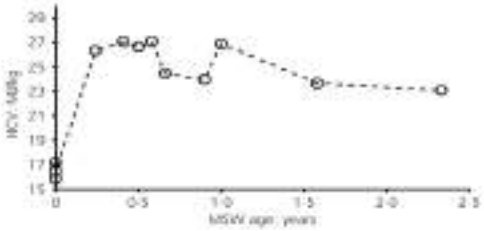

Fig.4 Higher Calorific Value obtained in a tropical MSW landfill [5]

Although Guimarães et al. [21] assessed mining potential from old closed dumpsites that operated between 1989 and 2015, their study provides data regarding waste composition (Fig. 5) which can lead to important findings: high percentage of plastics and low percentage of organics (probably showing that much of the organic matter had degraded).

Fig.5 Average composition of samples collected in 9 dumpsites [21]

DISCUSSION

Considering that in Brazil practically all MSW is sent for final disposal in landfills and thus has an insignificant low waste recovery rate (less than 10%), as can be observed in Fig. 6, and the estimated average gravimetric composition for Brazilian MSW (Fig. 7), the quantity and percentage of recoverable waste accumulated in landfills is probably high. There is a large presence of organic waste (45.3% of MSW) and waste with the possibility of energy recovery (more than 30% of MSW).

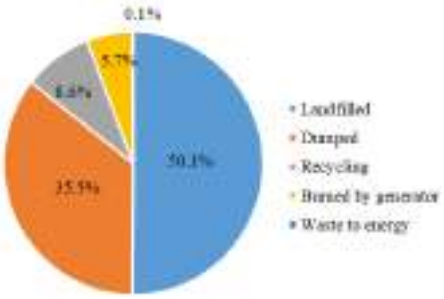

Fig.6 Brazilian MSW destination in 2023 [22]

In the case of LFM, the amount of organic matter is expected to decrease compared to the generated MSW; amounts of soil, stones, ceramics, glass, plastics and metals will remain the same; paper, cardboard, textiles, leather and rubber will degrade slowly, and their quantity should decrease slightly. In percentage terms, a lower percentage of organic matter is expected for the excavated material; and energy use is probably the best use for plastics, paper, cardboard, textiles, wood, foams, plastics, leather and rubber, since they are contaminated and can hardly be recycled.

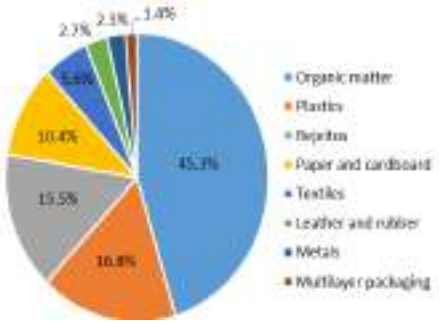

Fig.7 Brazilian MSW composition in 2023 [23]

However, there are few national studies on LFM. In many countries where LFM cases have been reported, the value of land is a significant factor in economic viability, which can be as significant as the revenue from materials that can be valued. In Brazil, a country of continental dimensions, the land freed up by LFM would not have such a great relevance in the economic viability. This is possibly the main reason for the lack of interest in this topic in the country.

Also, the circularity of the economy is still a new concept for Brazilian public managers, entrepreneurs in the sanitation sector, and the citizens in general. Since 2010, the year of publication of the National Policy for Solid Waste, a federal law, a legal and institutional framework has been slowly developing to meet the law's requirements. The first step was the improvement of land disposal and the need for municipalities to formulate and implement a plan for solid waste management. Recycling, reverse logistics, composting, and circularity are steps that are being implanted at different paces.

One of the potential ways to seek circularity of LFM is the use of the combustible fraction, the second largest typical fraction among mined waste as presented in the manuscript. There is a Brazilian law to regulate waste characteristics to be applied as RDF for the cement industry, which is very strong in Brazil. There is also a Brazilian law for composting and there are some practical experiences, but mostly from agrobusiness waste.

Additionally, there are geotechnical challenges that may make this solution less attractive: there are regions with high rainfall, limiting operation time along the year and increasing leachate generation; MSW has a high percentage of organic matter; landfills can be very high and with steep slopes, a combination that may generate additional costs due to the greater difficulty in excavation, among others. On the other hand, there is an already know-how developed in Brazil for the design and operation of tropical sanitary landfills [24], which allows overcoming these challenges.

LFM can also cause discomfort to neighborhoods, due to odor, noise and emission of particulate matter; however, in the long term, it could bring benefits such

as increasing the value of the surrounding area, recovering urban areas of considerable dimensions, and reducing risks to public health and environmental pollution. This challenge of acceptance by the surrounding community requires communication and dialogue with society.

It is important to consider the lessons learned and recommendations related to existing international studies. Therefore, in Brazil, field investigations should be carried out to assess the behavior of the waste composition and changes in the characteristics of the waste as a function of its age. Executing these investigations can subsequently allow planning, specifying and dimensioning appropriate processes for conducting pilot, large and full-scale studies, allowing the assessment of the performance and economic viability of LFM [25]. Local particularities should also be considered in the LFM assessment, such as local rainfall regime, since significant areas of Brazilian territory have locations with high rainfall distributed, which may interfere with waste extraction activities, waste processing and LFM feasibility.

In future studies to evaluate LFM, it is also important to consider different scenarios of separation, valorization, market issues for recycled materials - a vital issue in Brazil, where public policies for use of recycled material are incipient - and market for the fuel fraction. Guerreiro [26] analyzed the production of refuse-derived fuel (RDF) in Brazil. The annual RDF production is 176,000 tons, but just one plant utilizes MSW, with a yearly production of 30,000 tons (while 89 million tons MSW are collected yearly in Brazil). Another plant co-processes RDF from MSW, waste tires, biomass (wood chips), and paints and solvents, achieving a blend with high calorific power.

The technological route of waste excavation processes must be addressed, absorbing the know-how developed in landfilling operations. And, last but not least, the inclusion of waste pickers cooperatives in the sorting processes with capacitation for the different scenarios must also be taken into account, because they represent a significant percentage of the non-specialized labor force in Brazil.

CONCLUSIONS

Despite the existence of a significant number of scientific publications related to LFM, the number of full-scale cases reported is limited. The identified studies mostly involve conceptual analyses and pilot studies, with few reports of large and full-scale cases.

Particularly in Brazil the few studies on LFM refer to evaluation of composition and properties of excavated waste, in addition to the conceptual evaluation, particularly of the fraction with energy potential. Due to the average MSW composition and the history of practically low waste recovery before landfilling, the amount of landfilled waste with recovery potential is significant, showing that there is potential for the application of LFM.

To implement LFM in Brazil, lessons learned from international experiences should be used as a reference, but it is essential to consider local conditions and characteristics, such as the influence of rainfall on the landfill mining process, a variable that has the potential to significantly influence the behavior of waste in places with tropical climate.

IMPROVING THE PROPERTIES OF MATERIAL USED IN BUILDING CLAY HOUSES WITH CEMENT

Nathiya Jaokaenkaew[1], Pongsakorn Punrattanasin[2]

[1,2] Faculty of Engineering, Khon Kaen University, Thailand

ABSTRACT

This study focuses on improving the properties of clay soil for constructing eco-tourism earth houses to address issues related to structural weakness, lack of durability, and vulnerability to weather conditions and natural disasters. Cement was incorporated into the clay soil to enhance strength and resistance to strength loss after water immersion, simulating conditions in areas prone to flooding or heavy rainfall. In this research, cement was mixed into clay soil at proportions of 3%, 5%, 7%, 10%, 20%, and 25%. Experimental results indicated that the compressive strength of clay soil increased with both curing time and cement content. At 25% cement and a curing age of 28 days, the strength peaked at 61.75 ksc, compared to 34.91 ksc for untreated clay—an improvement of approximately 1.77 times. Untreated clay and clay mixed with less than 20% cement exhibited ductile fracture behavior. In contrast, specimens containing 25% cement showed brittle failure behavior. Strength loss due to water immersion, simulating rainy conditions, was observed to decrease with longer immersion durations. After 5 hours of water immersion, clay mixed with 25% cement retained a compressive strength of 20.25 ksc, whereas untreated clay measured 61.75 ksc indicating a strength reduction of approximately 3.05 times. Based on studies of both load-bearing capacity and strength loss, it can be concluded that clay mixed with 20% and 25% cement is the optimal ratio, as it provides good load-bearing ability and retains significant strength even when submerged in water.

Keywords: Clay, Earth Houses, Water Immersion, Cement, Curing Time

INTRODUCTION

Sustainable travel accommodations, recognized by the Travel Sustainable badge, have become increasingly popular worldwide, including in Thailand. [1] stated that earthen houses, inspired by traditional Thai wisdom, are built using natural materials and techniques passed down through generations, as shown in Fig. 1. However, since these construction methods were not originally developed based on engineering principles, they often face structural issues both during and after construction. Common problems include collapse due to heavy rainfall, flooding, and other natural disasters, resulting in a shorter lifespan and reduced durability. To improve the strength of earthen houses, the addition of cement has been widely explored. [2] and [3] conducted a study on cement mixing to improve soil. [4] conducted a study and found that mixing cement with clay soil enhances its compressive strength. Cement improves the load-bearing capacity of clay, making it more resilient. This research aims to further develop the compressive strength of build clay houses to enhance their durability against weather conditions and natural disasters. Additionally, the study must determine the appropriate ratio for practical application in actual construction.

SAMPLE PREPARATION

The clay collected from Ban Wang Thua, Wang Chai Subdistrict, Nam Phong District, Khon Kaen Province, mostly consists of topsoil clay that can be used for pottery (Fig.2). In preliminary tests, it was found that this clay is suitable for constructing eco-friendly earthen houses. According to the Unified Soil Classification System, this type of clay is

classified as Low Plastic Clay (CL), with details presented in Table 1. When the initial strength of the soil is assessed using a Pocket Penetrometer, clay in its natural moisture condition has a strength of less than 2 ksc. To strengthen the natural properties of the soil, only Type 1 Portland cement was added in this study. Six different proportions of dry cement were used: 3%, 5%, 7%, 10%, 20%, and 25% of the dry soil weight. Cement exceeding 25% was not used because preliminary tests showed that higher amounts made sample mixing and shaping difficult. For sample preparation, water was added at 20% of the total mixture weight. Once mixed, the material was placed into cylindrical molds with a diameter of 5 cm and a height of 10 cm. A pressing tool applied equal force to each sample, ensuring uniform material quantity and pressing energy, thereby making the results comparable. In the first part of the study, strength development over curing time was examined with four curing periods: 3 days, 7 days, 14 days, and 28 days. All samples were cured in an open room at 25°C without wrapping. The second part of the study simulated strength loss when an earthen house is exposed to rain with varying amounts of rainfall. For this, only 28 days old samples were immersed in water for three different durations: 1 hour to simulate light rain, 3 hours for moderate rainfall, and 5 hours for heavy rainfall. A total of 49 samples were tested, with details presented in Table 2.

RESULTS AND DISCUSSION

Strength Development

The strength of the clay samples and clay mixed with cement was evaluated using the stress-strain relationship from the unconfined compression test. The graph provides key parameters, including the maximum load-bearing capacity, the strain at maximum load, residual strength, and the failure mode, classified as either brittle or ductile. Figure 3 presents the relationship for samples cured for three days, with data from seven different sets. The first set, consisting of pure clay (S100C0), exhibited a maximum strength of 16.28 ksc at approximately 2.27% strain. When mixed with 3% cement (S97C3), the strength increased to 22.64 ksc. As the cement content increased, the strength continued to rise, reaching 52.66 ksc at 25% cement content (S75C25), which is approximately 3.24 times greater than that of pure clay. Failure mode analysis revealed that pure clay and clay mixed with less than 25% cement exhibited ductile behavior, meaning the samples retained some residual strength after peak load. However, samples with 25% cement demonstrated brittle failure, where strength was rapidly lost after reaching maximum load.

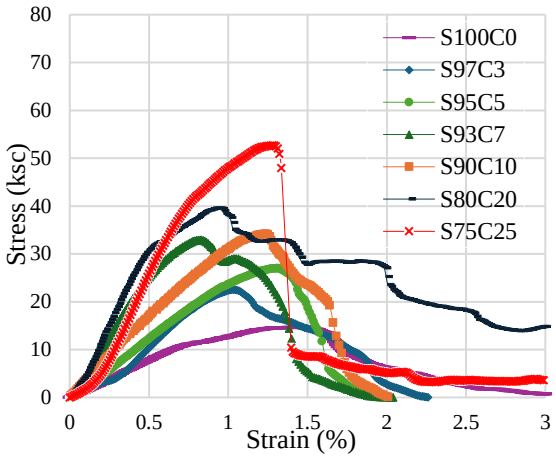

Fig.3 The relationship between stress and strain of soil and soil-cement at curing age of 3 days

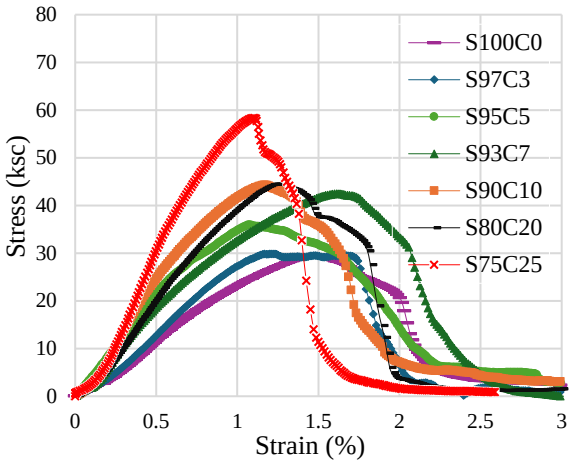

Fig.4 The relationship between stress and strain of soil and soil-cement at curing age of 7 days

Figures 4 to 6 illustrate similar trends for samples cured for 7, 14, and 28 days, respectively. The results indicate that both load-bearing capacity and strength increase with higher cement content and longer curing durations. The maximum load-bearing capacity of pure clay is 26.74 ksc, 32.97 ksc, and 34.91 ksc at curing ages of 7, 14, and 28 days, respectively. Increasing the cement content to 25% enhances the load-bearing capacity, reaching 58.32 ksc, 60.97 ksc, and 61.75 ksc for curing periods of 7, 14, and 28 days. For other mixtures, the load-bearing capacity of the samples is summarized in Table 3. When comparing load-bearing capacity at 28 days, it is observed that the strength of pure clay increases from 34.91 ksc to 60.53 ksc, 60.97 ksc, and 61.75 ksc with cement contents of 10%, 20%, and 25%, respectively. It can be said that adding 20-25% cement can enhance the load-bearing capacity of clay by approximately 1.7 times. However, cement content between 3% and 7% does not significantly enhance the strength. Unlike the results shown in Figure 3, where only the 25% cement-soil mixture exhibited brittle failure, other cement-soil mixtures displayed ductile characteristics. However, in Figures 4 to 6, nearly all cement-soil mixtures became stronger and demonstrated brittle-like behavior as curing age increased. The residual strength after reaching maximum capacity gradually decreased as strain increased. By using the values from Table 3 to analyze the relationship between curing age and unconfined compressive strength, the results are shown in Figure 7, indicating a linear correlation between curing age and load-bearing capacity. Similarly, Figure 8 illustrates the relationship between cement content and load-bearing capacity, which also exhibits a linear correlation, as observed in Figure 7. It can be preliminarily concluded that adding 10-25% cement to clay enhances its load-bearing efficiency compared to pure clay.

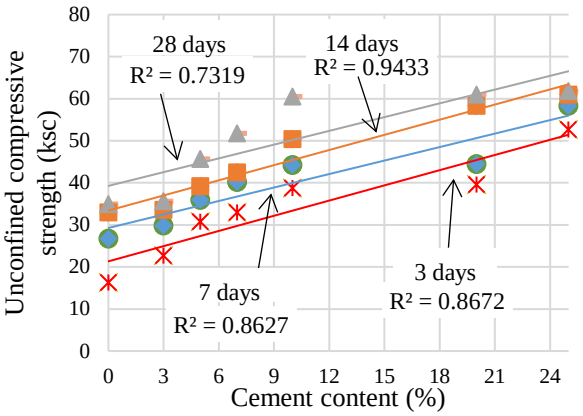

Fig.8 The relationship between cement content and unconfined compressive strength of soils

Strength Loss

In this second part of the experiment, the load-bearing capacity of the samples will be evaluated after water immersion, simulating conditions where cement-stabilized soil is submerged. The researcher selected only samples with a curing age of 28 days for this study. The immersion test consists of three scenarios: 1-hour immersion, representing light rainfall; 3-hour and 5-hour immersion, simulating heavy rainfall and flooding. This testing method helps earth-home builders understand the impact of prolonged submersion on their structures. The test results show the relationship between stress and strain, as illustrated in Figures 9 to 11. Figure 9 presents the results after a 1-hour water immersion, followed by a load-bearing capacity test. The effects of 3-hour and 5-hour immersion on the samples are shown in Figures 10 and 11, respectively. Table 4 summarizes the load-bearing capacity of soil and soil-cement after being submerged in water for different durations.

Figure 9 clearly shows that only four soil-cement mixtures could withstand compressive force. Pure clay, as well as 3% and 5% cement-clay mixtures, failed to maintain their structural integrity after brief water immersion, making compression testing unfeasible. The graph highlights the correlation between cement content and load-bearing capacity, with higher cement percentages preserving greater strength. According to the graph, the estimated load-bearing capacity for a 10% cement mixture is approximately 29.47 ksc, rising to 25% cement, and gradually decreasing to 22.72 ksc, 11.69 ksc, and 11.67 ksc as the cement content decreases to 20%, 10%, and 7%, respectively. The results in Figures 10 and 11 contrast with those in Figure 9, revealing that only three soil-cement mixtures maintained their load-bearing capacity after being submerged for 3 and 5 hours. These mixtures contained 10%, 20%, and 25% cement. However, upon closer examination, the 10% cement mixture demonstrated a load-bearing capacity of only about 6.41 ksc, which is relatively low. Therefore, only two soil-cement mixtures remain viable in terms of maintaining load-bearing capacity after submersion: those with 20% and 25% cement content.

When the results from the first part of testing are plotted alongside the water immersion test, the outcomes are presented in Figures 12 and 13. From Figure 12, for the 20% soil-cement mixture with a curing age of 28 days, the load-bearing capacity is 60.97 ksc. After 1 hour of water immersion, the strength decreases to 22.72 ksc, or approximately 37.3% of its original capacity. When submerged for 3 hours, the load-bearing capacity declines slightly further, and after 5 hours, it is reduced to 16.70 ksc, or approximately 27.4% compared to the dry state. For the 25% soil-cement mixture, the load-bearing capacity at 28 days without water immersion is 61.75 ksc. After 1 hour of immersion, the strength drops to

29.47 ksc, or about 47.7% of its original capacity. With 3 hours of immersion, the load-bearing capacity decreases slightly, and after 5 hours, it is approximately 20.25 ksc, or about 32.8% compared to the dry state. It is evident that both mixtures maintain a considerable load-bearing capacity even after being submerged for up to 5 hours. Therefore, based on this experiment, these two mixtures are suitable for constructing earth houses. When combined with the results from the first phase of testing, it can be concluded that the optimal mixture for improving clay strength and ensuring its durability against natural hazards such as rainfall is 20% and 25% cement with 20% water content.

CONCLUSIONS

Clay from Nam Phong District, known for its use in pottery, has the potential for constructing earth houses for eco-tourism. Various cement proportions, ranging from 3% to 25%, were tested. Preliminary experiments revealed that mixing cement with 20% water allowed for proper blending and sample formation. At each curing age, mixtures with higher cement content consistently demonstrated greater compressive strength, with the 25% cement mixture achieving the highest values. At 3 days, the 25% cement mixture showed a sharp, brittle failure, while all other mixtures, including pure clay, exhibited ductile behavior with residual strength after peak load. Mixtures with 3% and 5% cement showed only modest strength gains compared to pure clay, especially at later curing stages, indicating they may not be suitable for structural applications. Mixtures with 20% and 25% cement provided the best balance of strength and durability, making them the most suitable for constructing clay-based structures. These findings led to further tests examining water immersion resistance over different durations. Results indicated that only the samples containing 20% cement and 25% cement maintained sufficient durability and load-bearing capacity. Thus, this study concludes that cement proportions of 20%-25% are optimal for enhancing the strength of natural clay, making it suitable for constructing earth houses efficiently.

EFFECT OF ANTECEDENT RAINFALL ON POOR WATER PRESSURE DISTRIBUTION CHARACTERISTICS IN RESIDUAL SOIL UNDER TROPICAL RAINFALL

Mohamed Elbyhagi Elfadil

Saudi Electricity Company, KSA

ABSTRACT

Characteristics of changes in pore-water pressure distribution are the main parameters associated with slope stability analysis involving unsaturated soils, which are directly affected by the flux boundary conditions (rainfall infiltration, evaporation and evapo-transpiration) at the soil–atmosphere interface. Two slopes were instrumented at Universiti Teknologi Malaysia (UTM) Skudai campus (Malaysia). The field monitoring results were analyzed to characterize pore-water pressure distributions to study the effect of antecedent rainfall on pore-water pressure distributions in typical residual soil slopes under tropical climate. Slope stability analyses were also conducted at depth 1.0 meter and recorded in each slope to determine the range of factor of safety for the slopes. Results indicate that, antecedent rainfall; initial pore-water pressures prior to a significant rainfall event as well as the magnitude of the rainfall event play a crucial role in the development of the worst pore-water pressure condition in a slope. The role of antecedent rainfall in the development of the worst pore-water pressure condition was found to be more significant in residual soils with low permeability as compared with that in residual soils with high permeability. The factor of safety of residual soils with low permeability was found to be unaffected by the worst pore-water pressure condition.

Keywords: Rainfall; Antecedent Rainfall; Pore-Water Pressure; Slope Failure; Factor of Safety

INTRODUCTION

Rainstorm is one of the most significant triggering factors for slope failures. It is widely recognized that rainfall-induced slope failures are mainly caused by infiltration of rainwater [5]; [15]; [7] and [20]. A number of studies have also indicated that slope failures can be attributed to several factors such as climatic conditions, geological features, topography, vegetation or a combination of these factors. These factors and their contribution to slope instability vary with geographical locations. Some studies have attempted a simple correlation between incidences of landslides with rainfall patterns. Simple direct correlations have been made for Brazil [3], [14] and [5]. More complicated correlation attempts are available for New Zealand [10]; [8]; [16] and [5].

Although the significance of rainwater infiltration in causing landslides is widely recognized, there have been different conclusions as to the relative roles of antecedent rainfall to landslides. [5] Suggested that antecedent rainfall was not a significant factor for landslides in Hong Kong and this limited influence of antecedent rainfall was attributed to the high permeability of local soils. [5] Suggested that the majority of landslides in Hong Kong were induced by localized and short duration rainfall of high intensity.

The objectives of this study are (i) to characterize pore water pressure distributions and (ii) to evaluate the effect of antecedent rainfall on pore-water pressure distributions in typical residual soil slopes under tropical climate.

Fig. 1 Shows Site-1 Field on 20th December 2006 and Site-2 Remain Stable.

METHODOLOGY

The study comprises the collection of field data, obtaining soil properties through field and laboratory tests, and performing slope stability analysis.

Field data collected from the sites are the geometry of the slope, rainfall data and matric suction. Site-1 was instrumented with nine tensiometers while Site-2 was instrumented with a rain gauge and 27 tensiometers (Fig. 1). Field permeability tests were also conducted at the sites. Undisturbed samples were collected at depth of 1m and 2m at several occasions between July and December 2006 to obtain water content at normal condition and at extreme condition i.e. after the prolonged and intense rainfall on December 2006.

Laboratory tests were conducted to obtain soil index properties, shear strength parameter, and the permeability of soil forming the slope. The shear strength of soil was evaluated by shear box test. The

soil water characteristic curves (SWCC) were obtained by pressure plate test. The apparatus and the procedure followed for obtaining the SWCC is explained in Wang and Benson (2004).

Infinite slope stability analyses were performed at depth 1.0 meter for slopes at normal condition and at wettest condition using the formula proposed by Fredlund et al.(1978). (Fredlund et al., 1987; Sung and Seung, 2002). The pore air pressure is atmospheric, the equation can be written as:

$$FOS = \frac{c' + (N - u_w)tan\emptyset'}{W\ sin\beta cos\beta} \qquad (1)$$

where c' = effective cohesion of the soil, N = normal stress applied on failure surface, $\emptyset'$ = effective friction angle, u_w = pore water pressure, W = total weight of the soil, β = the slope angle.

The survey work showed that both slopes can be considered as long slopes. The slope at Site-1 formed an angle of 30˚ while the slope at Site-2 forms an angle of 20.8˚. Field permeability test using Guelph permeameter show that the permeability coefficient of soil at Site-1 is 1.07×10-7 m/sec while that of Site-2 is 1.23×10-5 m/sec.

RESULTS AND DISCUSSION

The basic data for this study are the rainfall records on slope at site-2 which near the site-1, pore-water pressure measurements at various depths; 0.5, 1.0, 1.5 meter at each location at the slope; crest, middle and toe during raining season and dry season conditions across the year, site-1 monitored for six months and Site-2 monitored for one year, the data were characterized two periods; wet period and dry period for each slope were further characterized by key times, and the distribution of pore-water pressures along slope profile during these key times was examined. Key times were considered to be: (i) time at the end of a prolong dry period (ii) time following one or a series of significant rainfall event. The summary of rainfall records are presented on the graphs. The factor of safety was calculated for the slopes using the soil properties shown in table (1). The rainfall data and soil suction shown in the graphs. Infinite slope procedure was used to determine the factor of safety (FOS). The calculation was made for slip planes at different depths between 1 and 2.0 m with the interval of 0.2 m. Drained shear strength parameters obtained from direct shear test were used in the calculation. The results of the slope stability analysis performed for suction predicted based on water content and SWCC curve are presented in Table (2). The soil suction monitored in each slope during key times. The subsequent analyses discussion is based on individual slopes.

Table 1 summarizes the results of laboratory tests on disturbed samples obtained from both sites. It can be seen that sample from Site-2 contains more coarse particles than the sample obtained at Site-1. The soil at Site-1 has higher silt content which makes the soil prone to the erosion and dispersion; hence the slope is prone to fail at higher water content. The soil at Site-2 is a less plastic than the soil at Site-1. However, the difference is very small and it should be noted that only a small fraction of soil at Site-2 belongs to fine particles, thus the effect is very limited. Classification tests show that the soil at Site-1 is sandy silt of high plasticity (MHS) while the soil at Site-2 is silty gravel of low plasticity (GML).

Table 1 Soil properties

Parameter	Kolej 12 (Site 1)	Balai Cerapan (Site 2)
Unit weight (γ) kN/m3	17.2	18.0
Specific gravity (Gs)	2.68	2.64
Dry unit weight (kN/m3)	1.28	1.37
Composition, Gravel (%)	7	48
Sand (%)	30	15
Silt (%)	47	20
Clay (%)	16	17
Liquid Limit(LL) %	68.1	53.2
Plasticity index (PI) %	24.0	17.7
Soil type	MHS	GML
Shear Strength parameters		
Friction Angle(ǿ)	24.6˚	39.5˚
Cohesion (ć) KPa	2.6	3.3
Permeability (m/sec)		
Laboratory test	3.25×10^{-8}	2.04×10^{-6}
Field test	1.07×10^{-7}	1.23×10^{-5}

The drained shear strengths of soil from both sites were obtained from direct shear test. As shown in Table 1, the soil at Site-2 has higher shear strength than that in Site-1 especially in term of friction angle.

The permeability of soil at Site-2 is two orders of magnitude higher than that of Site-1. It is noted that the laboratory test gives lower value than the field test because the laboratory tests were performed on compacted soil.

The natural volumetric water content of soil in Site-2 varies slightly from 32.5% at depth of 1 m to 33.5% at depth of 2 m. The water content measured after the prolonged and intense rainfall in December 2006 is only slightly higher than the average, i.e 34.8% and 36.8% at depth of 1 m and 2 m respectively. Note that the volumetric water content at saturation for soil at Site-2 (Balai Cerapan) is 42.4%. Slight change in soil water content corresponding to depths and the rainfall is due to the presence of clay in soil.

The natural volumetric water content of soil at

Site-1 varies from 57% at depth of 1 m to slightly higher than 60% at depth of 2m. The water content measured a few days after the failure is 69% which is higher than the water content at saturation (64%). This shows that the soil has reached saturation at the time of failure.

Besides the saturated permeability of the soil, the soil water characteristics curve (SWCC) was another important characteristic of the unsaturated soil that influences the mechanism of rainfall-induced slope failure. Figure 2 shows the SWCC curves obtained by the pressure plate extractors for soil samples collected at both sites. The highest suction that may exist in a soil is limited by the suction at the residual volumetric water content. Beyond this point, the water content in the soil is hardly to be dissipated even though it is still possible. The highest suction could be recorded at Site-2, which consists of coarse grained soil, was 23 kPa at residual water content of 30%. As for the fine-grained soil, the maximum suction is very high (>1500 kPa). However the soil loss its suction gradually during the prolonged rainfall until the safety envelope was exceeded (Nurly Gofar, et.al, 2007)[17].

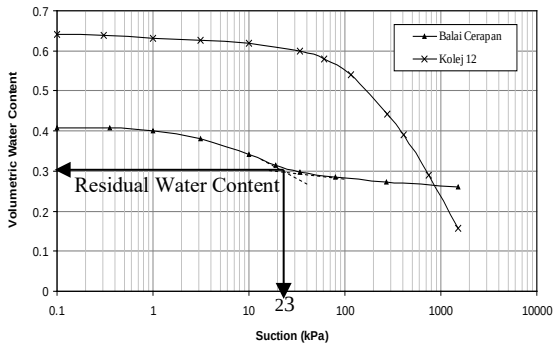

Fig. 2 SWCC curves for soils at Site-1 (Kolej 12) and Site-2 (Balai Cerapan)

The negative pore water pressure required for the calculation of factor of safety of slope was estimated based on the volumetric water content and the SWCC curve. Table 2 shows the variation of suction estimated based on SWCC of soils at both sites with depth.

Suction was actually measured at depth of 0.5m, 1m, and 1.5m. Comparison of the field data and the calculated suction based on SWCC curve shows that the SWCC curve gave higher suction values than the field measurement. However, for normal condition, the trend is similar. This shows that the response of soil to rainfall infiltration is faster than could be predicted by the SWCC curve.

Prediction of suction based on water content and SWCC curve for wet condition indicated the reduction of suction; however, the trend remained the same in which the suction decreases with depth. In contrast, measurement by tensiometer showed that the suction increases with depth. This discrepancies may be due to the time of measurement whereby tensiometer records the response right after rainfall while the sample obtained for water content determination was taken long time after the rainfall.

Table 2: Variation of Suction calculated based on SWCC curve

Elev (m)	Site 1 Normal		Site 2 Normal		Site 2 After rainfall	
	VWC %	Suction kPa	VWC %	Suction kPa	VWC %	Suction kPa
1.0	57	70	32.5	15	34.8	9.8
2.0	60	28	33.5	12.9	36.8	4.8

An interesting point can also be made from this study that the water content of soil at Site-1 remained high even after a long period dry condition. This means that the soil stays at saturated condition due to the accumulation of water caused by low permeability and mineral content of the soil mass.

Slope stability analyses were performed for both sites for two conditions i.e. normal and after the prolonged heavy rainfall in December 2006. It should be noted that the cumulative rainfall during 4 days before failure occurred at Site-1 was 489.4mm, and the maximum rainfall the day before the failure took place was 190.8mm. Infinite slope procedure was used to determine the factor of safety (FOS). The calculation was made for slip planes at different depths between 1 and 2.0 m with the interval of 0.2 m. Drained shear strength parameters obtained from direct shear test were used in the calculation. The results of the slope stability analysis performed for suction predicted based on water content and SWCC curve are presented in Table 3.

Table 3 The variation of factor of safety with depth

Depth m	FOS (Site 1)		FOS (Site 2)	
	Normal	December	Normal	December
1.0	5.45	1.14	4.79	4.08
1.2	4.21	1.08	4.29	3.58
1.4	3.33	1.04	3.94	3.21
1.6	2.66	1.01	3.68	2.97
1.8	2.15	0.99	3.49	2.86
2.0	1.83	0.97	3.34	2.78

Table 3 shows that the slope at Site-2 remained safe after rainfall, even though there is a decrease in factor of safety with depth. On the other hand, the slope at Site-1 became unstable at depth 1.8 m (FOS < 1) due to increase in water content which is beyond the volumetric water content at saturation. Table 3

shows that at normal condition, the slope Site-1 is more stable than slope at Site 2 for shallower depths, however FOS decreases as water started to accumulate at deeper elevation. Furthermore, the reduction of FOS at all depths at Site-1 is more significant than that at Site-2. It can also be seen from the table that there is a significant reduction of FOS with depth for both locations until a certain value. Then, the FOS becomes almost constant. The depth where the FOS becomes constant is considered as the critical depth. Table 4 shows the FOS obtained from stability analysis for which measured suction were used.

Table 4 FOS calculated based on measurement data

Depth m	FOS (Site-1)		FOS (Site-2)	
	Normal	December	Normal	December
1.0	2.97	1.14	4.43	3.48
1.5	2.41	1.02	3.94	3.39

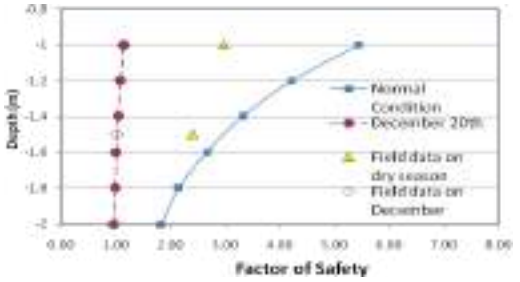

Fig.3 Depth of Slip Plane vs. FOS for Site-1

Figures 3 show the variation FOS with depth of slip surface for Site-1. The points indicated the FOS obtained for measured suction at depth of 1.0 and 1.5m. The FOS of slope at Site-1 decreases with depth. At normal condition, the minimum FOS of 1.83 was reached at depth of 2m. For wettest condition (December), FOS less than 1 was obtained at depth of 1.8m which agrees with the observed failure plane.

Based on field measurement, the minimum FOS of slope at Site-1 was 2.41, but decreases significantly to 1.02 at depth 1.5m after heavy rainfall in December 2006.

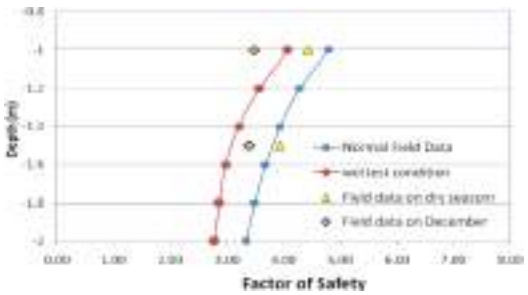

Fig. 4 Depth of Slip Plane vs. FOS for Site-2

The variation of FOS with depth of slip surface for Site-2 is presented in Figure 4. The points indicated the FOS obtained for measured suction at depth of 1.0, and 1.5m. The figure indicates that the slope at Site-2 (Balai Cerapan) remained stable even after the prolonged heavy rainfall. Based on field measurement, the FOS decreased slightly from 3.94 to 3.39 for slip plane at depth of 1.5m.

The FOS calculated based on water content and SWCC curve do not seems to agree with that calculated based on actual measurement of suction by tensiometers, however; the trend is similar. More variation of FOS with depth was obtained from the calculation based on SWCC as compared to the actual measurement. This shows that the actual variation of suction in soil is not as much as that predicted by SWCC curve. There are factors, other than the permeability and SWCC curve, affect the mechanism of rainfall infiltration in soil such as the mineralogy and the dispersibility of the soil. These will be the subject of further study. More attention should be given to the fine-grained soil slope during monsoon season.

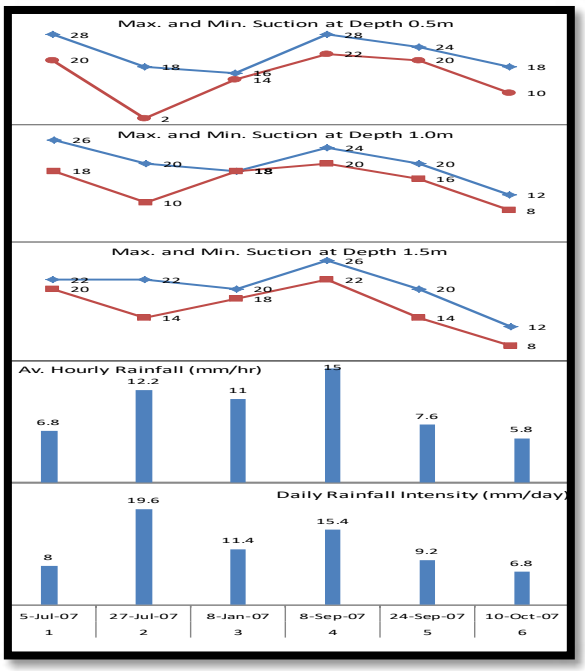

Fig. 5 Site-1 one day antecedent rainfall

Figure (5) shows readings at site-1 at three depths for one day rainfall after dry period. The events illustrated same amount and intensity of rainfall, ranged 6-20 mm/day and 6-15 mm/hours respectively. Events reflect same response at all depths except events 1 and 4 at depth 1.5 meter does not provide satisfactory explanation to why there is no change in reading 20kpa and 22Kpa respectively compare to 20Kpa and 22Kpa respectively at depth 0.5 meter. This suggests that their other factor affection water infiltration which is soil permeability as well as the

soil accommodated moisture at depth 1.5 meter.

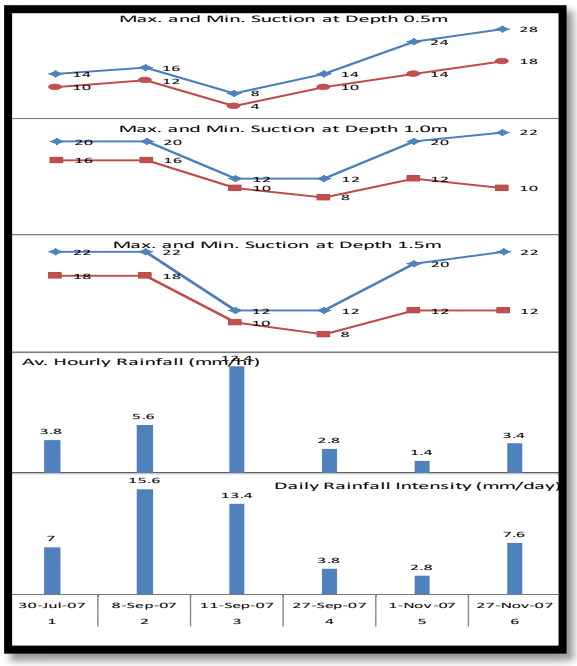

Fig. 6 Site-1 two days antecedent rainfall

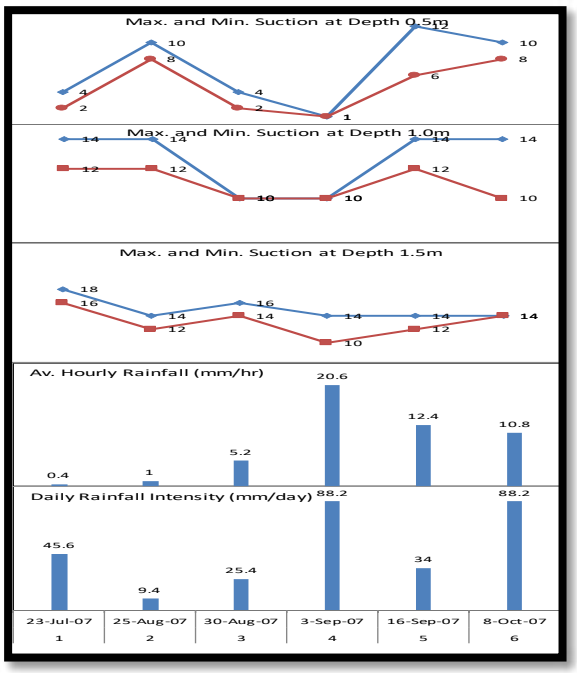

Fig. 7 Site-1 three days antecedent rainfall

Figure (6) shows readings at site-1 at three depths for two days antecedent rainfall. The events illustrated different amount and intensity of rainfall. The 1, 2 and 3 events provided high amount and intensity of rainfall 7, 15 and 13 mm respectively while the events 4, 5 and 6 provided low amount and intensity of rainfall 2.8, 1.4 and 3.4 mm respectively, even though the soil suction readings at depths 1.0 and 1.5 meter for the events 4, 5 and 6 recorded less than readings at depth 0.5 meter. This suggests that highest pore-water pressure profiles are not necessarily produced by the highest individual rainfall event. While the readings at depth 0.5 meter explained that the two days antecedent rainfall with low permeable soil does not has significant change on pore-water pressure at depths below 0.5 meter.

Figure (7) shows readings at site-1 at three depths for three days antecedent rainfall. Event 1 experienced significant amount of rainfall 45 mm with low intensity 0.4 mm per hour and the soil suction at depths 1.0 and 1.5 meter 12 and 16 Kpa respectively while the reading at depth 0.5 meter is 2 Kpa was changed significantly which provide satisfactory explanation that soil permeability affecting rainfall infiltration and readings at other two depths support the idea that soil accommodated water. Event 6 provide same explanation that water infiltration effect does not reach depth 1.5 meter due to soil permeability while the same readings at depths 1.5 and 1.0 meter means the soil accommodated water.

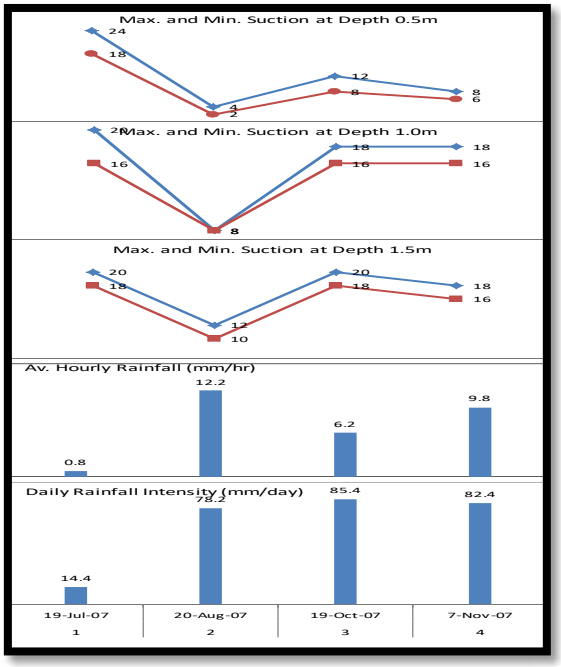

Fig. 8 Site-1 five days antecedent rainfall

Figure (8) shows readings at site-1 at three depths for three days antecedent rainfall. The event 1 show 18, 16 and 18 Kpa at three depths 0.5, 1.0 and 1.5 meter respectively under low amount of water and no heavy rainfall which means there is no effect at depth 1.0 meter as well as support the idea that the soil accommodated water at level below 1.0 meter.

Figure (9) shows readings at site-2 at three depths for one day rainfall after dry period. The events 1, 2, 3, 7 and 10 experience heavy rainfall 59, 38, 48, 37 and 49 mm respectively. The soil suction readings at three depths 0.5, 1.0 and 1.5 meter ware 2, 6 and 10 Kpa respectively. While the other events experienced low rainfall average 10 mm and the soil suction

average at three depths 0.5, 1.0 and 1.5 meter ware 5, 8 and 14 Kpa respectively. This provide satisfactory explanation that the soil response does not affected by soil permeability as well as there is no water accommodation in soil pores.

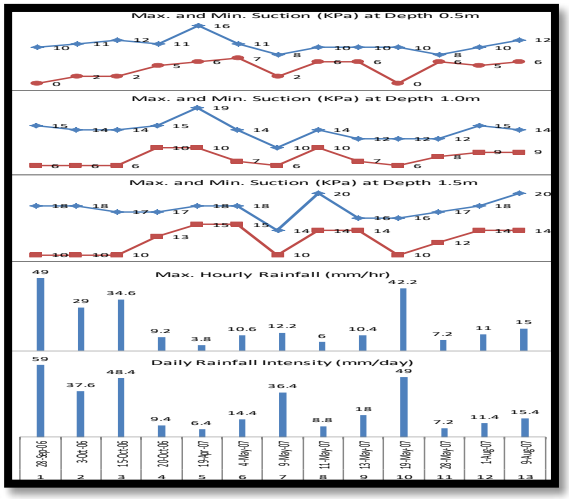

Fig. 9 Site-2 one day antecedent rainfall

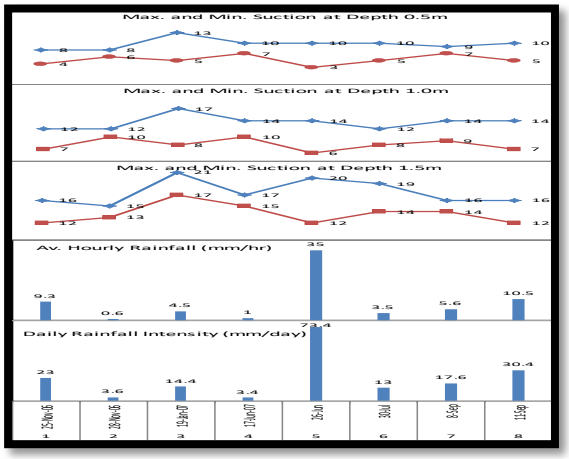

Fig. 10 Site-2 two days antecedent rainfall

Figure (10) shows readings at site-2 at three depths for two days antecedent rainfall. The event 5 experience heavy rainfall 74 mm while the events 1, and 8 experience rainfall 23 and 30 mm respectively. The soil suction readings for three events at three depths 0.5, 1.0 and 1.5 meter ware 4, 7 and 12 Kpa respectively. While the other events experienced low rainfall average 10 mm and the soil suction average at three depths 0.5, 1.0 and 1.5 meter ware 5, 8 and 14 Kpa respectively, which same response in one day rainfall. This provide satisfactory explanation that for permeable soil the soil response does not reflect difference in reading between one day rainfall and two days rainfall regard less the intensity of rainfall events at depth less than 2.0 meter.

Figure (11) shows readings at site-2 at three depths for three days antecedent rainfall. The event 1, 2, 6 and 9 experience heavy rainfall 59, 92, 58 and 88 mm. The soil suction readings for three events at three depths 0.5, 1.0 and 1.5 meter ware 3, 7 and 11 Kpa respectively. While the remaining events experienced prolong rainfall with low rainfall intensity ranged between 10 to 46 mm, the soil suction average at three depths 0.5, 1.0 and 1.5 meter ware 5, 8 and 14 Kpa respectively, which same response in one day and two days rainfall. Those supporting the previous explanation of figure 10.

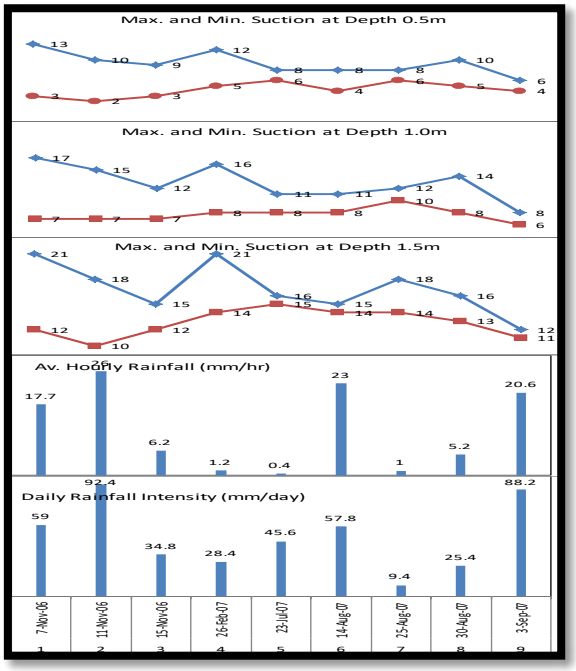

Fig. 11 Site-2 three days antecedent rainfall.

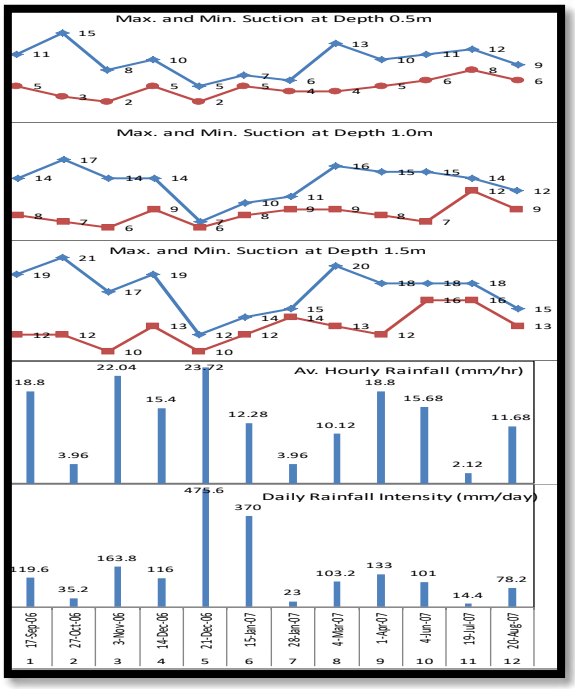

Fig. 12 Site-2 five days antecedent rainfall.

Figure (12) shows readings at site-2 at three depths for five days antecedent rainfall. The event 5 and 6 experience heavy rainfall 475 and 370 mm respectively, with different intensity 23 and 12 mm per hour respectively. The average soil suction readings for three events at three depths 0.5, 1.0 and 1.5 meter ware 3, 7 and 11 Kpa respectively which same readings for three days antecedent rainfall. While the events 1, 3, 4, 8, 9, 10 and 12 experienced medium rainfall 120, 164, 116, 103, 133, 101 and 78 respectively, with different rainfall intensity ranged between 10 to 22 mm, the soil suction average readings at three depths 0.5, 1.0 and 1.5 meter ware 5, 8 and 11 Kpa respectively. The events 2, 7and 11 experienced prolong and low Rainfall 35, 23 and 14 mm respectively.

The soil suction average readings at three depths 0.5, 1.0 and 1.5 meter ware 4, 7 and 12 Kpa respectively, which same response in one day and two days rainfall. This explains that the antecedent rainfall has no significant effect for high permeable soil comparing low permeable soil.

CONCLUSION

Several conclusions could be derived from the study on the response of soil slopes.

Firstly, antecedent rainfall play more significant role in residual soils with lower permeably than those with higher permeability in producing the highest pore–water pressure profile in a slope.

Secondly, it was observed that, in all the slopes monitored the highest pore-water pressure profile was reached when the total rainfall including 5-day antecedent rainfall was a maximum.

Thirdly, residual soils with low fines and high permeably pore-water pressure variation could take place over a wide range while in residual soils with relatively low fines and high permeably pore-water pressure variation occurs over a narrow range.

Fourthly, factor of safety varied rainfall magnitude for all slopes. On this consideration it appears that the factor of safety of residual soil slopes with relatively low permeability are unaffected by the worst pore-water pressures.

Fifthly, shallow slope failures are dominated by the combination of transient pore pressure in response to rainfall infiltration.

ABSTRACT

The rapid increase in demand for natural construction sand has exceeded its natural replenishment rate, leading to resource depletion and environmental concerns. Simultaneously, recycled glass (RG) generation continues to rise, occupying significant landfill space due to its extremely slow decomposition, which can take thousands to millions of years. RG exhibits comparable properties to natural sand; this study explores its potential use in civil engineering applications. However, RG alone does not meet the standard strength requirements for geotechnical applications. To address these limitations, cement was introduced as a stabilizing agent to enhance the strength and stiffness of RG. Cement was added at contents of 3% and 5% to assess geotechnical properties of RG. A comprehensive laboratory investigation, including particle size distribution analysis, compaction tests, California Bearing Ratio (CBR), unconfined compression strength tests (UCS), and repeated loading triaxial tests, was conducted. Results demonstrated that RG stabilized with 5% cement achieved a UCS value of 610 kPa. The CBR values for 3% and 5% cement-stabilized blends were 150% and 303%, respectively. The resilient modulus of the optimum blend ranged from 191 MPa to 461 MPa, indicating the potential of RG with 5% cement as a sustainable alternative for geotechnical engineering applications. This approach not only supports effective waste management but also contributes to the conservation of natural sand resources.

Keywords: Recycled glass, Ground improvement, Recycled waste, Sustainability, Stabilization.

INTRODUCTION

Sand is one of the most consumed natural resources on earth, second only to water [1]. However, high-quality sand suitable for construction, particularly river sand, is becoming increasingly scarce. This is primarily due to the construction industry's consumption rate far exceeding the natural replenishment rate of sand. Moreover, not all sand types are appropriate for industrial use, as particle size, shape, purity and other physical and chemical properties vary, making some types of sand suitable for specific applications [2]. For instance, desert sand, typically rounded due to win erosion, is unsuitable for construction. In contrast, river sand, with its angular particle shape and favorable chemical properties, is preferred in many industries [3].

The overexploitation of natural sand has raised significant social and environmental concerns worldwide. A major consequence is the rising cost of natural sand in many countries, largely due to stricter regulations. Despite the increasing cost of natural sand, global demand for natural sand was estimated at 50 billion tonnes annually in 2019-20 and is projected to rise to 60 billion tonnes by 2030 [1, 4]. According to the United Nations Environment Program (UNEP), if current consumption trends continue, natural sand may be depleted by 2050 or 2060 [4].

At the same time, the accumulation of waste glass is becoming an increasing environmental burden. In Australia alone, 1.50 million tonnes of waste glass were generated in 2020-21, with a recovery rate of only 58% or 0.91 million tonnes [5]. Although glass is infinitely recyclable, not all waste glass is suitable for remanufacture into new products. Challenges such as limitations in sorting technology, contamination, mixing with other waste, and the collection process with heavy equipment hinder effective recycling. Consequently, large quantities of waste glass remain in stockpiles or are sent to landfills.

In alignment with the Australian Government's circular economy initiatives, researchers have explored the potential use of recycled glass (RG) in concrete production, pavements, geomaterials, and fill materials [6, 7]. RG exhibits engineering properties similar to those of natural sand, offering a sustainable alternative that can divert waste glass from stockpiles and landfills [8].

However, RG alone does not fully meet the performance requirements for geotechnical applications. RG is typically limited to a maximum of 30% replacement and needs to be blended with high

quality aggregate or binders to achieve the necessary strength.

Portland cement is a commonly used binder to enhance the properties of materials [9]. Cement has gained favor in the construction industry for years. This is because of its versatility, strength, availability and cost effectiveness. Therefore, this study aims to evaluate the geotechnical performance of RG stabilized with cement.

RESEARCH SIGNIFICANCE

To align with the Australian Government's circular economy strategy, waste materials should be redirected from stockpiles or landfills and repurposed to be construction materials. The significance of this research lies in two key aspects: (1) the use of 100% RG as the primary material, and (2) the incorporation of cement to improve the strength and stiffness of recycled glass.

MATERIALS

RG was sourced from a local recycling facility in Victoria, Australia. The pre-wetted RG sample was oven-dried at 105 ± 5ºC for 24 hours. After drying, the bulk sample was reduced using a riffle splitter to obtain a smaller, representative portion for testing. RG had an angular shape, contributing to high interlocking effect within the samples, as shown in Fig. 1 (a) and (b).

Fig. 1 (a) RG physical appearance; (b) SEM image

The particle size distribution (PSD) of RG is also shown in Fig. 2. The maximum particle size was 4.75 mm, and the sample predominantly consisted of sand-sized particles. Based on the coefficients of uniformity (Cu=7.0) and curvature (Cc=1.08) as presented in Table 1, the RG was classified as well-graded sand. However, the PSD of RG fell outside the upper and lower bounds of the specification, making RG unsuitable for pavement applications in untreated form.

Cement was utilized as the binder to enhance properties of RG specimens. In this study, cement content of 3% and 5% by dry weight were used in accordance with specification set by the local authority, VicRoads [10]. A minimum curing period of seven days was adopted, as specified.

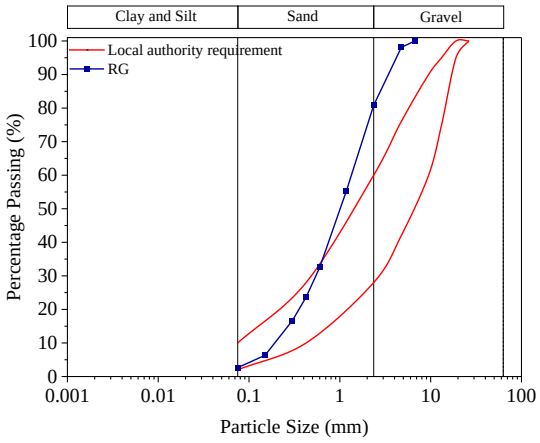

Fig. 2 PSD of RG.

Table 1 Properties of RG

Properties	RG	Standard
D_{10}	0.20	AS 1726 [11]
D_{30}	0.55	AS 1726 [11]
D_{60}	1.40	AS 1726 [11]
C_u	7.00	AS 1726 [11]
C_c	1.08	AS 1726 [11]
Fine content (%)	2.66	AS 1726 [11]
Classification	SW	AS 1726 [11]
CBR (3% cement)	150	AS 1289.6.1.1 [16]
CBR (5% cement)	303	AS 1289.6.1.1 [16]

METHODS

PSD analysis was conducted using a mechanical shaker, in accordance with AS 1289.3.6.1 [11]. A 2 kg sample was placed in shaker and processed for a minimum of 15 minutes. Maximum dry density (MDD) and optimum moisture content (OMC) were determined following the procedure outlined in AS 1289.5.2.1 [12]. Each blend, RG+3% LCC and RG+5% LCC, was compacted in five layers into a standard steel mould using modified compaction effort. The determined OMC and MDD values for each blend were subsequently used to prepare specimens for the California Bearing Ratio (CBR) test, conducted in accordance with AS 1289.6.1.1 [13]. For each blend, two CBR samples were prepared and submerged in water for 96 hours or four days, prior to testing to simulate the worst-case scenario.

Unconfined compression strength (UCS) testing, a standard method for evaluating the strength of stabilized materials, was used to identify the optimum blend. UCS specimens were prepared using a split metal mould with dimensions of 50 mm in diameter and 100 mm in height (a diameter-to-height ratio of 1:2), following the relevant ASTM D2166 [14]. Samples were compressed at respective MDD and

OMC values and cured at room temperature for seven days.

Resilient modulus (M_R) was performed in accordance with AASHTO T307-99 using repeated loading test machine (RLT) [15]. The RLT sample was prepared at the MDD and OMC and was cured at room temperature for seven days. Only the optimum blend (RG+5% cement) was prepared. The sample had dimensions of 100 mm in diameter and 200 mm in height.

RESULTS AND DISCUSSION

MDD of unbound RG was found to be 1.85 Mg/m^3, with an OMC of 9.80%. It is noticed that at lower water contents, a slight reduction in MDD was observed, followed by a gradual increase in MDD as the water content increased. This behavior is attributed to the capillary forces present in the pore water of RG particles [16]. Unbound RG alone does not satisfy the standard requirements for geotechnical applications and therefore requires stabilization [17].

Fig. 3 illustrates the compaction curves of both unbound and RG stabilized with cement blends. Among all the blends, unbound RG exhibited the lowest MDD and OMC, while the RG containing 5% cement gained the highest MDD and OMC values. A summary of MDD and OMC for all blends is presented in Table 2. Increasing the cement content from 3% to 5% resulted in higher MDD and lower OMC values. This improvement is due to the fine particles of cement filling the voids between RG particles, thereby enhancing density and reducing the moisture required for optimal compaction.

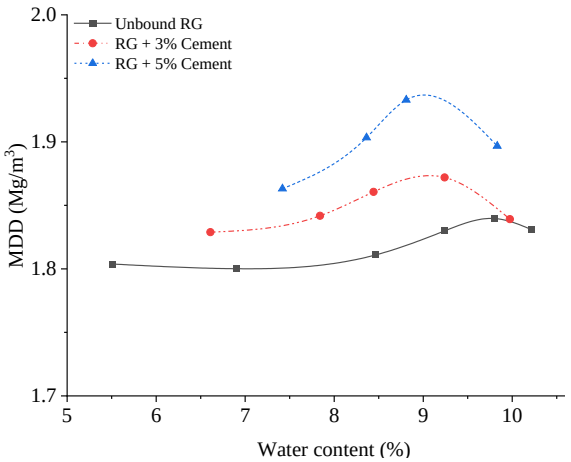

Fig. 3 Compaction curves of RG and RG + cement.

Table 2 summary of compaction properties of RG.

Samples	MDD (Mg/m3)	OMC (%)
Unbound RG	1.85	9.80
RG +3% cement	1.87	9.24
RG +5% cement	1.93	8.81

Fig. 4 shows the UCS values for RG stabilized with 3% and 5% cement. Since there is no standard requirement for UCS for granular or sand columns, the benchmark strength was adopted from specification for soil-cement columns used in soft soil, which is reported to be 600 kPa [18, 19]. This value was used as the standard reference strength for evaluating RG stabilized with cement in this study.

As RG is a cohesionless material, it was not possible to obtain a UCS value for unbound RG. The RG+3% cement blend exhibited a relatively low UCS of 76 kPa, which is significantly below the required standard. However, increasing the cement content to 5% resulted in a substantial improvement, with a UCS value of 610 kPa, which is slightly exceeding the target strength of 600 kPa [18]. In general, increasing the cement content led to an increase in UCS values. Nevertheless, for geotechnical applications, cement content is typically limited to a maximum of 6% [10]; thus, the present study restricted to cement dosage to 5%.

The significant improvement in UCS for the cement-stabilized RG samples is attributed to the hydration process of the cement. The hydration products act as a binding agent between RG particles, thereby enhancing the structural integrity and compressive strength of the mixture.

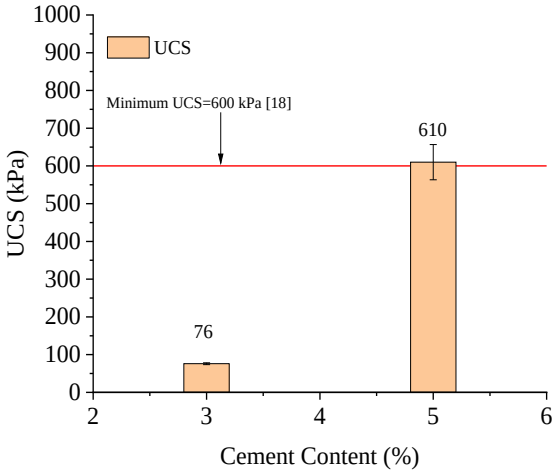

Fig. 4 UCS values of RG stabilized with cement.

Fig. 5 showed the CBR values of RG stabilized with cement after 96 hours under the water. The RG samples stabilized with 3% cement achieved a CBR of 150%, which is significantly higher than the 42-46% reported for unbound RG in previous studies [7, 16]. This indicates that RG stabilized with small amount of cement is sufficient to meet the minimum CBR requirements for base layer materials of 100% [20]. Increasing the cement content to 5% further enhanced the CBR, with the RG+5% cement blend reaching a value of 303%, more than double that the 3% cement blend. No swelling was observed in any

of the samples following the 96-hour submersion period.

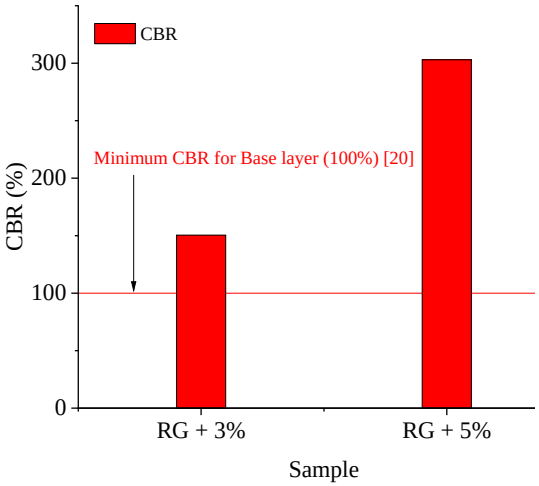

Fig. 5 CBR values of RG stabilized with cement.

Fig. 6 showed M_R of RG stabilized with 5% cement. The RLT test was carried out to investigate the elastic response of the material under cyclic loading. This assessment was performed only with the blend that met the required specifications. A total of 15 load sequences were applied during the test. As shown in Fig. 5, the M_R gradually increased with each load sequence, ranging from 191 MPa to a maximum of 461 MPa. This increase reflects the enhanced strength of RG+5% cement, demonstrating the ability to resist axial stress under repeated loading.

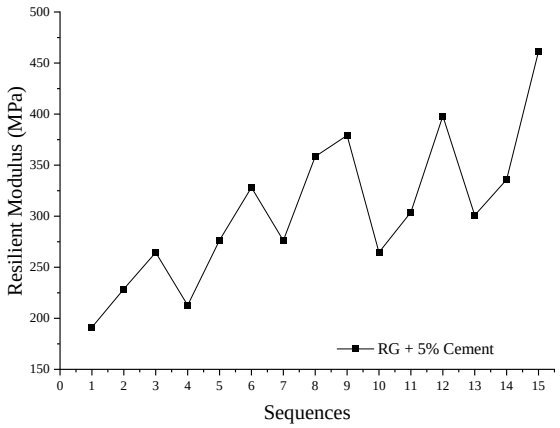

Fig. 6 Resilient modulus of RG+5% cement.

CONCLUSION

This study investigated the geotechnical properties of recycled glass (RG) stabilized with cement for potential use in ground improvement applications. The keys findings are summarized below:

1. MDD increased with higher cement content, while OMC decreased. This is attributed to the fine particles of cement filling the voids between RG particles, resulting in increased density and reduced pore water content.
2. UCS values of RG stabilized with 5% cement achieved a UCS of 610 kPa after seven days of curing. In contrast, the 3% cement blend did not result in a significant gain in strength.
3. CBR for both RG stabilized with 3% and 5% cement blends exceeded the minimum requirements for road base layers, indicting their suitability for use in pavement construction.
4. Resilient modulus (M_R) of RG stabilized with 5% cement blend ranged from 191 MPa to 461 MPa under cyclic loading, indicating good elastic performance.

PRACTICAL APPLICATION OF GEOLOGICAL STRENGTH INDEX FOR EXCAVATABILITY ASSESSMENT

John Victor Smith[1,2]

[1]School of Engineering, RMIT University, Australia; [2]CMW Geosciences, Australia

ABSTRACT

The geological strength index (GSI) has become a prominent method of defining the condition of rock mass for various purposes. The GSI method was developed based on having a visual appreciation of the rock mass conditions, in particular the pattern of naturally occurring fractures (discontinuities) and also observations of the frictional conditions of the discontinuity surfaces. Excavatability assessment is typically needed for conditions where the material cannot be readily observed other than from isolated locations such as boreholes or trial excavation pits. In this paper an appraisal of the structure (blockiness) and surface conditions (interface friction) categories of the GSI method is presented. Methods for quantifying and categorizing field observations in terms of the GSI framework are collated and reviewed. The structure rating can be quantified with reference to joint set spacing and appreciation of the three-dimensional aspects of joint patterns relative to the direction of drill hole investigations. The surface condition rating can be obtained by field observations and by laboratory testing. The GSI method incorporates an approximation aspect that can lead to a low level of clarity in its application. By outlining the practical ways that rock mass observations can be assessed and quantified the use of GSI in excavatability assessment can be enhanced.

Keywords: Geological strength index, GSI, Excavatability, Rippability

INTRODUCTION

A prominent excavatability assessment method is that of Pettifer and Fookes [1] which is based on a chart with an x-axis based on rock strength (specifically, the point load index) and a y-axis based on the spacing of natural fractures (discontinuities). Discontinuities were considered 'effective' [1] where they 'clearly formed planes on which rock blocks could be dislodged, and were therefore persistent on the scale of individual blocks' [1]. They excluded 'joint planes healed by … mineralization and poorly defined bedding planes which simply represented a change in lithology' [1]. The Pettifer and Fookes method also emphasized that the discontinuity spacing must be considered in three-dimensions even when the data is collected in a single direction. The method also includes an adjustment factor of up to 50% for the spacing parameter based on the favorability of the discontinuity pattern and orientation of discontinuities [1].

The geological strength index (GSI) has become a prominent method of defining the condition of rock mass for various purposes [2-6]. GSI was developed based on having a visual appreciation of the rock mass conditions [2]. The GSI system has also been applied to excavatability assessment [7,8]. Excavatability assessment is typically needed for conditions where the material cannot be readily observed. Geophysical methods are complementary to GSI however, the GSI rating may be restricted to isolated observations from boreholes. A range of studies over many decades have proposed methods of excavatability assessment [9-15].

In this paper an appraisal of the structure (blockiness) and surface conditions (interface friction) categories of the GSI method as applied to excavatability assessment [7,8] is presented. Methods for quantifying and categorizing field observations in terms of the GSI framework are collated and reviewed.

The structure rating can be quantified with reference to joint set spacing and appreciation of the three-dimensional aspects of joint patterns relative to the direction of drill hole investigations. The surface condition rating can be obtained by field observations and by laboratory testing.

The GSI method incorporates an approximation aspect that can lead to a low level of clarity in its application. By outlining the practical ways that rock mass observations can be assessed and quantified the use of GSI in excavatability assessment can be enhanced.

RESEARCH SIGNIFICANCE

This paper reviews the practical issues related to applying the GSI methodology to excavatability. The paper does not review the accuracy of the published GSI chart with respect to the outcomes of such assessments. Excavatability assessment is often carried out based on limited investigation data. Geophysical methods are well established but they require corroboration with direct geotechnical

observation. Direct geotechnical observation can also contribute to awareness of the abrasive character of materials. Excavatability assessments are the basis of some very significant decision-making around the selection of equipment. Whether this is at a conceptual stage or feasibility stage of a site study the financial implications of the excavatability assessment can be very significant. The link between field data and GSI application as outlined in this paper plays an important role in the quality of the assessment.

GEOLOGICAL STRENGTH INDEX (GSI)

Categorical Assessment

The GSI method originated from a grid of descriptive categories. The terminology of the descriptions was carefully framed to address observable features that influence rock mass behavior [2].

Quantitative Assessment

GSI values

The grid of descriptive categories in the GSI method is overlaid with oblique lines representing GSI values from 0 to 100. These values increase from bottom right of the chart to the top left of the chart. This quantification is a way of showing how different features of a rock mass may combine to produce conditions which may be similar in a geotechnical sense (e.g. excavatability) while being very different in a geological sense [2].

Quantification of chart axes

While the GSI chart originated based on descriptive categories, various researchers have attempted to quantify the axes of the chart. These attempts at quantification cannot be assumed to over-ride the descriptive nature of the categories as originally defined. Methods of quantification for the y-axis of the chart (structure) include RQD [16], fracture spacing [17] and block volume [17]. These methods are not directly comparable [19,20] so cannot be applied without careful consideration of other factors such as block shapes (Fig.1)[21].

Determining block shape from borehole data has been addressed by various researchers including the current author [22]. A review of gneiss, for example, showed that some gneisses are schistose with a tabular block shape while others are equidimensional indicating that the gneissic banding was not a significant weakness in the rock [23].

Structure Categories

The GSI chart has six categories defining the y-axis as summarized in Table 1.

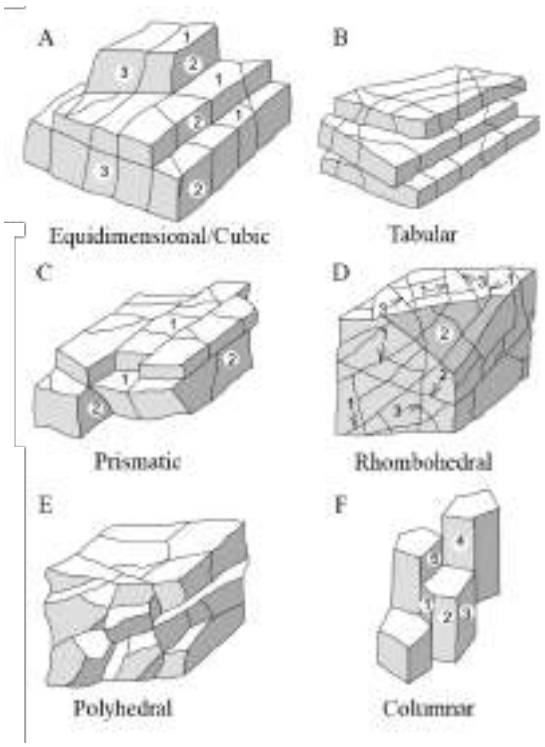

Fig.1 Block shapes [21]

Table 1 GSI Structure Categories

Category	Name	Description
S1	Intact or massive	Intact rock specimens or massive in situ rock with few widely spaced discontinuities
S2	Blocky	Well interlocked undisturbed rock mass consisting of cubical blocks formed by three intersecting discontinuity sets
S3	Very Blocky	Interlocked partially disturbed mass with multi-faceted angular blocks formed by 4 or more joint sets
S4	Blocky/ disturbed/ seamy	Folded with angular blocks formed by many intersecting discontinuity sets. Persistence of bedding planes or schistosity
S5	Disintegrated	Poorly interlocked, heavily broken rock mass with mixture of angular and rounded rock pieces
S6	Laminated/ sheared	Lack of blockiness due to close spacing of weak schistosity or shear planes

The descriptions indicate that a blocky rock mass

has equidimensional/cubic blocks shapes whereas a very blocky rock mass would correspond to the polyhedral block shape. The tabular, prismatic and rhombohedral block shapes are defined by three joint sets but would be difficult to assign into a structure category based on borehole data.

Discontinuity Condition Categories

There are five discontinuity categories forming the x-axis of the GSI chart (Table 2). Various attempts at quantifying this parameter have been proposed [16-18].

Table 2 GSI Discontinuity Condition Categories

Category	Name	Description
D1	Very good	Very rough, fresh unweathered surfaces
D2	Good	Rough, slightly weathered, iron stained surfaces
D3	Fair	Smooth, moderately weathered and altered surfaces
D4	Poor	Slickensided, highly weathered surfaces with compact coatings or fillings or angular fragments
D5	Very poor	Slickensided, highly weathered surfaces with soft clay coatings or fillings

Excavatability Types

Four excavatability types are defined on the GSI charts. These are blasting, hammer, ripping and digging. Hammer is labelled 'and blasting' to indicate that blasting can be used for this material. The excavatability types do not strictly follow GSI values. At various parts of the chart the excavatability type fields cross GSI lines and follow structure category boundaries. Therefore, the excavatability types are not uniquely defined by GSI values.

Excavatability Assessment

The GSI has been divided into four excavatability method fields with boundaries formed by GSI lines and in some areas structure category boundaries. Some excavatability fields overlap the cells defined by the GSI chart categories. The excavatability assessment can be made by firstly, selecting one of the two charts according to the point load index strength. Secondly, establish a structure category (S1-6) followed by a discontinuity condition category (D1-5). The excavatability assessment outcomes, including the GSI value separating two excavatability types within one cell of the chart, are summarized in Table 3.

Table 3 GSI Chart Excavatability Assessment

Str. Cat.	I_{s50} < 3MPa	$I_{s50} \geq$ 3MPa
S1	D1-3 Blasting	D1-3 Blasting
S2	D1 Blasting	D1 Blasting
	D2 Blasting(65)Hammer	D2-3 Blasting(60)Hammer
	D3 Hammer(55)Ripping	D4 Hammer(45)Ripping
	D4-5 Ripping	D5 Ripping
S3	D1 Blasting(70)Hammer	D1-2 Blasting(60)Hammer
	D2 Hammer(55)Ripping	D3 Hammer(45)Ripping
	D3-4 Ripping	D4-5 Ripping
	D5 Ripping(25)Digging	
S4	D1 Hammer(55)Ripping	D1 Blasting(60)Hammer
	D2 Ripping	D2 Hammer(45)Ripping
	D3 Ripping(35)Digging	D3-4 Ripping(30)Digging
	D4-5 Digging	D5 Digging
S5	D1 Ripping	D1-2 Ripping
	D2-3 Ripping(35)Digging	D3 Ripping(30)Digging
	D4-5 Digging	D4-5 Digging
S6	D3-5 Digging	D3-5 Digging

Note: Str.Cat. = Structure category. S1 with D4-5 and S6 with D1-2 are designated 'not applicable'. GSI values at boundaries are in brackets.

FIELD EXAMPLE

The Triassic age mudstone and sandstone of the Torlesse beds in the Wellington area of New Zealand were assessed to be typically rippable at required depths of excavation due to the fracture spacings present [24]. As was noted in that study, boreholes cannot provide information on persistence of discontinuities and can also result in directional bias related to discontinuity orientation. Therefore, it is necessary to conduct field observations during initial excavation to confirm any assessment based on borehole data.

The Wellington area is notable for the presence of bedded and faulted rocks. Boreholes are needed to overcome the lack of outcrop in the area. Boreholes (and televiewer) can be good at characterizing bedding and sheared zones which they penetrate as these features tend to be continuous and can be correlated between boreholes in a way that individual discontinuities generally cannot [24].

It is helpful to identify domains or sub-areas with relatively homogeneous properties. These domains are often related to structures such as folding and faulting or changes in rock types. It is also necessary to apply knowledge of scalable parameters. For example, a thick zone of infill in a discontinuity or fault implies greater length of that structure than a similar structure with a thin infill [24].

Field exposures of the soil and rock show the typical characteristics of the area (Fig.2). Within about 2 m of the land surface the ground is rocky with

close-spaced fracturing (Fig.2 A and B). Deeper down the rock mass has more widely spaced discontinuities (Fig.2C).

The sandstone at these locations typically has a point load index greater than 3 MPa, however the observed structure and discontinuity conditions have been plotted on both GSI excavatability charts (Fig.3). The assessments are labelled on Fig.3 according to the relevant parts of Fig.2. The shallow highly fractured rock (Fig.2 A,B) would overlap the digging and ripping fields for lower strength rock (I_{s50}<3 MPa) but would be in the ripping field for higher strength rock ($I_{s50}\geq$3 MPa).

Fig.2 Outcrops showing features relevant to excavatability (Makara, New Zealand)

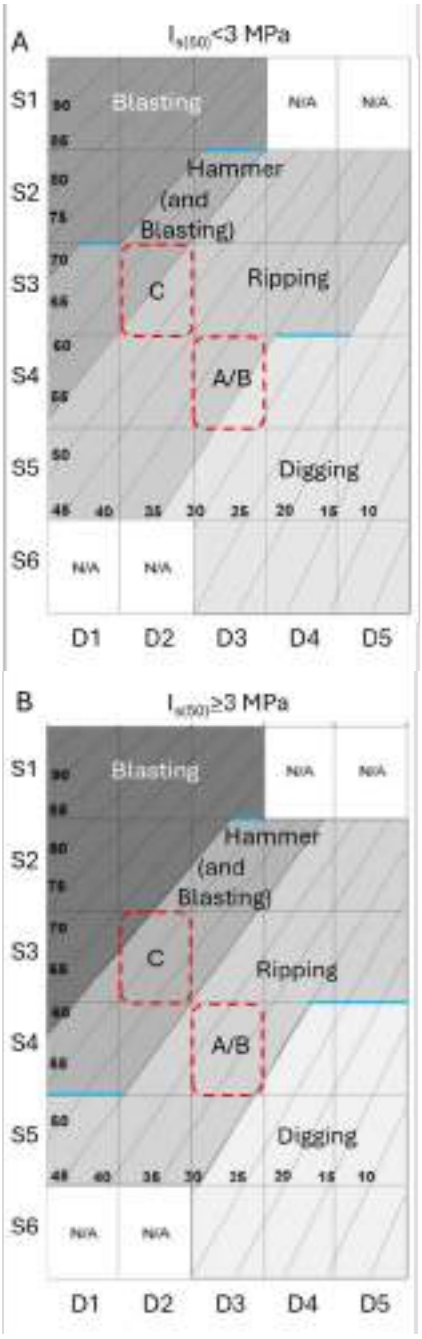

Fig.3 GSI chart showing example excavatability classification [7,8]. Blue lines highlight boundaries based on structure categories not GSI values

CONCLUSIONS

The Geological Strength Index (GSI) chart has been applied to excavatability assessment. The accuracy of the chart for excavation equipment selection has not been evaluated here. The composition of the GSI chart has been reviewed in detail, in particular the parameters used to define the categories on the x and y axes of the chart.

Data from cored boreholes and down-hole televiewers can be used to collect the relevant

parameters. The y-axis is related to the three-dimensional pattern of discontinuities in the rock mass and therefore may require input beyond the boreholes themselves. The additional input may come in the form of geological mapping in the area of interest and regional knowledge of the typical geological structures. Knowledge of the local rock types and the typical patterns of jointing and other discontinuities that form the rock mass will also be required to correctly ascertain the y-axis category on the GSI chart.

Establishing a GSI value to represent a rock mass requires firstly that the rock mass is assigned to the categories on the x and y axes of the chart. The method of excavatability assessment using the chart has fields for various excavation equipment types which generally follow the GSI lines of the chart but not at all parts of the chart. All the equipment type fields on the chart include some boundaries that follow the structure categories rather than the GSI values. Therefore, the GSI value alone is not sufficient to assign an excavatability type. It is more appropriate to use the categories defining the chart to identify 'cells' on the chart that are representative of a rock mass. Some of these cells overlap two equipment type fields meaning that the GSI chart implies such a rock mass is marginal to the excavation methods indicated.

ABSTRACT

Slope failures often happen when earthquakes. The 2024 Noto Peninsula Earthquake in Japan caused a many slopes failure over a wide area and high-density distribution. First, this study presented characteristics of slope failure distribution of the above recent earthquake, that is, this study clarified relationship between slope failure distribution and primary causes (i.e. factor of slope failure hazard). In addition, this study suggested earthquake-induced slope failure potential mapping method based on watershed unit in the Noto Peninsula district in Japan using analytic hierarchy process (AHP) method and geographic information system (GIS). An earthquake-induced slope failure risk assessment system used here is based on landslide distributions (NIED, Japan) in the Hida belt district including the Noto Peninsula district, Japan. We considered the relationship between landslide distribution and factors of landslide hazard (elevation, slope angle, slope type, flow accumulation, geology and vegetation). These relations are introduced to pairwise comparisons of factors in the AHP method. Slope failure potential rank is evaluated based on AHP. An earthquake-induced slope failure potential map is created based on the slope failure potential rank of 1 to 10. In this full paper, an evaluation of earthquake-induced slope failure potential using AHP method and GIS will be presented based on our analyzed data.

Keywords: Slope failure potential mapping, watershed, AHP, The 2024 Noto Peninsula Earthquake

INTRODUCTION

At 16:10 JST on January 1, 2024, an earthquake with a magnitude of 7.6 and a maximum seismic intensity of 7 struck the Noto Peninsula in Ishikawa Prefecture [1]. The earthquake triggered many slope failures throughout the region (Fig. 1). According to landslide and sediment distribution data provided by the Geospatial Information Authority of Japan (GSI) [2], the earthquake triggered 2345 slope failures. Several studies have reported the characteristics and causes of slope failures [3-5]. However, the mechanisms of earthquake-induced slope failures must be further clarified to develop effective hazard assessment methods, predict runouts using numerical simulations, and prioritize disaster mitigation measures. Similar to other major earthquakes of the 21st century, such as the 2018 Hokkaido Eastern Iburi, 2016 Kumamoto, 2008 Iwate-Miyagi Nairiku, and 2004 Mid-Niigata Prefecture earthquakes, earthquake-induced slope failures tend to occur over wide areas with high density. Although implementing preventive measures on all slopes would be ideal, such an approach would be inefficient and financially unfeasible. Therefore, slopes with a high potential for seismic landslides must be identified, and investigations and countermeasures must be prioritized accordingly.

Kohno et al. [6] proposed a landslide hazard mapping method for the Chugoku region of Japan

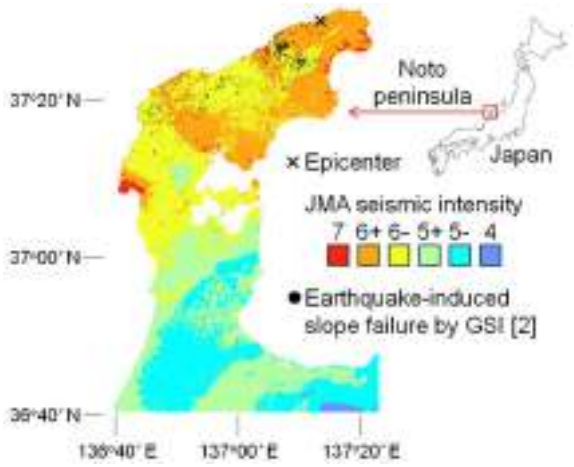

Fig. 1 JMA Seismic intensity distribution of the 2024 Noto Peninsula earthquake in Japan and distribution of earthquake-induced slope failure by the GSI [2].

using the Analytic Hierarchy Process (AHP) and Geographic Information System (GIS) methods. Their approach aimed to extract slopes with hazard levels equivalent to those on which past slope movements occurred. In the pairwise comparisons used in the AHP, they introduced quantified relationships between the database of landslide distribution maps [7] and the evaluation criteria. The resulting hazard maps demonstrated the effectiveness of identifying unstable slopes. Fig. 2A shows the

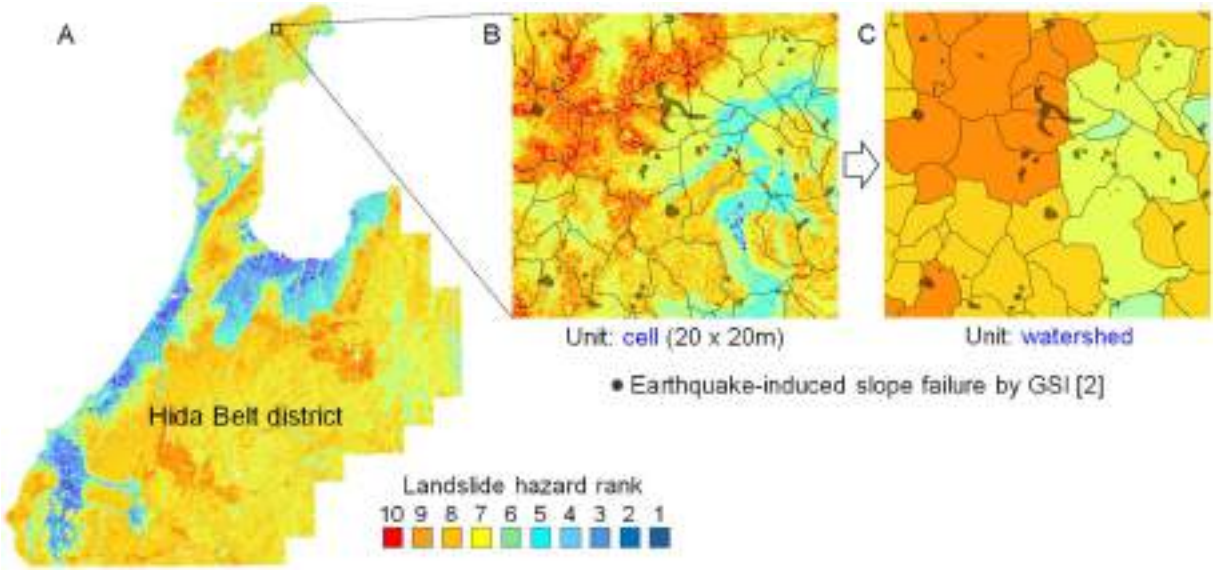

Fig. 2 Representative landslide hazard map of the Hida Belt district (A). Panels B and C show the cell and watershed units, respectively.

application of Kohno et al.'s method [6] to the Hida Belt region [8], which includes the areas affected by the 2024 Noto Peninsula earthquake. As illustrated in Fig. 2B, slope failures predominantly occurred in areas with relatively high hazard ranks. This method, which is based on 20 m mesh cells, allows for a detailed assessment of landslide hazards at the cell level in a given region. However, because of the complex mixture of high- and low-hazard cells in close proximity, assessing the hazards of landslides at varying scales or determining clear priorities for investigation and countermeasures is not always straightforward.

In this study, we examined the distribution characteristics of slope failures triggered by the 2024 Noto Peninsula earthquake. We then applied the AHP- and GIS-based cell-unit hazard mapping methods proposed by Kohno et al. [6, 9] to the affected region to explore the relationship between the landslide hazard ranks and observed slope failures. Finally, based on the cell-level hazard ranks (Fig. 2B), we proposed and tested a method for estimating watershed-level landslide hazard ranks (Fig. 2C).

METHODOLOGY

Overview of landslide hazard mapping using the AHP method

First, based on a database of landslide distribution maps [7] in the Hida Belt [8] region, we investigated the relationship between landslide-prone areas and evaluation factors and elements, specifically the area ratio between them. In this study, we prioritized factors that are easy to obtain and have high general applicability. Accordingly, six evaluation factors were selected for landslide hazard assessment using the AHP at hierarchy level 1: elevation, slope angle, slope type, flow accumulation, geology, and vegetation. Based on these evaluation factors, a hierarchical system was developed to assess landslide hazards. Within this system, importance weights were first calculated among the elements at hierarchy level 2 and then among the evaluation factors at hierarchy level 1. Although conventional AHP methods typically rely on subjective expert judgment for pairwise comparisons, our method quantifies the relationships between landslide-prone geomorphology and elements and uses these values to objectively derive the importance weights. A landslide hazard score was assigned to each evaluation factor using the calculated importance weights for each hierarchical level. These scores were then summed using a GIS to create a landslide hazard map. For further methodological details, please refer to previous studies [6, 9, 10]. Based on the cell-unit landslide hazard map, we reconstructed a landslide hazard map at the watershed-unit scale. To represent the hazard level of each watershed, we tested three approaches: the average hazard rank of all cells within the watershed, the maximum hazard rank, and the proportion of high-hazard cells. As in Kohno et al. [9], the study area was defined based on the geotectonic subdivisions of the Japanese Archipelago [8], focusing on the Hida Belt region, which includes areas affected by the 2024 Noto Peninsula earthquake (Fig. 2A). Notably, most slope failures were concentrated in areas that experienced instrumental seismic intensity of 5.5 or higher, primarily in the Noto Peninsula. Therefore, the subsequent analysis is limited to areas with seismic intensity ≥5.5, as extracted using the QUIET+ (QUick Identification of Earthquake Threat PLUS) system [11].

Overview of the data used in this study

ArcGIS Pro (ESRI) was used as the GIS software platform. The database of landslide distribution maps was obtained from the landslide geomorphology GIS dataset published by the National Research Institute for Earth Science and Disaster Resilience (NIED) [7]. Because the sizes of mapped landslide features vary greatly, we did not treat each mapped landslide as a single cell. Instead, we focused on the moving body portion of each landslide (polygon data), which was converted to raster format for analysis. As the minimum unit of raster cells is 20 m, the boundaries of landslide features appeared jagged due to rasterization. Note that scarp lines (line data), which lack area information, were excluded from the analysis. Topographic data were obtained from the 10 m mesh Digital Elevation Model (DEM) provided by the Geospatial Information Authority of Japan [12]. Surface analysis was conducted using a GIS to generate maps of elevation, slope angle, slope type, and flow accumulation for the study area. Geological data were taken from the 1/200,000 Japan Seamless Geological Map [13]. Vegetation data were obtained from the 1/50,000 existing vegetation map compiled between 1979 and 1998 by the Biodiversity Center of Japan, as part of the basic survey on natural environmental conservation [14].

RESULT AND DISCUSSION

Relationship between slope failures and evaluation factors

For each classification domain of the evaluation elements, the slope failure area (SA, expressed as the number of raster cells) and proportion of slope failure area within each domain (SAp [%], slope failure area

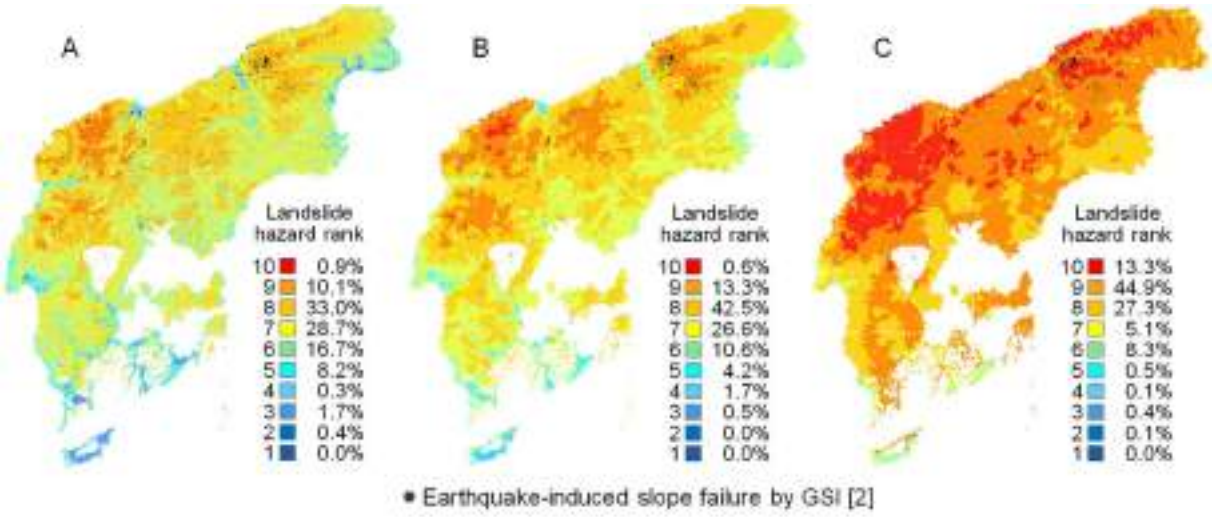

Fig. 4 Representative examples of landslide hazard maps in the Noto Peninsula district in Japan. A: cell unit (same as Fig. 2A), B: watershed unit (average value of cell unit hazard rank within the watershed), C: watershed unit (maximum value of cell unit hazard rank within the watershed).

occupancy) were calculated. The relationships between the distribution of slope failures caused by the 2024 Noto Peninsula earthquake and evaluation factors are shown in Fig. 3.

As shown in Fig. 3A, the SA was the highest in the elevation range of 0 to 200 m and tended to decrease with increasing elevation. However, the SAp did not significantly vary across different elevation ranges. Notably, slope failures were not observed at elevations above 600 m. Fig. 3B shows that the SA was the most prominent in the slope angle range of 20 to 40°. In contrast, the SAp tended to increase as the slope angle increased. Notably, although the SA was very small in the 50 to 70° range, the SAp was remarkably higher than that of other slope angle classes. According to Fig. 3C, the SA was the highest on concave ridge-and convex valley-type slopes, followed by convex ridge-and concave valley-type slopes. Very few slope failures occurred on the other slope types. Although the differences in SAp among these four slope types were not large, they all exhibited higher SAp values than the others. This indicates a strong correlation between the landslide-prone geomorphology and slope type. Fig. 3D shows that the SA generally decreases as the flow accumulation increases, excluding the flow accumulation value of 36. However, a clear trend in SAp was not observed across different flow accumulation classes. As shown in Fig. 3E, the SA was the highest in areas of Neogene volcanic rocks, followed by Neogene sedimentary rocks. In terms of SAp, slope failures were most frequently observed in areas of Quaternary sedimentary rocks, Neogene volcanic rocks, Cretaceous sedimentary rocks, and Jurassic intrusive rocks. These observations suggest a strong relationship between geological units and slope failure distribution. Fig. 3F reveals that the SA was the highest in areas classified as substitutional communities in the Camellietea japonica region, followed by plantation and cultural land. Moreover, the SAp was relatively high in areas classified as natural vegetation in the Fagaetea crenate region and exhibited substitutional communities in the Fagaetea crenate region. No slope failure was observed in the natural vegetation of the Vaccinio-Piceetea region.

Comparison between cell-based and watershed-based unit landslide hazard mapping

Fig. 4 shows three types of landslide hazard maps for the Noto Peninsula. Fig. 4A shows that most of the study area was occupied by hazard ranks of 6 to 8 according to cell-based units. Hazard ranks 9 and 10 were primarily concentrated in the eastern part of the region. Fig. 4B shows that the watershed-based unit distribution pattern was similar to that shown in Fig. 4A. However, areas with hazard ranks of 8 or higher occupied the majority of the map according to watershed-based units (Fig. 4C). The relationship between the landslide hazard rank and slope failure distribution resulting from the 2024 Noto Peninsula earthquake is shown in Fig. 5, and the corresponding ROC curves are presented in Fig. 6. In Figs. 4A and 4B, the SAp generally increased with hazard rank, peaking at rank 8 or 9 and then declining at rank 9 or 10. This indicates that earthquake-induced slope failures did not necessarily occur in areas with the highest hazard ranking. However, the AUC values showed that watershed-based units (Fig. 4B) outperformed cell-based units (Fig. 4A) in terms of predictive capability. In contrast, in the example shown in Fig. 4C, the SAp increased consistently with the hazard rank, suggesting a good correspondence between the hazard map and actual slope failure distribution. Notably, most slope failures occurred within watersheds classified as hazard rank 10,

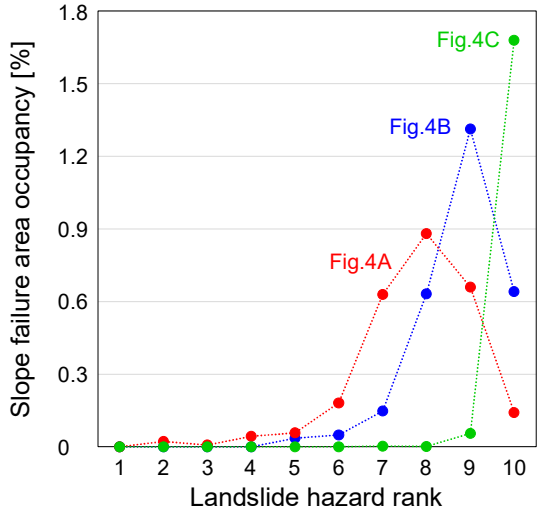

Fig.5 Relationship between landslide hazard rank and slope failure area occupancy.

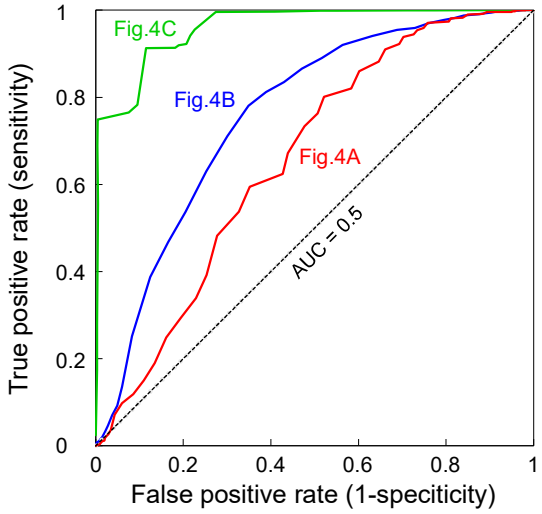

Fig.6 ROC curves for Fig. 4.

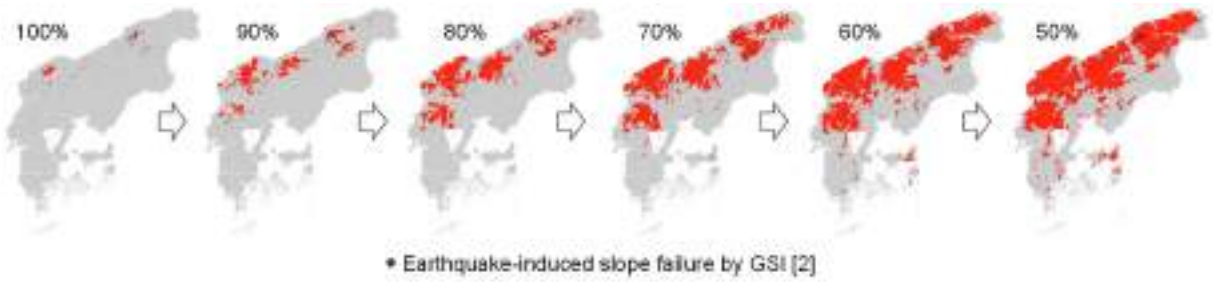

Fig. 7 Example of a watershed (red area) extraction with 100% to 50% of the watershed having a hazard rank of 8 or higher.

resulting in high AUC values. Although the relationship in Fig. 5 and the AUC value in Fig. 6 suggest that Fig. 4C provides the best representation of slope failure distribution, this may be attributed to the fact that high-hazard rank areas occupy a large portion of the study area in this case. Therefore, it was difficult to definitively determine the most appropriate mapping method for this stage. In the next section, we examine a method of determining the hazard rank of each watershed based on the proportion of high-hazard cells within it.

Landslide hazard mapping based on the proportion of high-risk cells within each watershed

Fig. 7 illustrates an example of a watershed where 100 to 50% of the constituent cells were classified as having a hazard rank of 8 or higher. The figure shows that the number and distribution of the extracted watersheds vary depending on the proportion of high-rank cells. Similarly, we extracted watersheds containing 100 to 50% of cells ranked 6 or higher, 7 or higher, ..., and 10 or higher and analyzed their correspondence with actual slope failures (Fig. 8). In

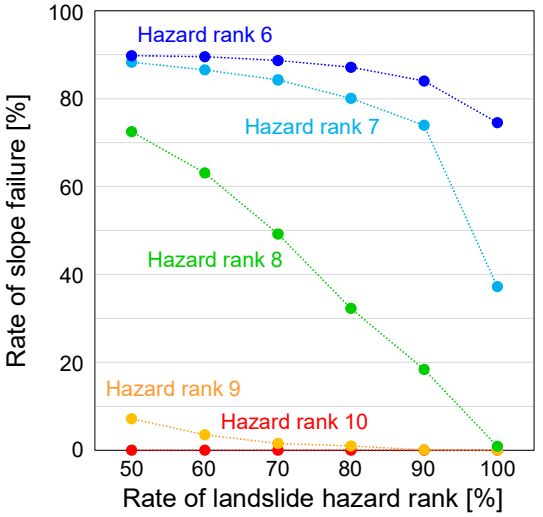

Fig.8 Relationship between the rate of landslide hazard rank and rate of slope failure.

Fig. 8, the vertical axis represents the percentage of slope failures occurring within the extracted watersheds. A value of 100% indicates that all slope failures in the study area were located within those watersheds. For hazard ranks 9 and 10, the extracted

watershed areas were limited, resulting in low slope-failure capture rates. For ranks 6 and 7, the capture rates were approximately 80%, except when the cell ratio was 100%. This result likely reflects the fact that many watersheds were extracted, covering most of the study area. Interestingly, in the case of a hazard rank of 8 or higher, a good correspondence was observed between the proportion of high-hazard cells and the slope-failure occurrence rate. Specifically, when extracting watersheds where 80% or more of the cells were ranked 8 or higher, approximately 30% of the slope failures from the 2024 Noto Peninsula earthquake could be captured within those areas.

CONCLUSION

In this study, we conducted landslide hazard mapping at the watershed scale based on cell-based landslide hazard rankings for areas affected by seismic landslides triggered by the 2024 Noto Peninsula earthquake. We examined three representative methods for assigning hazard ranks to watersheds that used the average, maximum, and proportion of hazard ranks within each watershed. Although some challenges remain, our results indicated that under certain conditions, the proportion of high-hazard cells is strongly correlated with the occurrence rate of seismic landslides. Future work will focus on investigating the relationship between watershed selection criteria and the occurrence of seismic landslides, taking into account the influence of seismic motion.

ABSTRACT

This paper presents a study of liquefaction in Lhokseumawe, Indonesia, a topic of urgent importance due to the 2004 Andaman Earthquake (Mw 9.2) and the 2016 Pidie Jaya Earthquake (Mw 6.5). Evaluations of liquefaction potential were conducted in conjunction with particle size distribution analyses and data collected from three Cone Penetration Test (CPT) and three Standard Penetration Test (SPT) locations, which assessed the engineering characteristics and geological conditions of the area. Latitude and longitude coordinates from the sites of the hand-bore, SPT, and CPT tests were utilised to determine the peak ground acceleration (PGA) values associated with these two significant earthquakes. The analysis of liquefaction potential in Lhokseumawe, employing SPT and CPT data, utilised semi-empirical methods. The distribution of soil particle sizes played a crucial role in determining the potential for liquefaction. The findings indicate that the study area is primarily composed of poorly graded sand (SP) and well-graded sand (SW). Potential liquefaction sites were generally observed at a depth of 1 meter; however, significant liquefaction potential was also identified at depths of 15 and 18 meters below the surface. Overall, the results of this study emphasise the crucial importance of conducting preliminary investigations into soil liquefaction before commencing construction activities.

Keywords: Liquefaction Potential, Geology, Deep Liquefaction Potential, SPT, CPT

INTRODUCTION

Liquefaction is a critical geotechnical hazard that occurs when saturated, unconsolidated soils temporarily lose strength and stiffness in response to seismic shaking, resulting in significant ground deformation [1,2]. This phenomenon poses serious threats to infrastructure and human safety, particularly in seismically active regions with loose sandy soils and shallow groundwater tables. The 2004 Andaman earthquake, with a magnitude of Mw 9.2, and the 2016 Pidie Jaya earthquake, with a magnitude of Mw 6.5, are significant seismic events that have had a profound impact on the region and are crucial in understanding the liquefaction potential in Lhokseumawe. [3] The 2016 Pidie Jaya earthquake has underscored the vulnerability of various areas in Aceh Province, Indonesia, to earthquake-induced hazards, including liquefaction [4].

Lhokseumawe, a coastal city located in the northern part of Aceh Province, is situated within a geologically complex region characterised by recent alluvial and volcanic deposits. The area is located between two major tectonic features: the Sunda megathrust and the Sumatran fault system. These tectonic boundaries are known to generate significant seismic activity, raising concerns about the potential for liquefaction during future earthquakes.

Although several studies have examined regional seismic hazards in Aceh [5]. Considering the city's economic and strategic significance, a site-specific liquefaction analysis is not only necessary but could also significantly impact disaster preparedness and informed urban development. This study could provide crucial insights for disaster management professionals and urban planners.

The use of site investigation data is crucial in supporting the analysis of liquefaction. This is because soil resistance can play a significant role in enhancing liquefaction resistance. Otherwise, the cyclic stress from the earthquake could degrade the liquefaction resistance. Therefore, the information related to the site investigation data must be first known before conducting the liquefaction potential analysis.

This study aims to assess the liquefaction potential in Lhokseumawe through a combination of field and analytical approaches. The primary methods employed include Standard Penetration Test (SPT)-based analysis, utilising the simplified procedure developed by Seed et al. in 1985, which involves estimating the cyclic resistance ratio (CRR) based on the SPT data, and updated correlations from the Idriss and Boulanger method in 2008. The Cone Penetration Test (CPT)-based analysis employs the Robertson and Wride method of 1998, which assesses the soil behaviour type and liquefaction potential based on the CPT data.

Evaluation of the cyclic stress ratio (CSR) from site-specific seismic loading parameters, including peak ground acceleration (PGA) and earthquake magnitude. Calculation of the factor of safety (FS)

against liquefaction by comparing CSR and CRR.The insitu CRR was determined using SPT and CPT field tests. Data for this study were collected from subsurface investigations, borehole logs, and geotechnical reports, as well as regional seismic hazard data from the Meteorology, Climatology, and Geophysics Agency (BMKG) of Indonesia.

RESEARCH SIGNIFICANCE

The significance of the study lies in the importance of assessing liquefaction potential in the Lhokseumawe area beach. The area is characterised by a well-defined spatial arrangement, with industrial buildings clustered in designated zones, a centrally located government activity centre, and surrounding areas supporting diverse economic activities. The findings of this study could have a significant impact on the safety and resilience of these structures and activities.

GEOLOGY SETTING AND SEISMICITY

Seismic activity in the Lhokseumawe area has been influenced by major tectonic events, notably the 2004 Andaman earthquake and the 2016 Pidie Jaya earthquake. The impact of the 2004 Andaman earthquake was documented by [6], while the effects of the 2016 Pidie Jaya earthquake were reported by [7]. The epicentres of these earthquakes are plotted in Fig. 1. Lhokseumawe is located between the Sunda megathrust and the Sumatran fault system, within a basin composed of recent alluvial and volcanic deposits [8].

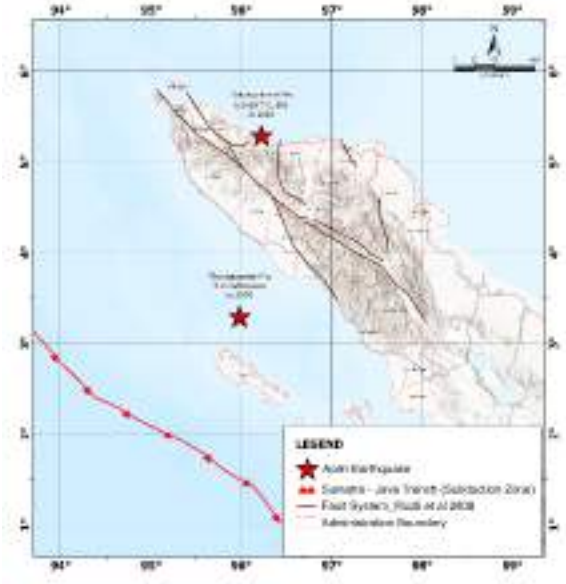

Fig 1. Seismicity in the Lhokseumawe area

Lhokseumawe is situated in a graben area (Fig. 2) composed of the Seureula Formation (Tps), Julurayeu Formation (QTjr), IDI Formation (Qpi), and Young Alluvium Deposits (Qh) [9]. According to [9]. The geology of Lhokseumawe primarily consists of layered sedimentary deposits, including gravel, sand, silt, and fluvial deposits, which are found along the active Sumatran trench.

METHODS AND THEORY

This research was conducted along the coastal area of Lhokseumawe City, Aceh Province. Soil resistance tests were conducted at six locations using the Standard Penetration Test (SPT) and Cone Penetration Test (CPT) methods. The assessment of liquefaction potential in the Lhokseumawe area was carried out using a deterministic approach based on N-SPT and CPT data, following the methodology proposed by Idriss and Boulanger in 2008. This method involves comparing the Cyclic Resistance Ratio (CRR), which represents the soil's resistance to liquefaction, with the Cyclic Stress Ratio (CSR), which reflects the seismic loading induced by an earthquake.

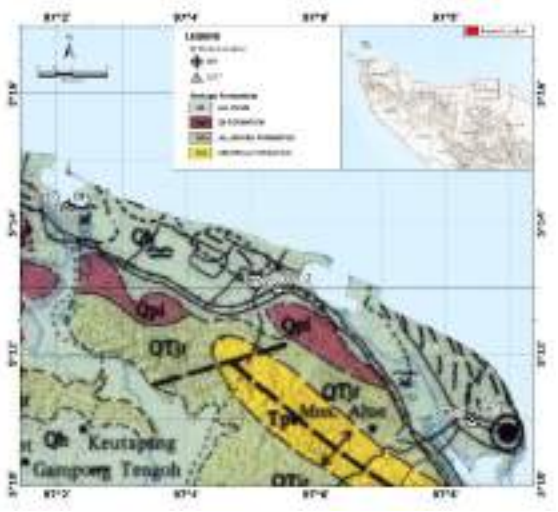

Fig 2. Geological map of the Lhokseumawe area

Soil Classification for Each Subsurface Layer

The identification and classification of soil types for each soil layer were conducted based on laboratory test results of undisturbed soil samples taken from each respective layer. The soil types were classified according to the Unified Soil Classification System (USCS). Additionally, the site classification was conducted in accordance with the Building Code of the Indonesian National Standard for Seismic Resistance Design [10], which provides guidelines for seismic design based on local soil conditions. The potential for liquefaction and loss of soil strength was evaluated using site-specific peak ground acceleration (PGA), earthquake magnitude, and source characteristics consistent with the Maximum Considered Earthquake Ground Motion (MCE_G). The

MCE_G is a measure of the maximum ground motion that can be expected at a site due to a specified earthquake. Peak Ground Acceleration (PGA) is calculated using Equation 1, which provides a quantitative basis for evaluating seismic loading at the site.

$$PGA_M = F_{PGA} \times PGA \quad (1)$$

Where PGA_M is the peak ground acceleration for the Maximum Considered Earthquake Ground Motion (MCE_G) adjusted for site class effects, PGA is the value obtained from the seismic hazard map based on the Indonesian Earthquake Map regulations (accessible via the Puskim application), and F_{PGA} is the site amplification factor corresponding to the site classification.

Earthquakes induce cyclic stress and contribute to the potential for liquefaction. Approximately 65% of the peak cyclic stress is considered in evaluating this potential, which is defined as the Cyclic Stress Ratio (CSR). The CSR can be calculated using Eq. 2.

$$CSR = 0.65 \times \left(\frac{\sigma_{vc}}{\sigma'_{vc}} \right) \times PGA_M \times r_d \quad (2)$$

where σ'_{vc} is the effective vertical stress and σ_{vc} is the total vertical stress at depth *z*. The parameter r_d is the shear stress reduction factor. Soil strength and stiffness were obtained from field tests using the Standard Penetration Test (SPT) and Cone Penetration Test (CPT). These strength parameters are used to determine the Cyclic Resistance Ratio (CRR) [11]The factor of safety against liquefaction potential can be calculated as the ratio of the Cyclic Resistance Ratio (CRR) to the Cyclic Stress Ratio (CSR) induced by an earthquake. The factor of safety against liquefaction triggering can be expressed by Eq. (3).

$$FS_{liq} = \frac{CRR_{M,\sigma'vc}}{CSR_{M,\sigma'vc}} \quad (3)$$

Where FS_{liq} is the factor of safety against liquefaction. If FS_{liq} is less than 1.0, the soil is considered susceptible to liquefaction. Conversely, if FS_{liq} is greater than 1.0, the soil is considered safe from liquefaction potential.

RESULTS AND DISCUSSION

The Peak Ground Acceleration (PGA) values were obtained using the latest Indonesian earthquake map, which was analysed based on probabilistic seismic hazard analysis. The information is available on the website https://rsa.ciptakarya.pu.go.id/2021 by entering the coordinates of locations BH-1, BH-2, and BH-3. Standard Penetration Test (N-SPT) data was used to determine the soil site class in the Lhokseumawe area, referring to SNI-1726-2019, and the soil was classified as Medium (SD). By entering the geographic coordinates of the N-SPT test locations into the Indonesian seismic map, the PGA values for each site were found to be 0.41g, 0.45g, and 0.48g, respectively.

The calculated values of the factor of safety against liquefaction (FS_{liq}) will be illustrated through liquefaction potential curves, providing a visual representation of the soil's susceptibility to liquefaction with depth.

The soil parameters presented in Table 1 were used for the liquefaction potential analysis, employing the simplified procedure proposed by Idriss and Boulanger in 2008.

Liquefaction Potential Based on SPT Data

Figure 3 shows that the depth of the drill hole is 30.45 meters below the ground surface. Liquefaction potential was identified at depths ranging from 3 meters to 15 meters under the earthquake scenario of M_w 9.2. The analysis at BH-1 indicates the presence of deep liquefaction. Similar cases of deep liquefaction were reported by [12] following the 2011 Canterbury Earthquake, where firm ground shaking was found to trigger widespread liquefaction significantly [13].

Table 1: Soil Parameters

Items	Ground water level (m)	γ (kN/m^3)	γ_{sat} (kN/m^3)
BH-1	0.80	17.0	19.5
BH-2	1.85	17.0	19.5
BH-3	2.00	16.5	18.8
CPT-1	0.8	17.0	19.5
CPT-2	1.85	17.0	19.5
CPT-3	2.00	16.5	18.8

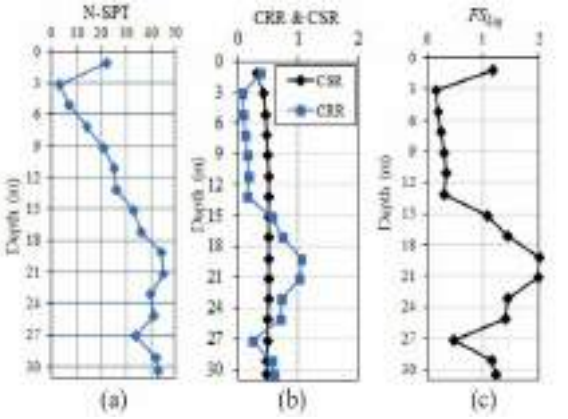

Fig. 3. Liquefaction Potential Curves at BH-1 for Mw 9.2: (a) N-SPT Data, (b) CRR and CSR Curves, (c) Factor of Safety against Liquefaction

The SPT data was used to analyze the liquefaction potential for a scenario with Mw 9.2 at BH-2 (Fig. 4) and BH-3 (Fig. 5). Figure 4 shows that liquefaction

potential was found at depths between 3 and 12 meters. A non-liquefying layer was identified between 12 and 17 meters depth. The liquefaction potential was analyzed for a scenario with Mw 6.5 at BH-1, BH-2, and BH-3, as shown in Figure 6. The depths at which liquefaction was observed were similar to those in the Mw 9.2 scenario, with a slightly reduced severity.

Liquefaction Potential Based on CPT Data

The CPT data was used to analyse the triggering of liquefaction potential, following the simplified procedure proposed by Idriss and Boulanger (2008). The liquefaction assessment was conducted under the assumption of level ground conditions for a moment magnitude (Mw) 6.5 earthquake, with Peak Ground Acceleration (PGA) values of 0.41g, 0.45g, and 0.48g. These PGA values represent the geometric mean of ground shaking observed during the 2016 Pidie Jaya earthquake.

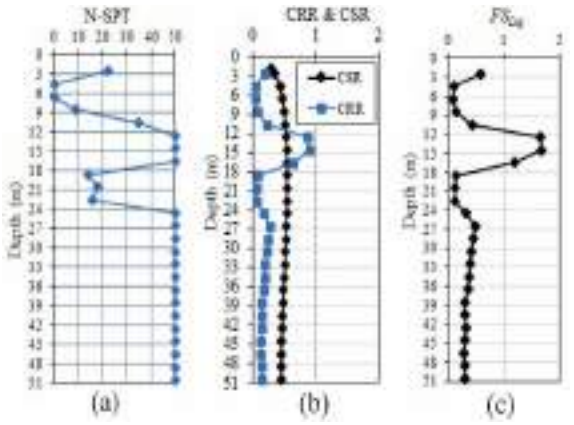

Fig.4 Liquefaction Potential Curves at BH-2 for Mw 9.2: (a) N-SPT Data, (b) CRR and CSR Curves, (c) Factor of Safety against Liquefaction

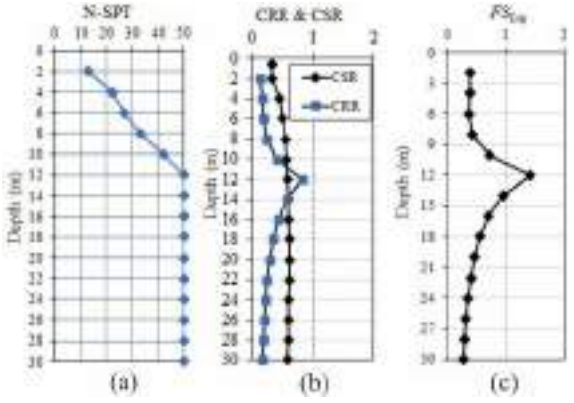

Fig.5 Liquefaction Potential Curves at BH-3 for Mw 9.2: (a) N-SPT Data, (b) CRR and CSR Curves, (c) Factor of Safety against Liquefaction

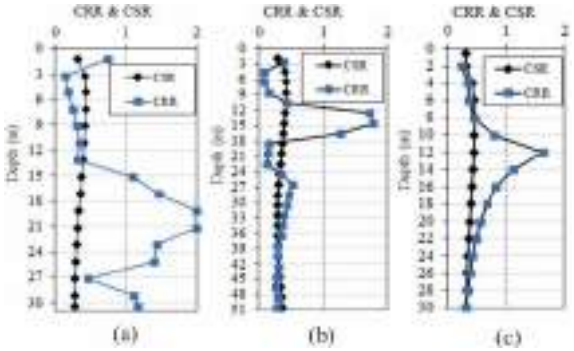

Fig.6 Liquefaction Potential Curves at BH-1, BH-2, and BH-3 for Mw 6.5: (a) CSR and CRR Curves at BH-1, (b) CSR and CRR Curves at BH-2, (c) CSR and CRR Curves at BH-3

In addition to the Mw 6.5 scenario, the CPT data were also used to evaluate liquefaction potential under a Mw 9.2 earthquake scenario, following the 2004 Andaman earthquake [14]. Liquefaction potential was identified at depths ranging from 2 to 8 meters below the ground surface (Figs. 7-8). The analysis used Peak Ground Acceleration (PGA) values of 0.41g, 0.45g, and 0.48g, which represent the geometric mean of ground shaking based on the Indonesian National Standard.

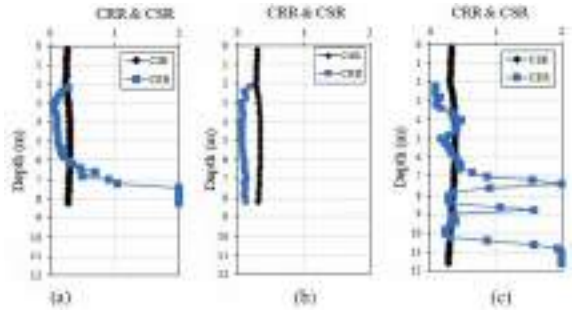

Fig.7 Liquefaction Potential Curves at CPT-1, CPT-2, and CPT-3 for Mw 6.5: (a) CSR and CRR Curves at BH-1, (b) CSR and CRR Curves at BH-2, (c) CSR and CRR Curves at BH-3

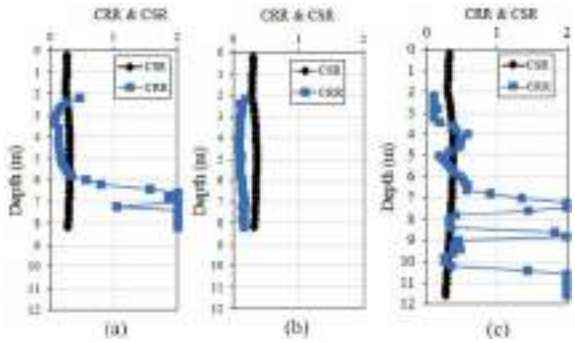

Fig.8 Liquefaction Potential Curves at CPT-1, CPT-2, and CPT-3 for Mw 9.2: (a) CSR and CRR Curves

at BH-1, (b) CSR and CRR Curves at BH-2, (c) CSR and CRR Curves at BH-3

CONCLUSIONS

The liquefaction potential analysis was carried out using both N-SPT and CPT data. Liquefaction potential was identified at depths ranging from 2 to 11 meters below the ground surface. Two earthquake scenarios, based on the Pidie Jaya and Andaman earthquakes, revealed the possibility of deep liquefaction. The effects of such liquefaction could cause significant damage to infrastructure facilities.

NONLINEAR INERTIAL EFFECTS IN CAISSON FOUNDATIONS WITH SUPERSTRUCTURES: AN EXPERIMENTAL STUDY UNDER VARIABLE-AMPLITUDE SEISMIC LOADING

Zain Bin Mazhar[1], Faruk Md Omar[2] and Masato Saitoh[3]

[1,2,3]Graduate School of Science and Engineering, Saitama University, Japan

ABSTRACT

Nowadays, as the expected earthquake motions become significantly larger, the ultimate seismic performance of large foundations, such as the caisson foundation, needs to be investigated. This study examines the seismic response of a caisson foundation connected to a superstructure modeled as a single-degree-of-freedom system. This study focuses on the inertial effects and nonlinear soil-structure interaction of the entire system under four simulated earthquake records with varying amplitudes. In particular, attention is given to soil nonlinearity (yielding and failure) and interface nonlinearity between the soil and the caisson surface in contact with the soil. These factors may influence the inertial system of soil-caisson-superstructure in terms of its resonant period and damping characteristics.

To investigate the seismic response under 1g condition, a 1/40 scaled model of a caisson foundation and superstructure is used, with a diameter and height of 350mm and 500mm, respectively. The effects of soil and interface nonlinearities on the stiffness and damping of the superstructure interacting with the soil are evaluated using transfer functions, phase differences, pressure responses, and mean shear strain. Furthermore, the study examines the potential shift in dominant vibration modes, such as increased rocking motion of the caisson foundation with larger loading amplitudes. This research highlights the significance of soil and interface nonlinearities on the inertial behaviour of the soil-caisson-superstructure system under stimulated earthquake ground motions.

Keywords: Soil structure interaction, Caisson foundation, Non-linear analysis, Superstructure, Seismic motion

INTRODUCTION

Dynamic soil-structure interaction plays an important role in evaluating the seismic performance of the foundation attached to the soil and coupled with superstructure. With the increasing strength of predicted earthquake ground movements, it has become crucial to properly evaluate the seismic performance of large foundations connected to the superstructures, particularly the caisson foundations. Amid high-amplitude earthquakes, the soil may undergo yielding both globally and locally. The presence of global and local nonlinearities in the soil medium can lead to complex soil-structure interaction behaviour. To have a better understanding of these mechanisms, it is imperative to delve deeper into the key parameters such as strain-dependent soil properties related to global nonlinearities and near-field pressure response associated with local nonlinearities.

Such effects are often overlooked in the design practice, where the superstructure is assumed to be fixed at the base; however, this assumption doesn't accurately reflect the real behaviour [1]. The analysis of seismic response for soil-caisson foundation is therefore of utmost importance, as caisson foundations support structures like highway bridges, that are prone to failure under strong seismic activity. Several of such structures experienced severe damage during the devastating earthquake event in Kobe, Japan, on 17 January 1995 [2]. The damage highlights the importance of understanding the transmission of inertial forces between soil, foundation, and superstructure. The interaction of these inertial forces results in the propagation of them through the soil-foundation-structure system, leading to the elongation of the structure's natural period during seismic activity. The propagation of inertial forces and elongation of natural period can produce devastating effects on the soil-caisson system under the influence of high-amplitude seismic waves. Hence, the overall safety of the soil-foundation-structure is strongly influenced by these inertial forces [3].

Monitoring the transfer function of the soil-foundation-structure provides a valuable insight into the changes in stiffness and damping due to nonlinearities. This study investigates the variations in the amplification ratio and the phase difference owing to global and local nonlinearities. The global change in shear strain alters the soil's shear modulus of the soil, which ultimately affects the damping characteristics of soil. As seismic waves propagate, the strain-dependent properties of soil, like shear modulus and stiffness of the material undergo significant changes, impacting the dynamic response of the entire structure [4, 5]. Additionally, this study further explores the local failures as described in a

study done by [6, 7], which determined that the variation in the transfer function is also closely related to the local nonlinearity failures. Analyzing near-field pressure response of the soil-foundation-structure for such local failures can provide insight into pronounced reduction in the amplitude of transfer function with the increase of seismic amplitude [8, 9].

While most researchers have concentrated on the inertial effects of superstructure and pile foundation assuming linear soil behaviour, often overlooking the nonlinear soil behaviour and its interaction with caisson foundation supporting superstructure, this study is intended to address this gap. It closely monitors the behaviour of the caisson foundation coupled with the single degree of freedom (SDOF) superstructure under the influence of four different earthquake records. The main objectives of this research are: 1) To investigate the response of caisson foundations under seismic motions with large amplitudes, aiming to capture critical system behaviors and conditions that lead to severe damage, 2) To study the effects of amplitude on the amplification ratio and the natural period elongation, 3) To examine the mechanics of soil-caisson-structure interaction, such as pressure response for local nonlinearities and mean shear strain for both global and local nonlinearities.

RESEARCH SIGNIFICANCE

This research highlights the importance of bridging experimental gaps in understanding the critical response of soil-caisson-structure interaction for caisson foundations. By considering the non-linear nature of soil, this study analyzes the natural period elongation and amplification ratio against high-amplitude seismic records. It provides valuable insight into the dynamic response of the soil-caisson-structure system, which can be beneficial in improving resilience, enhancing the understanding of global changes in soil material and local interface failures between soil and the foundation. These failures may result from the inertial effects of seismic activity itself or from the superstructure. Ultimately, this research work will contribute to the safer design of the infrastructure subjected to strong seismic activity.

MODEL TEST

Scaling rules are essential to accurately build a relationship between the real model and its prototype for experimental studies in small-scale environments. The experimental setup of this study is preferred to be scaled as per the scaling rule developed by [10]. The similar scaling model is also used by [11, 12]. It considers the effect of low confining pressure values. The correspondence of scale for the angular frequency ratio of the model to the prototype is evaluated as shown below, considering both geometry and density conditions.

$$\frac{\omega_m}{\omega_p} = \lambda^{-0.25}\eta^{-0.75} \quad (1)$$

In the equation shown above, λ represents the geometrical properties, whereas η represents the material density characteristic. As per the same scaling law, the model-to-prototype strain ratio is stated as:

$$\frac{\gamma_m}{\gamma_p} = \lambda^{0.5}\eta^{0.5} \quad (2)$$

The rules and factors as per the law, for both the prototype and the model, are compiled in Table 1.

Table 1 Model to prototype scaling parameters

	Quantity	Law of similitude	Factor of similitude	Value of every quantity		
				Prototype	Target value	Attained value
Subsurface Layer	Depth of Layer (m)	λ	0.03	17	0.4	0.4
	Density (t/m3)	η	0.8	1.8	1.4	1.5
	Natural Frequency (Hz)	$\lambda^{-0.25}\eta^{-0.75}$	17	2.2	37.3	38.1
	Shear Velocity (m/s)	$\lambda^{-0.25}\eta^{-0.25}$	0.4	150	64	65.5
Bedrock Layer	Depth of layer (m)	λ	0.03	8	0.2	0.2
	Density (t/m^3)	η	0.8	2.0	1.5	1.6
	Shear Velocity (m/s)	$\lambda^{-0.25}\eta^{-0.25}$	0.4	400	171	142
Foundation	Length (m)	λ	0.03	17	0.4	0.4
	Diameter (m)	λ	0.03	14	0.4	0.4
	Thickness (m)	λ	0.03	0.8	0.02	0.02
	Yung's Modulus (KN/m^3)	$\lambda^{0.5}\eta^{0.5}$	0.1	2.5 x 10^7	3.5 x 10^6	3.0 x 10^6
	Moment of Inertia (m^4)	λ^4	4.093 x 10^{-7}	700.47	2.87 x 10^{-4}	2.87 x 10^{-4}

EXPERIMENTAL SETUP

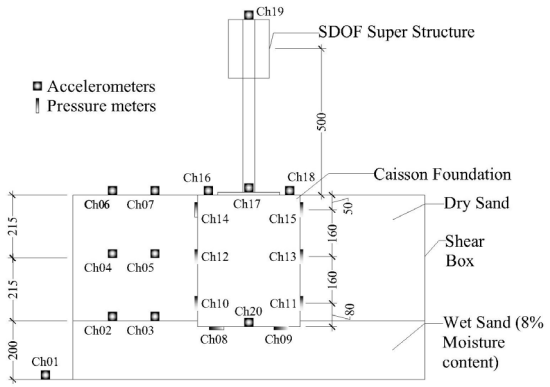

Fig. 1 Schematic representation of the test setup

Fig. 1 shows the experimental configuration of this study. The caisson foundation in this experiment is placed within a laminar shear box with inner dimensions of 1200mm, 800mm, and 1000mm for length, width, and depth, respectively. These dimensions of the shear box are similar to the one used by [13, 14]. The shear box is bolted on the top of a unidirectional shaking table of Saitama University, Japan. It is filled with cohesionless Gifu sand arranged in two different layers. The bottom layer, containing 8% moisture, provides firm support for the base of the caisson foundation, while the top layer comprises dry cohesionless sand with a specific gravity of 2.64.

The layer at the base is manually compacted with a heavy weight dropped under the influence of gravitational force, whereas the layer of dry sand which is filled in three equally width layers is compacted by providing base vibration to the system of 6m/s^2 and 40Hz frequency to achieve the target density of 1.46Mg/m^3. At the center of the laminar shear box, a caisson foundation model with a 350mm diameter and 450mm height is placed. The hollow cylindrical caisson, featuring a wall thickness of 20mm, is meticulously filled with dry Gifu sand. The mass and volume are carefully adjusted to achieve the desired scaled parameters. A Single degree of freedom (SDOF) superstructure, measuring 500mm in height and carrying 56.8 kg of mass at its head, is attached to the head of the caisson foundation, with a natural frequency of 23.7 Hz.

The experiment was conducted using four earthquake records: the 1940 El-Centro (NS), the 1995 JMA Kobe (NS), the 2004 K-Net Ojiya (EW), and White noise. All four earthquake records were scaled and adjusted in amplitude to simulate realistic earthquake conditions. The input motions were applied to the system in 7 distinct cases, - S1, S2, L1, L2, L3, L4, and L5. For each case, the relative displacement, defined as the distance covered by sand particles at the ground surface relative to the base due to deformation, was measured. Additionally, the mean shear strain that describes the shear strain distribution along the depth of the sand was also measured to support the study's objective.

Relative displacement and mean shear strain

Fig. 2 shows the change in mean shear strain values for different earthquake records as amplitude increases. The graph demonstrates the results from the top to bottom of the sand. For lower amplitudes, the minimum shear strain remains minimal, but for the amplitudes above 10m/s^2, the mean shear strain increases drastically because the soil softens upon transition from linear to nonlinear state. This high-strain behaviour results in high energy dissipation as the particles slip and rearrange themselves.

The resultant values of relative displacement and mean shear strain produced by each case are shown in Table 2.

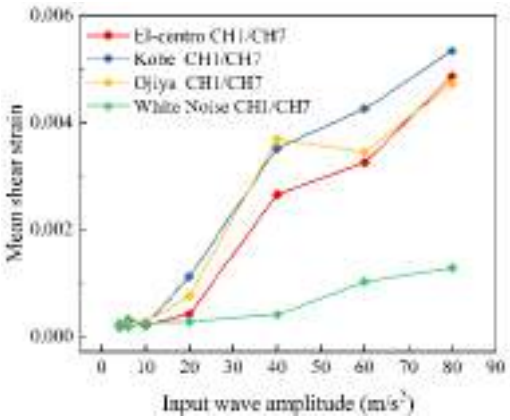

Fig. 2 Mean shear strain from the base of sand to the top of sand

Table 2 Relative displacement and mean shear strain

Case	Relative displacement (m)	Mean shear strain (Avg.)
S1	0.0001953	0.031%
S2	0.0002443	0.039%
L1	0.000232	0.037%
L2	0.0006348	0.101%
L3	0.0025653	0.407%
L4	0.0029888	0.474%
L5	0.004046	0.642%

The inertial properties of the soil-foundation-structure system are studied by combining all seismic records of the same case, as discussed in the results section.

Each set of experiments was instrumented with accelerometers and pressure meters to record the

acceleration and pressure at different locations shown in Fig. 1. Schematic representation of the test setup. In total, 11 accelerometers and 8 pressure meters are used in this study.

DATA PROCESSING

The experimental data were recorded in the form of time histories of both acceleration and pressure. Fourier Transformation (FFT) was used to convert the time domain data to the frequency domain, followed by the calculation of the transfer function using the cross spectrum and power spectrum from multiple response waveforms that were recorded under the same conditions. The noise was then removed using an averaging process applied to the spectra.

Finally, the magnification ratio curves were prepared for the superstructure head with respect to the ground surface and for the caisson foundation head with respect to the ground surface, concerning the input motion. To measure near-field pressure from time history, the peak pressure for all earthquake records was recorded for their respective amplitudes.

RESULTS AND DISCUSSION

Superstructure head

Horizontal transfer function

Fig. 3 illustrates the amplitude of the horizontal transfer function (amplification ratio) at the head of the superstructure with respect to the ground surface, subjected to the earthquake records of increasing amplitude. At amplitudes lower than L1, the system depicts the linear state. Case L1 can be considered as the transitional amplitude, as indicated by Table 2, which shows smaller mean shear strain values for S1 and S2, with a sudden rise above L1.

As the soil yields with the increase in mean shear strain, the shear modulus decreases rapidly. This reduction intensifies with the increase in shear strain. This phenomenon reflects global nonlinearity, where the soil-structure system exhibits a nonlinear response. The loss of stiffness and strength of the soil material leads to prominent energy dissipation. resulting in increased damping, consequently, a decrease in the amplification ratio. Besides this, for higher amplitudes, local nonlinearity is predicted as the soil undergoes large amounts of strain for localized areas near the foundation.

Before yielding, the small-strain behaviour dominates, where the shear modulus remains relatively constant. After yielding, the soil transitions to a plastic deformation state, resulting in a significant reduction in the overall stiffness, closely linked to the decrease in the elastic modulus of the soil. This represents global nonlinearity in the soil, where the entire soil system undergoes significant changes. Furthermore, at the higher strain levels, phenomena such as dropping of shear modulus to a minimum level and rising of the damping to its maximum level significantly influences the soil-structure interaction. Here, the separation between the soil and the foundation can also be predicted, indicating local yielding.

As a result, the peak of the amplification ratio decreases with the increase in loading amplitude, eventually becoming almost flat for the state of soil where a large amount of energy has been dissipated due to a significant increase in damping accompanied by a massive reduction in strength and stiffness.

Additionally, for higher amplitudes, a backwards shift in the peak of the graph towards lower frequencies can also be seen. This reduction in the natural frequency of the system is because of the softening of the soil. This softening of soil reduces the stiffness of soil, where the system can no longer sustain the vibrations at the original frequency, resulting in a shift of the peak.

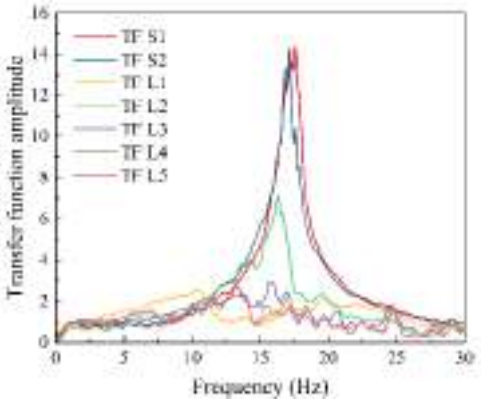

Fig. 3 Transfer function at the head of the super structure with respect to the ground surface

Phase difference

Fig. 4 shows the phase angle at the superstructure with respect to the ground surface, reinforcing the explanation discussed in the horizontal transfer function section. At lower amplitudes, the phase of the superstructure and the phase of the ground are the same, which is why below 15Hz, the phase difference is zero. However, this value suddenly drops at the resonance point of the system. While the general behaviour remains similar for all amplitudes, the trend differs significantly when the system shifts from linear to non-linear state.

As mentioned in the horizontal transfer function section, L1 is the transitional amplitude. After this, the soil softens, and a huge amount of energy dissipates as compared to the lower amplitude cases. From amplitudes L2 and higher, the system tends to regain the prior state but fails due to significant loss of stiffness already occurred. Interestingly, this effect is prominent for L5, where the graph of the transfer function also flattens, and the phase difference to follows the similar trend to other nonlinear cases.

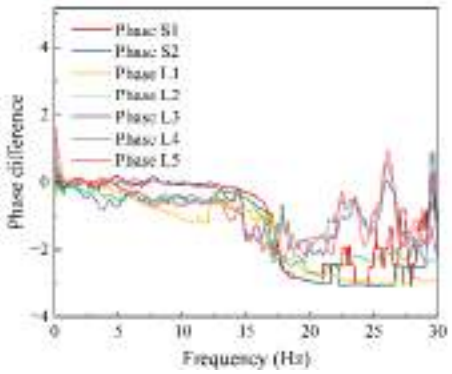

Fig. 4 Phase difference at the head of the super structure with respect to the ground surface

Caisson foundation head

Horizontal transfer function

Fig. 5 illustrates the amplitude of horizontal transfer function (amplification ratio) for the foundation head with respect to the ground surface, subjected to earthquake records of increasing amplitude. From the figure, for the caisson foundation head, the magnitude of the peak decreases with the increase in the magnitude of loading. This decrease is more pronounced in higher amplitudes of loadings. Similar to the observations for the superstructure, L1 acted as a transition amplitude, as seen in Table 2, where the values of mean shear strain are smaller for cases S1 and S2, followed by a sudden rise from L2 to L5. Beyond L1, the strain-dependent properties of sand become more pronounced. Hence, after yielding with the increase in strain, the sand undergoes softening, which reduces its stiffness and causes the peak shifts towards lower frequencies.

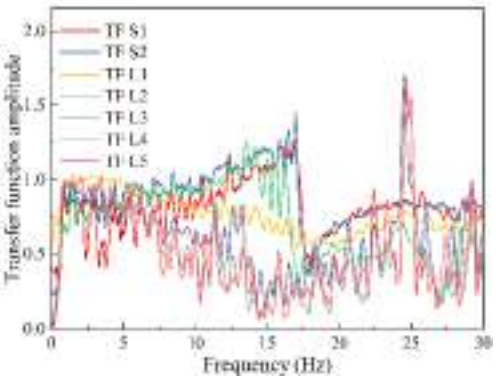

Fig. 5 Transfer function at the head of the caisson foundation with respect to the ground surface

Phase difference

Fig. *6* portrays the phase angle at the caisson head with respect to the ground surface. The figure demonstrates the behaviour similar to superstructure head, where the response of both the caisson head and the ground surface is identical at lower frequencies. The shifting in the phase of the caisson head has been observed simultaneously when the soil-foundation system shifted from linear to non-linear state, beyond L1. Additionally, a backward shift in the steady rise of the graph is observed. The loss of stiffness of the soil hinders the efficient stress transfer between soil medium and the caisson foundation.

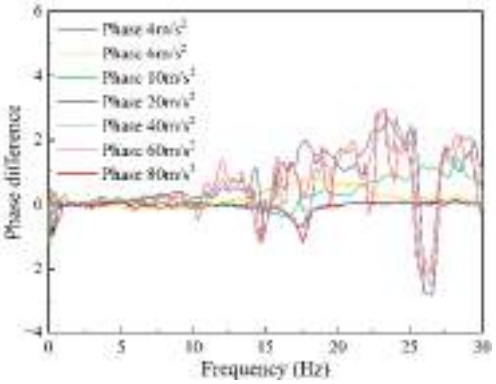

Fig. 6 Phase difference at the head of the caisson foundation with respect to the ground surface

Near Field Pressure Analysis

Fig. 7 a to d illustrates the near-field maximum pressure response for each distinct earthquake record. The response of the pressure meters provides evidence of the existence of local nonlinearity. Within the linear range (at lower amplitudes), the pressure increases with the increase in loading rate, owing to the linear elastic properties of the soil material. However, as the system transits into the non-linear range at higher amplitudes, the sand exhibits inelastic behaviour. This post-yield response, localized to specific areas, leads to the degradation of the stiffness in the soil. Beyond this point, further deformation doesn't result in increased pressure, as the stress transmission mechanism diverges from that observed before local yielding. Consequently, the pressure values demonstrated variability with increasing loading amplitudes. Which can also be attributed to the generation of a gap between the sand material and the foundation, driven by local interface nonlinearity.

Fig. 8 demonstrates the time histories of pressure meter responses attached to the sides of the foundation close to the ground surface. The figure demonstrates the separation between the foundation and the soil, as one pressure graphs plunges to zero on one side while the opposite side reaches the peak, simultaneously. Additionally, contact loss is also evident for higher amplitude loadings. For instance, At S2, the proportion of positive and negative values of pressure is almost equal, indicating no separation at lower amplitudes. However, at higher amplitudes, the pressure meters record only positive values with the increase in the amplitude, confirming the existence of a separation between the foundation and the soil.

CONCLUSIONS

By focusing on critical systems behaviours and conditions that might result in significant damage, this study presented the experimental results on the nonlinear inertial effects in the soil-caisson-structure system against increasing amplitude of different earthquake records. It further explored the effects of rising amplitude on the amplification ratio and the mechanism of soil-structure interaction, including near-field pressure response for local nonlinearities and mean shear strain for both local and global nonlinearities.The resonance peaks are obtained for the amplification ratio graph with the increase in the amplitude. The findings reveal that these resonance peaks in the horizontal transfer function (for the superstructure top and the caisson head) flatten as the loading amplitude increases. This is attributed to the increased energy dissipation in soil, leading to high damping because of global nonlinearities in the soil. In global nonlinear behaviour, when the stiffness of the soil decreases, the dissipation of energy increases, leading to an increase in damping. Owing to this, the peak of the amplification ratio reduces progressively as the amplitude increases, while the natural time period elongates, reflecting the degradation in the stiffness of soil. The observation is further supported by the mean shear strain, which shows higher values at higher loading amplitudes.In addition to global nonlinearity, the near-field pressure response justifies the observation of local nonlinearity in the system. The pressure values increase gradually at lower amplitudes, whereas they become staggered at higher amplitudes, reflecting the presence of some local interface nonlinearities. The prediction of the separation between the foundation and the soil is also validated from the time history of pressure responses. The loss of contact between the foundation and the structure is observed at higher amplitudes,

significantly compromising the transmission of inertial forces.

These findings highlight the necessity of accounting for both global and local nonlinearities in the design of the structure. By considering them, this study offered critical insights for resilient and safer infrastructure capable of withstanding extreme seismic conditions.

ABSTRACT

Prefabricated Vertical Drains (PVDs) have long been utilized for ground improvement, with electro-osmosis (EO) emerging as a potential enhancement method. While laboratory-scale studies have demonstrated promising results, the practical implementation of EO-enhanced PVDs in field conditions remains a challenge. This study aims to bridge the gap between laboratory experiments and field applications by employing a sandbox experiment to downscale PVD fieldwork. The electrode configuration was designed based on electrical resistivity survey concepts, allowing for a more realistic simulation of field conditions. The research compared conventional PVD performance with that of PVD incorporated with EO, focusing on settlement rates and water drainage volumes. Results unequivocally demonstrate that the integration of EO significantly accelerates settlement rates and enhances water drainage efficiency. These findings provide valuable insights into the potential benefits of EO-enhanced PVDs in real-world applications. Furthermore, this study offers a methodological framework for upscaling experiments towards full-scale field implementation, potentially leading to substantial time and cost savings in PVD ground improvement projects. The outcomes of this research contribute to the advancement of geotechnical engineering practices and pave the way for more efficient and cost-effective ground improvement techniques in the future.

Keywords: Prefabricated vertical drainage (PVD), Electro-osmosis, Sandbox experiment, Electrical resistivity configuration, Ground improvement

INTRODUCTION

A variety of ground improvement techniques have been utilized in conjunction with conventional prefabricated vertical drains (PVD) to enhance soil consolidation and stability. These methods include preloading with PVD installation, vacuum preloading, and vacuum consolidation. Despite their widespread use, certain techniques present limitations that can make them impractical for specific field conditions. For instance, in some project sites, the availability of filling material may be constrained, leading to significant delays in project timelines and additional expenses associated with transportation and placement [1]. In such cases, vacuum preloading (VP) is often favored as a more cost-effective and time-efficient alternative to conventional surcharge preloading. This is particularly true in coastal and reclaimed areas where sourcing and transporting large volumes of filling material may be logistically challenging and financially prohibitive. Nevertheless, the effectiveness of VP is largely dependent on the subsurface conditions. In locations characterized by highly permeable soil layers—such as sand or sandy clays, the efficiency of the vacuum system can be compromised due to the difficulty in maintaining an airtight seal. As a result, supplementary construction measures, such as the installation of cut-off walls extending into deeper impermeable strata, become necessary to minimize air leakage and preserve suction. These additional engineering interventions significantly increase the overall complexity and cost of the project [2]. Furthermore, variations in atmospheric pressure play a crucial role in vacuum system performance. In practice, vacuum pressures applied in the field typically range between 60 and 80 kPa, imposing a physical limitation on its effectiveness [3].

Given these constraints, electro-osmosis (EO) has emerged as an alternative technique for ground improvement, particularly in applications requiring accelerated dewatering of soft clay soils. This method, which leverages the movement of water through soil under the influence of an electrical field, has demonstrated its potential to enhance soil

consolidation while mitigating several issues associated with traditional ground improvement approaches. EO has the unique ability to not only expedite the removal of pore water but also improve soil strength characteristics through electrochemical effects. In some cases, EO can be further optimized to achieve near-zero hydraulic flow in fine-grained soils, offering substantial advantages in challenging ground conditions [4]. Moreover, it facilitates the strength development by generally diminishing sensitivity [5].

When properly applied, EO-driven consolidation results in flow rates that are 100–1000 times higher than those achieved through conventional hydraulic gradient effects, owing to the electro-osmotic permeability coefficient (k_e) being significantly greater than hydraulic permeability (k_h) [4]. Studies have estimated that the electro-osmotic permeability coefficient for most soil types is approximately 5.0×10^{-9} m²/V.sec, demonstrating its applicability for treating soft or problematic soils. Additionally, EO employs electrode-based conversion techniques that can permanently alter soil properties, reducing sensitivity, while improving overall soil integrity. The result is a more uniform improvement effect, which can be beneficial for large-scale construction projects involving soft ground conditions [6].

Despite the advantages associated with EO, its practical implementation in soft ground improvement projects is accompanied by several technical challenges. Notable issues include the formation of cracks near the anode due to localized drying effects, temperature fluctuations that can impact system efficiency, pH imbalances at the electrode terminals, and electrode corrosion, which can diminish soil-electrode contact and reduce overall effectiveness. These factors can contribute to operational inefficiencies, limiting EO's broader adoption in field applications. Additionally, high energy consumption and material degradation have been identified as significant drawbacks that constrain EO's feasibility for large-scale ground improvement efforts. Given these challenges, this study does not examine EO's electrochemical mechanisms in detail but instead focuses on evaluating its effectiveness in enhancing water discharge when combined with prefabricated vertical drains (PVD) and vacuum preloading. The primary objective is to determine whether EO can facilitate faster drainage by promoting pore water migration and sustaining vacuum efficiency over extended periods. Preloading is incorporated into the methodology to improve soil-electrode interaction and reduce uneven settlement, thereby enhancing the overall performance of the EO–VP integration. The research specifically compares the effectiveness of sequential and simultaneous EO–VP applications relative to conventional PVD setups, with the goal of assessing whether the combined approach improves water removal efficiency and soil stabilization under soft ground conditions.

MATERIALS AND METHODS

Sample Collections and Properties Testing

Samples are collected at a depth of 3 to 4 m from Asian Institute of Technology (AIT) campus for the experiments. Undisturbed samples are collected according to ASTM D1587-09 and disturbed samples used for reconstituting the soil inside the Sandbox are collected by using backhoe. Properties testing such as natural moisture content (ω), specific gravity (G_s), and Atterberg limits, etc., are carried out before commencing any test. Hydrometer analysis and sieve analysis tests are carried on soft clay and sand used as preloading. In addition, pH, along with Electrical Conductivity (EC), are measured (Table 1).

Table 1. Properties of Bangkok soft clay

Properties	Value
Water content, ω (%)	54.56
Liquid Limit, LL	94.6
Plastic Limit, PL	23.62
Specific gravity, G_s	2.72
Soil type	CH
pH	6.8
Electrical conductivity, EC (S/m)	0.2205
Salinity (mg/l)	1.4112
Resistivity, ρ (Ω.m)	4.535

Sample Preparation

Samples are prepared by adding water amount which makes moisture content to become 1.5 times its liquid limit. Before commencing the test, clay samples are soaked with that water amount for two weeks in order to easy when it stir with the mixer. Once the soil slurry is properly mixed, it is passed through a nylon mesh to separate unwanted materials such as organic matter, unmixed clay clumps, and other solid impurities. The prepared soil samples are carefully placed into the container box and total height reaches 30 cm. Once the soil has been fully placed, a geomembrane layer is applied on top to cover and protect the soil. This geomembrane serves as a protective barrier and is further loaded with a sand layer. The sand layer not only provides surcharge loading but also serves as a stable benchmark for the settlement plate, ensuring accurate monitoring of soil settlement during experimentation as shown in Fig. 1.

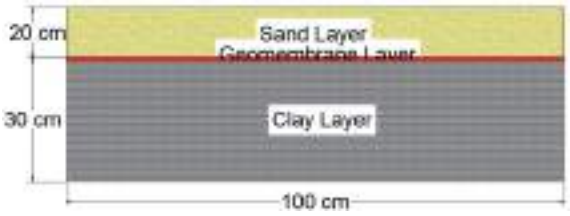

Fig. 1 Placement of geomembrane layer between the clay and sand in the sandbox model

Equipment Installations

PVD installation

PVDs are inserted in a rectangular pattern and are sealed totally with the rubber membrane at joint with top caps end to create a tightly sealed environment for the application of vacuum pressure. The PVDs are installed from the bottom of the box, considering the bottom layer as an impervious boundary, and allowing for one way drainage in the vertical direction. These drains are extended up to the top of the geomembrane layer (i.e., 30 cm in height), minimizing the risk of heaving or disturbances in the sand blanket during vacuum assisted experimentation. Spacing between each PVDs are 40 cm and 30 cm from the corner as can be seen in Fig. 2.

Vacuum system installation

The vacuum system comprised of: (1) vacuum machine for generating suction to suck out water from the PVDs; (2) air-water separation system to prevents excess water going into the vacuum pump and separate extracted air from the water to be sure vacuum system operates efficiently; (3) water container sitting on the balance to measure collected discharged water amount throughout the testing time; and (4) pipes and valve attached at every PVD to allow controlled suction while ensuring an even and efficient drainage system as shown in Fig. 3.

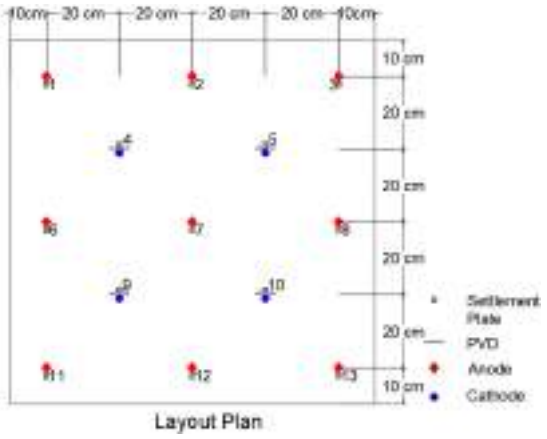

Fig. 2 Layout plan of PVD, electrodes and settlement plate

Fig. 3 Vacuum system used in this study

Electrical apparatus installation

Stainless steel rods, each with a length of 30 cm, are selected as electrodes due to their excellent corrosion resistance and high conductivity. Each electrode is systematically divided into three functional sections: (1) the embedded portion (5 cm), which is inserted directly into the clay layer to establish electrokinetic contact with the soil; (2) the middle section (20 cm), which pass through the sand blanket and is encased within a PVC pipe to prevent electrical leakage and current interference into and with the sand layer; and (3) the external portion (5 cm), which is extended above the surface and is connected to a clipper for power transmission. The installation configuration for a single electrode is illustrated on Fig. 4. The electrical current is supplied by two direct current (DC) power units, which are specifically calibrated to provide controlled voltage and current levels necessary for the resistivity and electro-osmotic tests. A total of thirteen stainless steel electrodes are installed following the Wenner array configuration, comprising four cathodes and nine anodes (Fig. 2). This arrangement is carefully designed to optimize current distribution across the testing area, facilitate uniform electro-osmotic flow throughout the consolidation process.

Fig. 4 Electrode installation and connection at location No.3

Measurement instrument installation

Firstly, as can be seen in Fig. 5, the settlement plate is specifically designed to measure vertical soil deformation. It comprises a square steel base plate with dimensions of 10 × 10 × 0.5 cm, along with a

two-part rod assembly: a 5 cm steel rod base for anchoring and a 70 cm vertical wooden rod. The wooden rod is chosen due to its nonconductive and corrosion-resistant properties, ensuring that it would not interfere with the electrical field during electro-osmotic (EO) treatment. To secure the rods, epoxy is used after drilling into the wooden base, and each rod is carefully aligned with a bull's eye level to maintain vertical positioning. Reference marks are placed near the top of the rods to facilitate settlement measurements related to the sand blanket surface. Vacuum pressure is monitored using a vacuum gauge installed on the vacuum pump, while water collection is tracked with a container placed on a balance. During and after the EO treatment, pH levels and electrical conductivity (EC) are measured using a portable pH/EC meter. Voltage and current within the EO system are recorded using a digital multimeter, which is connected to various electrode pairs—particularly between selected anodes and the central cathode (e.g., No. 4 to 1, 4 to 2, 4 to 6, and 4 to 7 as mentioned in Fig. 2)—to measure voltage (V) and current (A). These readings are utilized to check current distribution throughout the test.

Fig. 5 Measurement instruments

Testing Procedures

The methodology is divided into several key stages to systematically observe the soil's response to each treatment condition. The sequence began with self-weight consolidation (Self-Settlement), which served as the baseline to measure natural consolidation without any external forces. This is followed by mechanical preloading, using a sand blanket to simulate traditional surcharge induced consolidation. Next, vacuum preloading is applied by integrating a negative pressure system through PVDs, aiming to accelerate pore water dissipation. Finally, EO is introduced, both as a standalone and combined method with vacuum preloading, to examine the synergistic effects of electrokinetic water migration under electrical fields.

Firstly, Self-Settlement is designed to simulate the natural primary consolidation that occurs due to the soil's inherent overburden stress and gravitational forces, without any artificial intervention. The objective is to observe soil behavior over a 14-day period under natural conditions and determine whether self-weight alone could contribute to the consolidation process. By analyzing settlement behavior and water discharge patterns recorded during this initial phase and comparing them with results from later methods, the effectiveness of each treatment could be quantitatively assessed.

Secondly, the preloading stage is conducted to simulate construction-induced surface loading. In this phase, a uniform sand layer is placed over the prepared clay surface to apply surcharge pressure, promoting additional consolidation. The objective is to assess whether mechanical loading alone, without vacuum pressure or electrokinetic enhancement, could effectively induce settlement and facilitate water movement through installed drainage pathways. To closely replicate field conditions, PVDs are installed in the clay layer before applying the surcharge, allowing for the evaluation of natural pore water dissipation through the PVDs without external load. A geomembrane is placed between the clay and the sand blanket to prevent water infiltration, ensuring that settlement resulted solely from surcharge pressure.

Thirdly, following the preloading experiment, a new sandbox is prepared to conduct the vacuum preloading test, ensuring the elimination of residual effects and allowing for independent observation of vacuum-induced consolidation. The test box is filled with reconstituted Bangkok soft clay, following identical procedures from previous stages to maintain consistency in sample preparation. Settlement plates are installed during clay placement to enable precise monitoring of vertical deformation from the outset, ensuring the impact of vacuum pressure is recorded from the initial application phase. Since these plates are embedded within the reconstituted soil, continuous tracking is possible without disrupting the soil structure. In this phase, PVDs are connected to a vacuum system to induce negative pore water pressure and accelerate consolidation. Unlike the earlier stage, where PVDs are passive, they now actively facilitate vacuum-driven water flow. To create a sealed environment, a geomembrane is placed over the soil surface and securely fastened to prevent air leakage. A sand blanket is then positioned above the membrane to ensure uniform vacuum distribution and function as both a sealing and load transfer layer.

The final experimental phase is integrated electro-osmosis (EO) with vacuum preloading (VP) to assess their combined impact on the consolidation behavior of Bangkok soft clay. This approach aims to enhance water removal by leveraging both vacuum suction and electrokinetic flow, particularly in low-permeability zones where vacuum alone may be insufficient. In this setup, PVDs function as cathodes for the EO system while simultaneously

serving as drainage channels for vacuum suction. Stainless steel anodes are placed around the sandbox perimeter to facilitate electric current flow through the saturated clay (Fig. 2). A DC power supply and a vacuum pump are operated simultaneously to induce electro-osmotic water migration and negative pore pressure. This phase is designed to optimize pore water extraction efficiency while evaluating settlement uniformity, consolidation rate, and energy performance under dual treatment conditions.

Data Analysis

During the experiments, surface settlement is tracked using settlement plates installed during the placement of the reconstituted clay. Displacement readings are recorded at regular time intervals. The data is plotted as settlement vs. time graphs, which are used to evaluate the consolidation rate for each treatment method. Asaoka's method is used to predict the degree of consolidation. Water discharged from the system is collected in designated containers from each PVD outlet. The cumulative discharge is plotted and compare across all methods to determine which technique facilitates the most efficient removal of pore water. For tests involving vacuum preloading, pressure readings are taken using digital vacuum gauges installed at various points along the vacuum line. This data is used to evaluate the consistency of vacuum pressure applications, detect leaks, and correlate pressure stability with settlement response and water discharge trends. Electrical filed distribution and power consumption are also measured. After finishing the tests, soil samples are taken from three different depths: top, middle, and bottom layers to determine final water content distribution, pH and EC inside the soil. This allowed for the evaluation of how effectively each method reduces moisture content across the soil profile.

RESULTS AND DISCUSSIONS

This section presents the results of a series of laboratory scale experiments conducted to evaluate the consolidation behavior of Bangkok soft clay under various ground improvement techniques. This study focuses on three primary configurations: natural Self-Settlement (baseline), preloading with PVDs, and vacuum preloading with and without the integration of EO stimulation. The experimental program is categorized into three test series: T-1a (vacuum preloading only), T-1b (vacuum preloading followed by EO activation), and T-2 (simultaneous application of vacuum preloading and EO). Settlement progression and water discharge volumes were systematically recorded throughout each testing phase to assess the soil's response under varying drainage and loading conditions.

Observed Settlement and Water Drainage during the Performance of Self-Settlement and Preloading Experiment

During the self-weight consolidation phase, the soil is allowed to naturally settle under its own overburden stress without additional loading, drainage systems, or sealing membranes. The exposed clay surface facilitates moisture evaporation and drainage; however, no significant settlement is observed during the testing period (Figs. 6-7). This outcome highlights the low permeability of Bangkok soft clay and suggests that gravitational forces alone are inadequate to induce consolidation by overcoming internal pore pressure.

In the preloading phase, a uniform sand blanket is placed over the clay layer to simulate construction-induced surface loading. PVDs are installed to provide vertical drainage, but no vacuum or electrokinetic forces are applied. However, as indicated in Figs. 6-7, the increase in settlement is minimal, merely no settlement and water discharge remained very low. The PVDs, lacking vacuum assistance, proved ineffective under these low-pressure conditions.

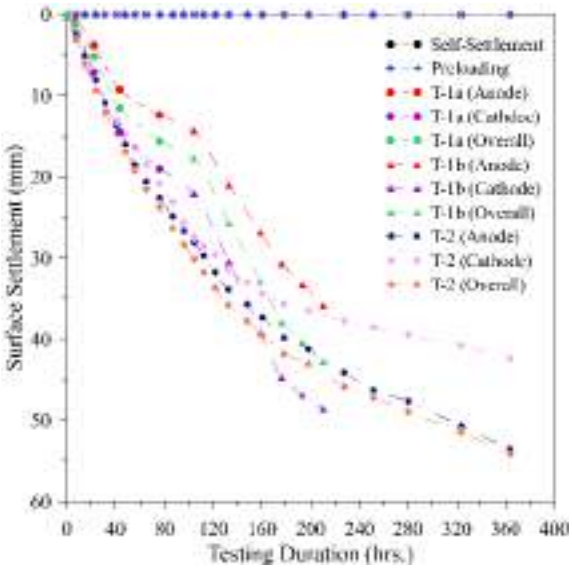

Fig. 6 Measured surface settlement from all testing conditions

Observed Settlement and Water Drainage during the Performance of Vacuum Preloading Experiment

In T-1a, surface settlement coming from vacuum preloading significantly outperformed Self-Settlement and Preloading methods at around 15.63 mm, 12.39 mm, and 19 mm in overall, at anode side and cathode side when it stops as can be seen in Fig. 6. T-1a is ended when the collected discharged water amount is lower than 10 ml for two consecutive

hours and the represented degree of consolidation estimated using Asaoka method when it ends is 66.3104%.

Throughout the vacuum preloading process, pressure readings are continuously monitored at both the vacuum pump and the water collection outlet. In the early stage of the test from 0 to 43.36-hour, high negative pressure values are maintained at around 58.44 kPa and overall settlement rate is 0.27 mm/hrs. (Fig. 8), corresponding to 6000 cm^3 of cumulative discharged water (Fig. 7).

However, as the experiment progressed, vacuum pressure reduces to 23 kPa between 43.36 to 76 hours of testing duration, particularly at the collection container, indicating a reduction in suction efficiency (Fig. 8). Thus, the vacuum preloading experiment demonstrates a strong initial response in both settlement and water discharge, confirming its effectiveness in accelerating primary consolidation in Bangkok soft clay. However, as pore water is progressively removed and the clay structure becomes denser, the efficiency of vacuum preloading declines.

This is evident from the steady decrease in settlement rate and collected cumulative discharged water amount between 43.36 to 76 hours of testing duration (Fig. 8). These findings suggest that vacuum preloading is most effective during the early consolidation phase when the soil contains substantial free water and the pressure differential is at its highest. Beyond this stage, further improvement becomes increasingly limited, as vacuum suction alone cannot easily extract tightly bound pore water from deeper or less permeable zones. Although vacuum preloading significantly outperformed self-weight and surcharge methods, its efficiency remains constrained by time and soil permeability.

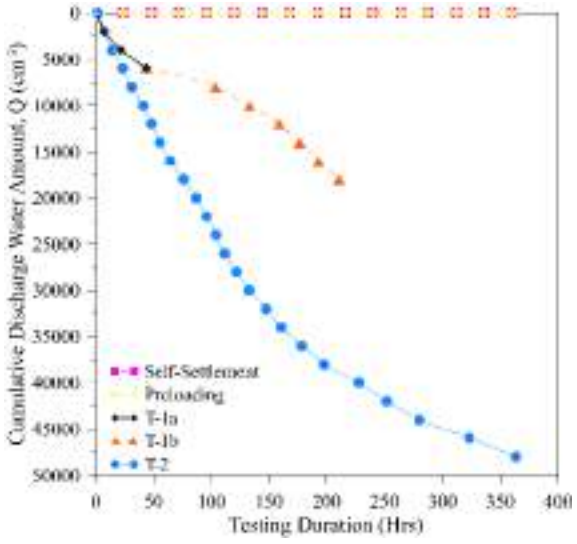

Fig. 7 Cumulative discharged water amount

Observed Settlement and Water Drainage during the Performance of EO Combined Vacuum Preloading Experiment

In Test Series T-1b, EO is applied after the vacuum preloading phase plateaued at approximately 76 hours (Fig. 6 and 7) to evaluate its effectiveness in reactivating and extending consolidation. As can be seen in Fig. 6 and 8, settlements gradually increased from 76 to 104.11 hours and sharply increased beyond it to till the end of the test especially near the cathode, corresponding to 42.8 mm in overall, 35.85 mm at anode, and 48.6 mm at cathode, respectively, which is 2.7 times higher than T-1a. Similarly, the overall settlement rate gradually decreases from 0.21 to 0.17 mm/hrs. within 76 to 104.11 hours of testing duration, and it increased back to 0.21 mm/hrs. up to 193.04 hours of testing duration and stop at 0.2 mm/hrs. when the test ends. Interestingly, the degree of consolidation measured using Asaoka method when the test ends is 27.079%, meaning that if the test is continued, the settlement would be higher than the present observed values and application of EO is pronouncedly effective even application when the vacuum pressure is very low.

Thus, this secondary response confirms that EO reinitiated consolidation by mobilizing additional pore water from deeper or previously unresponsive zones. The settlement behavior observed in test series T-1b indicates a noticeable reactivation of the consolidation process. Additionally, water discharge, which has diminished during the final vacuum treatment stage, shows a resurgence, with EO-induced cumulative discharge increased back from 6000 to 18,000 cm^3 (Fig. 7). This confirms EO successfully restored water flow via electrokinetic migration, particularly in low-permeability regions where vacuum pressure alone is insufficient.

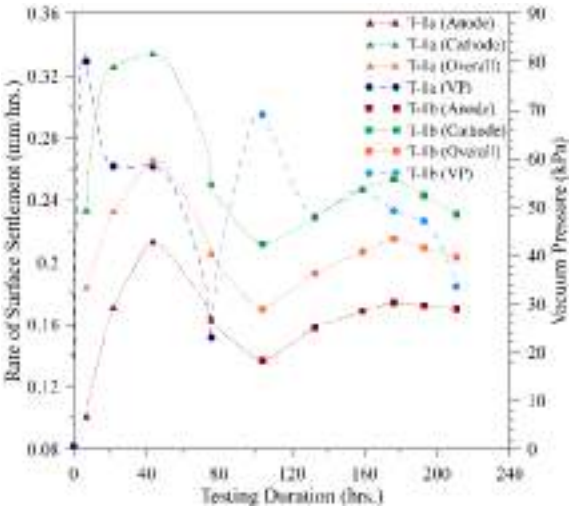

Fig. 8 Rate of surface settlement and effective vacuum pressure from T-1

Observed Settlement and Water Drainage under the Continuous Application of EO Combined Vacuum Preloading Experiment

In the test series T-2, EO treatment is implemented concurrently with vacuum preloading from the outset of the experiment to evaluate the effectiveness of a fully integrated system in expediting the consolidation process. From the beginning, the combined effects of vacuum-induced suction and electrokinetic flow facilitated a substantial outflow of pore water. During the initial phase (0–76 hours), the discharge volume consistently exceeded 2000 cm^3 per day, reaching peaks of over 3000 cm^3 at certain intervals, thus it becomes over 18,000 cm^3 in cumulative discharged amount, which is approximately 2.5 times higher than the amount from T-1a (i.e., approximately 7000 cm^3) as illustrated in Fig. 7. This increase in outflow is indicative of the enhanced drainage capacity achieved through the simultaneous activation of hydraulic and electrical gradients, enabling the rapid expulsion of free water from the low-permeability clay matrix.

As the experiment progressed into the stabilization phase (76–210 hours), discharge volumes remained relatively high, ranging between approximately 1,000 and 2000 cm^3 per day and thus, collected cumulative discharged water amount of 40,000 cm^3, approximately 2.2 times greater than T-1b (i.e., 18,000 cm^3). This consistency demonstrates the system's ability to sustain continuous pore pressure dissipation and mitigate the onset of drainage decline. In the later phase (beyond 210 hours), water discharge gradually decreased; however, the recorded values remain significantly higher than those observed in standalone vacuum. Even during the final intervals, discharge volumes frequently exceeded 535 cm^3 per day, underscoring the prolonged effectiveness of the combined EO and vacuum system.

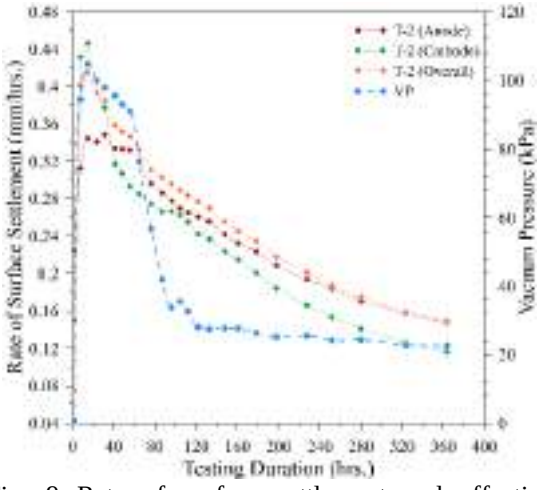

Fig. 9 Rate of surface settlement and effective vacuum pressure from T-2

From a quantitative perspective, the overall settlement rate during the early phase peaked (0 to 76 hours) at around 0.27 to 0.43 mm per hour, a substantially greater value than those recorded in the T-1a and T-1b configurations. This high settlement rate highlights the system's capability to swiftly reduce void ratios within the clay structure, leading to a measurable and efficient volumetric change. As the experiment progressed into the mid-to-late phases (76–210 hours), settlement rate steadily decreases, generally ranging from 0.17 to 0.31 mm per hour. Furthermore, effective vacuum levels remained consistently above 90 kPa in the early hours (up to 56 hours) and reduce from 90 to 25 kPa between 56–225 hours and remain stable at 25 kPa during later stages (Fig. 9). This can be due to the reduction in pore water availability within the soil. However, the absence of a settlement plateau, sustained water discharge, and consistent vacuum pressure collectively confirm that the simultaneous application of EO and vacuum preloading not only accelerates initial consolidation but also ensures long-term effectiveness. These results establish this configuration as the most efficient and robust among those tested.

Furthermore, the degree of consolidation estimated by using Asaoka method when the test ends is 91.18% corresponding to 59.134 mm which is not much different from the measured settlement amount such as 54.21 mm in overall, 53.52 mm at anode, and 42.34 mm at cathode side.

Changes in Moisture Content, pH and EC

During the experiment, it is observed that EO induced notable changes in the moisture content, and chemical properties of Bangkok soft clay, particularly in pH and EC. To evaluate the persistence of these effects, moisture content, pH and EC measurements are taken immediately after the tests and again one week after EO deactivation.

Moisture content has decreased from 146.28% (i.e., 1.5 times LL) to 122.35 after T-1a. It is reduced to 105.4% on the anode side, 103.58% between anode and cathode, and 90.91% at cathode side in T-1b. In addition, it is reduced to 89.24% at the anode side, 89.47% between anode and the cathode, and 77.96% at the cathode side in T-2. Interestingly, it can be seen that the reduction in moisture content near the cathode side is higher than anode and middle, which can be due to the suction pressure coming from PVD closet to the cathode side.

In T-1b (EO after vacuum preloading), the pH near the anode dropped to values as low as 4.86–5.10, while the cathode zone maintained slightly higher pH values between 6.83–7.05, reflecting the localized acidification and alkalization effects of electrolysis. In Test Series T-2 (simultaneous EO + VP), the pH values were even lower, with the anode

zone reaching 3.11–3.49 and the cathode ranging from 4.50–4.85, confirming stronger electrochemical gradients under prolonged electrical loading. Remarkably, one week after EO deactivation, the pH values remained stable (anode: 3.33–3.49; cathode: 4.15–4.55), indicating that EO does not cause rapid chemical to rebound and that the system has reached a steady state condition during treatment. Electrical conductivity also exhibits significant changes. After EO treatment in T-1b, EC values at the cathode drop to 0.52–0.69 mS/cm, while in T-2, EC is even lower, particularly at the cathode, where values fell to 0.06–0.08 mS/cm. These reductions suggest ion migration and accumulation at targeted zones, consistent with electrokinetic transport mechanisms. Notably, EC values remain low one week after EO shutoff, particularly in the cathode zone of T-2 (0.07 mS/cm), confirming the lasting electrochemical impact of EO treatment.

CONCLUSION

This study systematically analyzes two electrokinetic ground improvement methods for Bangkok soft clay: (1) sequential self-settlement followed by vacuum preloading and electro-osmosis (EO), and (2) simultaneous activation of EO and vacuum preloading (VP). Both approaches are tested under identical laboratory conditions to assess their effectiveness in accelerating consolidation, enhancing pore water discharge, and maintaining vacuum efficiency.

The results show that the simultaneous EO-VP system performs better in all key aspects. With 363 hours of testing time, T-2 achieved 91% degree of consolidation. Settlements in T-2 exceeded 53 mm, while in T-1a and T-1b record as approximately 15.63 mm and 42 mm in overall settlement, respectively. Water discharge from T-2 is 2.5 times higher than T-1a and T-1b. Although the settlement rate from T-2 is higher than T-1a and T-1b from 0 to 76 hours of testing time and lower than T-1b from 76 to 210 hours of testing time, the discharged water coming from T-2 is still higher than T-1a and T-1b.

These findings confirm that integrating EO from the beginning improves pore pressure dissipation, accelerates consolidation, and enhances drainage through electrokinetic migration. This combined mechanism increases consolidation efficiency while ensuring more uniform and deeper soil improvement in low-permeability conditions. Further research through large-scale field trials, economic assessments, and long-term monitoring is recommended to validate feasibility, optimize cost-effectiveness, and address electrode performance challenges.

ABSTRACT

The construction of the MRT Purple Line extension in Bangkok faces challenges due to deep, cohesive soils, primarily composed of stiff clay and sand layers. These conditions necessitate the use of ground improvement techniques to ensure the stability and safety of the infrastructure. Jet grouting, a common ground improvement method, is hindered in cohesive soils due to the increased viscosity of the sludge. This study investigates the application of chemical admixtures, specifically FAJ-20 (Naphthalene sulfonic acid type) and HPX-50 (Naphthalene sulfonic acid polycarboxylic acid type), named "Admion," to reduce viscosity and improve the effectiveness of jet grouting. Laboratory and field tests were conducted to assess the impact of different admixture concentrations on grout flowability and compressive strength in two soil types: Bangkok 2nd sand and Bangkok 2nd stiff clay. The results indicate that while the admixtures in Bangkok show promise, they did not fully achieve the same level of success as those observed in Japan. Comparisons with additional tests conducted in Japan, which tested similar admixtures, suggest that differences in chemical composition and admixture concentrations may account for these variations. Despite the differences, the comparison highlights the potential of chemical admixtures in overcoming challenges posed by cohesive soils. While the Bangkok results show some success, they also underscore areas for further improvement. This comparison provides valuable insights for future ground improvement efforts, particularly in refining the applicability of jet grouting methods with chemical admixtures in stiff cohesive soils and sand layers.

Keywords: Ground improvement, Jet grouting, Chemical Admixtures, Viscosity Reduction.

INTRODUCTION

The MRT Purple Line extension in Bangkok encounters challenges from deep, cohesive soils, mainly consisting of stiff clay and sand layers, necessitating the use of specialized ground improvement techniques. Jet grouting, a common method for these conditions, injects high-pressure grout to form solid columns [1, 2, 11]. However, in cohesive soils, the high viscosity of the discharged sludge hampers effectiveness, leading to operational inefficiencies, clogging, and less-than-ideal results. Pre-jetting with high-pressure water or enlarging the guide hole diameter can help release air and mud [3], while additional water may assist in managing the sludge.

To address these challenges, the use of chemical admixtures has gained attention as a promising solution. These admixtures, when added to the grout mixture, can reduce the viscosity of the discharged sludge, improving the flowability of the grout and ensuring more efficient jet grouting operations. The application of these chemical agents is particularly beneficial in Bangkok's unique soil conditions, where traditional jet grouting methods often struggle to achieve optimal results.

Two chemical admixtures named "Admion" were selected in the study. Laboratory and field tests were conducted to assess the impact of the chemical admixtures with various concentrations on grout flowability and compressive strength in two soil types: Bangkok 2nd sand and Bangkok 2nd stiff clay obtained from the MRT Purple Line project site.

For comparison purposes, additional testing using a chemical admixture named "GEOSPER" was conducted in Japan. Furthermore, a similar admixture, primarily composed of a polycarboxylic acid polymer, was tested in Japan [5]. The results of the laboratory and field tests obtained in this study were compared to those laboratory test results obtained in Japan. The findings of the comparison offer valuable insights into enhancing jet grouting techniques in challenging soil conditions, particularly in Bangkok's cohesive soils.

CHEMICAL ADMIXTURES USED IN THE STUDY

This study investigated the application of Admion chemical admixtures, specifically FAJ-20 and HPX-50, to improve the workability, flowability, and strength of cement-based materials. Admixtures

enhance concrete properties by reducing the water-to-cement ratio, preventing the weakening of strength caused by excessive water. They facilitate easier mixing with less water, improve flowability through air entrainment, and enhance workability by creating fine bubbles in the cement paste. High-molecular-weight surfactants in these admixtures help maintain fluidity and dispersibility during mixing. The properties of the two admixtures used in this study are provided in Table 1.

Table 1 Properties of the admixtures used in this study

Items	FAJ-20	HPX-50
Main ingredient	Naphthalenesulfonic acid type	Naphthalenesulfonic acid Polycarboxylic acid type
Property	Powder	Powder
Color	Yellowish brown	Yellowish brown
pH	7.0 - 9.0	7.0 - 9.0
Specific gravity	0.6 - 0.7	0.6 - 0.7

LABORATORY TESTING

Laboratory tests were conducted on two soil samples including Bangkok 2nd sand and Bangkok 2nd stiff clay. The samples were collected from the IVS-02 intervention shaft of the MRT Purple Line construction in Bangkok, from depths over 50 meters. Water from the Chao Phraya River was used to replicate the chemical and physical characteristics of field water conditions. The laboratory testing including flowability tests and unconfined compression tests was conducted, and the results of the testing are provided in the following sections.

Grout and Soil Properties

The Rapid Jet Grouting System was used in the construction of jet-grouted columns for the MRT Purple Line extension project [12, 13]. The properties of the jet grouting materials used in the large-diameter jet grouting technique are provided in Tables 2 and 3 in accordance with the construction specifications of the project. Table 4 indicates the basic soil properties of the sand and clay samples collected from the project site [4].

Table 2 Standard mix proportion of grout slurry

Material	Standard propotion (per 1 m^3)	
Ordinary cement	650 kg	207 L
Water	793 L	793 L
Total	1443 kg	1000 L

Table 3 Construction specifications of the large-diameter jet grouting technique

Type	R1
Diameter	2.5 m
Quantity of improved soil	4.91 m^3/m
Grouting flow	0.18 m^3/min
Lift rate	12 min/m
Quantity of hardening material	2.16 m^3/m

Table 4 Typical properties of Bangkok's soil from Sarkar et al. (2022) [4]

Soil Type	Unit Weight	Water content	SPT
	(kN/m^3)	(%)	
2nd stiff clay	19-22	11-21	20-80
2nd sand	21-22	13-16	>50

Sample Preparation

In the sample preparation phase, grout mixtures were prepared to represent spoil discharge during jet grouting, following the Japanese Geotechnical Society Standard (JGS 0821-2009) [6] to ensure consistency. Soil, grout, and chemical admixture were mixed in specific proportions to assess the effect of varying concentrations of the viscosity-reducing agent. Four admixture concentrations including 0% (no admixture), 0.3%, 0.5%, and 1.0% were used in the study.

METHODOLOGIES FOR LABORATORY TESTS

Flowability Tests

Bangkok 2nd Sand

The P-Funnel test, following JSCE-F 521-1994 [7], was used to measure the flowability of the Bangkok 2nd sand samples by recording the time taken for the sludge to flow out of the funnel. A shorter flow time indicates better flowability, which is crucial for efficient grouting. The bleeding test, following ASTM C940-2010 [8], assessed water separation from the mixture over time, impacting the grouting's performance and durability.

Bangkok 2nd Stiff Clay

Due to low natural water content, the grout mixture of the Bangkok 2nd stiff clay was too stiff to work with. To address this, additional water was added to the samples until workable consistency was achieved. The aim was to simulate field conditions and allow effective use of chemical admixtures. The table flow test, following JHS A313-1999 [9], was used to measure flowability by tracking flow length in two directions. The flow value was measured at

one-hour intervals, with 200 mm considered the standard for proper slurry handling.

Unconfined Compression Tests

The Unconfined Compressive Strength (UCS) test, following ASTM D2166 [10], measured the compressive strength of the grout mixtures at 7 and 28 days. Three samples were tested for each curing period, and the average UCS value was used to assess strength development.

RESULTS OF LABORATORY TESTS

Results of the flowability tests

Bangkok 2nd sand

Figure 1 illustrates the flowability test results for the Bangkok 2nd sand samples, showing the relationship between admixture concentration and flow time. The results demonstrate that both FAJ-20 and HPX-50 significantly reduce the viscosity of the grout-soil mixture, improving flowability during the jet grouting process. Without admixture, the baseline test showed a high average flow time of 27.4 seconds, indicating poor flowability.

Figure 1 also indicates that FAJ-20 reduced the viscosity as its concentration increased, with higher concentrations resulting in shorter flow times and improved discharge efficiency. HPX-50 also reduced viscosity effectively, outperforming FAJ-20 at comparable concentrations, suggesting it may be more efficient at lower doses in enhancing grout flow and jet grouting operations.

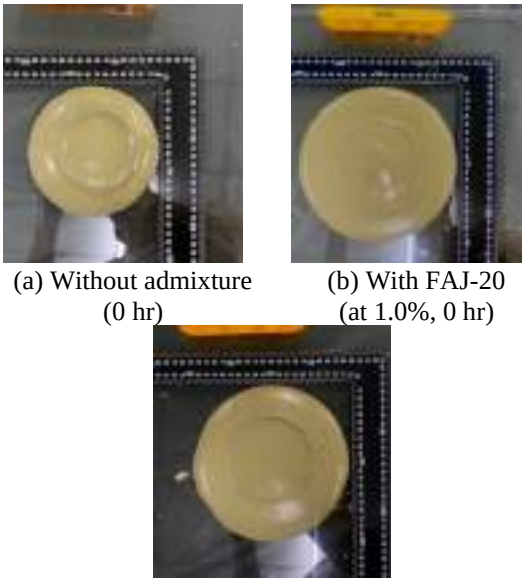
Bangkok 2nd Stiff Clay

Table 5 shows the results of the table flow tests for the Bangkok 2nd stiff clay samples. Figure 2 illustrates the measurements of the table flow tests. Figures 3 and 4 show the results of the flowability tests for the Bangkok 2nd stiff clay samples with FAJ-20 and HPX-50, respectively. Figure 3 indicates that the addition of FAJ-20 improved grout flowability, with higher concentrations resulting in better flow. At 1.0%, the flow value met the target, while at 0.0%, no flow occurred after 1 hour. Flowability decreased after 2-3 hours, emphasizing the importance of timely application during field operations.

Table 5 Results of table flow test (laboratory)

Amount of Admixture (%)		Flow Status		
		Elapsed time from mixing (hours)		
		0 hr	1 hr	2 hrs
w/o ad.	0.0	148 × 152 150	-	-
FAJ-20	0.3	160 × 160 160	-	-
	0.5	158 × 158 158	-	-
	1.0	200 × 202 201	104 × 104 104	104 × 106 105
HPX-50	0.3	180 × 180 180	118 × 122 120	114 × 114 114
	0.5	188 × 186 187	108 × 106 107	96 × 100 98
	1.0	198 × 200 199	110 × 114 112	96 × 104 100

Note: The 'a × b' values represent the flow length values on both sides of the spread grout sample, with the value in parentheses indicating the average length value.



(a) Without admixture (0 hr)

(b) With FAJ-20 (at 1.0%, 0 hr)

(c) With HPX-50 (at 1.0%, 0 hr)

Fig. 2 Results of table flow test measurements

Figure 4 shows that HPX-50 also improved flowability, with higher concentrations yielding better flow. At 1.0%, the flow value reached the

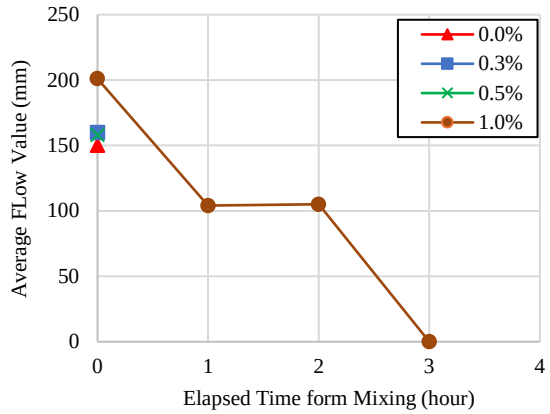


Fig. 3 Results of flowability tests for Bangkok 2nd stiff clay with FAJ-20 in the laboratory

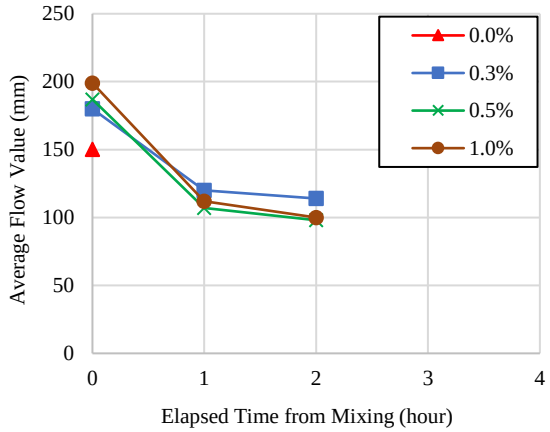

Fig. 4 Results of flowability tests for Bangkok 2nd stiff clay with HPX-50 in the laboratory

target, ensuring better workability. Similar to FAJ-20, flowability decreased after 2 hours, particularly at lower concentrations, highlighting the importance of careful timing.

Results of unconfined compressive strength

Bangkok 2nd sand

Figure 5 shows the results of the unconfined compressive strength (UCS) tests for the Bangkok 2nd sand samples with FAJ-20 and HPX-50, respectively. Figure 5 indicates that both with and without admixtures, the observed values fell short of the lab target strength of 6,000 kPa, based on a 3,000 kPa field target strength, suggesting a need for further investigation into the factors behind the lower UCS values. Despite this, the comparison of admixtures provides valuable insights into their effects on grout strength.

Figure 5 also indicates that for FAJ-20, the 0.3% concentration slightly improved or left the strength unchanged, but higher concentrations resulted in a decrease in compressive strength. In contrast, HPX-50 showed a slight decrease at 0.3%, but higher concentrations improved UCS, indicating that HPX-50 enhances grout strength at higher concentrations.

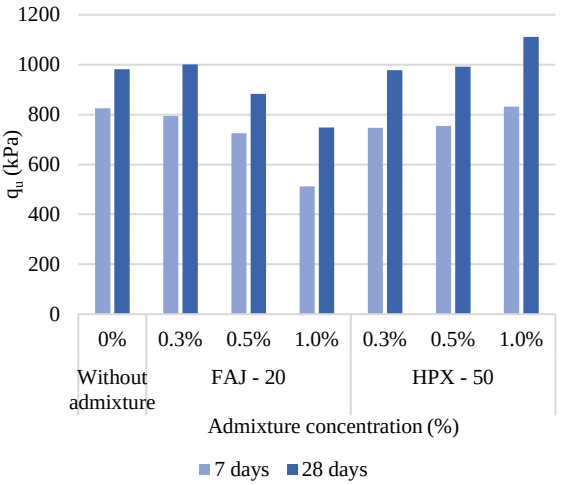

Fig. 5 UCS Results for Bangkok 2nd sand with FAJ-20 and HPX-50 (7 & 28 Days) in the laboratory

Bangkok 2nd stiff clay

The results of the UCS tests for the Bangkok 2nd stiff clay samples with FAJ-20 and HPX-50, respectively, are presented in Figure 6. Figure 6 shows variations in strength based on admixture type and concentration. Figure 6 shows that FAJ-20 enhanced strength with increasing concentration, reaching the target at 0.5% and 1.0%. For HPX-50, the UCS exceeded the target at 0.3%, with notable improvement at 0.5%, indicating its effectiveness at moderate concentrations.

Figure 6 also shows that grout samples with the admixture met the required lab target strength of 2,000 kPa (based on 1,000 kPa field target strength), whereas the grout samples without the admixture fell below the required strength. It is also important to note that less water was used when admixtures were added, yet the flowability improved, demonstrating that the admixtures helped make the mix easier to work with without compromising its quality.

FIELD TESTING

Field tests were also conducted on two soil samples, including Bangkok 2nd sand and Bangkok 2nd stiff clay, to compare the laboratory findings with real-world performance, allowing for an assessment of how well the laboratory-optimized admixture dosage translates to site conditions. In the field testing, the 1% admixture concentration, which was identified in the laboratory experiments as yielding

the best performance, was selected to validate its effectiveness under actual construction conditions. The field tests involved evaluating sludge viscosity immediately after jet grouting and performing unconfined compressive strength (UCS) tests on the grout columns after 28 days of curing.

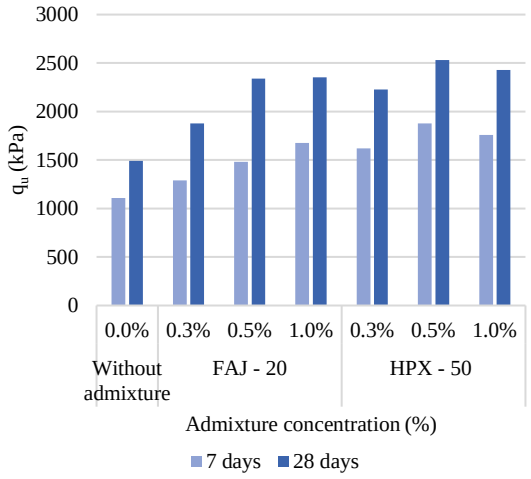

Fig. 6 UCS Results for Bangkok 2nd stiff clay with FAJ-20 and HPX-50 (7 & 28 Days) in the laboratory

Results of the flowability tests

Bangkok 2nd sand

Figure 7 illustrates the results of the flowability tests conducted in the field for the Bangkok 2nd sand samples with and without admixtures. The flowability results for the sludge, shown in Figure 7, were averaged from multiple tests conducted across different grouting holes. As shown in Figure 7, no significant difference in flowability was observed between the untreated and admixture-treated samples. It is expected that water content variations, due to the precutting process, naturally lower sludge viscosity, overlapping with the effect of the admixtures in the field. This complicates distinguishing the impact of the admixtures on viscosity reduction, as shown in Figure 7.

Bangkok 2nd stiff clay

Figure 8 illustrates the results of the flowability tests conducted in the field for the Bangkok 2nd stiff clay samples with and without admixtures. Figure 8 shows that both FAJ-20 and HPX-50 significantly improved flowability. The mixture without admixture had an initial flow value of 162 mm, while FAJ-20 increased it to 351.7 mm and HPX-50 to 335.5 mm, with FAJ-20 showing the highest flow.

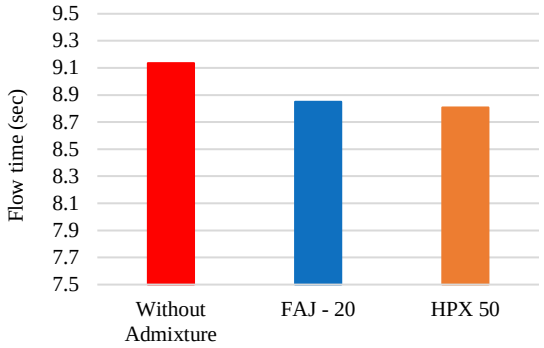

Fig. 7 Flowability test results for Bangkok 2nd sand with and without admixtures in the field

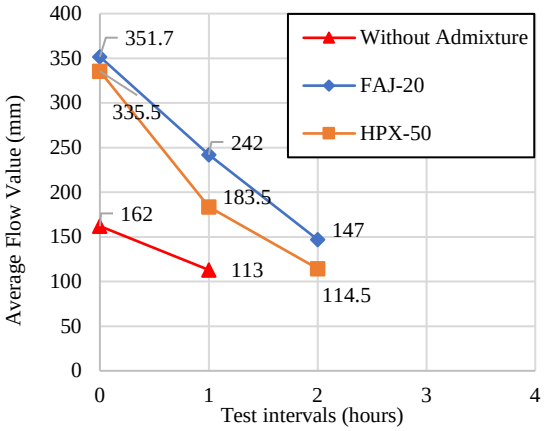

Fig. 8 Average Flow Value Over Time for Bangkok 2nd stiff clay with FAJ-20 and HPX-50 in the field

Results of unconfined compressive strength

Bangkok 2nd sand

The UCS test results for field samples taken from jet-grouted columns in the sand layer showed that the untreated sample reached 6,330 kPa and the FAJ-20 treated sample achieved 3,295 kPa. Due to limited sample availability, only one sample from each column was tested. Nevertheless, all samples, including those with admixtures, exceeded the target design strength, confirming that both untreated and admixture-treated grout met the required strength.

Bangkok 2nd stiff clay

The UCS test at the IVS-01 site yielded 4,760 kPa from a core sample taken from the intersection of three different types of grout columns: those without admixture, those with FAJ-20, and those with HPX-50. Despite limited core samples, the result exceeded the required strength target, confirming that the admixture-treated grout surpassed the target design strength.

COMPARISON WITH PREVIOUS STUDY IN JAPAN

Additional testing using a chemical admixture named "GEOSPER" was conducted in Japan. Furthermore, a similar admixture, primarily composed of a polycarboxylic acid polymer, was tested in Japan by Shimano et al. (2023) [5]. The soils tested in Japan were classified as clay. The results of these tests were compared to those obtained in Bangkok. The comparison of the test results provides a valuable benchmark for interpreting outcomes in Bangkok.

Flowability Performance

Figure 9 shows the flowability test results for the Bangkok and Japan samples with different admixture types and contents. Figure 9 indicates that the use of admixtures significantly improved the flowability of grout-sludge mixtures. In the Bangkok tests, the target flow value of 200 mm was achieved at 1.0% concentration of both FAJ-20 and HPX-50. However, it is important to note that additional water was introduced to the Bangkok stiff clay samples during laboratory preparation to reach a workable consistency, due to their initially low natural water content (11 – 21%). This adjustment aimed to better simulate field conditions. In contrast, Shimano et al. (2023) achieved flow values of approximately 250 mm at 2.0% admixture concentration using untreated Japanese clay with a much higher natural water content (62.1%) [5]. Additional flowability tests were conducted on cohesive soil samples mixed with 1% and 2% of "Japan (GEOSPER)" at a natural water content of 38%. The results are presented in Figure 9. As shown in Figure 9, the flow values of the samples were approximately 200 mm. The test results showed that high fluidity was maintained even after 1 hour. It was found that differences in the type of admixture not only increased the initial fluidity, but also made a difference in fluidity retention. The difference in required dosage may reflect not only the chemical composition of the admixtures but also the variations in baseline moisture, plasticity, and cohesion of the respective soils.

Strength Characteristics

Regarding unconfined compressive strength (UCS), both studies observed that the use of admixtures resulted in a slight reduction in compressive strength compared to untreated samples. Shimano et al. found that strength decreased by approximately 20 – 38% with increasing admixture content, although values still met the minimum design requirement of 1,000 kPa [5]. The same tendency was observed in "Japan (GEOSPER)". Similarly, in the Bangkok laboratory tests, UCS values declined with higher concentrations of FAJ-20, while HPX-50 demonstrated improved strength at 1.0%. In the field, the FAJ-20-treated grout sample in Bangkok achieved the UCS value of 3,295 kPa, exceeding the Japanese field average value of 2,100 kPa. This notable difference may result from soil heterogeneity, differences in grouting technique (such as precutting), and curing conditions during field operations.

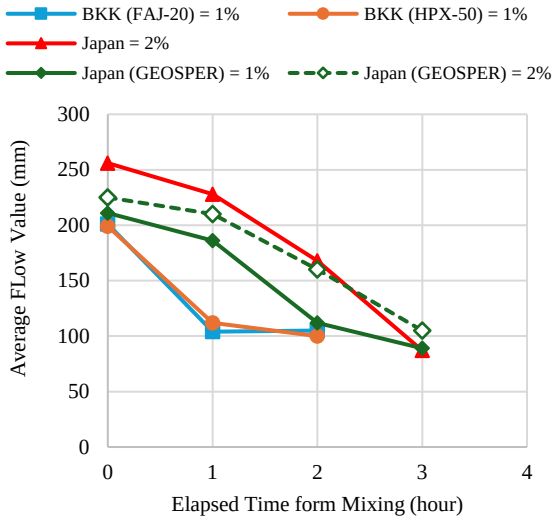

Fig. 9 Results of flowability tests for Bangkok and Japan samples with different admixture types and contents.

Differences in Admixture Composition

Another key distinction lies in the chemical composition of the admixtures used. Shimano et al.'s admixture [5] and "Japan (GEOSPER)" employed a yellow-brown liquid admixture composed purely of polycarboxylic acid polymer. In contrast, this study used FAJ-20, a powder-type naphthalenesulfonic acid-based agent, and HPX-50, a hybrid powder admixture containing both polycarboxylic and naphthalenesulfonic acid components, as shown in Table 1. These compositional differences may influence the rate of dispersion, mixing efficiency, and interaction with cement hydration. Notably, previous studies have shown that polycarboxylic acid superplasticizers exhibit stronger dispersion capacity and higher fluidity retention than naphthalene-based

types, due to their greater reduction in shear yield stress and more effective steric hindrance action [14]. The combined chemical structure of HPX-50, may have contributed to its UCS performance and flowability retention in the Bangkok soils.

These findings reinforce the importance of site-specific calibration when applying viscosity-reducing agents. While both studies confirm the potential of chemical admixtures to improve jet grouting in cohesive soils, variations in soil properties, admixture formulation, and field procedures significantly influence the optimal dosage and resulting performance.

CONCLUSIONS

This study demonstrated the effectiveness of chemical admixtures, particularly FAJ-20 and HPX-50, in enhancing jet grouting efficiency in Bangkok's second stiff clay and sand layers. Laboratory tests demonstrated that both admixtures significantly improved flowability, particularly at 1.0% concentration, with HPX-50. In terms of strength, the HPX-50 also showed better performance at higher concentrations. Despite the improvements, the UCS values for both without and with admixtures in the lab remained below the target strength in sand, suggesting that other factors such as curing conditions, soil-grout interaction, or mixing quality may need to be investigated.

Field testing validated the laboratory findings but also highlighted key differences due to uncontrolled variables such as soil heterogeneity, moisture variation from precutting, and field mixing conditions. In sand, flowability differences between treated and untreated samples were minimal, while in stiff clay, both admixtures yielded significantly higher flow values.

A comparative analysis, including additional admixture testing and a previous study in Japan, reveals that variations in soil properties, natural moisture content, and admixture composition and formulations contribute to differences in performance.

Overall, the findings confirm that chemical admixtures, particularly HPX-50, can significantly enhance grout flowability and contribute to strength development in cohesive soils. The results also underscore the importance of site-specific calibration, careful admixture selection, and the need for further research into optimal dosage levels and long-term performance. This study offers valuable guidance for enhancing jet grouting practices in complex urban geotechnical environments, such as Bangkok.

EXCAVATION TESTS ON ALUMINUM ROD MODEL GROUND TO SIMULATE GROUND HEAVE

Moe Yagawa[1], Hidetoshi Nishioka[2], Shinji Konishi[3] and Satoshi Sakata[4]

ABSTRACT

When performing the open-cut method, ground heave due to excavation may have an impact on existing structures, causing deformation and other effects. Therefore, it is important to predict the effects of ground heave near existing structures and consider countermeasures. However, the interaction between the structure and ground when ground heave occurs is not fully understood, leading to discrepancies between predictions and actual measurements. For this purpose, we analyzed the interaction between the ground and the structure through model experiments. As the first step, an excavation experiment was conducted using an aluminum rod model ground that can reproduce the behavior of sand in two dimensions, to investigate whether ground heave can be reproduced. This model allows image-based analysis to capture displacement and strain distribution near structures. Two earth retaining wall models, each 200 mm high, were placed in the model ground measuring 1000 mm in width and 400 mm in height. Using a ground anchor model, the earth retaining walls were subjected to tension equivalent to the earth pressure at rest. The primary experimental parameter was the distance between the earth retaining walls. The intervening ground was excavated, and images were analyzed to assess the resulting ground behavior. Results confirmed that the aluminum rod model ground could simulate the upward vertical displacement patterns similar to those of the actual ground. These findings provide valuable reference data for future model experiments involving embedded structures such as tunnels.

Keywords: Ground heave, Aluminum rod model, Excavation test, Image analysis

INTRODUCTION

Ground heave refers to the upward movement of the excavation bottom caused by the release of stress in the ground, which occurs because of a reduction in overburden pressure during excavation [1]. When using the open-cut method near existing structures such as tunnels, predicting the effects of ground heave accurately is essential. For this purpose, the interactions between the intervening ground and the structure must be analyzed. However, this interaction during ground heave has not been quantitatively analyzed and no simple method has been established to predict these effects. Therefore, there may be differences between predicted and actual measurements [2].

Therefore, this study was conducted to systematically analyze the interaction between existing structures and the ground during ground heave. As a preparatory experiment, an excavation test was carried out using an aluminum rod model ground. Aluminum rod model ground is one of the experimental techniques used since the 1960s and has been used in various experiments [3-5]. It is known to produce behavior similar to that of medium-dense sand (e.g., nonlinear characteristics of stress–strain relationships and dilatancy characteristics) [6]. This model enables image-based analysis to capture the displacement and strain distribution of the ground around the existing structure.

RESEARCH SIGNIFICANCE

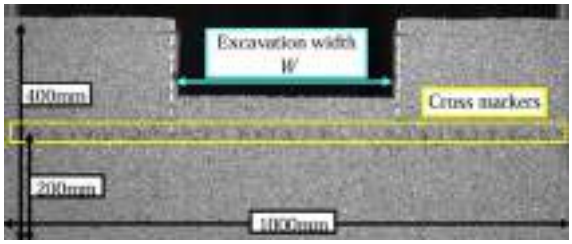
No previous studies have simulated ground heave using an aluminum rod ground model. This experiment enabled us to understand the ground heave characteristics of the aluminum rod model ground. The data provide fundamental information for future excavation experiments around the existing structure. Similar future experiments will contribute to improving the accuracy of predicting the impact of ground heave on existing structures.

EXPERIMENT SUMMARY

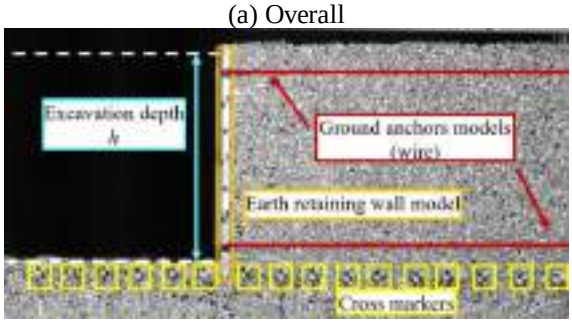
Model ground

Fig.1 shows the aluminum rod model ground, and Fig.2 illustrates the experimental apparatus used in this study. The model ground was constructed using three types of aluminum rods with diameters of 1.5 mm, 2 mm, and 3 mm in equal weight proportions (1:1:1). The overall dimensions of the model ground were 1000 mm in width and 400 mm in height.

Fig.1 Aluminum rods



(a) Overall



(b) Around the earth retaining wall on the right side

Fig.2 Experimental apparatus

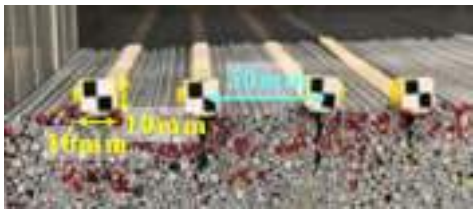


Fig.3 Cross markers

Construction involved layering 50 mm thick segments of aluminum rods and compacting each layer using a small vibrator. The unit volume weight was 21.5 kN/m^3.

When the model ground was constructed to a height of 200 mm (half the total height), a level was used to ensure the surface was parallel to the base. Cross markers were placed at intervals of 30 mm (Fig.3) for later use in image analysis. These markers consisted of cross-pattern blocks affixed to a wooden board (1 mm thick, 7 mm wide, and 160 mm long). Two aluminum retaining wall models (6 mm thick, 200 mm high, and 150 mm deep) were installed vertically at locations where the distance between

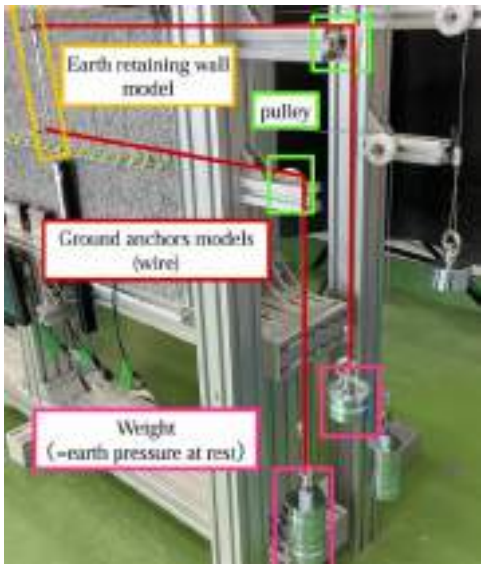

Fig.4 Attached wires and weights

them (excavation width, *W*) was either 400 mm or 250 mm (corresponding to positions 300 mm or 375 mm from both ends of the model ground). The remaining 200 mm height was then constructed using the same compaction method.

As illustrated in Fig.4, a wire simulating a ground anchor was connected to the top and bottom ends of each retaining wall. Weight equivalents to the static earth pressure at rest were attached to the ends of the wires. Since the deformation of the retaining wall was not the main objective of this study, static earth pressure was used to minimize the variation from experiment to experiment. These weights were suspended via pulleys to apply tensile force externally to the experimental apparatus.

Testing methods

Excavation of the ground model was performed as shown in Fig.5. The initial (pre-excavation) overburden was 200 mm. Excavation was conducted in incremental steps, with the thickness of each step decreasing progressively as the excavation depth increased. A laser level was used to project the target depth for each excavation step, serving as a guide for pushing the aluminum rod from the front to back of

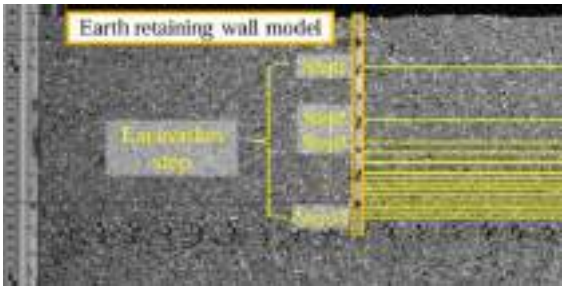

Fig.5 Excavation steps

Fig.6 Excavation of aluminum rods

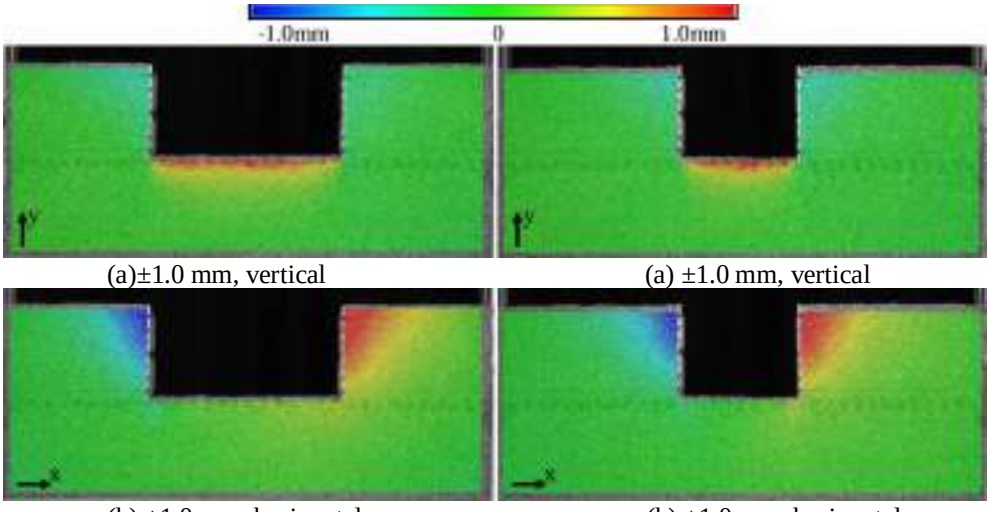
the model (Fig. 6). After each excavation, the weight of the excavated aluminum rod was measured and photographed using a digital camera (L4000 pixel, W6000 pixel, 0.2 mm/pixel) to capture the entire experimental apparatus. These operations were repeated until the excavation depth *h* reached 190 mm, leaving a 10 mm overburden directly above the cross makers. Each test was repeated thrice for excavation widths *W* of 400 and 250 mm, respectively.

EXPERIMENTAL RESULTS

Displacement distribution of model ground

Image analysis (Digital Image Correlation method with Ditect's DippStrain software) was used to obtain the vertical and horizontal displacement distribution at a depth of *h* = 190 mm (after excavation was completed). The results are presented in Fig.7–Fig.10.

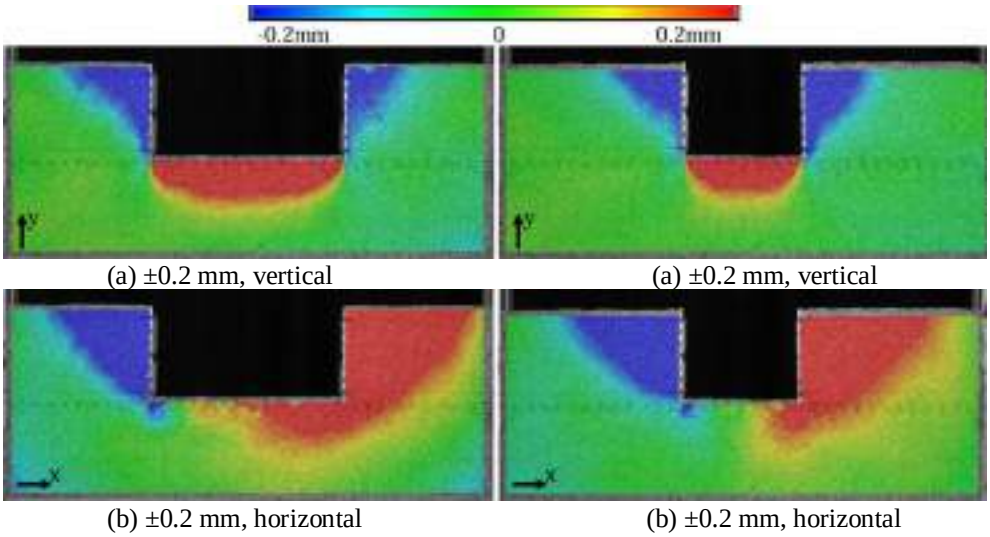
Fig.7 and Fig.8 show displacement distributions within a range of ±1.0 mm. Fig.7(a) and Fig.8(a)



(a)±1.0 mm, vertical (a) ±1.0 mm, vertical

(b) ±1.0 mm, horizontal (b) ±1.0 mm, horizontal

Fig.7 Displacement distribution (*W* = 400 mm) Fig.8 Displacement distribution (*W* = 250 mm)



(a) ±0.2 mm, vertical (a) ±0.2 mm, vertical

(b) ±0.2 mm, horizontal (b) ±0.2 mm, horizontal

Fig.9 Displacement distribution (*W* = 400 mm) Fig.10 Displacement distribution (*W* = 250 mm)

depict significant vertical displacements concentrated within a relatively narrow zone inside the retaining walls. This confirms the occurrence of ground heave in the model ground. Fig.7(b) and Fig.8(b) illustrate the horizontal displacement of the ground behind the retaining walls in the active pressure direction.

Fig.9 and Fig.10 show displacement distributions within a narrower range of ±0.2 mm. These figures reveal upward vertical displacement occurring approximately 100 mm below the excavation bottom within the retaining walls, along with horizontal displacements toward the center of the model. Similar displacement distribution results were obtained, regardless of *W*.

Vertical displacement of each cross marker

The distribution of vertical displacement—defined as the ground heave displacement δ_g—at each cross marker was analyzed. The vertical displacement of each cross marker at h = 190 mm (end of excavation) was calculated using image analysis (correlation tracking function of Ditect's Dipp-Motion V software). Note that this result was considered to have an error of approximately 1 pixel (= 0.2 mm). The relationship between δ_g and the distance from the left edge of the model ground is shown in Figure 11 for W = 400 mm and in Figure 12 for W = 250 mm. Each retaining wall was located at the positions indicated by the dotted lines in these figures.

The cross markers, located 300 mm (W = 400 mm) or 625 mm (W = 250 mm) from the left edge, were positioned beneath the retaining wall. As the retaining walls settled during excavation, δ_g near these regions was negative.

By contrast, within the excavation area, the distribution of δ_g appears approximately rectangular, when averaged, as indicated by the orange lines in Fig.11 and Fig.12. This rectangular distribution shape is generally consistent with the prediction of ground displacement by 3-dimensional finite element analysis by Okada et al. [7].

Although the heave displacement at the excavation bottom was not uniform, variations were observed among individual cross markers. Each experiment focused on cross markers within the retaining walls—12 points for W = 400 mm and 6 points for W = 250 mm—excluding any markers located less than 30 mm from the retaining walls. Box plots illustrating the range of variations of δ_g are shown in Fig.11 and Fig.12. Across the three

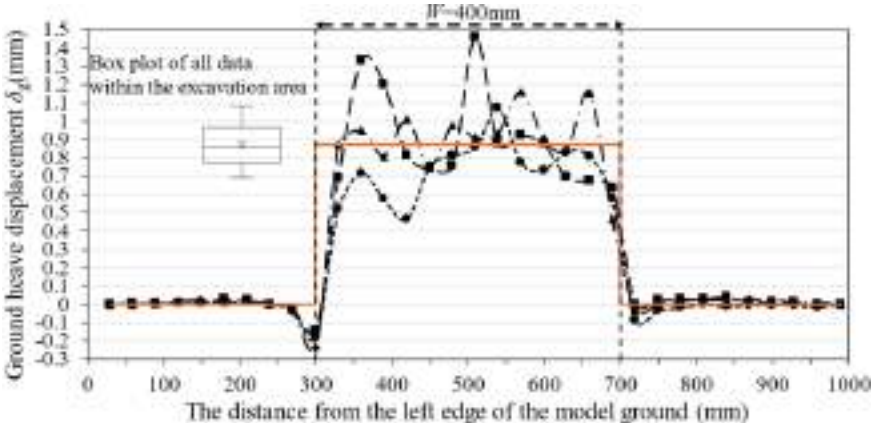


Fig.11 Horizontal distribution of ground heave displacement (W = 400 mm)

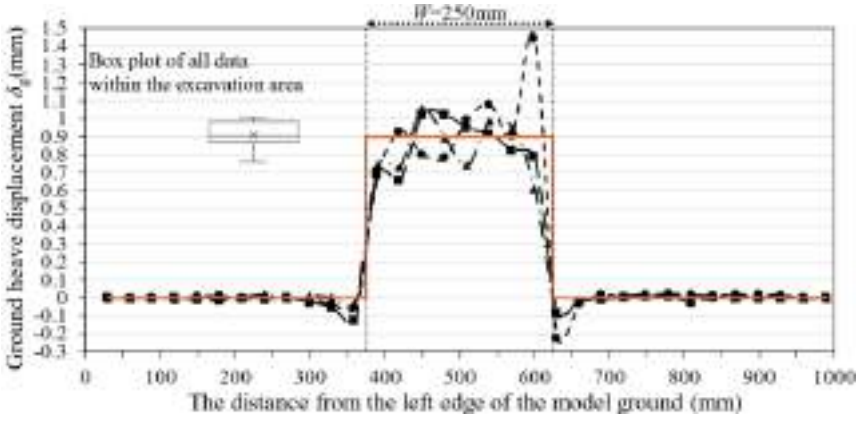

Fig.12 Horizontal distribution of ground heave displacement (W = 250 mm)

experiments, the averaged values were δ_g = 0.87 mm and 0.90 mm for W = 400 mm and 250 mm, respectively. The corresponding coefficients of variation were 12.5 % and 7.5 %. These variations may be attributed to accumulated errors in tracking cross markers during image analysis or to limitations inherent in the experimental method. For instance, removing all aluminum rods horizontally and simultaneously during excavation is not feasible, which may result in a slight localized displacement of the markers. However, when the displacement distributions were averaged, the results demonstrated good reproducibility across the three tests.

Change in amount of ground heave with progress of excavation

Fig.13 presents the results of δ_g at each excavation stage, following the previously described arrangement. The lower horizontal axis of Fig.13 shows the excavation rate, calculated by dividing h by the initial overburden thickness (200 mm). The overburden pressure corresponding to the excavation rate is indicated on the upper horizontal axis. The average axial strain of the lower ground, calculated by dividing δ_g (shown on the left vertical axis) by the height of the ground below its measurement position (200 mm), is shown on the right vertical axis. By considering the heave of the model ground as an increase in axial strain caused by unloading of the lower ground, we observed that the unloading behavior of the model ground is nonlinear elastic.

The aforementioned results confirm that the aluminum rod model ground can reasonably simulate the ground heave phenomena. Further, the usability of image analysis for measuring displacement was established.

However, the mechanism underlying this behavior in the aluminum rod model ground remains unclear, despite the relatively high bending stiffness and near-rigid properties of aluminum. Therefore, the relationship between the ground strain and heave displacement with changing overburden pressure, may differ significantly from that of the actual ground material (Fig.13). Nevertheless, we believe that this model sufficiently simulates ground behavior to meet the objective of this research, which aims to study the interaction between the ground and existing tunnels.

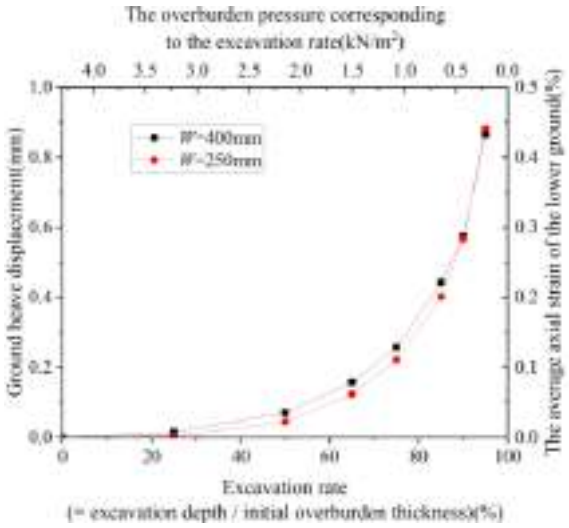

Fig.13 Variation in ground heave displacement according to the stage of excavation

CONCLUSIONS

In this study, excavation tests were conducted using an aluminum rod model.

Consequently, we confirmed that the ground heave could be simulated by combining image analysis with excavation tests using a model ground. Regardless of the excavation width, on average, the distribution shape of the excavation bottom was rectangular, which is consistent with the results of previous studies. Also, the change in the amount of ground heave with the excavation progress was confirmed to be nonlinear elastic.

The results of this study provide reference data for future excavation experiments. Future work will focus on subway tunnels and use the same experimental model to embed a model of an existing tunnel in the longitudinal direction. Subsequently, excavation over it was used to simulate nearby excavation work. The primary experimental parameters will include the excavation width and bending stiffness of the tunnel model. The influence of these factors on the vertical displacement of the tunnel caused by ground heave will be investigated.

TWO-DIMENSIONAL MODEL EXPERIMENTS ON THE SEISMIC BEHAVIOUR OF THE HEAD-FIXED DOUBLE SHEET PILE TEMPORARY EARTH RETAINING WALL METHOD

Akihiro Kikuchi[1], Hidetoshi Nishioka[1], Ayaka Nasu[2], Michitaka Okamoto[2] and Hideki Nagatani[2]

[1]Faculty of Science and Engineering, Chuo University, Japan; [2]Kajima Corporation, Japan

ABSTRACT

The head-fixed double sheet pile earth retaining wall method has been developed as a temporary, self-supporting earth retaining wall for excavation work. This method has been proven to reduce horizontal displacement during excavation, which improves economic efficiency and construction productivity. However, the seismic behaviour of this method is not yet fully understood. Therefore, two-dimensional modelling experiments were conducted using an aluminium-rod ground model to reproduce a temporary earth retaining wall under seismic movement after excavation by inclining the soil tank which provides horizontal seismic intensity. The relationships between the horizontal seismic intensity, inclination angle, and the horizontal displacement of the model sheet piles were analysed. Image analysis was also performed with photographs taken during the experiments to investigate the distribution of the strains of the model ground. The results show that the double earth retaining wall method is more resistant than the conventional single earth retaining wall during an earthquake; moreover, it reduces the rotational deformation behaviour at the bottom end of the model sheet pile compared to the single earth retaining wall with a more rigid model sheet pile.

Keywords: Self-supporting earth retaining walls, Aluminium rods, Excavation work, Seismic motion

INTRODUCTION

Earth retaining works involving soldier piles, laggings, or steel sheet piles are often used for underground construction. However, the earth pressure, which is influenced by the surrounding ground, causes horizontal displacements. To reduce the horizontal displacement, earth-retaining supports, such as struts with postpiles and soil nailing, are mainly used. However, struts can obstruct the use of large machinery, and soil nailing requires a large background space for penetration and specialised equipment for installation, resulting in higher costs.

To solve these problems, a head-fixed double-sheet pile earth retaining wall method was developed as a self-supporting temporary earth retaining system [1]. In this method, a pair of steel sheet piles is embedded in parallel, and their heads are rigidly fixed by concrete or welded braces. It is assumed that this method sufficiently reduces the horizontal displacement of earth retaining works during excavation because of the push-pull resistance of the two sheet piles and the resisting effects of the internal soil between the two sheet piles, as shown in Fig.1. Model experiments using X-ray computed tomography (CT) [2] and two-dimensional model experiments using an aluminium rod model ground [3] have confirmed the effectiveness of the double-earth retaining wall method in reducing displacements during excavation, and it has been increasingly used as a self-supporting earth retaining system in relatively shallow open excavations.

According to the Standard Specifications for Tunnelling [4], 'Temporary structures are generally built for a short period and, from an economic point of view, their design does not consider seismic resistance'. The seismic behaviour of the double earth retaining wall method has not been fully clarified. However, the same instruction also states the following: 'In cases where the installation period is particularly long or the structure is located close to an important building, it may be necessary for the structure to be designed while considering seismic safety'. Therefore, in this study, two-dimensional modelling experiments were conducted with an aluminium-rod ground model to reproduce a temporary earth-retaining wall under seismic motion after excavation by inclining the soil tank, resulting in horizontal seismic intensity.

	20	2.0 mm				

Two-dimensional Model Experiment on Model Ground of Aluminium Rods

Aluminium rods were used in this study to simulate the excavation work. Two-dimensional model experiments with aluminium rods have several advantages: the rods themselves are self-supporting, and allow easy observation of displacements and their behaviour in the model ground by moving the aluminium rods; the strength and displacement properties closely resemble those of a medium-density sandy soil; and the grain size characteristics remain constant, which ensures high repeatability of the experiments. Aluminium rods have already been used in two-dimensional model experiments to simulate not only earth retaining work using sheet piles [5] but also spread foundations [6], column foundations [7], pile foundations [8] and box tunnel [9].

Model Ground Preparation

In this study, the model ground was prepared by blending aluminium rods with a length of 150 mm and diameters of 3.0 mm, 2.0 mm, and 1.5 mm in a weight ratio of 1:1:1. Blending was performed in a rigid soil tank with a height of 300 mm, a width of 1,000 mm and a depth of 150 mm. The unit volume weight of the ground model was set at 21.5 kN/m^3.

Thin aluminium plates (Young's modulus E = 70 kN/mm^2) with a height of 300 mm, depth of 200 mm, and an embedded depth of 250 mm were used as model sheet piles. The front model sheet piles for the single- and double-earth retaining works were placed at the centre of the model ground after the foundation ground reached a thickness of 100 mm. To simulate a double earth retaining wall, the rear model sheet piles were manually embedded until they reached a depth of 250 mm at 50 mm head separation after piling up the model ground to 300 mm. To fix the two heads of the sheet piles, acrylic resin blocks were placed between the two model sheet piles and bolted to simulate a rigid bond.

Model experiment procedures and cases

As shown in Fig.2, the equipment used in this model experiment had a pin hinge at the bottom of the apparatus. By raising the right end of the equipment using a jack, the entire soil tank could be inclined to exert a horizontal static acceleration (horizontal seismic intensity, k_h) on the model ground. If the nonlinear response of a large earthquake is predominant, it must be assessed via vibration experiments. However, if the behaviour of the structure is up to the vicinity of yielding, the seismic earth pressure considered by Mononobe and Okabe can be applied [10,11]. Inclining experiments simulate this phenomenon almost directly and correspond to the seismic intensity method commonly used in seismic stability calculations.

Before the soil tank was tilted, the aluminium rods were removed by hand from the left side of the model sheet pile to achieve an excavation depth of

125 mm. The equipment was then jacked up at a rate of 0.40 mm/s and inclined until the front model sheet pile came into contact with the laser displacement meters installed on the side of the excavation face. The horizontal displacement δ_1 of the top of the model sheet pile excluding the protrusion was (the height of the ground surface before excavation) and displacement δ_2 of the model sheet pile at the level of the excavation floor were measured. The rotation angle of the earth retaining head θ was also measured using an accelerometer, and photographs were taken during the experiments for image analysis.

Table 1 lists the experimental cases. Four cases of double and single earth retaining with 0.5 mm, 1.0 mm and 2.0 mm thick model sheet piles were conducted. Fig.3 shows the relationship between the excavation depth and the horizontal displacement obtained from an excavation model experiment in the aluminium rod model ground [3]. The value $1/\beta$, the inverse value of the characteristic value β expressing the relationships between the coefficient of earth pressure and the stiffness of the sheet pile and βL, the product of value β and the penetration length of the model sheet pile L = 125 mm are also given in the table. The characteristic values β for each case apply to a single model sheet pile. To account for real structure parameters, we assumed that βL was equivalent between the prototypes and models [12]. For actual Type III U-shaped steel sheet piles in sandy soil with an N value of 24 [13], the reciprocal $1/\beta$ of the characteristic values β is 1.54 m. When the dimension ratio of the model is 1/20, the value of βL for Type III piles for a penetration depth after excavation L of 2.5 m is 1.62. Therefore, in this study, Case 10 can be interpreted as corresponding to 1/20-scale models of Type III U-shaped steel sheet piles. However, this similarity rule does not account for the perspective of the failure of the model ground. Therefore, test results at the stage when the model ground is close to failure cannot be converted to actual values and should be evaluated relative to each case.

RESULTS AND DISCUSSIONS

Relationships Between Seismic Intensity and Individual Measurement Items

A schematic representation of the experimental setup is shown in Fig.4. The horizontal seismic intensity k_h acting on the model ground was calculated using Eq. (1) based on the inclination angle, ψ, of the model soil tank. In Fig.4, θ shows the inclination angle of the head of the motel sheet pile with respect to the floor and was obtained from the measured values of the accelerometer installed at the head of the model sheet pile.

$$k_h = \tan\psi \tag{1}$$

The relationships of the horizontal seismic intensity k_h, with the inclination angle ξ of the earth retaining wall and the horizontal displacements δ_1 and δ_2 of the model sheet pile are shown in Figs.5-7, and the incremental relationships of the three items are shown in Figs.8-10. The inclination angle ξ refers to the angle of the earth retaining wall relative to the angle of inclination ψ of the model soil tank, as expressed in Eq. (2).

$$\xi = \theta - \psi \tag{2}$$

For double earth retaining, Cases 0505 and 1010 showed close relationships for the inclination angle ξ up to a seismic intensity k_h of approximately 0.17, whereas Case 0505 showed a slightly faster increase afterward (Figs.5,8). As in the excavation experiment (Fig.3), the higher the stiffness of the model sheet pile, the smaller the displacement that occurred after inclination. At k_h = 0.10, the incremental displacements $\Delta\delta_1$ and $\Delta\delta_2$ for Case 0505 (Figs.9,10, respectively) were 3.3 times those for Case 1010. However, for single earth retaining (Cases 10 and 20), Case 20 showed larger displacements than Case 10, which was contrary to the results of the excavation experiment. As the inclination angle ξ in Fig.5 suggests, Case 20 collapsed at k_h = 0.13, which was faster than that of Case 10, which collapsed at k_h = 0.18.

Next, Cases 10 and 1010 were compared, whose model sheet piles had the same stiffness. The increase in inclination angle ξ with increasing horizontal seismic intensity k_h is approximately parallel and the same for both Case 10 and Case 1010. In addition, two points with horizontal seismic intensity k_h can be observed where the earth retaining has a large inclination angle ξ. For Case 10 earth retaining, large tilts occurred at k_h = 0.15 and 0.17, and for Case 1010 at k_h = 0.16 and 0.18. The increase in horizontal displacement δ_1 with increasing horizontal seismic

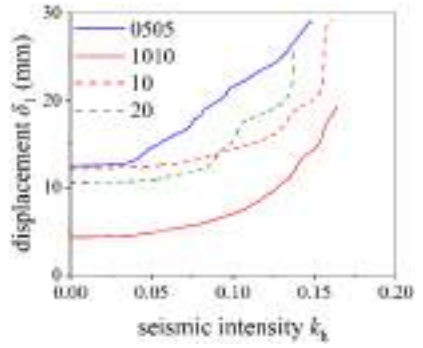

Fig.6 Relationships between horizontal seismic intensity k_h and horizontal displacement δ_1

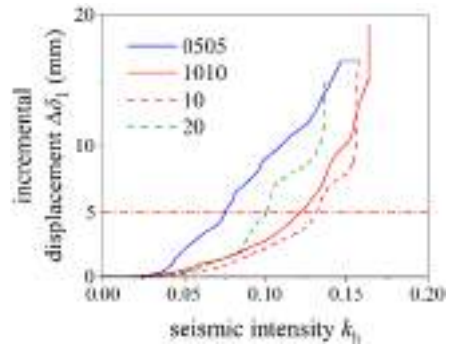

Fig.9 Relationships between horizontal seismic intensity k_h and incremental displacement $\Delta\delta_1$

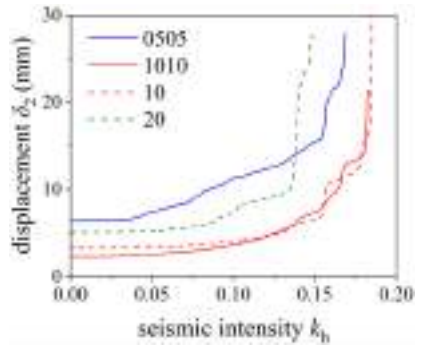

Fig.7 Relationships between horizontal seismic intensity k_h and horizontal displacement δ_2

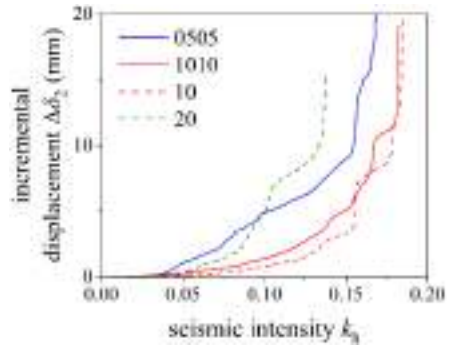

Fig.10 Relationships between horizontal seismic intensity k_h and incremental displacement $\Delta\delta_2$

intensity k_h proceeds faster for Case1010 than for Case10. In contrast, there is no difference in the relationship between the horizontal seismic intensity k_h and the horizontal displacement δ_2 between Cases 10 and 1010.

Finally, a comparison was made between Cases 0505 and 20, which showed close relationships between the excavation depth and the horizontal displacement in the two-dimensional excavation model experiments (Fig.3). In Case 0505, several points (horizontal seismic intensity k_h = 0.16, 0.17, 0.19) can be observed where a large head tilt angle ξ occurs at the earth retaining. In Case 20, the tilt angle increased rapidly when the horizontal seismic intensity k_h reached 0.13. In Case 0505, the horizontal displacement δ_1 increased monotonically with increasing horizontal seismic intensity k_h. In contrast, Case 20 showed a smaller displacement δ_1 than Case 0505. The horizontal displacement δ_2 deformed faster in Case 0505 with increasing horizontal seismic intensity k_h. However, a large displacement δ_2 occurred in Case 20 at a horizontal seismic intensity k_h = 0.14, which showed a more rapid increase in displacement δ_2 than in Case 0505. In the middle of the experiments (horizontal seismic intensity k_h = 0.13), Case 0505 showed a s-shaped deformation

(Fig.11) which is reflected in the measured results where Case 0505 showed a larger displacement δ_1 than Case 20 but a relatively close relationship in displacement δ_2.

These results suggest that although the double earth retaining wall method may show a slightly faster increase in horizontal displacement, it is more stable than a conventional single earth retaining wall.

Results of the Image Analysis

With the incremental horizontal displacement $\Delta \delta_1 \fallingdotseq 5.0$ mm (Fig.9), the distributions of normal strains were examined by performing a photographic image analysis using DippStrain, developed by Ditect. The distribution of normal strains in the horizontal direction in the model ground was visualised in all cases (Fig.12). The red areas in Fig.12 represent the expansion of the model ground, whereas the blue area represents the contraction.

The internal soil between the two model sheet piles of the double-earth retaining shows only minor deformations, apart from a slight deformation occurring near the model sheet pile. It can therefore be seen that the two steel sheet piles and the internal soil behave as a single wall.

The areas affected by the ground deformation are wider in the single earth retaining than in double earth retaining, and the strain region of the single earth retaining starts near the bottom of the earth retaining, whereas that of the double earth retaining starts slightly above the bottom edges. It is known that the earth retaining shows a rotational collapse behaviour when the strain region starts from the lower edge of an earth retaining [12]. This finding suggests that the double earth retaining method reduces the rotational behaviour more effectively than the use of highly rigid steel sheet piles as single earth retaining, although the displacements occurring during excavation are comparable.

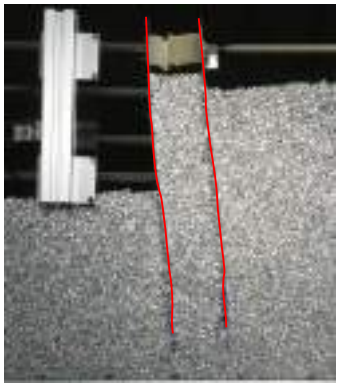

Fig.11 Deformation of Case 0505 at k_h = 0.13

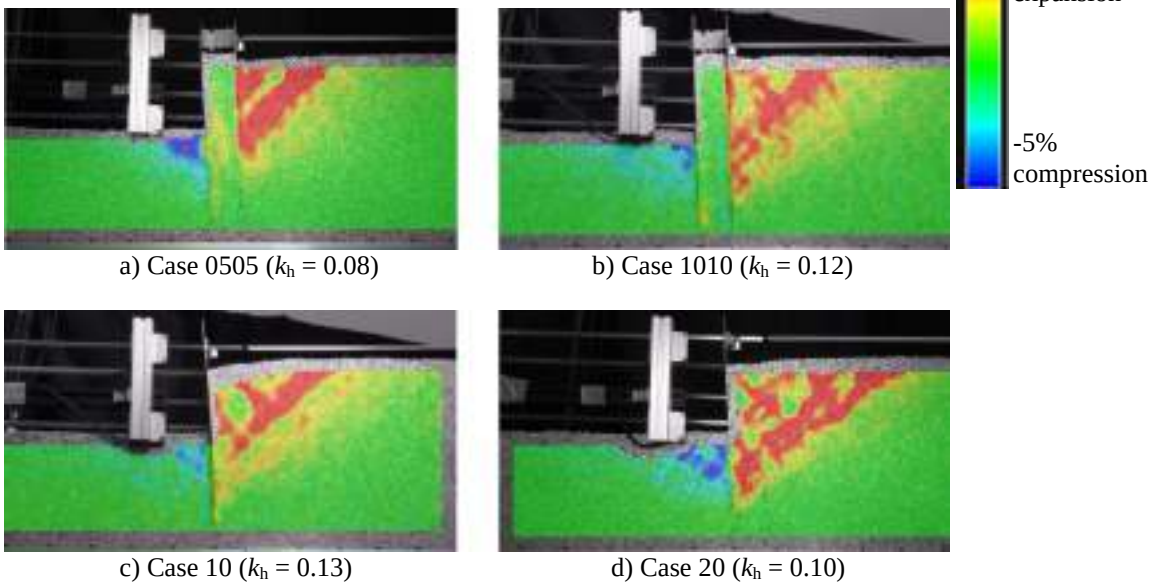
CONCLUSIONS

The following conclusions were drawn from the two-dimensional model experiment to examine the seismic behaviour of the head-fixed double-sheet pile earth retaining wall method. First, this method showed a faster increase in horizontal displacement than the single earth retaining wall, for example at k_h = 0.10, the incremental displacement $\Delta \delta_1$ of Case 0505 was 4 times larger than Case 10. However, the double-earth retaining wall was more resistant with s-shaped deformation (Fig.11). Second, the risk of rotational collapse of a double earth retaining wall during seismic movements is lower than that of a single earth retaining wall (Fig.12), whereas a double earth retaining wall



a) Case 0505 (k_h = 0.08) b) Case 1010 (k_h = 0.12)

c) Case 10 (k_h = 0.13) d) Case 20 (k_h = 0.10)

Fig.12 Distribution of the horizontal normal strain at $\Delta\delta_1 \fallingdotseq 5.0$ mm

can reduce horizontal displacement during excavation (Fig.3).

Further investigations will be conducted to explore the effects of displacement reduction with the head-fixed double-sheet pile earth retaining wall method by varying the conditions of penetration depth and by measuring the earth pressures acting on the model sheet pile.

TWO-DIMENSIONAL MODEL EXPERIMENTS ON SEISMIC RESISTANCE OF SPREAD FOUNDATION DAMAGED BY LOCAL SCOURING

Yuki Yamakuri[1], Tomohito Ishii[1] and Hidetoshi Nishioka[1]

[1]Faculty of Science and Engineering, Chuo University, Japan

ABSTRACT

In recent years, scour damage to the foundations of river bridge piers has become increasingly prevalent owing to the rising frequency of typhoons and heavy rain. When the extent of damage is moderate (manifesting as settlement or tilting of the foundation), foundations affected by local scour can be reused. Japan has witnessed several cases of such reuse. However, the seismic bearing capacity of foundations following local scour events remains poorly understood. In this study, two-dimensional model experiments using an aluminum rod ground model were conducted to investigate the horizontal bearing characteristics of a spread foundation damaged by local scour. A distinctive feature of our experimental methodology is the ability to precisely control the extent of scour while simultaneously observing the ground deformation behavior through image analysis. In this experiment, scour was induced by extracting an aluminum rod. Subsequently, horizontal loading experiments on a spread foundation were conducted, followed by image analysis. The horizontal resistance decreased as the scour amount increased. Nevertheless, the bearing capacity of the spread foundation damaged by scour was maintained under eccentric and inclined loading caused by seismic inertial forces.

Keywords: Scour, Earthquake, Horizontal Loading Experiment, Aluminum Rod, Image Analysis

INTRODUCTION

Recently, the foundations of river bridge piers have experienced significant scour damage owing to an increase in the frequency and intensity of typhoons and heavy rainfall. Most damaged river bridge piers use a spread foundation design [1, 2]. The types of damage observed can be categorized into large-scale and medium-scale. Large-scale damage typically involves the flowing or overturning of piers, whereas medium-scale damage is characterized by the settlement or inclination of piers. Generally, river bridge piers that have sustained scour damage are deemed unsafe for reuse. However, several instances have been reported in Japan where piers demonstrating medium-scale scour damage have been successfully rehabilitated after thorough safety assessments. The example of reused railroad bridge piers is shown in Fig.1 [3]. This underscores the necessity of accurately evaluating the bearing capacity characteristics of reused spread foundations.

Sasaki and Nishioka conducted vertical loading tests on local scoured spread foundations using aluminum rod ground model [4]. Hirano et al. used a similar experimental approach to examine the influence of internal erosion on the bearing capacity characteristics [5]. Furthermore, Hirano et al. enhanced the experimental apparatus to consider the dead load safety factor and systematically conducted simulations of scouring phenomena and vertical loading tests on locally scoured spread foundations. [6]. Yamakuri et al. analyzed the bearing capacity of a spread foundation after local scouring using the rigid plastic finite element method [7]. However, no studies have investigated the bearing capacity characteristics of spread foundations following scour damage under seismic inertial forces.

Fig.1 Example of reused railroad bridge piers (JR East, Gono Line, Nakamuragawa bridge pier)

To address this gap, in the present study, two-dimensional horizontal loading experiments aimed at assessing the seismic resistance of spread foundations that have suffered local scour damage were conducted. A distinctive feature of the experimental methodology is the ability to control the extent of scour while simultaneously observing the ground deformation behavior

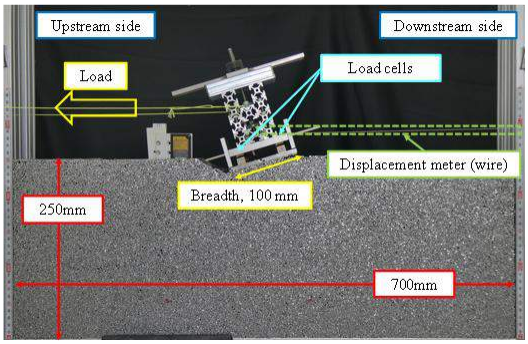

Fig.2 Experimental devices

RESEARCH SIGNIFICANCE

The reuse of river bridge piers that have been compromised by local scour is anticipated to become increasingly prevalent. In Japan, a country prone to frequent earthquakes, assessing the horizontal resistance of spread foundations is crucial. This study introduces a novel approach by examining the horizontal bearing capacity characteristics of a spread foundation in the context of combined multihazard risks of scours and earthquakes. The findings of this research are expected to make a substantial contribution to the timely restoration and ongoing safe use of scour-damaged bridge piers.

HORIZONTAL LOADING EXPERIMENTS ON ALUMINUM RODS

Experimental Devices

In this study, an aluminum rod ground model was used to simulate the behavior of two-dimensional sandy soil. The advantages of using the materials are [8, 9]:

1. They exhibit deformation and strength characteristics like those of medium-density sand.
2. The repeatability of the experiments is high because the particle size characteristics remain unchanged even after multiple tests.
3. The ground deformation behavior can be observed via image analysis using photographs of the aluminum rods.

Taking advantage of these features, model experiments have been conducted involving loading and unloading problems such as spread foundations [10] and excavations [11]. In addition, the variation in the experimental results has been confirmed to be relatively small in vertical loading experiments of spread foundations [12].

The experimental devices used for the horizontal loading experiments are shown in Fig.2. The model ground was constructed by mixing aluminum rods 150 mm long with diameters of 1.5, 2.0 and 3.0 mm, ensuring equal weights for each size. The ground model dimensions (height × width)250 mm × 700 mm. Sufficient compaction was performed to simulate the bearing stratum beneath the spread foundation and to minimize variation. Thorough compaction was conducted for each 50 mm thick layer using a small vibrator. The unit volume weight γ and angle of repose ϕ_r of the model were 21.6kN/m^3 and 32°, respectively.

Table 1 List of bridge pier models

$F_{s,DL}$	V_D [N]	H_c / B
3	59.68	0.77
4.5	41.55	0.79
6	30.01	0.74

The bridge pier model used a spread foundation design without a penetration depth, with the footing dimensions (breadth × length) measuring 100 mm × 150 mm. Three types of bridge pier models were used, as shown in Tab.1, with parameters including the total weight (referred to as model dead load V_D) and center of gravity height (H_c). The dead load safety factor $F_{s,DL}$ can be defined using the model dead load V_D and the ultimate bearing capacity of the normal ground V_{ult} (approximately 180 N) as follows:

$$F_{s,DL} = V_{ult} / V_D \quad (1)$$

H_c was established with reference to the actual pier foundations that were reused following a disaster [3].

To measure the horizontal displacement at the center of the footing's base, a horizontal displacement gauge was installed approximately 400 mm away, and connected through a wire to follow the settlement of the footing. During the horizontal loading experiments, the horizontal load was measured using a load cell installed on the horizontal loading jacks. Additionally, the reaction force moments at the base of the footing were measured using two-way load cells affixed to the bottom of the bridge pier model. The inclination angle of the footing was determined through accelerometers attached to the bridge pier model. The horizontal displacement at the loading point was calculated by combining the displacement determined from the inclination angle with the horizontal displacement measured at the center of the footing.

Modeling of the Local Scour

This section outlines the modeling of the local scour in these model experiments. First, the model dead loads were simulated by placing weights on a

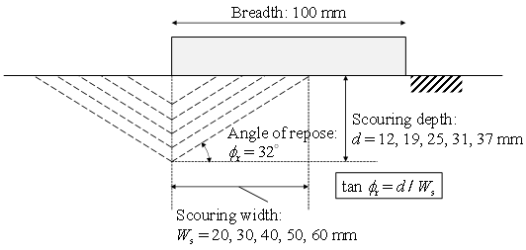

Fig.3 Experimental cases of the local scour area

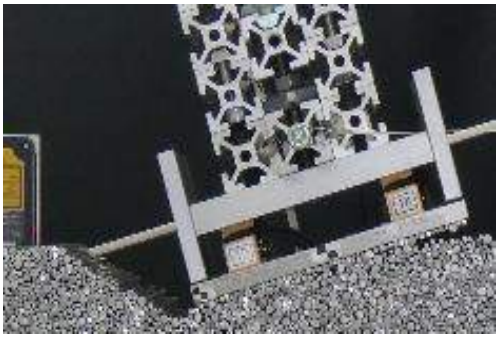

Fig.4 Modeling of local scour

horizontally positioned foundation model. Local scour was then simulated by removing aluminum rods situated beneath the base of the footing. The resulting shape of the local scour was modeled as an isosceles triangle, with its height defined as the scouring depth d, as shown in Fig.3. This shape was determined based on the tendency of the scour to form a cone, with its apex located at the base of the upstream side of the piers [13]. The relationship between the local scouring width W_s and scouring depth d is expressed as $\tan\phi = W_s/d$, where ϕ. represents the angle of repose. The bridge pier model after local scouring is shown in Fig.4. Horizontal loading experiments were conducted at several scouring depths, as shown in Fig.4.

Loading Procedure

The configuration of the horizontal loading experiments is shown in Fig.5. To simulate seismic inertial forces, strings were affixed to the center of gravity of the pier model, and loads were applied using a jack. Horizontal loading experiments were conducted for scouring depths of d = 0 mm (before scour) and d = 12, 25, and 37 mm (after scour) to investigate the effect of the scour area on the horizontal resistance of a spread foundation. Horizontal loading was performed until the jack reached its operational limit of 50 mm or the bridge pier model was overturned.

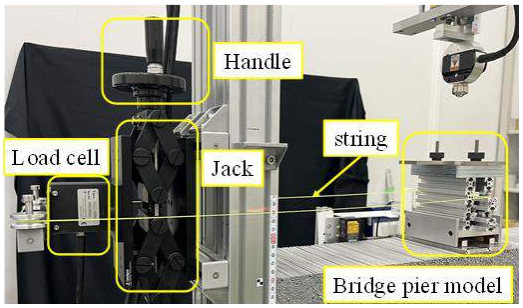

Fig.5 Setup of horizontal loading experiments

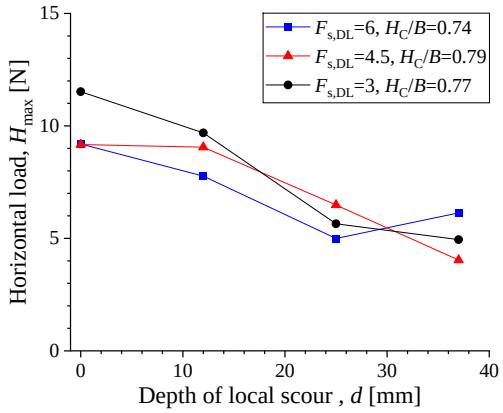

Fig.6 Relationship between the horizontal load and scoring depth

EXPERIMENTAL RESULTS

Relationship Between the Horizontal Load and Scouring Depth

The relationship between the maximum horizontal load H_{max} and scouring depth is shown in Fig.6. The horizontal load decreased as the scouring depth increased, regardless of the magnitude of dead load safety factor $F_{s,DL}$, except for the cases in which $F_{s,DL}$ = 6 and d = 37 mm. This reduction in the horizontal resistance resulted from the localized loss of contact area between the foundation base and the ground due to local scour, as well as from the residual inclination of the foundation structure.

The relationship between the horizontal seismic coefficient, defined as the horizontal load divided by the model's dead load and scouring depth, is shown in Fig.7. In general, a horizontal seismic coefficient of 0.2 is used in seismic design in Japan [14]. Across all scouring depths, the horizontal seismic coefficients decreased as the dead load safety factor decreased.

Thus, the horizontal resistance of a spread foundation is influenced by the dead load safety factor and scouring depth.

Table 2 Image analysis results

	$F_{sDL}=3, H_C/B=0.77$	$F_{sDL}=4.5, H_C/B=0.79$	$F_{sDL}=6, H_C/B=0.74$
d=0 mm			d=12 mm			d=25 mm			d=37 mm			

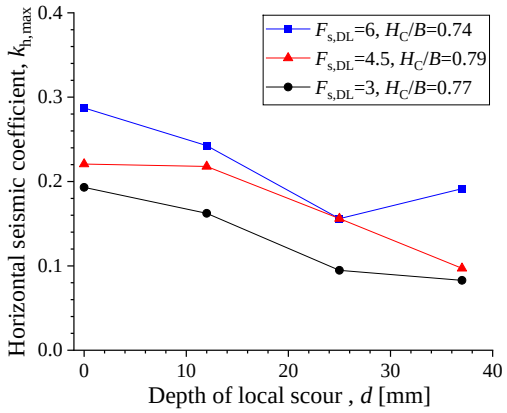

Fig.7 Relationship between the horizontal seismic coefficient and scouring depth

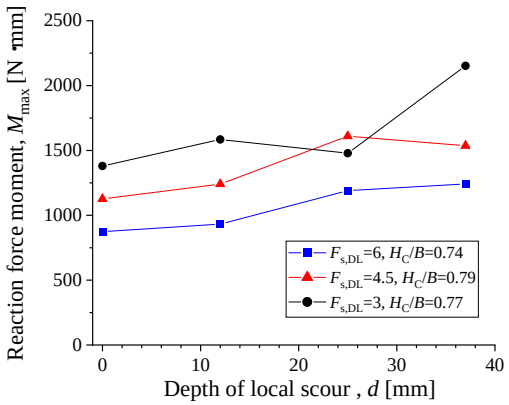

Fig.8 Relationship between the reaction force moment at the bottom and scouring depth

Relationship Between the Reaction Force Moment at the bottom and Scouring Depth

The relationship between the maximum value of the reaction force moment and scouring depth is shown in Fig.8. Although the horizontal resistance decreases due to scour damage, as shown in Fig.6, the reaction force moment does not decrease. Therefore, the influence of a reduced bearing capacity due to scouring on the seismic resistance of spread foundations is minor. In other words, these results indicate that the bearing capacity of a spread foundation damaged by scour is maintained under

eccentric and inclined loading caused by seismic inertial forces.

Image Analysis Results

To further investigate the displacement behavior of the model ground, image analysis was performed using Dipp-Motion (Ditect). The results of the image analysis are listed in Tab.2. Before local scouring (i.e., with a scouring depth d of 0 mm), a slip line was detected around the left edge of the footing, originating from the contact surface between the footing's base and the ground. Following local scouring (at a scouring depth d of 12 mm), a similar ground displacement behavior was observed over a wider area than before the disaster. At scouring depths of d = 25 and 37 mm, the left edge of the bottom of the bridge pier model settled toward the scour area and the footing detached from the base. Additionally, the left side of the footing remained in contact with the ground. For this reason, earth pressure acting on the sides of the footing serves as a lateral resistance force, enhancing rotational stability. This implies that the seismic resistance of the spread foundation improved despite the occurrence of scour damage.

However, since the failure mode is considered to depend on the height of the center of gravity, further experiments are required.

CONCLUSIONS

This study conducted two-dimensional horizontal loading experiments to investigate the seismic resistance of a spread foundation affected by local scouring. The key findings of this study are as follows:

1) The horizontal resistance of the spread foundation decreased as the extent of scouring increased.
2) The bearing capacity of a spread foundation damaged by scour was maintained under eccentric and inclined loading caused by seismic inertial forces.
3) The results indicate that the rotational resistance of the spread foundation increased with greater scouring depth. This phenomenon is attributed to enhanced contact between the left side of the footing and the surrounding soil, which increased the resistance to rotation.

Future research directions and prospects are as follows:

1) The factors that increase the resistance to rotation as the scouring depth increases should be clarified. To achieve this, we should measure the earth pressure acting on the side of the footing.
2) Since actual bridge piers have varying centers of gravity, it is necessary to conduct experiments using this as a parameter.
3) When reusing bridge pier foundations damaged by local scouring, a reinforcement method using sheet piles is applied (Fig.1). We will investigate the reinforcement effect of sheet piles on the horizontal bearing capacity of a spread foundation following local scouring.

ABSTRACT

Roadside and river embankment slopes are typically protected using vegetation-based stabilization methods. However, recent increases in heavy rainfall and flooding, attributed to climate change, have led to more frequent erosion damage caused by surface runoff on these vegetated slopes. Despite this, the influence of plant species and their growth conditions on erosion resistance remains poorly understood. To address this gap, we conducted erosion resistance tests on soil boxes vegetated with *Phalaris arundinacea* L. (reed canary grass). Our findings demonstrate that the development of stems, leaves, and roots significantly enhances resistance to erosion. Additionally, applying Structure-from-Motion (SfM) photogrammetry enabled effective visualization of changes in erosion resistance associated with plant growth.

Keywords: Erosion control effect, Vegetation works, Growth condition, Surface runoff, Photogrammetry

INTRODUCTION

Recent climate trends have led to a noticeable increase in average temperatures, even in cold and relatively dry regions such as Hokkaido. A rise in the frequency of short-duration, high-intensity rainfall events has accompanied this. In Japan, it is standard practice to stabilize slopes on roadsides and embankments with vegetation (Guidelines for Road Earthworks -Cut Slope Work / Slope Stability Work [1]). However, cold-resistant species such as Kentucky bluegrass, which have been widely used for this purpose, are becoming less viable under rising temperatures. At the same time, erosion caused by surface runoff has become more common during heavy rain events. While vegetation is known to mitigate erosion, quantitative relationships between plant growth and erosion resistance on slopes remain insufficiently clarified.

This study addresses this knowledge gap by focusing on *Phalaris arundinacea* L., a species more suited to warm climates than Kentucky bluegrass. We tested erosion resistance on vegetated soil boxes where *Phalaris arundinacea* L. was grown for varying durations. Water was introduced over the soil surface via overflow from a storage tank, simulating surface runoff conditions (following the method of Kajimoto et al. [2]). Previous research has shown that *Phalaris arundinacea* L. exhibits greater resistance to raindrop-induced erosion (Gorobe et al. [3]) and enhances soil shear strength (Utaka et al. [4]). During testing, we measured the sediment runoff, and after each test, we removed the above-ground biomass and created 3D models of the eroded surfaces using SfM photogrammetry.

OVERVIEW OF THE EXPERIMENT

Table 1 summarizes the experimental conditions for all test cases. Four primary test scenarios were

Table 1 Experimental conditions of specimens.

Case	Specimen name	Growth Period	Number of growing days (d)	Cumulative temperature (°C•d)	Cumulative sunshine duration (h)
1	S-1, 2	No vegetation	-	-	-
2	S-RCG1	2024/8/19 - 2024/9/16	29	590	190
	S-RCG2	2024/8/21 - 2024/9/18	29	587	192
	S-RCG3	2024/8/23 - 2024/9/20	29	574	182
3	S-RCG4	2024/7/31 - 2024/9/25	57	1136	331
	S-RCG5	2024/8/2 - 2024/9/27	57	1128	329
	S-RCG6	2024/8/7 - 2024/10/2	57	1090	333
4	S-RCG7	2024/7/17 - 2024/10/9	85	1647	464
	S-RCG8	2024/8/2 - 2024/10/25	85	1470	490
	S-RCG9	2024/8/6 - 2024/10/29	85	1406	484

established: Case 1 served as the control with no vegetation, while Cases 2 through 4 involved *Phalaris arundinacea* L. grown for 4, 8, and 12 weeks, respectively, from mid-July to early October 2024.

Figure 1 shows the grain size accumulation curve of the volcanic sandy soil collected from Bihoro Town in eastern Hokkaido. Only the portion passing through a 9.5 mm sieve was used. Figure 2 presents the compaction curve for this soil type.

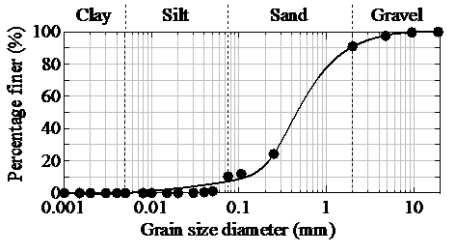

Fig. 1 Grain size accumulation curve

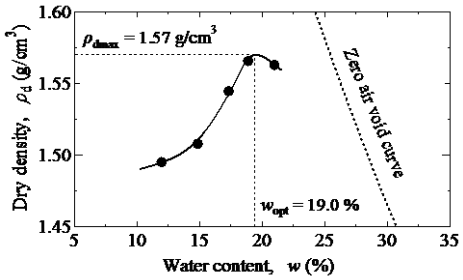

Fig. 2 Compaction curve

Figure 3 illustrates a schematic diagram of the soil box used in the experiment. The soil, adjusted to the optimum moisture content, was compacted in three layers to achieve a compaction degree of 85%. For Cases 2 to 4, *Phalaris arundinacea* L. seeds were mixed into the top layer at a seeding rate of 0.254 g,

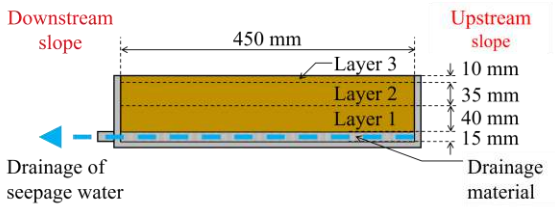

Fig. 3 Schematic diagram of soil specimen.

targeting an expected emergence of 3,500 plants/m². These boxes were placed outdoors in shaded conditions and maintained by a capillary water supply from the bottom, with twice-daily surface spraying to prevent drying.

Figure 4 provides an appearance of plant specimens, while Table 2 details the growth conditions for Cases 2 to 4. Before the erosion tests, the number of plants and plant height were measured in each box at three locations (upstream, midstream, and downstream) using the quadrat method. The vegetation cover rate was also quantified by processing top-view images of the soil boxes with the image viewer software *Pickmap*, in which stems, leaves, and soil were classified using binary image segmentation. After the erosion tests, the dry mass of roots was determined by sampling with PVC pipes (44 mm diameter) and drying the extracted roots. As shown in Figure 4 and Table 2, vegetation conditions varied depending on the location, even within the same box. This variation is thought to be primarily due to differences in sunshine duration at different locations within the box.

Figure 5 shows the relationship between plant growth and meteorological conditions. During the first 8 weeks after seeding, the plants exhibited steady elongation and development in accordance with cumulative temperature, but growth significantly slowed thereafter.

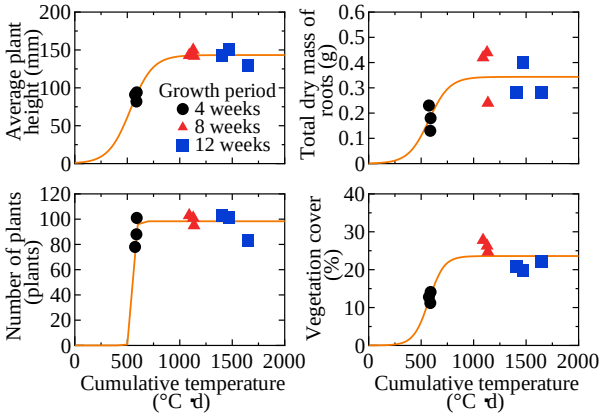

Fig. 5 Relationship between the growth conditions of plant specimens and cumulative temperature.

Fig. 4 Appearance of plant specimen.

Table 2 Number of plants, plant height, total dry mass of roots, and vegetation cover in the plant specimens.

Case	Specimen name	Measured before erosion tests									Measured after erosion tests			
		Number of plants (plants)				Plant height (mm)				V.c (%)	Dry mass of roots (g)

Note: Up = Upstream, Mid = Midstream, Down = Downstream, Ave. = Average, V.c = Vegetation cover

Figure 6 shows the schematic diagram of the erosion test apparatus (adapted from Kajimoto et al. [2]). In this study, erosion tests were conducted on a long embankment slope, assuming a scenario in which surface water generated at the top flows downward, causing erosion at the toe of the slope. Soil boxes were set on a 1:1.5 slope, and surface runoff was applied via overflow from a storage tank. The flow was controlled at 50 mm width and 1 L/min discharge. Each erosion trial lasted 30 seconds, after which the runoff sediment was collected, and its dry mass was determined. Tests were repeated until the drainage material at the bottom of the soil box became exposed (see Figure 3).

Upon completion of the tests, stems and leaves were cut and removed, and SfM photogrammetry was used to generate 3D surface models of the eroded areas for visual analysis.

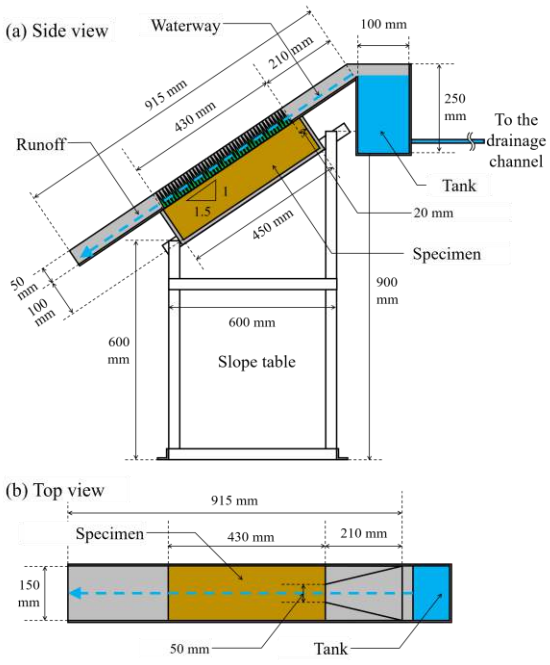

Fig. 6 Schematic diagram of erosion test apparatus.

RESULTS AND DISCUSSION

Figure 7 presents the appearance of specimens following the erosion test, highlighting representative outcomes from each case. In Cases 2 through 4, the

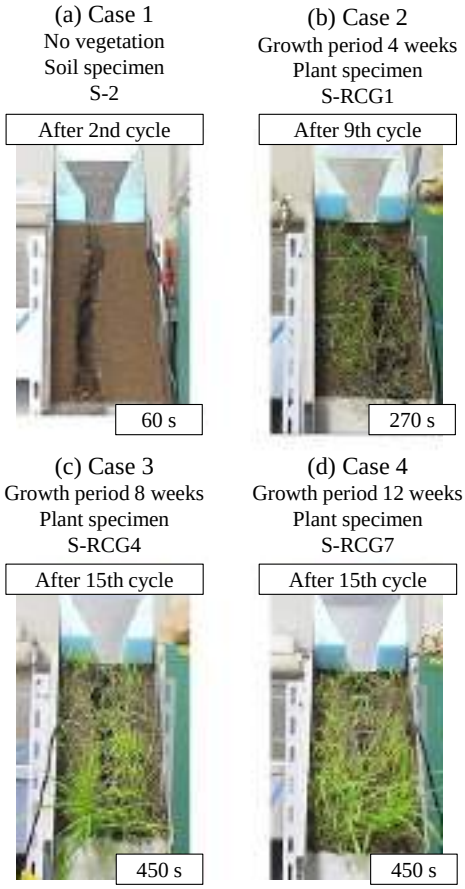

Fig. 7 Appearance of specimens following erosion test.

vegetative cover partially obscures the eroded surfaces, but visual comparison with Case 1 clearly shows that vegetation significantly reduced surface erosion.

Figure 8 illustrates the cumulative mass of sediment runoff across all trials. Due to the number of tests conducted, results are divided into Cases 1 and 2, and Cases 3 and 4. In Case 1 (bare soil), approximately 500 grams of sediment were lost during the first erosion event. The underlying drainage material became visible during the second test, leading to the termination of the trial. In Case 2, while the erosion rate was initially slower than in Case 1, all samples eventually reached similar cumulative sediment runoff within 10 trials, after which testing was concluded.

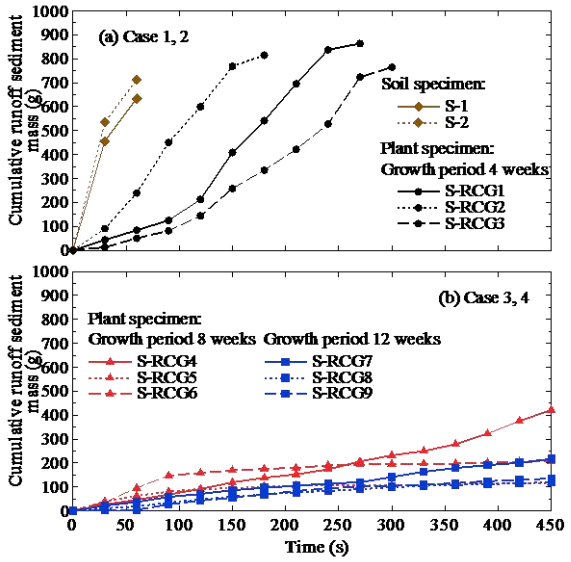

Fig. 8 Changes over time in cumulative runoff sediment mass in each case.

Conversely, in Cases 3 and 4, except for a single outlier (Test S-RCG4), the cumulative sediment runoff increased only marginally after the third trial. Even after 15 repetitions, the total sediment runoff remained about one-third of that observed in Cases 1 and 2. These findings demonstrate the enhanced erosion resistance of more mature *Phalaris arundinacea* L. vegetation.

Figure 9 shows the relationship between plant growth conditions and the maximum sediment runoff rate. The maximum sediment runoff rate, defined as the steepest slope in the erosion curve (from Figure 8), declined as plant height, root dry mass, and vegetation cover increased. This trend indicates that erosion resistance improves with plant development.

Figure 10 compares the soil box's post-test condition after removal of stems and leaves with contour maps generated using SfM photogrammetry based on the test results shown in Figure 8. The location and depth of erosion can be visually confirmed. In the test results for Cases 3 and 4 (S-RCG4 and S-RCG7), erosion in the downstream area

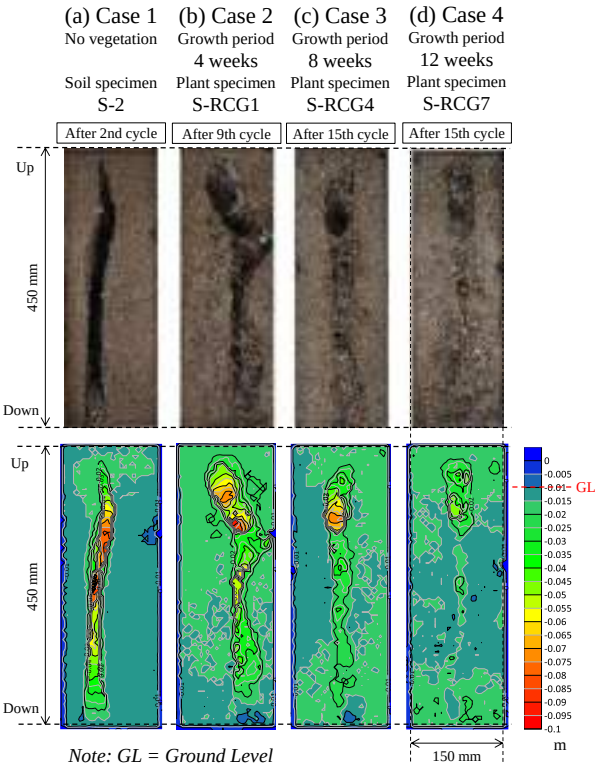

Fig. 10 Appearance of the soil specimen surface and the surfaces of the plant specimens, along with their contour maps, after the erosion test.

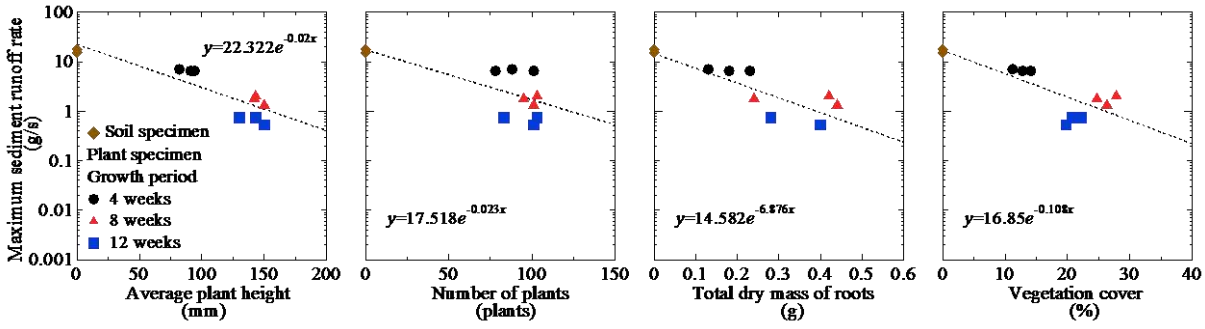

Fig. 9 Relationship between growth conditions of plant specimens and maximum sediment runoff rate.

was significantly reduced compared to Cases 1 and 2. This reduction is likely attributable to favorable plant growth conditions—specifically, greater plant height, higher vegetation cover rate, and well-developed rhizomes in the downstream area, as shown in Table 2.

CONCLUSION

This study evaluated the erosion resistance of vegetated slopes using *Phalaris arundinacea* L., a species suited for warmer climates. Erosion tests were conducted using soil boxes containing plants that had been grown for various durations. The results demonstrated that plant growth, especially root development, significantly improves resistance to erosion caused by surface runoff.

Additionally, the application of Structure-from-Motion (SfM) photogrammetry proved effective in visualizing the extent and depth of erosion. This technique enables the spatial analysis of changes in erosion resistance associated with different plant species and growth conditions, providing a valuable tool for evaluating vegetation-based slope stabilization strategies.

ENHANCING MITIGATION STRATEGIES FOR RAINFALL INDUCED ROADSIDE LANDSLIDES IN NEW ZEALAND

Roohollah Kalatehjari[1], Lokesh Vemuri[1] and Rajitha Sachinthaka[1]

[1] Built Environment Engineering Department, School of Future Environments, Auckland University of Technology, Auckland 1010, New Zealand

ABSTRACT

This study addresses the critical issue of rainfall-induced roadside landslides in New Zealand, focusing on enhancing mitigation strategies through lessons from international case studies. Rainfall-induced landslides pose significant risks to infrastructure, public safety, and economic stability, particularly given New Zealand's challenging topography, complex geology, and frequent intense rainfall events. The research employs a systematic literature review, adhering to Prisma guidelines, complemented by comparative analyses of international mitigation approaches from Japan, Italy, the United States, and China as the identified countries with comparable geological and climatical challenges to New Zealand. The research identifies and investigates essential mechanisms affecting roadside slope stability, including soil saturation, shear strength reduction, and slope geometry. International mitigation practices evaluated for their suitability in New Zealand include real-time monitoring systems, bioengineering approaches, geotechnical interventions, and comprehensive drainage systems. Findings highlight the potential effectiveness and adaptability of Japan's sensor-based early warning technologies, Italy's bioengineering slope stabilization practices, and geotechnical intervention strategies implemented in the United States. Through qualitative expert interviews and quantitative analyses of historical landslide and rainfall datasets, the study exposes gaps in New Zealand's current reactive management approach. Recommendations emphasize adopting cost-effective, proactive, and climate-resilient strategies, particularly advanced real-time monitoring technologies and bioengineering solutions adapted to New Zealand's unique environmental conditions. The outcomes establish a practical and sustainable framework for regional landslide mitigation, balancing economic viability and long-term environmental resilience.

Keywords: Rainfall-induced landslides; Slope stability; Landslide Mitigation strategies; Roadside Slope; New Zealand.

INTRODUCTION

Rainfall-induced landslides are one of the most dominant natural hazards affecting New Zealand, posing significant threats to infrastructure, public safety, and economic stability. The country's dynamic geological structure, consisting of steep slopes and weak soil formations, along with regular heavy rainfall, makes it significantly susceptible to landslides. The associated impacts are especially disruptive on New Zealand's road network, where landslides can cause substantial damage, extended closures, and significant economic losses, with $250-300 million annual estimated cost The urgency of tackling this issue is exacerbated by the rising effects of climate change, which has resulted in more frequent and severe downpour events [1].

Despite ongoing efforts to reduce the rainfall-induced landslide hazards, New Zealand's current landslide management strategy is mostly reactive, focused on post-event intervention rather than proactive prevention [2]. This approach not only increases susceptibility but also results in rising costs and environmental implications, such as habitat disruption, soil erosion, natural resource depletion, etc. Recognising the need for more effective measures, this study investigates novel mitigation practices from worldwide contexts, drawing on lessons from Japan, Italy, the United States (USA), and China – countries facing similar geological and climatic difficulties with a track record of advanced landslide studies.

This study looks at the mechanisms that influence roadside slope stability, such as soil saturation, shear strength reduction, and slope geometry, using a comprehensive assessment of the literature and a comparative assessment of international practices. It evaluates the possibilities of modern mitigation approaches such as Japan's real-time sensor-based monitoring systems, Italy's bioengineering slope stabilisation methods, USA's geotechnical interventions, and China's slope reinforcement and remote monitoring. These ideas are evaluated for viability and adaptability within New Zealand's specific environmental and economic frameworks.

The initial theoretical analysis will be further strengthened by utilising qualitative insights from expert interviews with quantitative assessments of historical landslide and rainfall data. This methodology emphasises the importance of a

transition toward a proactive, cost-effective, and climate-resilient approach by exposing major gaps in current policies and practices. The findings aim to assist stakeholders, ranging from policy makers, to project managers and geotechnical and civil engineers, on how to create a sustainable framework that not only improves resilience but also reduces long-term costs and environmental implications.

As rainfall patterns become increasingly unpredictable and extreme events occur with greater frequency, the adoption of innovative and adaptable solutions becomes critical [3]. This study contributes to the continuing discussion about landslide mitigation by proposing measures to protect New Zealand's infrastructure and communities against the growing hazard of rainfall-induced landslides.

RESEARCH SIGNIFICANCE

The importance of this research stems from the potential to improve New Zealand's approach to rainfall-induced landslide mitigation by incorporating learning from successful global practices. .The study highlights critical policy gaps and calls for proactive, cost-effective strategies tailored to New Zealand's environmental and economic context. It promotes low-cost, high-impact solutions through affordable technologies, efficient resource use, and climate-resilient approaches that remain effective under future climate scenarios. The findings are relevant for policymakers, engineers, and stakeholders, with a focus on enhanced monitoring technology, bioengineering approaches, and sustainable frameworks. Finally, this research helps to protect infrastructure, reduce economic losses, and build long-term resilience to the mounting hazards posed by climate-induced landslides.

METHODOLOGY

This study used a structured, qualitative approach to analyse international solutions for minimising rainfall-induced roadside landslides and their suitability to New Zealand's environmental, geological, and socioeconomic setting. The approach involved a systematic literature review (SLR), followed by analysing international case studies and expert interviews to develop recommendations.

Systematic Literature Review (SLR)

To ensure that the SLR is conducted and reported consistently and transparently, the study adopted the preferred reporting items for systematic reviews and meta-analyses (PRISMA2020) framework [4]. The goal was to identify and critically evaluate academic and scientific literature on slope stability, mitigation measures, and climate resilience approaches relevant to roadside rainfall-induced landslides. Scientific databases including Scopus, ScienceDirect, and Google Scholar and online records were searched to identify relevant sources published between 2000 and 2024. The search terms included "rainfall-induced landslides," "slope stabilisation/stabilization," "early warning systems," and "bioengineering." A total of 169 eligible records were identified for initial screening, from which 71 were selected for qualitative synthesis. Fig.1 illustrates the details of this process using a PRISMA flow diagram.

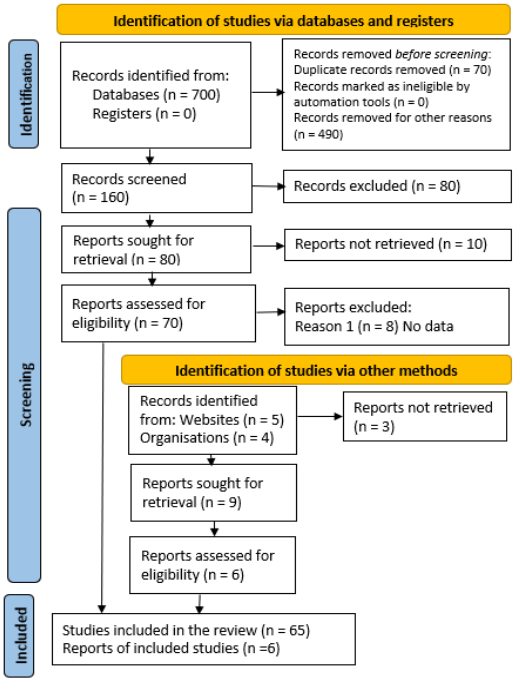

Fig.1 PRISMA flow diagram of the study

International Case Study Selection

Records from four countries were identified as potential case studies due to their environmental similarities and demonstrated success in landslide mitigation: Japan (Kyushu), Italy (Dolomites), the United States (California), and China (Three Gorges region). The effectiveness of measures such as real-time monitoring, eco-engineering, rockfall nets, drainage systems, and satellite-based risk assessment was evaluated in these studies. Each instance was assessed for technical viability, cost-effectiveness, scalability, and potential adaptation to New Zealand's particular topography and climate.

Expert Interviews in New Zealand

Semi-structured interviews were conducted with experts in geotechnical engineering, infrastructure planning, and environmental management. Interviewees were selected for their knowledge in slope stability, risk management, and national infrastructure projects. The discussions aimed to identify gaps in present New Zealand practices, validate research findings, and evaluate the

possibility of adapting international tactics to local settings.

Data Analysis and Synthesis

Data from literature and interviews were classified and analysed thematically, emphasising recurring issues and solution patterns. Quantitative data, such as rainfall records, landslide frequency, and mitigating costs, were utilised to conduct a comparison study. The synthesis resulted in an adaptive, hybrid mitigation strategy that balances technical, environmental, and socio-economic factors to improve road network resilience in New Zealand.

RESULTS AND ANALYSIS

Parameters of Rainfall-Induced Landslides

When driving forces surpass resisting forces on a slope, failure occurs. Landslides cause soil, rock, and debris flowing downslope, primarily due to gravity. Shear stress and strength interact in slope-forming materials to drive these processes. Rainfall-induced landslides are triggered by water infiltration, causing loss of matric suction, increased pore water pressure, and decreased effective shear strength [5].

Rainfall can cause landslides through a variety of hydrological factors. Infiltration creates positive pore pressures in shallow soil, reducing the slope materials strength. Saturation can lead to perched water tables and seepage along stratigraphic boundaries, especially in colluvial or residual soils. finally, excessive rainfall can destabilise slopes by creating surface runoff and increased hydraulic loading [6].

Rainfall-Induced Landslides in New Zealand

The New Zealand landscape is highly susceptible to rainfall-induced landslides. Approximately 60% of the land area has steeper slopes than 26°, with over 5% categorised as very erodible [7]. The terrain is primarily made up of young sedimentary and volcanic rocks that can degrade due to water saturation. Rainfall-triggered landslides have occurred in many places, including the North Island and upper South Island, especially during recent storms.

New Zealand's location in the southwest Pacific makes it susceptible to subtropical storms (cyclones), atmospheric rivers, and La Niña-related anomalies, resulting in excessive rainfall. From January to March 2023, Auckland (New Zealand's largest and most populated city) saw unprecedented rainfall of over 600 mm during two major storm events (Fig.2), resulting in over 200 landslides [1].

Landslide threats in New Zealand are exacerbated by tectonic activities and climate change. Seismic shaking can pre-condition slopes for failure, and climate change is expected to increase the frequency and intensity of heavy rainfall events, posing challenges for traditional mitigating techniques. New Zealand landslide database records (Fig.3) indicate the significance of this hazard.

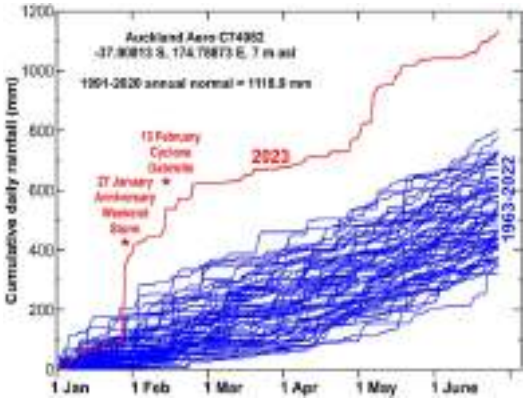

Fig.2 Comparison of Auckland's rainfall data from 1963-2022 with the first half of 2023 [1].

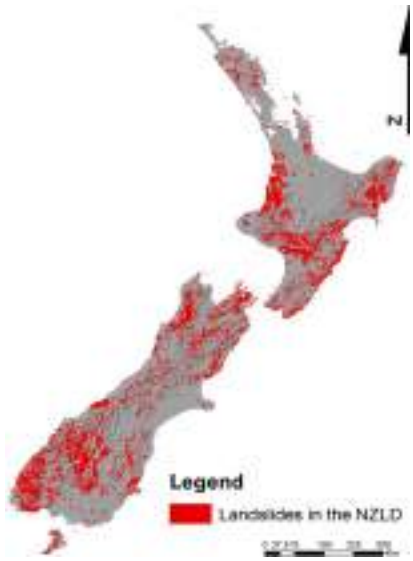

Fig.3 New Zealand landslide database records [7]

Causes and Triggers of Rainfall Landslides

Rainfall is the leading cause of landslides worldwide, accounting for roughly 90% of slope failures. New Zealand's landslides are frequently triggered by soil saturation due to prolonged rainfall, which increases pore water pressure, diminishes matric suction, and weakens shear strength in soils and weathered rock [8]. Water-induced increased soil mass and seepage forces exacerbate slope instability. Human activities such as deforestation, road excavation, and insufficient drainage systems multiply these effects. As urban development into hillside areas alters natural hydrology and removes vegetation, the imminent risk of landslides underlines the importance of proactive mitigation techniques [9].

Economic and Infrastructure Impacts

Roadside landslides in New Zealand pose considerable economic and infrastructure challenges. These disasters disrupt key transportation networks,

causing delays in logistics, limiting access to outlying populations, and resulting in significant repair expenses [10]. These landslides also disrupt emergency response systems, impede agricultural supply chains, and raise insurance and reconstruction costs. The yearly economic impact of landslides in New Zealand is estimated to be between NZD 200 and 300 million. With the intensification of rainfall patterns caused by climate change, these costs are anticipated to rise unless proactive mitigation methods and sustainable land-use planning are applied immediately [1].

LANDSLIDE MITIGATION STRATEGIES

As rainfall-induced landslides become more frequent and severe, governments around the world are implementing region-specific mitigation techniques based on their geotechnical and climatic conditions [11]. Recognising the diverse nature of landslide triggers and repercussions, this study assesses successful global methods in reducing landslide risk. Case studies from Japan, Italy, the United States, and China provide significant insights into various mitigation strategies, including advanced real-time monitoring systems, bioengineering techniques, geotechnical interventions, and effective drainage solutions. Each solution is evaluated based on its effectiveness, flexibility, and suitability to New Zealand's unique geography, geology, and environmental constraints. These international best practices serve as the foundation for the creation of a hybrid, adaptive framework that combines tried-and-true tactics into a cohesive, long-term plan for managing landslides in New Zealand.

Japan’s Early Warning and Slope Intervention

Japan, positioned in a geologically active and typhoon-prone zone, has prioritised the development of advanced landslide early warning systems and slope strengthening techniques. The Japanese Meteorological Agency (JMA) forecasts landslides in Kyushu using rainfall thresholds, soil moisture sensors, and real-time geotechnical monitoring [12]. These technologies have considerably reduced mortality by alerting communities and implementing evacuation measures. In high-risk regions, which are defined as areas susceptible to landslides due to steep terrain, loose soil composition, heavy rainfall, and frequent typhoons, geotechnical interventions like soil nailing, retaining walls, and surface drainage systems are used to stabilise slopes and redirect runoff. Japan’s policies also recommend vegetal slope protection and multi-tiered barriers along transportation corridors [14].

Italy’s Bioengineering and Flexible Barriers

The case study in Italy includes slopes preserved via ecological and geotechnical interventions due to their high topography and history of landslides. Bioengineering involves employing native vegetation to improve soil structure and infiltration control. Geotextiles, root mats, and shallow-rooted plant species help maintain surface soils, supporting these approaches [13]. Flexible net barriers and rockfall catchment fences are strategically positioned along roads and valleys to provide cost-effective and low-maintenance solutions. Italy's policy prioritises landscape-sensitive designs and engages local people in maintenance and response planning [16].

USA’s Engineered and Monitored Interventions

The case study of the USA includes landslides in California's coastal and mountainous areas, mitigated by engineered drainage, slope contouring, and real-time geotechnical monitoring. Subsurface drainage systems, including horizontal drains, toe drains, and lined ditches, help stabilise slopes by lowering groundwater levels. Highways and development zones use reinforced retaining walls and terracing. Using steel meshes or concrete cribbing [14]. LiDAR, GPS stations, and drones improve slope deformation tracking, allowing for proactive maintenance and emergency preparedness [18].

China’s Engineering and Remote Sensing

The Three Gorges region of China, which is prone to reservoir-induced landslides and strong monsoon rains, has used advanced engineering and monitoring measures to reduce slope instability [15]. Large-scale slope engineering solutions include the use of rock bolts, anchor cables, and concrete retaining walls to stabilise eroded rock faces and loess slopes [16]. These physical reinforcements are supplemented by cutting-edge remote sensing technologies such as Interferometric Synthetic Aperture Radar (InSAR) and high-resolution satellite imaging, which allow for early identification of slope displacement and targeted treatments. In addition, China makes significant investments in slope terracing and vegetation cover to reduce surface erosion, combining ecological restoration with engineering solutions [21].

The efficacy scores in Fig.4 were calculated using a qualitative synthesis of international case studies, peer-reviewed literature, and thematic insights from expert interviews. The performance of each country in Monitoring Systems, Bioengineering, and Structural Reinforcements (i.e., geotechnical interventions) was assessed using a normalised comparison index. This scale (High = 80-90%, Medium = 60-75%, and Low = 50%) examines implementation maturity, practical outcomes in high-risk zones, and alignment with New Zealand's climate and geography. For example, Japan's effective integration of slope sensors and early-warning

networks earned it a high monitoring score, while China and the USA have shown strong applications in satellite monitoring and engineered slope reinforcements. Italy's higher score in bioengineering comes from its decades of experience in vegetative stabilising efforts in alpine regions. Expert consultation was used to validate these scores in order to guarantee their relevance and contextual accuracy.

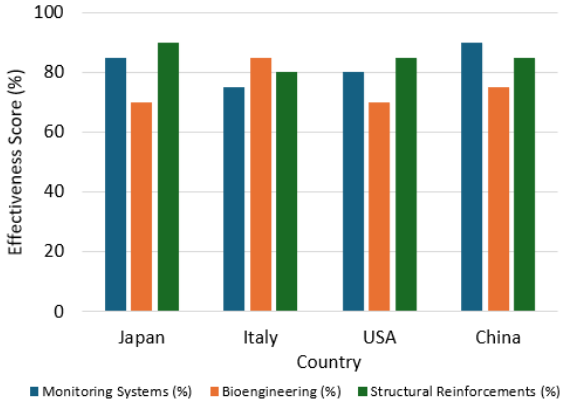

Fig.4 Comparative effectiveness of international landslide Mitigation Practices by Country

FINDINGS AND DISCUSSIONS

New Zealand's current landslide mitigation approach is based on a combination of traditional engineering procedures and centralised hazard monitoring systems [22]. Retaining structures, such as gabion walls and reinforced concrete barriers, are usually used to provide immediate structural support for unstable slopes. Likewise, drainage systems, which include both surface runoff channels and underground pipe networks, help to manage water infiltration and reduce pore pressure accumulation.

The GeoNet hazard monitoring network complements these physical measures by collecting and distributing real-time data on rainfall, seismic activity, and geological changes. However, these treatments are frequently reactive rather than proactive, reacting to recognised threats or failure incidents. They are also often prohibitively expensive in remote places, and not often connected with prediction technology or climate adaptation plans.

Through a synthesis of expert interviews, peer-reviewed analysis, and international comparative assessment, this study highlights the urgent need for a transformation in New Zealand's approach to managing rainfall-induced landslides. The findings show the limitations of reactive approaches, which rely primarily on post-event actions and historical risk assessments. Recent extreme weather events have exposed the vulnerability of New Zealand's current mitigation strategies [1, 17], especially when compared to successful practices in Japan, Italy, the United States, and China, which employ proactive, data-driven, and climate-responsive integrated systems [11, 12, 15].

The suggested hybrid mitigation methodology must be adaptable to a wide range of geotechnical situations throughout New Zealand while staying economically viable, especially in rural and infrastructure-sensitive areas. It also needs to emphasise on cost-sensitivity, promote the use of locally accessible resources and labour, while prioritising low-maintenance solutions such as vegetative stabilisation and modular drainage systems.

The use of real-time digital monitoring tools is an essential part of the model. Systems like InSAR, Light Detection and Ranging (LiDAR), and localised slope sensors are capable of identifying minute ground deformations and rainfall thresholds, allowing for predictive maintenance and early evacuation plans [17]. By enabling early detection, these systems redefine hazard response as a strategic rather than reactive approach.

The second component includes geotechnical intervention solutions such as subsurface drainage, slope contouring, soil nailing, and retaining structures. These approaches are essential in high-risk areas, particularly along critical transportation routes and locations prone to frequent slope failure. For long-term, sustainable, and cost-effective outcome, a combination of ecological and bioengineering solutions can serve as alternatives or complements to geotechnical interventions. Native vegetation, geotextiles, and root-reinforced barriers stabilise slopes while also improving environmental quality and biodiversity.

Table 1: Adaptability of Strategies to New Zealand

Mitigation Method	Technical Feasibility	Cost	Environmental Fit
Early Warning Systems	H	M	H
Reforestation	M	L	VH
Drainage Improvements	H	H	M
Soil Nailing	M	H	M
Slope Grading	H	M	L
Retaining Walls	H	VH	M

VH: Very High, H: High, M: Medium, L: Low, VL: Very Low

Table 1 presents a comparative assessment of the adaptability of selected international landslide mitigation strategies to the New Zealand context. The ranking criteria technical feasibility, cost, and environmental fit were developed through a synthesis of findings from international case studies (i.e., Japan, Italy, USA, China), expert interviews conducted as part of this study, and the thematic literature review. The evaluation is qualitative in nature and based on how well each strategy aligns with New Zealand's specific geotechnical, climatic, and socio-economic conditions. For example, early warning systems are ranked highly in technical feasibility and environmental fit due to existing infrastructure (e.g., GeoNet) and minimal physical intrusion. In contrast, retaining walls, though technically effective, are rated

"Very High" in cost due to their resource-intensive construction and maintenance, especially in remote areas. These rankings were informed by published data on implementation outcomes in each country, expert judgments regarding transferability, and environmental impact considerations specific to steep, rainfall-prone terrain in New Zealand.

CONCLUSION

This study evaluated the worsening issue of rainfall-induced roadside landslides in New Zealand, examining local challenges and insights from international best practices. Through a systematic literature review and site-specific hazard assessment, it found that New Zealand's current mitigation strategies – primarily retaining structures, drainage systems, and GeoNet monitoring – are largely reactive and insufficient to address the increasing challenges posed by climate change.

Using the PRISMA2020 framework, the study identified proven mitigation strategies from Japan, Italy, the United States, and China. These countries employ a strategic mix of geotechnical interventions, digital monitoring, eco-stabilisation, and community-based management. Semi-structured interviews with New Zealand industry experts reinforced these findings and highlighted key barriers, including technological limitations, high rural implementation costs, and limited integration of climate policy.

Thematic and comparative analysis revealed a significant opportunity for New Zealand to strengthen resilience through a hybrid mitigation strategy. This integrates real-time digital monitoring, geotechnical and bioengineering solutions, and community engagement to provide a scalable response to rainfall-induced landslides. Its relevance and robustness were confirmed through industry experts peer review.

This study advocates a shift from reactive to proactive, climate-resilient risk management. The proposed hybrid strategy is both feasible and adaptable, offering a forward-looking pathway to protect infrastructure, ecosystems, and communities in a changing climate.

RELATIONSHIP BETWEEN PUBLIC SPACE AND PEDESTRIAN BRIDGES IN SUBURBAN RESIDENTIAL AREAS

Ryunosuke Komatsu[1], Kazunari Tanaka[2]

ABSTRACT

The Japanese government has reported the need for maintaining and updating infrastructure. Dangerous road crossings are a known problem, such as when pedestrian crossroads do not have pedestrian bridges or crossings. The purpose of this study is to evaluate existing pedestrian bridges. We conducted fieldwork and discriminant analysis. First, we conducted surveys and analyses to clarify the relationship between pedestrian bridges and jaywalking. Next, we confirmed the reliability of the first survey by observing an actual pedestrian bridge. Then, we confirmed the relative locations of pedestrian bridges and surrounding facilities in Tondabayashi City, Osaka Prefecture. We also investigated the changes in housing around the pedestrian bridge. As a result of analysis, there was a significant relationship between jaywalking and explanatory variables. Additionally, we developed an equation to predict jaywalking. However, we found that the relationship between jaywalking and the time to cross a pedestrian bridge was weak. Therefore, we considered that it is possible to evaluate pedestrian bridges by combining predictions of jaywalking with other factors. As a result of the survey, there are many pedestrian bridges near residential areas far away from stations. Also, there are some of the pedestrian bridges near schools. In addition, we found that the number of houses around pedestrian bridges has been increasing over the past 20 years. We consider that by combining predictions of irregular crossings with changes in facilities, it will become an evaluation indicator for new pedestrian bridges.

Keywords: Jaywalking, Discriminant Analysis, Suburban Area, Building Transition

INTRODUCTION

In 2013, the Japanese Ministry of Land, Infrastructure, Information and Tourism reported the need for maintaining and updating infrastructure [1]. In addition, dangerous road crossings are a known problem, such as when pedestrian's crossroads without using pedestrian bridges or crossings [2]. According to previous research on jaywalking [3], the factors said to cause jaywalking were age, surrounding facilities, roadway width, and pedestrian crossing installation spacing. On the other hand, there is no said association between jaywalking and pedestrian bridges. In addition, jaywalking was related between vehicle behavior and road structure [4]. The relationship between these dangerous crossings and crossing facilities cannot be separated. Each municipality in Japan does not rate pedestrian bridges on the same items [5]. Many municipalities have identified declining numbers of users and aging. Jaywalking is also an item that some municipalities have incorporated. Therefore, we thought that predicting crossings outside of crossing facilities would facilitate consideration of the need for pedestrian bridges and lead to evaluation of new pedestrian bridges.

RESEARCH SIGNIFICANCE

In Japan today, each municipality is considering whether to remove or keep pedestrian bridges. The evaluation indicators differ slightly from municipality to municipality. The purpose of this study is to find common indicators for evaluating pedestrian bridges. Using them, the need for a pedestrian bridge will become apparent. It will then be easier to decide whether to keep or remove the pedestrian bridge. Ultimately, this will help solve the problem of aging pedestrian bridges.

DISCRIMINANT ANALYSIS

We show the methodology and results of our analysis of the relationship between pedestrian bridges and road crossings outside crossing facilities, focusing on the configuration of the road space.

Definition Of Jaywalking

Road crossing outside of a crossing facility was defined as "Jaywalking" in this study (Fig.1).

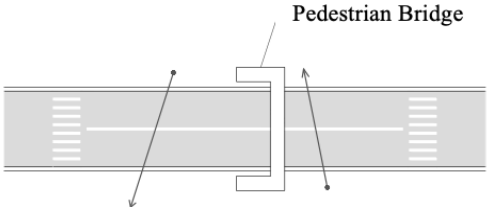

Fig.1 Positioning of jaywalking in this study

Preliminary Investigation

We conducted a discriminant analysis using IBM SPSS Statistics to determine what elements of the road space are associated with jaywalking. We used eight elements as explanatory variables in our analysis (Table 1). The objective variable is the presence or absence of jaywalking. We defined our target as a single point on the road as the "point" and collected data for each element at 25 points.

Table 1 Eight types of road space elements used

	Types of Elements	Notation
Element 1	Traffic Volume	Tv
Element 2	Number of Lanes	NL
Element 3	Distance from Point to Nearest Crosswalk	D1a
Element 4	Distance from Point to Crosswalk on Opposite Side of Element 3	D1b
Element 5	Distance from Point to Pedestrian Bridge	D2
Element 6	Availability of Median Strip	MS
Element 7	Availability of Signal at Crosswalks Near the Point	a
Element 8	Availability of Signal at Crosswalk on the Opposite Side of Element 7	b

We measured the distance from elements 3 to 5 using Google Earth, as shown in Figure 2.

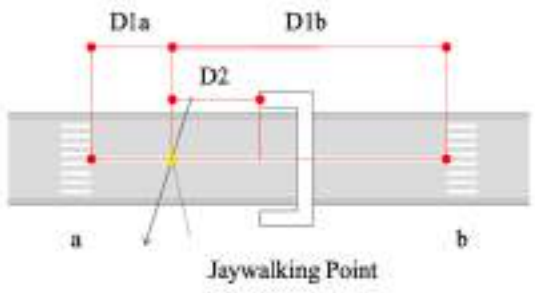

Fig.2 Measuring elements of distance

As a result of analysis, we had a canonical correlation of 0.652 (Table 2). Since this value is above 0.6, we know that there is a relationship between the objective variable, the presence or absence of jaywalking, and the eight explanatory variables. However, we obtained a non-significant result with a significance probability of 0.231, which is greater than 0.05 (Table 3). We also found from the structure matrix that "NL", "D2", and "Tv" are related to jaywalking in this function, in that order (Table 4).

Reasons for the lack of significance include the use of quantitative data as explanatory variables and the large number of explanatory variables relative to the number of subjects surveyed. We considered it important to increase the number of subjects surveyed and to make the explanatory variables quantitative data.

Table 2 Eigenvalue

D2	-0.309
MS	0.294
a	-0.223
b	0.222

Main Investigation

We defined a "section" between crosswalks because we thought that jaywalking is not necessarily a single point on the road. Therefore, we chose a new element (Table 5) and collected data for each element in 39 intervals, as in the preliminary investigation.

Table 5 Seven types of road space new elements used

	Types of Elements	Notation
Element 1	Number of Lanes	NL
Element 2	Distance between Crosswalks	D
Element 3	Distance of no Median Strip in Section	Dm
Element 4	Distance of no Planting or Guardrail in Section	Dp
Element 5	Time of Crosswalk Signal (red/green)	R1/G1
Element 6	Time of Crosswalk Signal (red/green) on other side of Element 5	R2/G2
Element7	Time to Cross the Pedestrian Bridge	Tp

From our preliminary investigation, we devised five equations to make the results of our analysis significant. Equation (1) showed the ratio of ease of crossing the roadway. Equation (2) showed the ratio of ease of exiting the sidewalk to the roadway. We defined a "signal cycle" as the sum of the red and

green times of a signal. Equations (3) and (4) showed the ratio of ease of crossing at a pedestrian crossing. Equation (5) showed the ratio of time spent crossing a pedestrian bridge to the time spent waiting for a crosswalk. The type of analysis was discriminant analysis, as in the preliminary investigation. Equation (1) and (2) showed elements of distance. Equation (3) to (5) showed elements of time.

$$Dm/D = Dmr \quad (1)$$

$$Dp/D = Dpr \quad (2)$$

$$G1/(R1 + G1) = T1 \quad (3)$$

$$G2/(R2 + G2) = T2 \quad (4)$$

$$Tp/\{(R1 + G1 + R2 + G2)/2\} = T3 \quad (5)$$

$$Jcv = 0.532 \times NL - 1.451 \times Dmr - 2.223 \times Dpr + 3.268 \times T1 + 2.947 \times T2 - 0.429 \times T3 - 1.836 \quad (6)$$

Explanatory variables are the value calculated by substituting the collected data into these equations and NL. The result of analysis, we had a canonical correlation of 0.678 (Table 6). Since this value is above 0.6, we know that there is a relationship between the objective variable, the presence or absence of turbulent crossings, and the six explanatory variables. We also obtained a significant result as the probability of significance was 0.002, well below 0.05 (Table 7). Moreover, we found from the structure matrix that "Dmr", "Dpr", and "NL" are related to jaywalking in this function, in that order (Table 8). In addition, we found the coefficients of each element from the canonical discriminant function coefficients and could develop Eq. (6) using them (Table 9). In this study, Eq. (6) is referred to as the jaywalking prediction equation. Substituting the collected data into this equation gives the value "Jcv" that determines whether jaywalking. If Jcv is a positive number, determine that jaywalking occurs. Conversely, if it is a negative number, it is determined that it does not occur. When we substituted our data from main investigation into the jaywalking prediction equation, we found a hit rate of 87.5%.

However, two of the sections where predictions failed were those with pedestrian bridges. We also supposed that one of the reasons was the small area between pedestrian crossings. Furthermore, it is clear from Table 8 that the time factors T1, T2, and T3 are weakly related to jaywalking. Therefore, we considered only the jaywalking prediction equation to be insufficient as an indicator to evaluate pedestrian bridges.

Table 6 Eigenvalue

SURVEY OF CHANGING IN HOUSING AROUND THE PEDESTRIAN BRIDGE ON GIS

We thought it would be possible to evaluate pedestrian bridges by relating them to other factors than jaywalking. Therefore, we investigated changes in the residences and facilities around the pedestrian bridge. They were new factors to combine with jaywalking. The reason for choosing this factor was that the demand for pedestrian bridges is influenced by the number of people living in the vicinity and the volume of traffic.

The survey covered the area around the Fumigaoka Pedestrian Bridge and Nishikigaoka Pedestrian Bridge in Tondabayashi City, Osaka Prefecture. We chose this location because it is a suburban residential area where building changes have been documented, and the data is available to the public. We used Tondabayashi City's open data to check the building's transition in QGIS. The building

transition period is 20 years, from 2004 to 2024.

We compared maps of the pedestrian bridge area in 2004 (Fig.3) and 2024 (Fig.4). In consequence, we found an overall increase in housing especially the area circled in red in Fig 4.

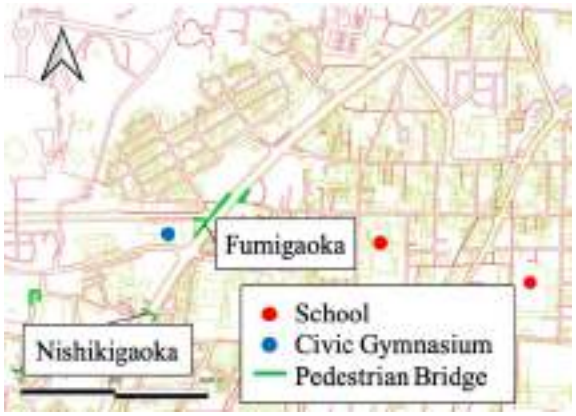

Fig.3 Map around the pedestrian bridge in 2004

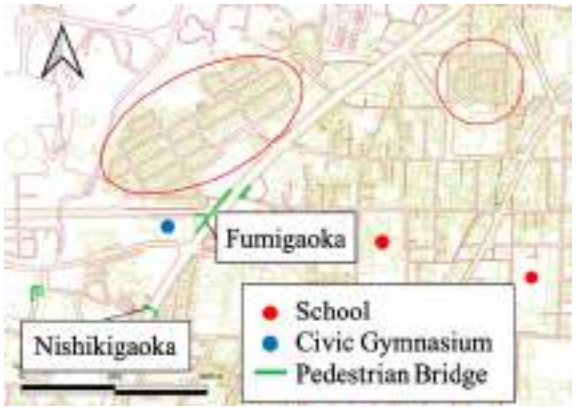

Fig.4 Map around the pedestrian bridge in 2024

The Fumigaoka Pedestrian Bridge was located near the civic gymnasium. Thus, we determined that as the number of households increases, the number of people using the gymnasium will also increase. Additionally, the residential area northwest of the Fumigaoka pedestrian bridge was included in the school district of the school shown on the map [6]. Therefore, we also inferred an increase in student use for commuting to school due to the increase in the number of households.

There were apartments, housing complexes, and a high school in the vicinity of the Nishikigaoka pedestrian bridge. However, the number of buildings did not increase compared to the area around the Fumigaoka pedestrian bridge. Furthermore, the school district was different from that around the Fumigaoka pedestrian bridge. Therefore, we estimated that the number of pedestrian bridge users would not increase much.

CONCLUSION

In this study, we were able to develop a prediction equation of jaywalking based on elements of the road space. However, that equation had a weak relationship to the pedestrian bridge. Therefore, we found that adding the transition of the facilities surrounding the pedestrian bridge could potentially evaluate the pedestrian bridge. We considered that it is the change in demand for pedestrian bridges due to housing transition which may affect the likelihood of jaywalking.

In addition to the street space elements we used in this investigation, there are several other elements that could be added. Examples include no signal or push-button signals, pedestrian attributes, and time of day. Furthermore, we consider that research on pedestrians' impressions of the presence of pedestrian bridges will clarify the relationship between pedestrian bridges and street space. In this map-based survey, we had only identified residential changes. We consider that future studies could better reveal changes in demand for pedestrian bridges by identifying declines in facilities and buildings, such as train stations and hospitals.

METHOD ON THE PREDICTION ABOUT FLOW LINES IN WALKING SPACES

Ryuga Toda[1], Kazunari Tanaka[2]

[1] Architecture, Civil Engineering and Urban Design, Osaka Institute of Technology, Japan
[2,] Faculty of Engineering, Osaka Institute of Technology, Japan

ABSTRACT

The number of foreign visitors to Japan is increasing due to the end of the COVID-19 pandemic and the depreciation of the yen. In 2024, the number of foreign tourists reached a record high. Therefore, it is necessary to develop walking spaces around tourist attractions and public transportation facilities that maintain walkability and attractiveness. The purpose of this study was to analyze the relationship between human behavior and gradient in walking spaces and to predict flow lines as part of measures to create more comfortable walking spaces. Based on a survey conducted in Maruyama Park, an evaluation method using only contour lines was devised. Using this evaluation method, we compared human behavior in walking spaces along the Seta River and the Yodo River. The two evaluation methods successfully captured the major characteristics of human flow lines; however, the details were not well predicted. These results suggest that additional elements are needed to improve the method's practicality.

Keywords: Trajectory, Contour line, Projective transformation, Gradient

INTRODUCTION

In Japan, the number of foreign visitors to Japan is increasing due to the end of the COVID-19 pandemic and the depreciation of the yen [1]. In 2024, the number of foreign tourists reached a record high. Public transportation and walking spaces in and around tourist attractions are becoming increasingly important. At the same time, Japan is facing challenges such as a declining population, falling birth rate, and aging population [2,3]. As a result, there are concerns about the decline in regional vitality due to the shuttering of shopping arcades and vacant houses. Therefore, there is a growing need to enhance urban attractiveness and create livelier spaces.

On June 26, 2018, the "Conference on Creating Urban Diversity and Innovation" compiled a proposal entitled "Urban Renewal Starting with 'Comfortable and Inviting Towns to Walk Around' [4]. This initiative aims to shift from car-centered cities to people-centered city centers to support rich lifestyles. For these reasons, it is necessary to develop walking spaces that maintain walkability and attractiveness.

Previous studies have evaluated walkability. Yamada [5] clarified the characteristics of walking acceleration and the connection to psychological walkability. Morioka [6] clarified the environmental factors affecting the "ease of walking" and the "desire to walk." We believed that if we could predict the flow lines, we could create more walkable spaces. In this study, we evaluated walking spaces to predict flow lines by focusing on the relationship between human behavior and gradient.

PURPOSE AND METHODS

The purpose of the research was to analyze the relationship between human behavior and gradient and to predict flow lines by using a gradient walking space that is unaffected by cars. We first conducted a study in Maruyama Park and then devised an evaluation method for predicting human flow lines. To verify the accuracy of this evaluation method, we conducted experiments at two additional locations.

RESEARCH SIGNIFICANCE

This study focuses on the relationship between gradient and walking behavior and aims to identify the conditions that make walking spaces comfortable. The findings may provide new insights into pedestrian-centered space design, as well as contribute to the development of design guidelines to improve safety and comfort. In addition, it may contribute to creating more attractive walking spaces in urban planning and landscape design by reflecting the actual movement of people.

SURVEY 1

This survey investigated how gradient affects human behavior when people walk in a pedestrian space. Maruyama Park in Kyoto City was selected due to its maximum gradient of 8° unaffected by cars and mostly gentle gradients of 3° to 6°. It is a popular tourist destination, ideal for observing more unconscious behavior patterns. Before performing the

field survey, a topographic analysis of the site was conducted using QGIS. The survey method consisted of multiple video recordings, each about 10 minutes long, which were analyzed using Kinovea, a video analysis software. The trajectory was separated into a starting point and an ending point, and 23 different trajectories were taken each time.

We flattened the trajectories on the images using Photoshop, then compared with contour maps generated with QGIS. The contour interval for the topographic analysis was 10 cm.

Fig.1 Subject location in Maruyama Park

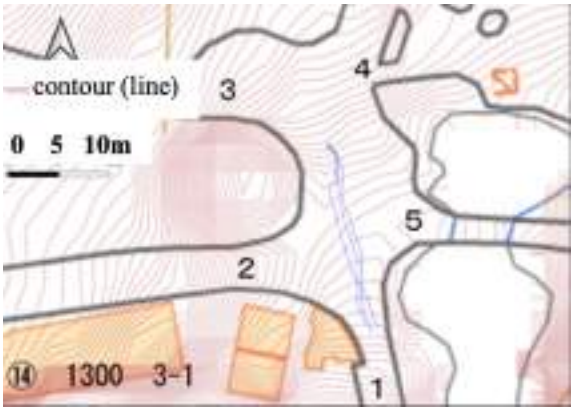

Fig.2 Contour lines and trajectories

Survey Results

The results of the survey revealed that the trajectories from the same starting and end points follow similar trajectories, regardless of the time of day. The walking range was also similar. Those walking perpendicular to the contour lines had somewhat coherent trajectories, whereas those walking along the contour lines tended to spread out horizontally.

Considerations

The direction of movement is shown in Figure 3. Looking at the angle of the walking direction relative to the contour lines, the angles are similar. Therefore, a reference line was placed in the east-west direction, and color-coded points indicated changes in the contour lines of the same height. The direction of movement shows that the green line, yellow line, and orange line are advancing in that order. If we look at each line based on the reference line, we see that the angles are similar in the order of the direction of travel. Given that people are most likely to walk in this order, people are likely to go to a contour line that is close to the angle of the contour line they passed. In other words, the smaller the angle difference from the contour line, the easier it is for people to walk.

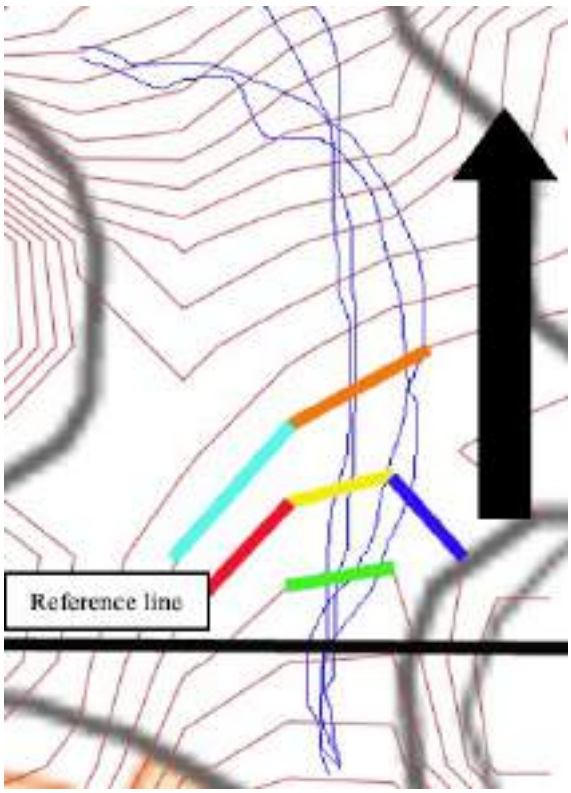

Fig.3 Flow lines and angle differences

SURVEY 2

Based on the findings from Survey 1, we attempted to predict human behavior using only contour lines. Two locations were chosen for the experiment: one along the Seta River in Otsu City, Shiga Prefecture, and the other along the Yodo River in Osaka City, Osaka Prefecture. Both were pedestrian-only, straight walking spaces where the characteristics of human behavior are easily observed. As an example, the subject location along the Seta River is shown in Figure 4. We used two evaluation methods to evaluate the two walking spaces. In making our assessment, we drew a mesh on the map. We determined the size of one mesh by considering the width and distance of the experimental site. As in Survey 1, the contour interval was set at 10 cm for the topographic analysis. We compared the contour lines of the topographic analysis to the map and drew a

mesh on the map for evaluation.

Fig.4 Walking space along the Seta River

Evaluation Method 1

In Evaluation Method 1, the less the angle difference between the contour lines, the easier it is for people to walk. Therefore, the evaluation is highest when the angle difference between the contour lines is 0° and 180°. After determining the angle for each mesh, the angle difference between neighboring meshes is calculated and converted to a 45-step evaluation. We used this 45-point scale to evaluate the mesh.

The 3D representation of the evaluation results along the Seta River is shown in Figure 5. From the evaluation, it is predicted that few people will walk in the middle in the walking space, while many are expected to walk along the edges.

The 3D representation of the evaluation results along the Yodo River is shown in Figure 6. From the evaluation, it can be predicted that people will generally walk on the south side of the Yodo River, as the evaluation decreases toward the north.

Fig.5 Evaluation Method 1 along the Seta River

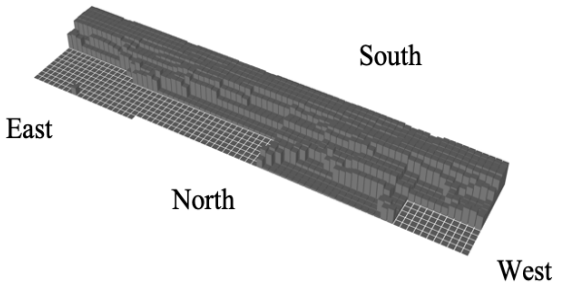

Fig.6 Evaluation Method 1 along the Yodo River

Evaluation Method 2

This method expands on Method 1 by also assigning high scores to paths when the angle difference was 90° because it was easier to walk along the contour lines.

The 3D representation of the evaluation results along the Seta River is shown in Figure 7. From the evaluation, people are expected to move from west to east around the middle of the beginning and end of the evaluated walking space. Fewer are expected to walk on the west side.

The 3D representation of the evaluation results along the Yodo River is shown in Figure 8. From the evaluation, it can be predicted that many people walk on the south side of the road as in Method 1. Also, the evaluation is lower the closer one goes to the middle of the road, which means that fewer people are expected to walk in the middle of the road.

Fig.7 Evaluation Method 2 along the Seta River

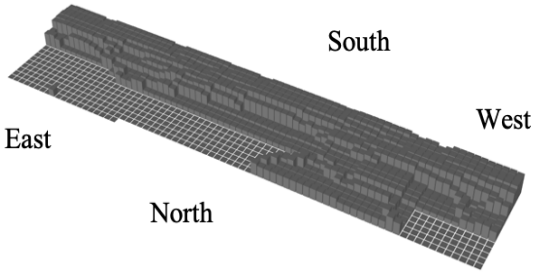

Fig.8 Evaluation Method 2 along the Yodo River

Experiments and Results

We conducted the field survey in the walking space along the Seta River. 21 people were surveyed. All those who moved from west to east and east to west moved around the middle of the start and end of the evaluated walking space. Eight continued walking on the west side, three continued walking on the east side, one continued walking in the center, seven moved from the west side to the east side, and three moved from the east side to the west side. The most people walked on the west side of the street, but the second most moved from the west side to the east side. In this evaluation, we were able to capture the characteristics of the locations where people move.

Next, we conducted the field survey in the walking space along the Yodo River. 13 people were observed. The survey results found that no one moved from south to north or north to south. Eight people continued to walk on the north side, and five people continued to walk on the south side. The most common result was that people continued to walk on the north side of the street, which was the lowest evaluated side. In addition, no one walked near the center, which was in line with the evaluation.

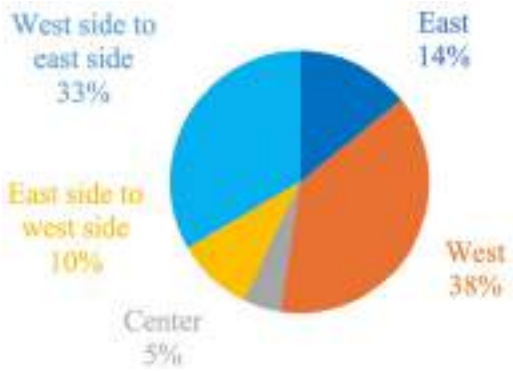

Fig.9 Percentage by category along the Seta River

Fig.10 Percentage by category along the Yodo River

From the above, the two evaluation methods were able to capture the major characteristics of each, but one evaluation method failed to capture multiple characteristics.

Considerations

In the Yodo River survey, the contour interval was set at 10 cm, which may have resulted in a lower evaluation because the contour lines were not marked on the north side of the walking space in the topographic analysis. A more detailed evaluation could be made by reducing the contour interval.

CONCLUSIONS

This study analyzed the relationship between human behavior and gradient to predict flow lines in walking spaces. Based on a survey conducted in Maruyama Park, an evaluation method using only contour lines was devised. Using this evaluation method, we compared human behavior in walking spaces along the Seta River and the Yodo River.

In this research, we were able to understand the relationship between flow line prediction and gradient in walking spaces based on our original evaluation methods. While the method successfully captured the major characteristics of human flow lines, it was not detailed enough for precise predictions. To improve practical use, incorporating additional factors is necessary.

ARTIFICIAL INTELLIGENCE-BASED EARLY WARNING SYSTEMS FOR RIVERBANK EROSION IN THE MEKONG DELTA REGION

Thang Ngoc Nguyen[1], Phong Vu Phuong Le[2] and Tru Thi Tu[3]

[1,2,3]Faculty of Engineering Technology, Tien Giang University, Vietnam

ABSTRACT

The Mekong River Delta is facing severe riverbank erosion, significantly impacting life, the economy, and the environment. The main causes are climate change, excessive sand mining, and changes in water flow. In this context, the application of Artificial Intelligence (AI) in early warning systems for riverbank erosion is gaining attention. AI models such as Machine Learning (ML) and Deep Learning (DL) can analyze data from geological sensors, satellite imagery, and hydrological data, helping to accurately identify high-risk areas. Research has shown that AI has the potential to improve accuracy in predicting erosion and supporting disaster prevention efforts, especially in heavily affected areas like Tien Giang Province. However, AI still faces some challenges, such as a lack of high-quality data, the need for complex computations, and difficulties in integration with current warning systems. If implemented effectively, AI will help protect riverbanks, minimize damage, ensure the safety of residents, and promote sustainable development in the Mekong Delta.

Keywords: Artificial Intelligence, Early warning, Mekong Delta, Riverbank erosion, Sustainable development

INTRODUCTION

The Mekong Delta is a region characterized by a dense network of rivers, primarily nourished by alluvial deposits from major rivers such as the Tien and Hau Rivers, along with their tributaries. Thanks to these features, the Mekong Delta has become one of Vietnam's largest rice-producing areas, making a significant contribution to the national economy. However, due to its extensive river systems and alluvial soil geology, this region is also highly vulnerable to natural phenomena, especially riverbank erosion [1].

The alluvial soil in the Mekong Delta is soft and easily subject to erosion and landslides, particularly in areas experiencing strong changes in water flow or excessive sand mining activities. Riverbank erosion is an urgent issue in the Mekong Delta, leading to the loss of farmland, houses, and causing serious impacts on transportation and infrastructure (Fig.1). The causes of this phenomenon include changes in water flow due to hydraulic structures, climate change with rising sea levels, and extreme weather events such as floods and storms. Riverbank erosion not only directly affects people's lives but also causes long-term economic damage, especially for rural residents who rely heavily on the land for their livelihood [2].

Fig.1 Erosion along the Cho Gao riverbank [3]

In addition, the rapid development of urban areas and industrial zones has exacerbated the impacts of erosion. Construction projects along riverbanks, rampant sand mining, and a lack of attention to riverbank protection have worsened the situation. This not only affects the environment but also threatens the stability of aquatic ecosystems, leading to the loss of native biodiversity [4].

Given this situation, early warning of riverbank erosion has become a crucial factor in protecting people's property and lives. Modern technology-especially AI-has opened up new opportunities for forecasting and issuing alerts regarding riverbank erosion. AI can analyze and process large volumes of data from various sources such as satellites, geosensors, and historical records to predict high-risk erosion areas. Through predictive modeling, AI can provide timely warnings, enabling authorities and communities to take responsive measures and reduce damages [5]. Emerging technologies such as machine learning and satellite image analysis are increasingly proving effective in monitoring and analyzing riverbank changes, thereby supporting erosion prevention efforts.

RESEARCH SIGNIFICANCE

This research holds significant value as it addresses the urgent issue of riverbank erosion in the Mekong Delta region critical to Vietnam's agricultural and economic stability. By applying AI to early warning systems, the study offers a modern, data-driven approach to predicting and mitigating erosion risks. The integration of geotechnical, hydrological, and satellite data with AI models

enhances forecasting accuracy, supports proactive disaster management, and promotes sustainable development. The research provides a foundation for developing practical, scalable solutions that can be applied both locally in Tien Giang Province and more broadly across vulnerable riverine regions.

AI AND ITS APPLICATION IN LANDSLIDE FORECASTING

AI, particularly machine learning and deep learning models, is increasingly being applied in predicting riverbank landslides because it can analyze and process large volumes of data from various sources. These technologies can help analyze vast amounts of information, thereby providing more accurate forecasts of landslide risks in vulnerable areas [6].

One of the most important data sources for forecasting riverbank erosion is geological measurement sensors. These sensors can collect detailed information on soil moisture, pore water pressure, and ground movement, which helps identify changes in soil structure and detect early signs of landslide processes. Collecting data from geotechnical sensors allows scientists and managers to gain deeper insights into the geological conditions of an area, enabling timely and effective preventive measures. This information can be integrated into AI models to identify factors influencing erosion and predict high-risk areas.

In addition, satellite imagery plays a crucial role in analyzing and assessing erosion conditions. With its wide and continuous observational capability, satellite images help monitor morphological changes of riverbanks over time. These changes may indicate soil weakening, erosion, or strong impacts from external factors. Utilizing satellite imagery enables the creation of accurate maps of high-risk areas, allowing authorities to make timely decisions in erosion prevention efforts. Moreover, combining satellite imagery with AI enables the automation of identifying and analyzing weakened zones, thereby improving the accuracy of forecasting.

Hydrological data is also an essential factor in landslide forecasting. Hydrological elements such as changes in water levels, flow velocity, and rainfall directly influence the riverbank erosion process. For example, rising water levels or strong flows can exert significant pressure on riverbanks, increasing the risk of erosion and landslides. Variations in water level and flow, especially during the rainy season or during major flood events, can significantly raise the risk of landslides. When integrated with AI models, hydrological data allows for an accurate assessment of these influencing factors, supporting effective prediction of vulnerable areas.

AI algorithms are developed to recognize and analyze data patterns from various sources, including geotechnical sensors, satellite imagery, and hydrological data. AI can learn from historical data and predict future landslide trends, providing early warnings for high-risk areas [7]. Applying AI in landslide forecasting enables authorities and communities to respond proactively and mitigate damage. Early warnings generated by AI can help protect people's property and lives while enhancing the effectiveness of disaster management.

COMMON AI MODELS IN LANDSLIDE FORECASTING

In riverbank landslide forecasting, AI models are increasingly being applied due to their ability to analyze and process large volumes of data from various sources [8]. Below are some of the most commonly used AI models, each with its strengths that contribute to improving the accuracy of landslide prediction and early warning.

Linear Regression

Linear regression is one of the most basic yet effective models for predicting riverbank landslides. This model uses historical data to forecast the extent of future erosion. Specifically, linear regression analyzes the linear relationship between factors such as water level, flow velocity, geological characteristics, and other environmental variables. Despite its simplicity, this model can yield highly effective results in cases where the data is not overly complex or when there are few variables to analyze. It enables quick and easy-to-understand predictions, especially in areas with relatively stable conditions.

Artificial Neural Networks (ANN)

ANNs are more powerful models, particularly useful for handling complex and nonlinear data. ANN can learn from data and improve itself over time, enabling more accurate predictions of areas at risk of landslides. This model can integrate a wide range of complex factors-including changes in geological, hydrological, and climatic conditions, as well as human impacts-into a unified prediction. Thanks to its deep learning capabilities and robust analytical power, ANN can generate more precise and detailed forecasts, making it well-suited for areas with high variability.

Convolutional Neural Networks (CNN)

In satellite image analysis, CNNs are a very useful tool. CNN can identify detailed features from images, helping to detect changes in the morphology of riverbanks over time. Satellite images can reveal small but significant changes on the land surface, such as the formation of cracks, erosion, or soil movement, which traditional models may struggle to detect. CNN can learn and identify subtle transformations in images, enabling earlier identification of areas at risk of landslides, while improving the accuracy of forecasts.

Decision Tree and Random Forest

Decision tree and random forest models are also commonly used in landslide forecasting. A decision tree works by splitting data into branches based on specific conditions (such as water levels, flow velocity, and soil characteristics). This splitting process helps make predictive decisions about the level of landslide risk for each area. Random forest is an advanced version of decision trees, combining multiple decision trees to provide more accurate forecasts. This model enhances accuracy and minimizes errors in classification, especially in situations with complex or incomplete data.

Support Vector Machines (SVM)

SVMs are a powerful machine learning model, particularly suited for classifying areas at high risk of landslides. SVM can optimize the data classification space to separate data classes most optimally. This is crucial for identifying areas with a high or low likelihood of landslides based on environmental and geographical factors.

These AI models each have their own advantages and can be applied in different situations. Not only do they improve the accuracy of landslide forecasting, but they also aid in more effective prevention and management. By applying AI technologies, authorities and communities can receive early warnings and take timely responsive actions. This helps protect property, minimize damage, and safeguard the lives of people in vulnerable areas such as the Mekong Delta.

EFFECTIVENESS AND CHALLENGES IN AI APPLICATION

AI has demonstrated significant effectiveness in riverbank landslide forecasting, particularly in its ability to analyze and process large amounts of data from various sources such as geotechnical sensors, satellite imagery, and hydrological data (Fig.2). AI models can accurately predict areas at risk of landslides, providing early warnings that help reduce damage and protect both lives and property. However, despite the great potential of AI in this application, its implementation in practice still faces several major challenges.

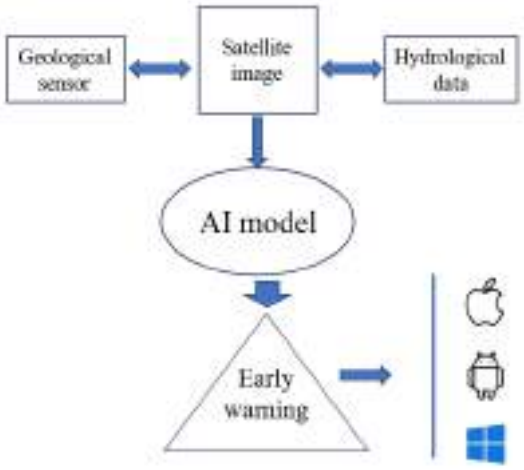

Fig.2 Early Warning Principle

Lack of High-Quality Data

One of the main challenges in applying AI to landslide forecasting is the lack of high-quality data. AI models rely heavily on input data, especially data from geotechnical sensors, satellite imagery, and hydrological data. To make accurate predictions, this data needs to be collected continuously and at high resolution, ensuring it reflects the current conditions of the area. If the data is incomplete or inaccurate, the predictions will be biased, reducing the effectiveness of the early warning system. Moreover, collecting and maintaining high-quality data requires significant costs and time, particularly in hard-to-reach areas.

Computational Resources and High Costs

Implementing complex AI models, especially deep learning algorithms or artificial neural networks, requires a large amount of data to train the model. This means that powerful computational resources are needed, such as high-performance servers and specialized hardware. These systems come with significant investment costs, which can be a major barrier to deploying AI on a large scale, particularly in areas with limited resources or lacking technological infrastructure. Therefore, the implementation of AI will face difficulties without financial support or collaboration between government agencies and international organizations.

Integration of AI with Traditional Methods

Although AI has strong capabilities in landslide forecasting, traditional methods such as using geological maps, hydrological models, and conventional forecasting systems still play an important role in disaster prevention efforts. Integrating AI with these traditional methods presents

a major challenge, as traditional systems have been in use for a long time and may not be fully compatible with the new AI models. This requires close collaboration between experts from various fields and the development of integrated tools to ensure the warning system operates effectively and stably. Without coordinated integration between AI and traditional methods, the forecasting results may not be optimal, reducing the overall effectiveness of the system.

Accuracy and Reliability of the Model

Although AI has the ability to analyze complex data and make accurate predictions, AI models are not perfect. These models can encounter errors, especially when the training data is incomplete or does not fully reflect the changing factors in the real environment. These errors can lead to false warnings, negatively impacting landslide response efforts. Therefore, it is crucial to test and calibrate AI models to ensure the accuracy and reliability of the predictions.

Despite these challenges, if addressed, AI holds significant potential for forecasting and preventing riverbank landslides [9-11]. Solutions such as improving data quality, developing simpler AI models, or using cloud computing systems can help reduce costs and increase technology accessibility. Furthermore, the integration of AI with traditional methods will optimize effectiveness in landslide prevention efforts, reduce risks, and protect both people and their property.

CONCLUSION AND FUTURE DEVELOPMENT

The application of AI in forecasting riverbank landslides in the Mekong Delta has proven to play a crucial role in enhancing early warning capabilities and minimizing the damage caused by natural disasters. AI helps analyze and process complex data, thereby accurately predicting high-risk areas and supporting effective prevention efforts. However, to fully harness the potential of AI in the future, it is essential to continue improving forecasting models, enhancing the quality and continuity of data, particularly from sensors and satellite imagery. Furthermore, close collaboration between research institutions, local governments, and communities is necessary for implementing an effective and sustainable AI system. Enhancing the capacity and awareness of the community about this technology will help AI become a powerful tool, contributing to the protection of people and the environment, while supporting sustainable development in the Mekong Delta.

Future work orientation: The future focus will be on developing an early warning model for riverbank landslides along a 1-kilometer stretch of river in Tien Giang Province. This model will integrate advanced technologies such as AI, hydrological–geotechnical simulation models, on-site sensor systems, and remote sensing data. The objective is to provide accurate and timely landslide forecasts to effectively support disaster prevention and response efforts by local authorities. Additionally, the model will contribute to sustainable land and water resource planning and management, with an emphasis on climate change adaptation. Ultimately, this project aims to enhance disaster resilience and reduce risk for Tien Giang Province and neighboring areas, fostering stable and long-term regional development.

ACKNOWLEDGMENTS

The authors would like to express their sincere gratitude to Tien Giang University for providing support and resources throughout the research process. Special thanks are extended to local authorities and communities in Tien Giang Province for their valuable cooperation and insights. We also appreciate the contributions of colleagues and experts who offered constructive feedback and technical assistance. This research would not have been possible without the dedication and collaboration of all those involved.

ECOFRIENDLY SLOPE STABILIZATION: FIELD APPLICATION OF BIOCEMENTATION WITH NATIVE BACTERIA AND LOW-COST MATERIALS

Azizul Moqsud[1]

[1]Faculty of Engineering, Yamaguchi University, Japan

ABSTRACT

In this study, a field test of biocementation was carried out in a natural slope in Ube City, Yamaguchi University, Japan. Low-cost commercial materials have been used instead of laboratory-grade materials to reduce the overall cost of the biocementation. A 50 x 50 cm area on a slope has been selected, and the culture medium and nutrient medium have been applied for 10 days. The same area has been selected to compare the data of biocementation and without biocementation, and there was no culture or nutrient medium has been applied. A dynamic cone penetration test, along with a direct shear test, has been conducted. Image analysis has been conducted on the surface of the slope after the heavy rainfall. It has been observed that the soil strength increased after the biocementation up to 15 cm from the surface. Image analysis reveals that the surface of the biocemented soil is more stable compared to the uncemented soil.

Keywords: Biocementation, Field Application, Low-Cost, Native Microbes, Slope Soil

INTRODUCTION

Biocementation of soil is a natural process in which the microbes produce calcium carbonate to bond the soil particles and hence increase the soil's strength [1,2]. It is an environmentally friendly approach to protect the natural slope, as no chemical cement is used for this process. The biocementation of natural slopes can be a good solution for the protection against geo-disasters such as landslides, surface erosion, and liquefaction phenomena [3-7]. However, due to the cost of the laboratory-grade materials and the availability of effective bacteria is always a problem for the field application or the scale-up of this process [8-10].

In this study, to overcome the challenges of the current problems, native bacteria, which are easily found in the natural slope on the main island of Japan, have been tried. The low-cost, commercially available materials have been used in large-scale applications in a cost-effective way.

Recent studies have demonstrated the effectiveness of biocementation in slope stabilization. For instance, Moqsud and Gochi (2024) reported that biocemented soil surfaces exhibited up to 80% reduction in erosion under simulated rainfall conditions, with crusts capable of withstanding wind velocities exceeding 55 km/h. Similarly, Dubey et al. (2023) found that MICP-treated soils showed enhanced compressive strength and erosion resistance, while maintaining favorable hydrological properties [19]. A comprehensive bibliometric review by Omoregie et al. (2025) highlighted the growing body of research supporting biocementation as a viable technique for slope management, particularly in environmentally sensitive areas [21].

Despite its potential, biocementation faces challenges related to scalability, cost of reagents, and long-term durability.

The main objective of this study is to check the effectiveness of biocementation by using the commercially available materials and native bacteria in a natural environment. Both the dynamic penetration test and the direct shear test have been carried out to check the strength at different depths and surface of the slope.

RESEARCH SIGNIFICANCE

The significance of the study is to apply the biocementation process on a natural slope with low-cost commercial materials and native bacteria found in the main island. So far, biocementation is carried out in a controlled environment with expensive laboratory-grade materials.

MATERIALS AND METHODS

The natural slope has been chosen in Ube city, Yamaguchi prefecture, near the faculty of engineering, Yamaguchi University. It has been found that the natural slope is around a 30-degree slope angle. The slope soil is classified as decomposed granite soil with some amount of organic matter. The nutrient solution was prepared by using urea fertilizer and snow melting agents which are easily found in the commercial market. The snow melting agent, which is basically calcium chloride salt, can be used instead of pure laboratory-grade materials. The culture medium was used as a

laboratory grade material and can be used effectively in the field, as the amount of if used in the field is small. For the cone penetration test, the dynamic cone penetration test has been applied, developed by Hasegawa Corp., Japan.

Table 1 Nutrient solution and culture medium materials

Culture medium		Nutrient solution	
Distilled water	500ml	Distilled water	500ml
Yeast Extract	10g	Urea	15g
Ammonium sulfate	5g	Calcium chloride	27.8g
1.03Mtris	7.875g		
Peptone	5g		

Bacteria used in this study

Microbes are islolated from the natural slope of Yamaguchi prefecture and Miyagi prefecture which are located at the south and north part of main island of Japan. The microbial analysis confirmed the presence of Ureolytic bacteria which are mainly responsible for biocementation are present both in the northern and southern part of Japan and can be utilized for the field applications. The name of the native bacteria which was isolated and used in this experiment is *Cytobacillus horneckiae.* The details of the isolation and DNA analysis of this native bacteria and the urease tests have been described in the previous research [12-15].

Field test

The slope has been divided into four equal sections (50 x 50 cm). They have been named A, B, C, and D. Figure 1 shows the section where A and B were selected with grass, and C, D without grass. B and D were without biocementation. The same amount of culture medium and nutrient solutions has been used for A and C sections and applied from the surface. The culture medium was applied only for the first day, but the nutrient solution was used for 10 days. All the A,B,C,D section were experimented in same weather conditions.

After ten days, the penetration test and direct shear test were carried out.

Fig. 1 Field test of biocementation

For conducting the direct shear test, three molds were prepared (60mm diameter and 20 mm height) in the nearby field, and the same amount of culture medium and nutrient solutions were applied for the same period. The direct shear test was conducted with 50,100 and 150 kN/m^2 confining pressure [16-20]. However, due to the space limitation only the result of 100kN/m^2 has been described in this paper in the later section.

Scanning electron microscope (SEM) analysis was conducted to see the amount of calcium carbonate generated on the surface of the soil.

RESULTS AND DISCUSSION

Figure 2 shows the result of the penetration test with grass. It has been observed that the penetration depth of the blank is more compared to the biocemented slope

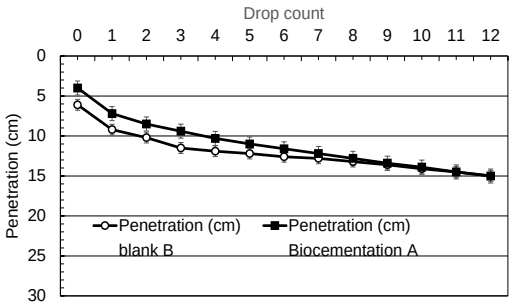

Fig. 2 Penetration test result with grass A, B

The penetration test with grass showed a similar trend both for the blank and the biocemented slope sections. The nutrient solution is applied with a sprayer from the surface of the slope, both with and without grass, respectively. However, some nutrient solutions can be hindered from reaching the soil surface due to the presence of grass on the surface.

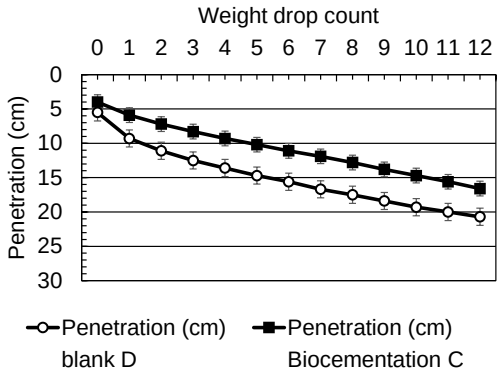

Fig. 3 Penetration test result without grass C, D

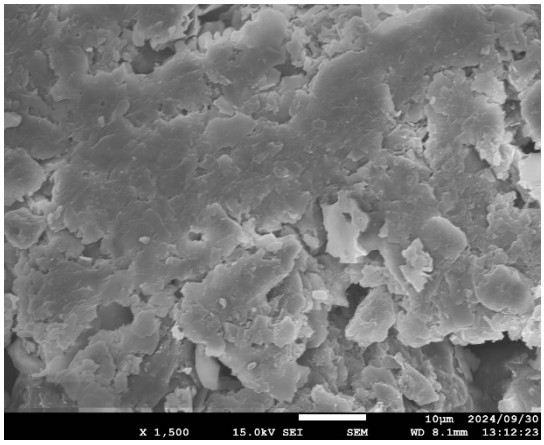

Fig. 4 SEM with grass A (with biocementation)

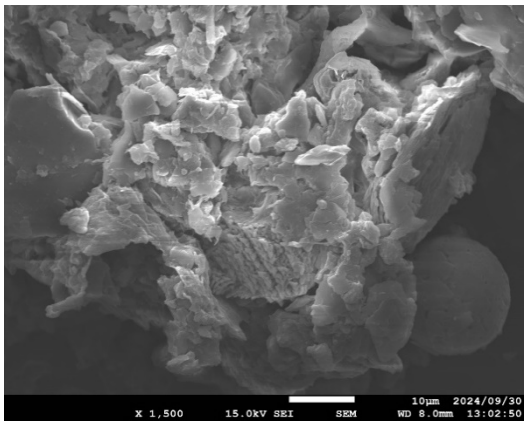

Fig. 5 SEM result with grass B (without biocementation)

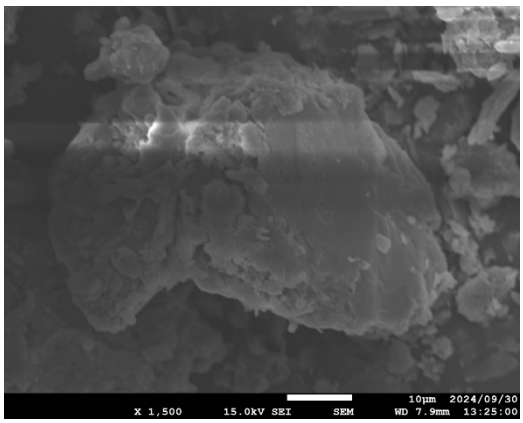

Fig. 6 SEM and EDS result with grass C (with biocementation)

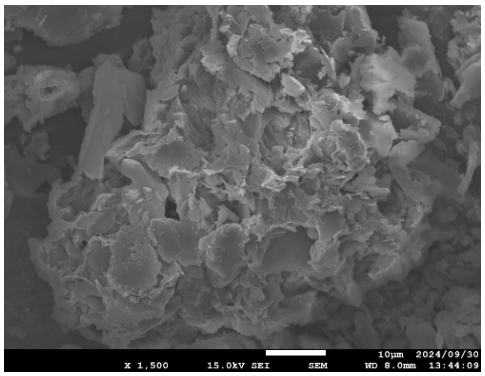

Fig. 7 SEM and EDS result with grass D (without biocementation)

Figures 4 and 5 illustrate a scanning electron microscopy view of the samples for blank samples and with biocementation samples without grass. It has been visible that the biocementation shows more calcium carbonate on the surface of the soil particles. The yellow color represents the calcium carbonate, and it demonstrates the amount of calcium carbonate generated on the surface of the soil particle, more in the biocemented slope. This is the reason for the soil strength increase in various depths. The penetration test reveals that soil strength increased after the biocementation up to 15cm. The blank slope did not show much strength near the surface (up to 15 cm). This proves that biocementation can increase the soil strength even outside of the laboratory and in natural environmental conditions.

Figures 6,7 show the SEM results for C and D sections of the slope. A similar trend has been observed for this case as well.

Figure 8 presents the outcomes of direct shear tests conducted on soil samples C and D, both before and after biocementation treatment. The post-treatment results reveal a marked improvement in shear strength, indicating the efficacy of biocementation in reinforcing soil structure. This observation aligns with findings from previous studies, such as those by DeJong et al. (2006) and Ivanov & Chu (2008), which demonstrated that microbial-induced calcium carbonate precipitation (MICP) can significantly enhance soil mechanical properties.

A comparative analysis between untreated and biocemented samples underscores the positive impact of biocementation on shear resistance. The increase in shear strength is attributed to the formation of calcite bonds between soil particles, which enhances interparticle cohesion and reduces deformability under stress.

Figure 9 further illustrates the relationship between normal stress and shear stress for slope

samples devoid of vegetation, comparing blank and biocemented conditions. The data clearly indicate an increase in both cohesion (c) and internal friction angle (φ) following biocementation. These improvements are consistent with the theoretical framework proposed by Mitchell & Santamarina (2005) [23-24], which suggests that cementation processes contribute to both strength and stiffness gains in granular soils.

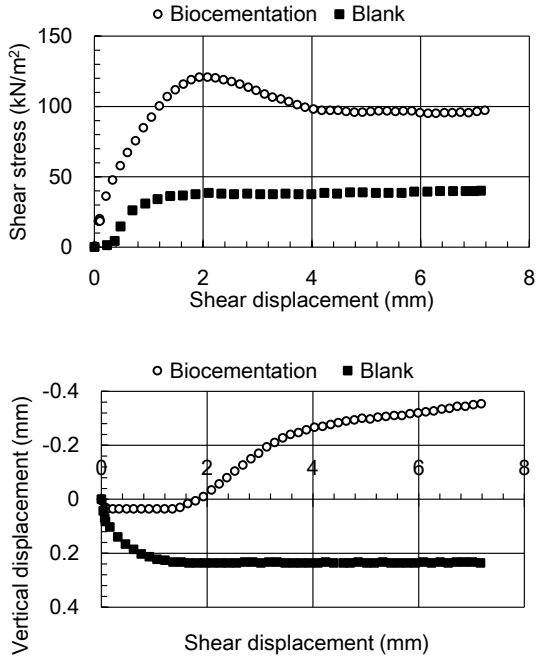

Fig. 8 Direct shear test with and without biocementation for C,D

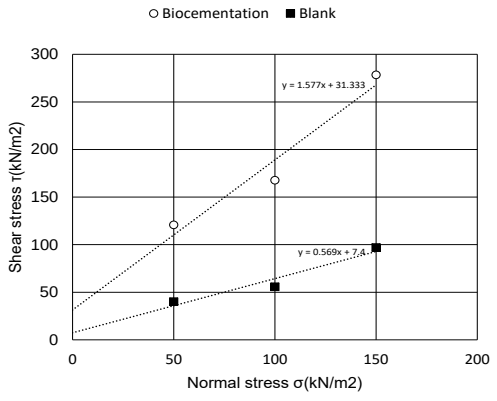

Fig. 9 Relationship between normal stress and shear stress for C and D (Biocemented and blank for without grass)

Additionally, the volumetric strain observed during shear testing was significantly reduced in biocemented samples, suggesting enhanced structural integrity and reduced susceptibility to deformation. This reduction in volumetric change is critical for slope stability, particularly in erosion-prone or load-bearing applications, as highlighted in the work of Whiffin et al. (2007) [25-26]. However, the blank slope showed opposite trend and indicated the lower strength of slope which is easy to erode and consequently prone to geohazards such as landfill and liquefaction.

CONCLUSIONS

The field application of biocementation shows a promising result to increase the strength of the slope surface. However, the application of nutrient solution and culture medium can increase the strength upto 15cm from if they applied from the surface. The rainfall effect and long term stability check should be done. The low-cost commercial materials can be used for the biocementation. The native bacteria can increase the chance of biocementation in the main island of Japan, which can reduce the risk of biohazards. This study proves that biocementation can be an environmentally friendly solution for the natural slope protection from surface erosion or landslide, along with liquefaction. Notably, the use of local microbial strains *Cytobacillus horneckiae* not only increases the likelihood of effective calcite precipitation but also mitigates the ecological risks often associated with introducing non-native species.

These findings affirm that biocementation is a viable and green alternative to conventional engineering solutions in protecting vulnerable slopes from erosion, landslides, and liquefaction. As Japan continues to confront geological and climatic challenges, such bio-based interventions offer a meaningful pathway toward resilient infrastructure and ecological preservation. Future implementation and scaled-up applications of this technique could mark a transformative shift in geotechnical engineering, aligning technological advancement with environmental stewardship. However, the long-term durability of the biocemented slope should be monitored.

ABSTRACT

In tunnel construction employing the New Austrian Tunneling Method (NATM), one of the most significant safety risks is rock spalling, where rock fragments fall from the tunnel face. This hazard typically results from fractures, weathering, and surface irregularities of the rock mass. As most such incidents occur at the tunnel face, effective preventive measures are critical to ensuring worker safety. In tunnel construction, apart from standard preventive measures such as shotcrete, rock-bolts, or steel arch support, additional auxiliary methods are also employed. Although various auxiliary methods exist, a lack of quantitative comparison regarding their effectiveness under different ground conditions remains. In practice, the selection of auxiliary methods often depends on empirical knowledge and site experience. Therefore, further analytical evaluation is needed to establish objective and reproducible criteria. This study assessed the effectiveness of support methods through finite element analysis, focusing on their ability to reduce horizontal and vertical displacements of the tunnel face. Displacement magnitude was used as an indicator of potential rock spalling risk. In addition, changes in stress states associated with each method were analyzed to gain further insight into their deformation behavior. The analysis revealed that the auxiliary bench and umbrella arch methods were effective in suppressing both horizontal and vertical displacements, while other methods primarily reduced displacement along a single axis. Horizontal displacement was effectively managed using long face bolts, and vertical displacement was minimized through forepoling and steel arch support. Furthermore, the auxiliary bench method remained effective regardless of ground conditions.

Keywords: Conventional tunnelling method, Tunnel face, Rock spalling, Finite element analysis, Auxiliary methods

INTRODUCTION

There are two tunneling methods for mountain tunnel construction: the conventional tunneling method and the New Austrian Tunneling Method (NATM). Since the late 1980s, the use of NATM has increased, gradually replacing the conventional method in road tunnel construction in Japan. Today, NATM is used in nearly all mountain tunnels, except where ground conditions are particularly complex.

One of the most serious safety risks in NATM tunnel construction is rock spalling, where fractured rock detaches and falls from the tunnel face. From 2000 to 2010, a total of 44 work-related injuries due to rock spalling were recorded in Japan [1]. These incidents frequently occurred at the tunnel face and gallery, regardless of the ground hardness. Therefore, implementing effective preventive measures in these areas is critical to ensure worker safety and reduce casualties.

This study assessed the effectiveness of various support methods through finite element analysis, focusing on their ability to reduce horizontal and vertical displacements of the tunnel face. Displacement magnitude was used as an indicator of potential rock spalling risk. In addition, changes in stress states associated with each method were analyzed to gain further insight into their deformation behavior. The displacement suppression rate calculated and the quantification of the effectiveness of the countermeasure methods can be used as a guide for selecting a countermeasure to prevent rock fall hazards. Being able to compare the advantages and disadvantages of each method, it can help propose an optimal countermeasure method to reduce the number of casualties during tunnel construction using NATM.

TUNNEL COUNTERMEASURE METHODS

In the NATM, three methods are commonly used as part of a single cycle during excavation: shotcrete to improve the self-supporting ability of the tunnel face, steel arch supports installation to prevent the collapse of the surrounding rock, and rock-bolts that are radially installed in the cross-sectional direction to resist tensile stresses. Additionally, depending on the ground conditions, auxiliary methods may be employed. These auxiliary methods are used when conventional supports cannot fully address the situation, or when it is not advisable to rely solely on standard support methods.

These methods are primarily applied to the crown and cutting face of the tunnel. The selection of the appropriate technique is based on safety, construction

reliability, and its impact on the surrounding environment. For tunnel face stability, commonly used methods include face-shotcrete, which enhances self-supporting capability through concrete application, and face-bolts, which are installed in the excavation direction to improve stability. As countermeasures for the crown area, techniques such as fore-poling and umbrella arch are employed. In these methods, bolts or pipes are installed from the tunnel face along the outer perimeter of the upper half arch to increase the apparent shear strength of the crown and prevent collapse.

In addition to reinforcement measures, modifying the excavation method itself can also contribute to face stability. Among these, full-face excavation method with auxiliary bench is particularly effective in improving both face stability and excavation efficiency. This method is applied in ground conditions where conventional full-face excavation is difficult, by incorporating temporary benches while allowing simultaneous excavation of the upper and lower sections (Fig.1).

OUTLINE OF FINITE ELEMENT ANALYSIS

The analysis domain used in this study is presented in Fig. 2. It is assumed to be a road tunnel with a tunnel completion radius of 5.4 m [3], which is based on the standard cross-section used in the Japanese design guidelines for mountain tunnels.

The parameters related to the ground are shown in Table 1, and standard values corresponding to each ground classification are used [4,5]. Ground classification is defined as an index of ground stability, with grade B being considered the most stable in this analysis.

The ground was modeled as an elasto-plastic material, adopting the Drucker–Prager yield criterion. To incorporate cohesion (c) and the internal friction angle (φ), a model was employed where the Drucker–Prager yield criterion aligns with the inner boundary of the Mohr–Coulomb yield criterion (Fig. 3). Furthermore, a tension cut-off model was utilized to prevent overestimation of tensile strength, which is negligible in most ground conditions (Fig. 4).

The excavation process consisted of 11 steps, with the first 10 following the standard NATM procedure, which includes excavation, shotcrete, steel arch support (for CII-b, DI, and DII only), and rock-bolt installation. The tunnel face at the end of the 11th excavation step was selected as the measurement surface, to which a specific countermeasure was applied. The countermeasures included conventional supports (shotcrete, steel arch supports, and rock bolts) as well as four auxiliary methods: face-shotcrete, long face-bolts, forepoling, and umbrella

arch, each modeled as elastic materials. These methods were applied simultaneously with the excavation process.

For the full-face excavation method with auxiliary bench, the length of bench 1-step (e.g., 1 m for DII) was left at the final excavation step. However, for the DII pattern, the end of the bench experienced tensile failure, and the equilibrium of forces could not be maintained, preventing convergence. As a result, the tension cut-off model was deactivated for the DII pattern to allow the analysis to proceed.

The physical properties of the countermeasure methods are shown in Table 2 [4,5,8–10]. The modulus of elasticity for the shotcrete used in the standard support pattern was 6000 N/mm², corresponding to high-strength concrete after 28 days of curing. For the region-of-interest section, the Young's modulus of the concrete was set to a lower value of 330 N/mm² to account for the fact that workers may enter the tunnel face 10 to 15 minutes after spraying, when the material has not yet reached full strength [8]. The shotcrete and face-shotcrete were modeled using thin layer elements [9].

The forepoling was set to a length of 3 meters, with an installation angle of 15° from the horizontal, while the umbrella arch was set to 12.5 meters in length and an installation angle of 4° [9]. Long face-bolts were applied with a length of 12.5 meters and installed horizontally, with a glass density of 1784 kg/m³ [10]. These specifications reflect commonly adopted values in Japanese tunnel practice. The area of the rock bolts was assumed to be 353 mm² for the CII-b pattern and above (using regular twisted steel) and 433 mm² for the DI pattern and below (using high-strength twisted steel). These four countermeasures were modeled using truss elements, which are suitable for axial-force dominant members.

Steel arch supports were applied to both the upper and lower sections in DII and DI pattern grounds, but only the upper section was used in CII pattern grounds. Steel arch support was not used in relatively stable ground conditions such as CI and B patterns. These supports were modeled using beam elements, as they transfer bending and axial forces.

The measurement locations for horizontal and vertical displacements at the tunnel face, which were the focus of this study, are shown in Fig. 5. The calculated displacement values represent the average displacements in the x and y directions at the eight vertices of a 0.5-meter cube. To calculate the displacement suppression rate, the displacement of the Region of Interest (ROI) was denoted as d_0 when

Table.2 Physical properties of countermeasure methods [4,5,8-10]

	Element type	Young's Modulus (N/mm²)	Poisson's ratio	Density (kg/m³)
Shotcrete (Standard)	Thin layer	6000	0.2	2300
Shotcrete (Others)	Thin layer	330	0.2	2300
Rock-bolts	Truss	2.1×10^5	0.3	7850
Steel arch support	Beam	2.1×10^5	0.3	7850
Long face-bolts	Truss	2.0×10^4	0.3	1784
Forepoling Umbrella arch	Truss	2.1×10^5	0.3	7850

the previous section was excavated.

The displacement at the ROI was then recorded after excavation with no countermeasures applied (no support), denoted as d_1, and the displacement when a specific countermeasure was applied simultaneously with excavation was denoted as d_x (Fig. 6). After all analyses were conducted, the displacement suppression rate was calculated using Eq. (1).

$$R_{r_x} = (d_1 - d_x) / (d_1 - d_0) \times 100 \quad (1)$$

RESULTS OF FINITE ELEMENT ANALYSIS

The suppression rates of horizontal and vertical displacement in the tunnel face are presented in Fig. 7 and Fig. 8. In addition, the stress state of each countermeasure is shown in Fig. 9 (for the DII pattern) using von Mises stress. This stress is derived such that the shear strain energy of a multiaxial stress field, which includes multiple stress components, is equivalent to the short-axis stress. Since it is energy-based, von Mises stress is always positive, as it is a scalar quantity without direction. This has the advantage of allowing a quick assessment of stress magnitude from the distribution diagram. From Fig. 7, the most effective countermeasure in terms of horizontal displacement suppression was the installation of an auxiliary bench with a 1-step length, achieving a maximum suppression rate of 28%. Furthermore, it was found that the auxiliary bench method effectively suppressed displacements regardless of ground conditions. This can be

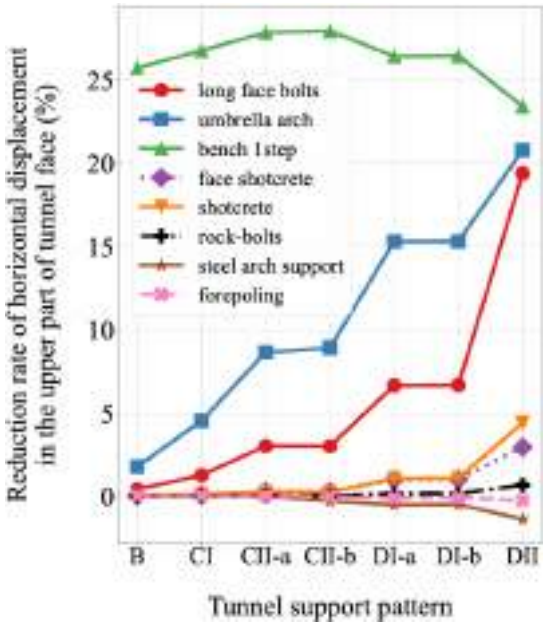

Fig.7 Summary of horizontal displacement reduction rate

(d) Primary shotcrete (e) Steel arch support (f) Forepoling

Fig.9 (a)～(f) Summary of stress state (for DII pattern)

attributed to both its structural function and its geometric role as an integral part of the surrounding rock mass.

The auxiliary bench reduces the excavated area at the tunnel face, thereby minimizing the release of in-situ stress and alleviating stress concentration. This reduction in excavation volume not only limits deformation but also facilitates a more favorable redistribution of forces around the tunnel face. As a result, extrusion displacement is significantly mitigated, contributing to the overall stability of the face. Following the auxiliary bench, the next most effective measures were the umbrella arch and long face-bolts, both achieving high suppression rates of approximately 20%. The effectiveness of these methods is associated with their length of 12.5 meters. In the case of face-bolts, the fact that they were installed in the direction of tunnel advancement played a significant role (Fig. 9a and 9b). After comes the shotcrete and face-shotcrete. Given that the primary shotcrete used a modulus of elasticity equal to 15 minutes of curing, that is based on actual construction conditions, the maximum reduction rate of displacement was limited to approximately 4%. In the previous section of the tunnel face, the secondary shotcrete had already been completed. Thus, in the direction of tunnel advancement, the primary shotcrete, in continuity with the secondary shotcrete in the previous section, generated a reaction force in the direction of tunnel advancement, leading to better results compared to face-shotcrete. On the other hand, face-shotcrete is thought to resist face extrusion through its own tensile and shear resistance (Fig. 9c and 9d). Other methods, such as forepoling, steel arch supports, and rock-bolts, did not show significant effectiveness in suppressing horizontal displacement and, in some cases, resulted in negative suppression rates. For vertical displacement suppression, the most effective countermeasure was similarly the installation of an auxiliary bench. Again, it was found that the auxiliary bench method effectively suppressed displacements regardless of ground conditions. The effectiveness of the countermeasures decreased in the following order: steel arch supports, face-shotcrete, umbrella arch, forepoling, rock-bolts, and long face-bolts. Steel arch supports and forepoling were particularly effective in suppressing vertical displacement, as they concentrate on stress near the crown (Fig. 9e and 9f). The reason why face-shotcrete showed a high suppression rate for both horizontal and vertical displacements is likely because it is sprayed across the entire face, which allows for reaction forces from the lower section. Also, when integrated with shotcrete applied to the tunnel sidewalls, steel arch supports and rock-bolts are believed to increase rigidity and toughness, contributing to the overall stability of the tunnel cross-section. The displacement distribution of the tunnel excavation cross-section for the case with no support is shown in Fig. 10a, and for the case where the full-section excavation method with an auxiliary bench is employed, in Fig. 10b. From these images, it

is visually evident that in the case with no support, extrusion displacement is concentrated at the center of the tunnel face. However, when an auxiliary bench with a length of one excavation step is provided, this displacement is significantly alleviated. This suggests that reducing the excavation target area and introducing geometrical constraints is effective in mitigating extrusion deformation and stabilizing tunnel face behavior under various ground conditions.

These findings suggest that the displacement suppression performance of each countermeasure can guide the selection of auxiliary methods in tunnel construction.

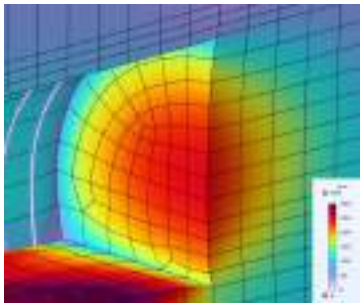

Fig. 10a Displacement distribution (no support)

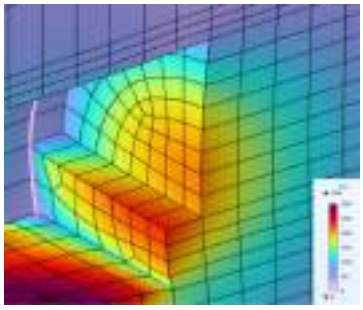

Fig. 10b Displacement distribution (auxiliary bench)

CONCLUSIONS

In this study, finite element analysis was employed to examine the displacement suppression effects of rock spalling mitigation measures, focusing on the horizontal displacement of the tunnel face and the vertical displacement at the tunnel crown. The analysis revealed that the auxiliary bench and the umbrella arch method were effective in suppressing both horizontal and vertical displacements, with other methods primarily reducing displacement along a single axis. Horizontal displacement was effectively managed using long face-bolts, whereas vertical displacement was minimized through forepoling and steel arch support. Notably, the auxiliary bench method achieved over 20% reduction in horizontal displacement and remained effective regardless of ground conditions.

ABSTRACT

This study investigates the development and practical implementation of subsurface utility engineering (SUE) in Thailand from 2003 to 2024. Using drawings from over 300 infrastructure projects and detailed field surveys across 21 locations, the research evaluates the accuracy of two primary detection technologies, ground penetrating radar (GPR) and electromagnetic pipe locators. Environmental conditions—especially soil moisture—have significant impacts on detection performance. When applying a practical accuracy threshold of ±0.3 meters, the pipe locator achieved this standard at approximately 81% of the test sites, while GPR met the criterion at around 67%. The pipe locator also demonstrated a lower average error and greater consistency across varied soil conditions. These findings highlight the importance of selecting detection technologies based on site-specific characteristics and integrating both detection methods, supplemented with physical verification, to enhance utility mapping accuracy. While the results are based on a limited number of test locations, the study provides practical insights and supports the advancement of SUE implementation and quality control in Thailand.

Keywords: Subsurface Utility Engineering, Ground Penetrating Radar, Pipe Locator, Utility Detection

INTRODUCTION

Rapid infrastructure expansion below ground since World War II resulted in a global complexity of subsurface utility networks. Nearly 20 million miles of pipelines, cables, and wires have been installed [1]. The 20–50-year design life span of most utility systems now poses significant obstacles for present-day maintenance operations. The rapid growth of infrastructure and urbanization in Thailand has become a significant problem because of inconsistent documentation of the earliest utilities.

The methods for locating underground utilities fail to satisfy contemporary needs in infrastructure construction. The monitoring systems and visual surveys typically diverge from actual positions by 15–30% [2]. According to recorded data, at least 104,000 US utility damage incidents occurred in a single year, while gas pipeline hits from third-party sources caused US$83 million in damages [3]. The available data clearly demonstrates why better utility detection and mapping methods must be developed.

The development of Subsurface Utility Engineering (SUE) practices in Thailand reflects both global technological evolution and unique local challenges. The current research examines this development through analysis of over 300 projects spanning two decades, documenting the progression from basic electromagnetic detection to integrated multiple-technology approaches. The investigation particularly focuses on quantifying accuracy improvements and establishing best practices for Thai urban environments, where high utility density and varied soil conditions create significant challenges for underground utility detection and mapping.

Recent studies have demonstrated that human factors, particularly stakeholder behaviors, play a significantly more important role in damage prevention than previously believed [4]. The fast-growing utility infrastructure of Thailand will face implementation challenges that affect SUE programs due to workforce capabilities, communication problems, and procedural issues. SUE efforts require technological advances, effective stakeholder coordination, and regulatory structures with standardized procedures.

RESEARCH SIGNIFICANCE

This study provides critical empirical data on SUE technology performance in Thailand's specific environmental conditions. The research quantifies accuracy differences between ground penetrating radar and electromagnetic pipe locators across varied soil types and moisture levels, establishing practical guidelines for technology selection. These findings enable optimization of utility detection strategies, reducing infrastructure damage risks and project costs. The work advances SUE implementation standards in Thailand and provides a comparative framework applicable to similar tropical environments with high soil moisture variability.

SUBSURFACE UTILITY ENGINEERING

Subsurface utility engineering implements a structured system to identify and manage underground utility risks by accurately detecting underground utilities and mapping their exact locations. Utility detection through SUE operates by electromagnetic induction where alternating electrical currents in conductors create magnetic fields which analysts use to determine utility types and positions [5]. SUE technology began in the 1970s and then progressed into extensive engineering procedures that merge several scientific approaches and methods [6].

SUE practices gained adoption across the world because they effectively control risks associated with underground infrastructure. Twenty-two states in the United States operate SUE programs for their highway projects. Virginia has mandatory SUE regulations for all their highway projects. The PAS 128 specification of the United Kingdom [7] includes SUE principles as a standard for underground utility detection systems. Australia established the AS 5488 standard [8] for similar purposes. Singapore together with Malaysia adopted SUE practices as part of their infrastructure development, but they follow different implementation protocols depending on regional conditions and requirements.

SUE implementation depends on quality levels which ascend from basic to advanced accuracy according to ASCE 38-02 [9] specifications. Quality Level D remains the most fundamental information source since it uses existing utility records together with verbal descriptions as its sole data source. The initial location information derived from existing records faces challenges because research indicates these records provide locations that may differ by 15–30% from actual positions. Quality Level C builds upon basic information by adding surface feature surveys that connect what is seen above ground, such as manholes and valve boxes, with database records to boost location accuracy.

The implementation of geophysical detection methods under Quality Level B (QL-B) marks a significant advancement in the subsurface utility engineering process. This phase, known as "Designating," utilizes modern technologies such as electromagnetic locators and ground penetrating radar (GPR) to enhance the identification and mapping of underground utilities. It builds upon previous levels by incorporating real-time field data for improved reliability.

The highest level of accuracy is achieved at Quality Level A (QL-A), referred to as "Locating." This involves physically exposing the utility using vacuum excavation or similar non-invasive techniques, enabling precise three-dimensional measurement and direct verification of utility characteristics. The SUE quality levels are summarized in Table 1.

Table 1 SUE quality levels and characteristics

Level	Definition	Data Sources	Methods
QL-D	Record-based information	Existing utility records, as-built drawings	Document research
QL-C	Surface feature correlation	QL-D + visible utility features	Site reconnaissance, survey of visible features
QL-B	Geophysical detection	QL-C + field detection data	Electromagnetic locators, GPR, magnetic methods
QL-A	Physical exposure	QL-B + direct observation	Vacuum excavation, test holes, direct measurement

The capability to select and effectively perform with detection technology relies on understanding fundamental principles together with environmental conditions. Radiodetection Ltd. [5] indicates that electromagnetic pipe and cable locators work within multiple frequency ranges from 512 Hz to 100 kHz. Lower frequencies achieve longer distances while higher frequencies enhance detection accuracy in difficult conditions. These detection systems use two methods to recognize magnetic fields that either naturally originate from utility conductors or through artificial stimulation. Ground penetrating radar functions through electromagnetic wave reflection from subsurface interfaces to develop utility images beneath the surface. It identifies both metallic and non-metallic utilities but its success depends on soil conditions [10, 11].

Environmental factors play a critical role in influencing the accuracy of detection systems. Soil conductivity together with moisture content and composition control signal transmission for electromagnetic and GPR systems in equal measure. According to Jung [6], the detection of buried utilities depends on three essential factors, utility material properties, burial depth, and environmental interference. Higher soil moisture levels along with

clay substrates lead to reduced detection capability. Sandy dry conditions tend to enhance signal transmission. The number of utilities located in a specific area creates specific challenges for accurate detection since urban density hinders detection outcomes.

Modern subsurface utility engineering practices integrate multiple detection technologies as complementary systems to effectively address known challenges in underground utility mapping. Pressurized pipes receive their best detection from acoustic methods whereas ferrous material detection leads to superior results with magnetic methods. Thermal imaging detection adds heat-generating utility to the comprehensive tools used for detection purposes. Current best practices in subsurface utility engineering combine multiple detection technologies under the support of well-developed quality management systems [12].

The financial advantages of correctly implementing subsurface utility engineering are extensively supported by research. A study conducted by Jung [13] involved 22 SUE and 8 non-SUE projects which produced benefit-cost ratios between 3.21 and 33.93. The strength of economic gains from SUE implementations shows a better relationship between how utility system complexity is compared to project expenses because site-specific quality selection outranks expense-based choices. The current research indicates that SUE projects with greater complexity generate more significant benefit-cost advantages which shows why comprehensive SUE methods succeed in difficult site conditions. Studies from the present day demonstrate that SUE deployment generates $11.39 in total savings per dollar invested in complex utility projects where utility relocations contribute roughly 40% of these benefits [10, 14, 15].

DEVELOPMENT OF SUE PRACTICES IN THAILAND

The development of SUE practices in Thailand followed three distinct stages that brought major improvements to both methods and technology. Recent development in SUE technology combines global trends with the specific challenges of Thailand's urban infrastructure and environmental context.

Initial Phase (2003-2008)

Introduction of SUE practices to Thailand started in 2003 through which basic implementation methods and limited technological systems prevailed. The main detection method of this period depended on electromagnetic tools, which received additional support from existing documentation alongside as-built drawings. During this time researchers undertook comprehensive surveys for oil and gas facilities that included extensive work for a service station network that has more than 250 sites throughout Thailand.

The first implementation phase faced difficulties due to imprecise utility network detection and shallow depth ranges in addition to heavy documentation dependency. During this period the employed methods created horizontal errors exceeding 1.0 meter when surveying areas with many utilities. The initial SUE projects set up a base that led to more developed SUE techniques, but also revealed the requirement for improved detection strategies. During the initial phase, electromagnetic equipment served as the primary tools for underground utility detection, as shown in Fig. 1.

Fig. 1 Radiodetection RD4000 electromagnetic pipe locator used for underground metallic pipe detection during the early development of SUE practices in Thailand.

Development Phase (2009-2015)

This phase brought much progress through the adoption of innovative technologies and advanced methodologies into SUE practice. The SUE approach progressed through four main developments during this period, ground penetrating radar technology adoption, detection method combination, digital documentation system development, and GPS mapping system implementation.

The SUE practices moved outside of Thailand to include Cambodia together with the Lao PDR as part of cross-border infrastructure development projects. Southeast Asia became part of a regional expansion that allowed for the transfer of knowledge and standardization of practices throughout the area. The adoption of quality-level classification systems together with systematic documentation methods brought substantial improvements to project results. The second phase marked significant advancement with the introduction of ground penetrating radar technology, as illustrated in Fig. 2.

Fig. 2 MALA Easy Locator Ground Penetrating Radar system introduced during the development phase (2009-2015) of SUE practices in Thailand.

Current Phase (2016-Present)

The present stage shows sophisticated SUE practices that employ combined methodologies and enhanced quality control systems. The present implementation of SUE utilizes multi-frequency GPR systems (Fig. 3) alongside high-precision electromagnetic detectors, GPS mapping solutions, and digital data platforms, along with building information modeling (BIM) integration, as presented in Fig. 4. Physical verification through water jet excavation was employed to provide ground truth data for accuracy assessment.

Fig. 3 US Radar Quantum Imager, a multi-frequency GPR system representing the advanced technology adoption in the current phase (2016-present) of SUE development in Thailand.

Thailand requires a full system of laws and regulations to achieve systematic implementation of SUE practices. The Kingdom should adopt institutional approaches to benefit from established methods like those used by its neighboring country, Malaysia, including the National Underground Utility Database (NUUD) and mapping standards [16]. Malaysia provides a framework that combines international standard utility quality levels and defined stakeholder responsibilities along with centralized data management platforms that Thailand can adopt.

CASE STUDY: ENVIRONMENTAL FACTORS AFFECTING UTILITY DETECTION ACCURACY IN THAILAND

A comprehensive field investigation was conducted to obtain empirical data on the performance of ground penetrating radar (GPR) and pipe locator technologies in Thailand. This section describes the study area and methodology employed.

Study Area

This research project examined 21 survey locations along natural gas pipeline routes in the eastern region of Thailand, specifically within Rayong and Chonburi provinces, as shown in Fig. 5. The selected pipeline segment represents a critical infrastructure component of Thailand's energy network, connecting the offshore natural gas facilities in the Gulf of Thailand to inland industrial areas. This pipeline corridor was chosen for its strategic importance and because it traverses through a variety of soil conditions with different physical and environmental characteristics, making it ideal for comparative analysis of detection technologies. The survey points were strategically distributed to encompass diverse geological settings, including coastal areas with sandy soils and inland regions with varied clay content. This provided a representative sample of the typical subsurface conditions encountered in Thai infrastructure projects.

Methodology

The research employed a systematic approach using three complementary detection methods. Physical verification through water jet excavation provided ground truth data for accuracy assessment, as shown in Fig. 6. The primary detection instruments utilized were a Radiodetection RD4000 electromagnetic pipe locator with a TX-3 transmitter

(Fig. 7) and a MALA Easy Locator Ground Penetrating Radar system (Fig. 8). These non-destructive detection technologies represent the standard equipment used in SUE practice in Thailand during different developmental phases.

Fig. 5 Study area showing a natural gas pipeline route through Rayong and Chonburi provinces.

Both GPR and a pipe locator were used to detect underground pipes at each location. The horizontal and vertical coordinates obtained from utility detection through both methods were recorded. The actual utility position was verified through water jet excavation. The horizontal (ΔH) and vertical (ΔV) differences between the water jet and the other two methods were then compared. Soil samples were collected (Fig. 9) at each location and laboratory tested for an evaluation of environmental factors that influence detection precision.

The obtained soil samples were examined to determine their engineering properties. Standard gravimetric methods were employed to determine the sample moisture contents. Sieve analysis of particles helped identify their textural class. A laboratory performed soil classification following the Unified Soil Classification System (USCS) procedures to obtain standardized groupings. A set of tests based on Atterberg's limits determined the important properties related to soil plasticity. Standard penetration test (SPT) data collection provided information about soil density and compactness measurements at all locations.

Fig. 7 The 2nd author conducting underground pipe locating by a Radiodetection RD4000 pipe locator system.

Fig. 8 The 3rd author conducting underground pipe locating by a MALA Easy Locator GPR system.

Based on the laboratory test results, survey locations were categorized according to soil type (based on SPT-N value, soil consistency, and relative density) and soil moisture content (below 10% and

above 10%). By establishing these classification categories, the environmental factors impacting detection precision can be evaluated. Each detection method obtained accuracy measurements by analyzing the absolute distance deviations between detected utility locations and their actual positions. Data measurement formed a foundation for the performance evaluation of detection systems under different environmental settings.

RESULTS AND DISCUSSION

Comparative Analysis of Detection Technologies

Empirical analysis of underground pipeline detection technologies in Thailand yielded critical insights into their relative accuracy under varying environmental conditions. Table 2 summarizes the depth measurement errors for GPR and pipe locator methods at 21 survey locations.

Table 2 Summary of depth measurement errors for GPR vs. a pipe locator

Error Metric	GPR Error (m)	Pipe Locator Error (m)
Horizontal (mean ± σ)	0.34 ± 0.22	0.24 ± 0.17
Vertical (mean ± σ)	0.30 ± 0.26	0.22 ± 0.21
Horizontal (min - max)	0.00 - 0.80	0.00 - 0.70
Vertical (min - max)	0.04 - 0.96	0.02 - 0.89

The pipe locator demonstrated superior overall accuracy compared to GPR across the survey area. It provided more consistent results, with an average vertical error of 0.22 meters, compared to 0.30 meters for GPR. When applying a practical accuracy threshold of ±0.3 meters, the pipe locator met this criterion at approximately 81% of the test locations, whereas GPR achieved it at around 67%. These results suggest that the pipe locator is generally more reliable for subsurface utility detection under soil conditions in the study area. The example of the result obtained from both the pipe locator and the ground penetrating radar is presented in Fig. 10.

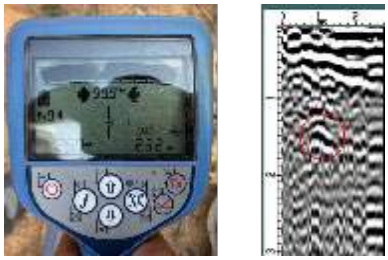

Fig. 10 The example of result obtained from pipe locator and GPR (a) The pipe locator screen shows the location and depth of the buried pipeline. (b) Identified abnormally from radargram present the location and depth of underground pipeline.

Absolute vertical depth errors between the technologies are compared in Fig.11 through a mapping of survey location-specific measurements. Most of the recorded points are situated beneath the diagonal reference line demonstrating that the pipe locator produced lower errors than GPR measurements primarily in non-clay soil conditions. The visual display shows that the pipe locator performed better than GPR in measuring depth at most locations in the survey.

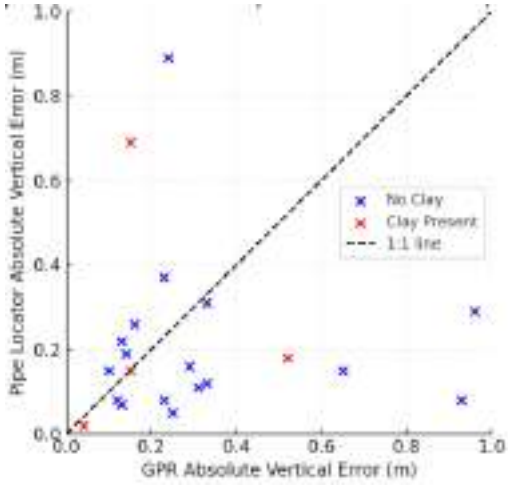

Fig. 11 Comparison of absolute vertical depth errors for GPR vs. pipe locator at surveyed locations. Points below the 1:1 dashed line indicate locations where the pipe locator demonstrated superior accuracy.

Environmental Factors Affecting Detection Accuracy

The study evaluated three environmental factors affecting detection performance through analysis of soil type, soil density, and soil moisture content.

Detection performance was most impacted by the soil moisture content among all considered environmental factors.

The detection accuracy of equipment depended heavily on soil composition because performance showed distinct results between clay and sandy areas. The accuracy of the pipe locator increased to 0.21 meters in sandy or silty soils containing low clay contents when compared to a 0.33-meter vertical error. The pipe locator produced an average error of 0.26 meters in clay-rich areas but GPR measured slightly better with a 0.22 meters error even though one location produced an outlier that influenced this comparison.

Soil density, as measured by standard penetration test (SPT) results, showed some correlation with detection performance, though the relationship was not as strong as with soil type or moisture content. The analysis did not reveal a meaningful trend between SPT-N values and error magnitude for either technology, suggesting that while soil density may influence detection accuracy to some degree, it is not the dominant environmental factor.

A comparison of GPR and pipe locator detection accuracy shows a clear pattern through the data presented in Fig. 12's box plot regarding soil moisture levels. The research data separates into two categories based on moisture levels (≤10% and >10%) under both scanning technologies. GPR measurements display wider (taller box) error spreads along with larger variability when moisture exceeds 10%. The pipe locator produces consistent performance through its narrow error distribution which operates within all tested moisture ranges.

The pipe locator displays better overall accuracy and fewer outside readings when compared to GPR measurements as demonstrated in Fig. 12 through horizontal dotted lines indicating a ±0.3 meters practical accuracy threshold. The response of GPR measurement to moisture levels demonstrates increased sensitivity and some readings exceed threshold limits specifically in the region of high soil moisture. The graphical representation confirms that pipe locators maintain superior measurement stability across different soil moisture levels although GPR measurements suffer from environmental impacts.

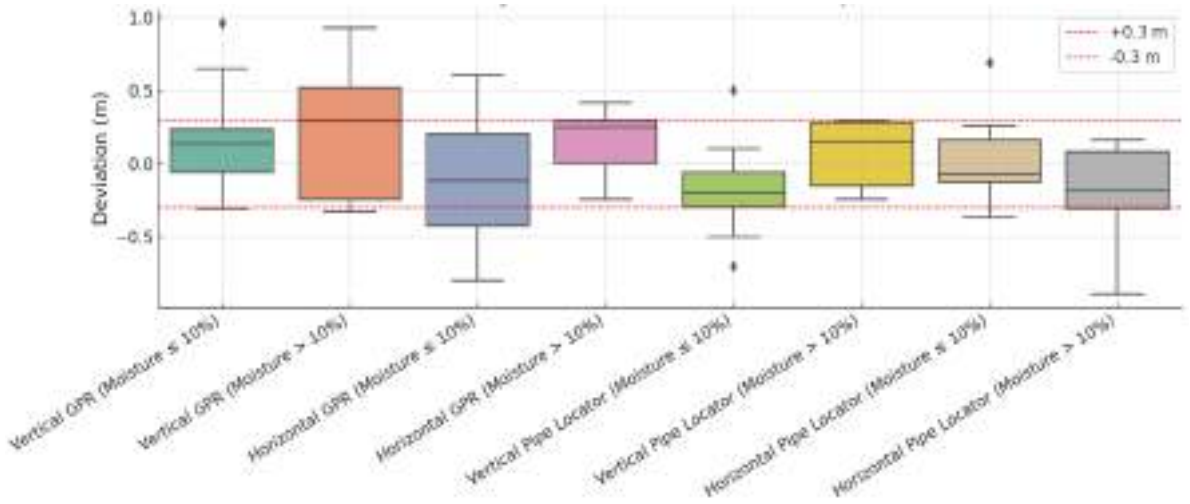

Fig. 12 Horizontal and vertical deviation of GPR and pipe locator vs. soil moisture content

The obtained results deliver essential guidelines regarding SUE methodology usage in Thailand's professional practices. Selection of detection technologies for site-specific environmental conditions should begin with the use of a pipe locator for metallic utilities and high-moisture/clay sites while GPR serves as a complementary or alternative method for situations where electromagnetic methods are inadequate. The most reliable utility mapping for critical infrastructure projects requires the combined use of GPR with water jet excavation for physical verification.

CONCLUSIONS

Over the past two decades, the development of subsurface utility engineering practices in Thailand has significantly advanced underground utility detection and management. Based on field data from 21 test locations, this study finds that:

(i) The pipe locator demonstrated more consistent accuracy than GPR, with a mean vertical error of 0.22 meters, and met the ±0.3-meter accuracy threshold at 81% of test sites, compared to 67% for

GPR.

(ii) Soil moisture was identified as the most influential environmental factor, particularly affecting GPR performance, which declined sharply in high-moisture conditions.

(iii) Soil type also influenced detection accuracy, with both technologies performing better in clay soils than in sandy soils.

(iv) While soil density parameters (based on SPT-N values, consistency, and relative density) showed some influence on detection performance, this relationship was not as pronounced as the effects observed from soil moisture content and soil type.

For effective field application, it is recommended to use pipe locators for detecting metallic utilities, particularly in environments with high moisture contents or clay soils. Ground penetrating radar (GPR) should be applied for identifying non-metallic utilities or used as a complementary tool alongside other methods. In critical infrastructure projects, combining both detection technologies with physical verification ensures the highest accuracy. Ultimately, the selection of detection methods should be guided by the specific environmental conditions present at each site.

It is important to note that these findings are based on a limited sample size (21 locations). Further testing across a wider range of sites is necessary to validate and generalize these conclusions for broader application in Thailand.

ACKNOWLEDGMENT

The authors express their appreciation to the Underground Investigation Company Limited for providing the field information used in this paper.

ANOMALY DETECTION FOR SLOPE EXCAVATION WORK USING BACKGROUND SUBTRACTION AND OPTICAL FLOW

Masoho Ide[1], Nobutaka Hiraoka[2] and Kazuya Itoh[3]

[1,3] Graduate School of Integrative Science and Engineering, Tokyo City University, Japan
[2] National Institute of Occupational Safety and Health, Japan

ABSTRACT

Slope failure accidents during excavation work have resulted in serious industrial incidents, including fatalities and injuries. To prevent such accidents, it is important to develop a system that can detect early signs of slope failure and make timely decisions regarding worker evacuation. In this study, we focused on an alternative approach by analyzing images captured by cameras installed on-site to detect anomalies on slopes. Full-scale slope excavation experiment was conducted, and two image processing techniques (background subtraction and optical flow) were applied to detect subtle displacements preceding slope failure. The analysis specifically targeted post-excavation slope conditions to evaluate whether anomalies could be identified before slope failure occurred. The results showed a creep-like gradual increase in the number of changed pixels detected by both methods in cases where a collapse eventually occurred. These findings suggest that slope monitoring through image analysis can be a practical method for early anomaly detection at excavation sites, contributing to enhanced safety and accident prevention.

Keywords: Anomaly detection method, Industrial incidents, Slope excavation work, Background subtraction, Optical flow

INTRODUCTION

In Japan, slope failures and cave-ins have resulted in 10–20 casualties (including fatalities and injuries) annually as industrial accidents, with approximately half of these incidents occurring during slope excavation work [1]. To mitigate such industrial accidents, it is critical to develop a system capable of reliably detecting early signs of slope failure and enabling the prompt evacuation of workers. Minute slope displacements are recognized as precursors to collapse, and several studies have explored monitoring slope dynamics using various sensors, such as extensometers and inclinometers [2-4]. However, these sensor-based approaches are limited by high equipment costs and complex installation requirements.

Image-based methods have also been explored for slope monitoring, including the use of CCD (Charge Coupled Device) cameras and Particle Image Velocimetry (PIV) to calculate displacement vectors associated with landslides [5,6]. However, these techniques have mainly been applied in the context of natural disasters, and there are few studies that specifically address slope failures occurring during construction work as industrial accidents.

This study proposes an anomaly detection method for slope failure based on image analysis using footage from monitoring cameras installed at excavation sites. Specifically, we investigate the feasibility of detecting subtle displacements preceding collapse by applying two image processing techniques—background subtraction and optical flow—to data acquired from a full-scale slope excavation experiment.

FULL-SCALE SLOPE EXCAVATION EXPERIMENT

A full-scale slope excavation experiment was conducted to acquire images of the slope before and after failure during the excavation process. The experimental embankment measured 4.0 m in height, 3.0 m in width, and 16 m in length. Excavation was performed in a stepwise manner from the base of the slope. A fixed camera, positioned in front of the slope, continuously monitored and recorded the slope conditions throughout the experiment, capturing the onset and progression of failure. The embankment was designed as a two-layer model: the base layer comprised Kanto loam, whereas the upper layer consisted of loosely deposited mountain sand to facilitate instability in the measurement region. The mountain sand was sourced from Kimitsu City, Chiba Prefecture, and its grain size distribution curve is presented in Fig.1. Prior to excavation, the mountain sand exhibited an average dry density of 1.46 g/cm³, a compaction ratio (Dc) of 89.4%, and an average water content of 1.73%. The initial slope angle of the embankment was 36.1° (1:1.37) [7].

Six excavation steps conducted during the experiment. Each excavation step was carried out at intervals of at least 30 min, with the subsequent step initiated only after confirming the absence of

significant movement in the monitoring data. Medium-scale slope failures occurred after the third and fourth excavation steps, while large-scale failures were observed following the fifth and sixth steps. Prior to each collapse, displacement signals were recorded by dynamic sensors installed at the top of the slope.

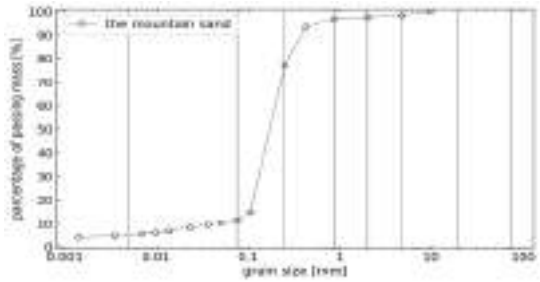

Fig.1 Grain size distribution curve for the mountain sand

IMAGES USED FOR ANALYSIS

Images for analysis were acquired using a GoPro HERO12 camera, which captured frames at 1-s intervals with a resolution of 4872 × 5568 pixels. This paper focuses on the medium-scale slope failure that occurred after the third excavation. A total of 521 images, captured from the end of the third excavation (11:29:00) to the point after the slope failure (11:37:40), were used for the analysis. Two distinct slope failure events were observed during this interval, occurring at 11:36:59 and 11:37:31, respectively. To improve analysis efficiency, a preprocessing step was implemented to crop the images, isolating the target slope area. The resulting images were then resized to 1500 × 3900 pixels. Figs.2–4 present the preprocessed images at the end of excavation and at the time of collapse. The red boxes in these figures highlight the areas where the slope failures occurred.

BACKGROUND SUBTRACTION

Background Subtraction Method

Background subtraction method is an image analysis technique used to extract moving objects by comparing the luminance difference between a background image and an input image against a predefined threshold. In this study, background subtraction was performed under two different conditions. In Case 1, the background image was fixed to the image captured at the end of excavation (11:29:00). In Case 2, the background image was updated to the frame captured 1 min prior to each input image. The analysis was implemented using the OpenCV library, with the luminance threshold value set to 25 [8]. All computations were performed in a CPU environment. To reduce false detections caused by illumination changes, the analysis was restricted to

Fig.2 The end of the third excavation (11:29:00)

Fig.3 Time of 1st slope failure (11:36:59)

Fig.4 Time of 2nd slope failure (11:37:31)

the slope measurement area. Specifically, the region of interest was de fined as the rectangular area spanning pixel coordinates (900–3000, 100–1000), with the top-left corner of the image designated as the origin (0, 0). The analyzed region is indicated by the blue frame in Fig.5.

Fig.5 Area of background subtraction

Result of Background Subtraction

Changes detected through background subtraction were overlaid on the input images to visualize the differences. The results of Case 1 and Case 2 are shown in Figs.6 and 7, respectively. In these images, the blue pixels indicate regions where changes were detected. The area outlined in red indicates the location where the slope failure occurred. In Case 1, changes were primarily observed around the excavation area. As the time of the first slope failure event (11:36:59), noticeable changes became increasingly evident on the left side of the slope, where the failure eventually occurred. The results visually captured this trend. In contrast, Case 2 detected differences only at one-min intervals, resulting in a lower overall number of changed pixels

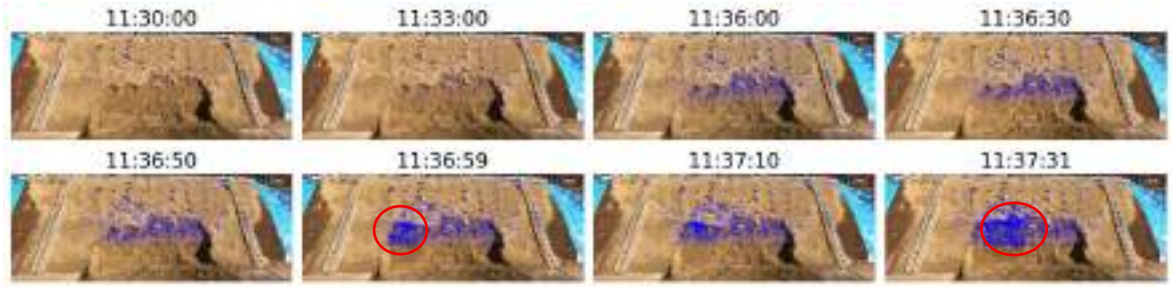

Fig.6 Execution result of background subtraction using the time of the end of drilling as the background image (Case 1)

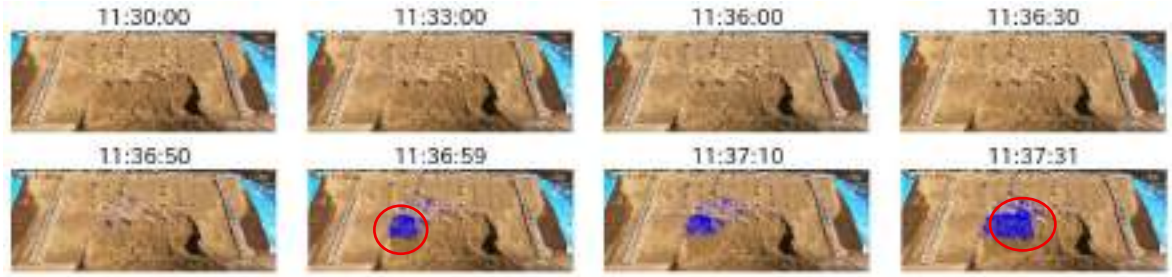

Fig.7 Execution result of background subtraction using the image from one minute ago as the background image (Case 2)

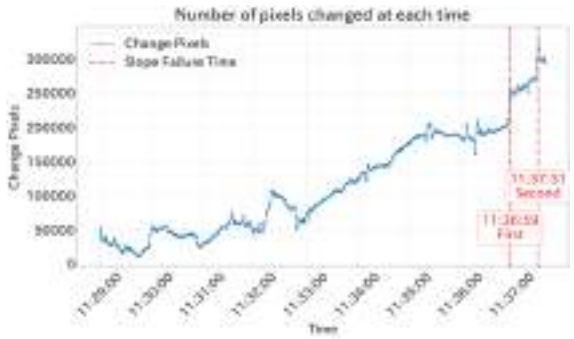

Fig.8 Number of pixels changed at each time (Case 1)

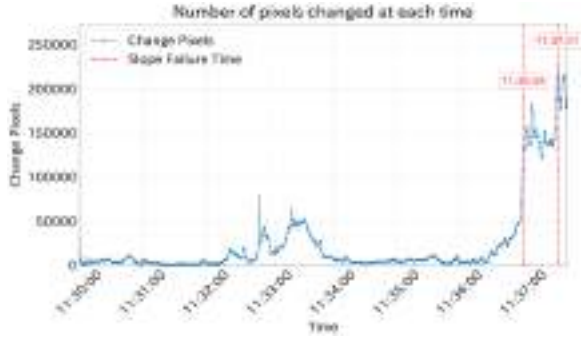

Fig.9 Number of pixels changed at each time (Case 2)

compared to Case 1. However, from approximately 30 s before the slope failure (11:36:30), a progressive increase in change was observed, particularly around the cracked area in the upper left part of the slope. Furthermore, in the right-side region of the slope, where no failure occurred, almost no changes were detected even after the collapse event.

The number of changed pixels detected at each timestamp is shown in Figs.8 and 9, where the red lines indicate the times of the slope failure. In Fig.8 (Case 1), a general increasing trend in the number of changed pixels is evident starting approximately 4 min prior to the failure event (11:33:00) with the increase becoming more pronounced as the failure approached. By contrast, Fig.9 (Case 2) shows smaller fluctuations in the number of changed pixels before the slope failure compared to Case 1. This suggests that frequently updating the background image helps mitigate the influence of illumination and environmental changes. In Case 2, a distinct increase in the number of changed pixels is observed starting around 30 s before the slope failure (11:36:30). Additionally, between 11:32:30 and 11:33:30, up-and-down fluctuations in the number of changed pixels were observed, likely caused by camera shake due to wind.

It is known that precursory phenomena, such as slight surface displacements and small-scale peeling of the surface layer, often occur before a slope failure. In this analysis, Case 2 successfully captured these momentary changes, indicating the potential of this approach to detect early warning signs.

The processing times for each method were 264.60 s for Case 1 (0.51 s per image) and 242.13 s for Case 2 (0.51 s per image). These results suggest that both methods are suitable for real-time.

Summary of the Background Subtraction Method

A comparison between Case 1 and Case 2 revealed that both methods detected an increase in the number of changed pixels prior to the slope failure.

Interpreting these pixel changes as indicators of precursor activity, anomalies were identified approximately 4 min before the failure in Case 1 and at least 30 s before the failure in Case 2, suggesting the potential for early warning detection.

However, determining the specific threshold at which pixel changes reliably indicate a dangerous situation requiring evacuation remains an open issue that warrants further investigation.

Considering practical application in field conditions, Case 2—being more adaptable to environmental changes—offers a more stable analysis. Nevertheless, the current method has limitations, including noise caused by camera shake and the inability to detect anomalies during the first minute of analysis. To achieve higher detection accuracy, improvements such as optimizing the background update interval or incorporating image analysis using multiple cameras are necessary.

It should also be noted that this analysis was conducted during a period with relatively stable sunlight conditions. In Case 1, in particular, changes were detected in areas without actual displacement, such as shadows cast by sensors at the top of the slope. For practical deployment, it is essential to implement countermeasures to reduce the effects of lighting variability, including techniques such as gamma correction and shadow removal.

Since the background subtraction method detects changes based on the brightness values of individual pixels, it is highly susceptible to false detections caused by sunlight and environmental fluctuations. To address this limitation, the following chapter explores the application of optical flow, which estimates motion based on the brightness values of multiple pixels, as a means to suppress false detections induced by sunlight variations.

OPTICAL FLOW

Optical Flow Overview

Optical flow is an image analysis technique that detects motion or changes within video sequences by estimating motion vectors at the pixel level. It relies on assumptions such as brightness constancy of objects between consecutive frames and motion coherence among neighboring pixels [9].

In this study, optical flow was computed using the calcOpticalFlowPyrLK function from the OpenCV library, which implements the pyramidal Lucas–Kanade method [10]. Due to its ability to capture both local variations and large or abrupt movements with high precision, this method is well suited for detecting slope failures. Additionally, its localized and hierarchical computation reduces computational cost, enabling real-time processing.

Distribution of Feature Points

In the pyramidal Lucas–Kanade method, feature points are distributed across the image, and their movements are tracked over time to assess motion changes. In this analysis, 1,000 feature points were evenly distributed across the slope surface, as illustrated in Fig.10. The points were confined within the slope region bounded by ladders visible at both edges of the image. Additionally, regions exhibiting concentrated changes, such as cracks on the slope surface, were automatically assigned a higher density of feature points to capture detailed motion in these critical areas.

Fig.10 Distribution of feature points

Optical Flow at 10-Frame Intervals

In this analysis, each image was treated as a single frame, and optical flow was computed at 10-frame intervals, corresponding to motion detection over 10-s periods. Motion trajectories were visualized by propagating the displacement of feature points across successive frames. The results are presented in Fig.11, where only feature points with displacements of at least one pixel on the slope were displayed. Prior to the first slope failure (up to 11:36:50), a small number of feature points exhibited movement in the upper-left section of the slope, the eventual failure site. At 11:37:00, coinciding with the first slope failure, a substantial increase in moving feature points was observed, particularly around the failure zone and along the left side of the slope. By 11:37:40, following the second slope failure, numerous feature points in the failure area had shifted significantly downward, indicating large-scale displacement.

Fig.12 shows the number of displaced feature points over time. Except for the initial frame and a spike just before 11:33:00, the number of displaced points remained near zero throughout the analysis. A slight increase in displaced points was observed immediately prior to the first slope failure, suggesting a potential precursor signal. However, based on the current data, it remains unclear whether this change reliably indicates impending failure. The abrupt spike near 11:33:00 is likely noise caused by camera movement rather than actual slope deformation.

The minimal detection of prefailure displacement in this analysis may be due to the 10-frame interval being too short to capture subtle slope movements. To improve sensitivity to such small displacements,

Fig.11 Results of optical flow execution at 10-frame intervals

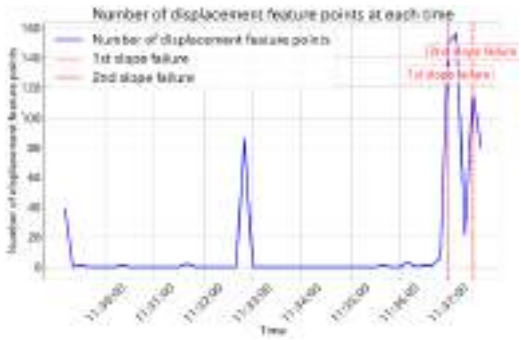

Fig.12 Number of displacement feature points (10-frame intervals)

subsequent analysis will be conducted at 60-frame intervals, following the same approach used in the background subtraction method.

Optical Flow at 60-Frame Intervals

In this analysis, the frame interval was set to 60 frames, and optical flow was computed between each frame and the one 60 frames earlier. The results are presented in Fig.13. The analysis revealed that as the first slope failure approached at 11:36:59, the number of displaced feature points on the left side of the slope, where the failure eventually occurred, increased. These results demonstrate that, compared to the optical flow analysis conducted at 10-frame intervals, the 60-frame interval enables more precise detection of subtle prefailure displacements.

A graph plotting the number of displaced feature points at each time step is shown in Fig.14. The results indicate a clear increasing trend in the number of displaced points, occurring in a creeping manner on the slope surface, beginning approximately 30 s before the first slope failure. The behavior of this graph closely resembles that of the 60-s interval background subtraction analysis shown in Fig.9. As in that case, a significant increase in the number of displaced points was observed between 11:32:30 and 11:33:30, despite the absence of any actual changes on the slope surface. This suggests that the analysis was affected by camera instability, thereby introducing noise into the results. The total processing time for the entire sequence was 573.78 s, corresponding to approximately 1.25 s per frame. This duration is more than twice as long as that required for the background subtraction analysis, indicating a significantly higher computational cost.

Summary of Optical Flow

In this study, optical flow analysis using the pyramidal Lucas–Kanade method was conducted to detect subtle displacements. The results demonstrated that in the 60-frame interval analysis, the number of displaced feature points gradually increased approximately 30 s before the slope failure. This finding is consistent with the results of Case 2 in the background subtraction analysis, suggesting that optical flow can detect micro-displacements that serve as precursors to slope failure.

However, the analysis was impacted by noise due to camera instability, and the computational cost was higher, resulting in longer processing times compared to background subtraction. Therefore, further studies are needed to explore methods that could reduce the computational load, such as optimizing frame intervals.

Optical flow estimates displacement based on pixel intensity patterns. As a result, it is less affected by variations in lighting conditions compared to the background subtraction method. In the background subtraction results changes were detected on the right side of the slope and in areas under the shadow of the sensors, even though no actual movement occurred. In contrast, the optical flow analysis did not indicate significant displacement in these regions. This indicates that optical flow analysis might be more resilient to errors resulting from variations in sunlight. It should be noted, however, that while the pyramidal Lucas–Kanade method offers relatively low computational cost, it cannot estimate displacement in regions lacking distinct feature points. To enhance detection coverage and accuracy, future analyses should consider alternative optical flow algorithms, such as the Farneback method, which enables displacement estimation across all pixels.

CONCLUSIONS

This study applied background subtraction and

Fig.13 Results of optical flow execution at 60-frame intervals

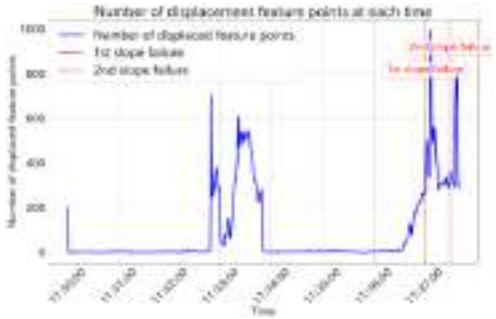

Fig.14 Number of displacement feature points (60-frame intervals)

optical flow techniques to analyze a full-scale slope failure following excavation. The results demonstrate that both methods can potentially detect micro-displacements that serve as precursors to slope failure. However, challenges remain, including susceptibility to false detections caused by variations in lighting and environmental conditions. Moreover, no definitive threshold values currently exist to distinguish between normal and abnormal conditions.

To suppress false detections caused by such external factors, various measures should be considered, including background subtraction methods that exclude bright information, the use of image stabilization features to reduce camera shake, and analysis based on multiple camera viewpoints. Such efforts are essential to assess the generalizability and practical viability of the proposed anomaly detection approaches.

SLOPE STABILITY STUDIES BASED ON DIFFERENT MATERIALS AND CONSTRUCTION METHODS

Satoe Suzuki[1], Shin-ichi Kanazawa[1]

[1]Faculty of Engineering, Niigata University, Japan

ABSTRACT

Although many cases of embankment collapse due to sudden heavy rain have been reported in recent years, the causes and mechanisms of embankment collapse due to heavy rain have not yet been sufficiently elucidated. In addition, with the introduction of performance-based design methods, it is essential to consider safety considering various construction conditions and environmental factors, but research focusing on the slope of embankments has not been widely conducted. It is necessary to understand and study the influence of slope gradient on embankment. Therefore, in this study, we used an unsaturated soil/water/air coupled finite analysis code to analyze rainfall on numerical simulations of embankment construction and subsequent rainfall infiltration were carried out using three different compaction methods to investigate the influence of embankment material properties and construction techniques on stress distribution and deformation behavior. The results indicate that differences in embankment materials can increase the risk of failure, including slip surfaces and overall slope instability.

Keywords: embankment, Unsaturated soil, finite element analysis, rainfall analysis

INTRODUCTION

In recent years, sudden heavy rainfall such as torrential rain and typhoons due to climate change has been increasing. According to the Japan Meteorological Agency [1], the number of rainfall events with rainfall exceeding 50 mm per hour will be approximately 330 times per year over the 10-year period from 2014 to 2023. This is an increase of approximately 1.5 times from the average number of events over the 10-year period from 1976 to 1985, when statistics began, which were approximately 226 events. This is an increase of 28.2 events per decade, and it can be said that the amount of intense rainfall is increasing.

Embankment structures are earth structures that are widely used in the construction of houses, roads, railways, etc., and can be said to be social infrastructure structures that are closely related to our lives. Because they also function as lifelines such as roads, if they are breached by an earthquake or heavy rain, the damage will be enormous. In addition, recent typhoons and linear precipitation zones have led to localized, intense rainfall events that pose a significant threat even to embankments that have been properly constructed and maintained in accordance with legal standards. Therefore, the importance of mitigating embankment failures induced by heavy rainfall has been increasing. There have been many reports on the stability of embankment structures during rainfall [2][3], but the collapse mechanism of embankments due to natural disasters has not been fully elucidated, and its elucidation is an urgent task.

Although embankment structures are originally designed and constructed based on compaction control in accordance with the Road Earthwork – Embankment Engineering Guidelines [4], it is considered that the stress state within the embankment can undergo significant changes due to the history of rainfall infiltration. If the initial stress state immediately after construction differs, subsequent stress conditions within the embankment may also vary, even under similar rainfall infiltration scenarios. In addition, different types of materials have different properties of the ground, resulting in different stress states even when the same construction method is used. Therefore, it is important to understand the initial stress state of the embankment. Therefore, in this study, we used the air-dissolved unsaturated soil/water/air coupled finite element analysis program (DACSAR-MP [5]) to simulate the construction of embankments using three types of compaction methods. We investigated the effects of differences in the construction process on the initial stress state of the embankment. Rainfall analyses were also performed on embankments constructed using different methods to compare how they changed from their initial stress state and to study the effects of different materials and construction processes on the rainfall-exposed embankments.

ANALYSIS SUMMARY

Air-Dissolved Unsaturated Soil / Water / Air Coupled Finite Analysis

In this study, we use the air-dissolved type unsaturated soil/water/air coupled finite element analysis code (DACSAR-MP [5]). The unsaturated soil constitutive model used in this code is based on the S_e model proposed by Ohno. [6]. This model represents the mechanical behavior of unsaturated soil by incorporating effective saturation as a parameter that controls the expansion and contraction of the yield surface, thereby accounting for the increase in stiffness due to soil unsaturation and the collapse phenomenon caused by water ingress. Additionally, to avoid transitioning to a singular point that is non-differentiable in numerical calculations, the EC model proposed by Ono. [7], which does not have singular points, has been incorporated. Furthermore, to represent the irreversible mechanical response of the soil's structural skeleton and, in particular, to consider the volume change characteristics of the soil's structural skeleton associated with repeated shear, the model proposed by Iizuka. [8] considering the lower load surface has also been incorporated. The yield function of the elastoplastic constitutive model is as shown in equation (1).

$$f(\boldsymbol{\sigma}', S_e, \varepsilon_v^p, R) = MD\ln\frac{p'}{\xi p'_{sat}} + \frac{MD}{n_E}\left(\frac{q}{Mp'}\right)^{n_E} - \varepsilon_v^p - MD\ln R = 0 \quad (1)$$

Here, p'_{sat} is the preconsolidation stress under saturated conditions, p' is mean effective stress, q is the deviator stress, M is the q/p' in the limit state, D is the dilatancy conefficient[14], ξ is the Interpolation function for determining the multiplier of the consolidation yield stress in unsaturated soils, ε_v^p is the plastic volumetric strain, n_E is the fitting parameter for the EC model, R is the similarity ratio between the normal yield surface and the subloading surface. ξ is the function of effective saturation and can be expressed by equation (2).

$$\zeta = \exp\left[(1-S_e)^b \ln a\right] \quad (2)$$

Here, b is the parameter for adjusting the interval between isosaturation lines on the $e-\ln p'$ surface, a is the increase in stiffness due to unsaturation is the parameter that determines the magnification of the maximum consolidation yield stress. In particular, a is often treated as a fitting parameter.

In addition, the effective stress of unsaturated soil can be expressed by equation (3).

$$\boldsymbol{\sigma}' = \boldsymbol{\sigma}^{net} + S_e s\mathbf{1} \quad (3)$$

Here, $\boldsymbol{\sigma}'$ is the effective stress tensor, $\boldsymbol{\sigma}^{net}$ is the base stress tensor, $\mathbf{1}$ is the second order unit tensor, s is the suction, S_e is the effective degree of saturation.

Analysis Methods

The analysis model adopted in this study was designed to represent a full-scale embankment structure. The slope gradient was set at 1:1.5, referring to the values specified in the Road Earthwork – Embankment Engineering Guidelines[4]. Fig. 1 shows the finite element mesh diagram of the analytical model.

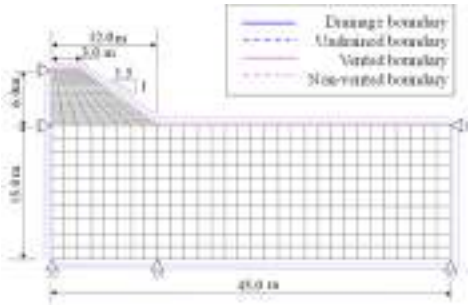

Fig.1 Analysis mesh model

Material Parameters

Tables 1 and 2 present the material parameters of the two soils used in this analysis. The soil-water characteristic curves are shown in Fig.2, and the compaction curves obtained in this study are presented in Fig.3.

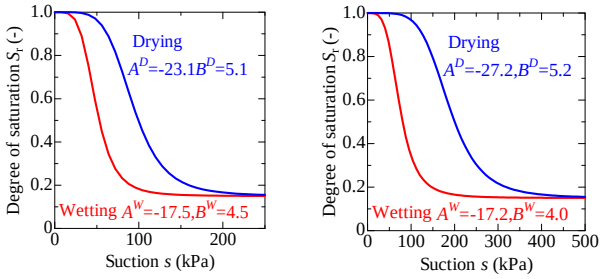
Table 1 Material parameters (Material 1)

Item	λ	k	m
Silty sand	0.100	0.010	0.80
S_{r0}	a	v	G_s
0.70	10.0	0.333	2.70
k_a(m/min)	k_w(m/min)	ρ'_{sat} (kPa) (foundation)	ρ'_{sat} (kPa) (embankment)
1.00×10^{-5}	1.00×10^{-3}	30.0	6.0
e_0	γ_t(kN/m^3)	n	n_E
0.90	1.610	1.00	1.30

Table 2 Material parameters (Material 2)

Item	λ	k	m
Silty sand	0.120	0.012	0.00
S_{r0}	a	v	G_s
0.70	10.0	0.333	2.70
k_a(m/min)	k_w(m/min)	ρ'_{sat} (kPa) (foundation)	ρ'_{sat} (kPa) (embankment)
1.00×10^{-5}	1.00×10^{-3}	30.0	6.0
e_0	γ_t(kN/m^3)	n	n_E
1.00	1.605	1.00	1.30

In this analysis, two types of silty sand were assumed based on the classification of embankment materials provided in the Road Earthwork – Embankment Guidelines[4]. The same material was used for both the foundation and embankment zones, with Material 2 containing a higher silt content than Material 1. The material constants are, respectively, λ: swelling index, κ: compression index, m: expansion rate of the lower



I; Material 1 II; Material 2

Fig.2 Soil-water characteristic curves

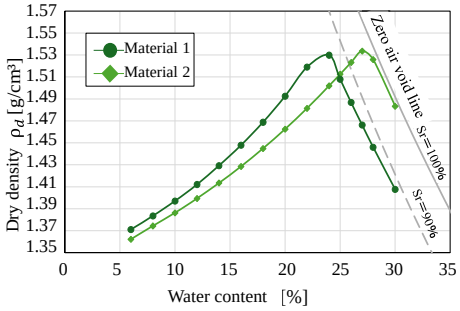


Fig.3 Compaction curves

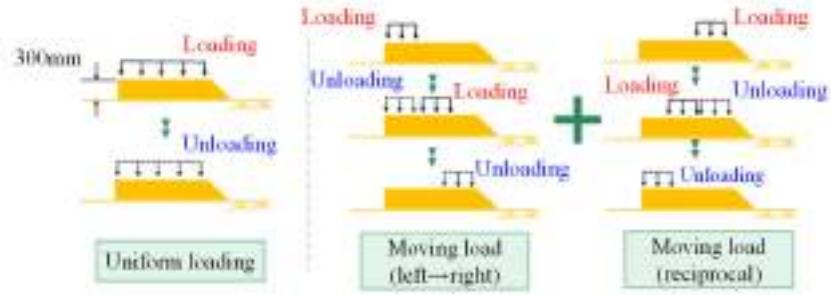

Fig.4 Three different construction methods for embankment

load surface, S_{r0}: initial saturation, a: unsaturated stiffness coefficient, v: Poisson's ratio, G_s: soil particle specific gravity, k_a: permeability, k_w: hydraulic conductivity, ρ'_{sat}: yield stress, e_0: initial void ratio, γ_t: wet density, n: the magnification parameter for consolidation yield stress in the unsaturated state, and n_E: a fitting parameter for the EC model.

The initial pore water pressure head and suction values were determined from the soil-water characteristic curves shown in Fig. 2. In this study, the initial saturation was set to 70% for both materials, and a value between dry and wet was taken out of the corresponding suction by reading the initial saturation from the soil-water characteristic curve. From the compaction curves shown in Fig. 3, the optimum moisture content was found to be 24% for Material 1 and 27% for Material 2. The maximum dry density ρ_{dmax} is approximately 1.53g/cm^3 for Material 1 and 1.54g/cm^3 for Material 2.

The dry density ρ_d that satisfies the control criterion value of 90% at optimum moisture content[4] is as follows:

-Material 1 $\rho_d = \rho_{d\max} \times 0.9 = 1.38(g/cm^3)$

-Material 2 $\rho_d = \rho_{d\max} \times 0.9 = 1.39(g/cm^3)$

The dry density ρ_d that satisfies the control standard value of 90% at the optimal moisture content can be calculated as above, so in this study the condition was that the void ratio of the entire ground be below this value. Here, ρ_s is the particle density of soil.

-Material 1 $e = \rho_s/\rho_d - 1 = 2.7/1.38 - 1 \approx 0.96$

-Material 2 $e = \rho_s/\rho_d - 1 = 2.7/1.39 - 1 \approx 0.95$

Construction Analysis

In this analysis, three different methods were used to analyze the construction of the embankment considering compaction in accordance with the actual construction. Fig. 4 shows the construction methods. The construction process is as follows.

① Create the foundation ground. At this time, the top surface of the foundation ground is set to drainage conditions.

② Create the first layer of embankment elements.

[Uniform loading]

③ Load the top surface of the elements of the first layer of embankment with 300kPa, then unload the same area with 300 kPa.

④ Create the second layer of embankment.

⑤ Load the top surface of the elements of the second layer of embankment with 300 kPa, then unload.

⑥ Repeat steps ④ and ⑤ for 20 layers until the embankment height is 6.0 m.

[Moving load (left to right)]

③Load the top surface of the two elements at the left end of the first layer of embankment with 300 kPa, then move from the left end to the right end and load one element at a time. After the loading area, unload with 300 kPa while moving.

④ Create the second layer of embankment.

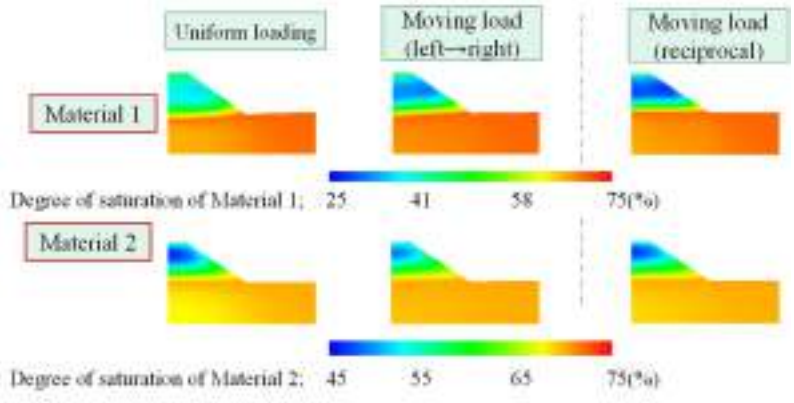

Fig.5 Distribution of degree of saturation at the completion of embankment construction for Materials 1, 2

⑤ Repeat steps ③ and ④ until the embankment height is 6.0 m.

[Moving load (reciprocating)]

③ Apply a load of 300 kPa to the top surfaces of the two leftmost elements of the first layer of the embankment, then move from the left end to the right end and load one element at a time. After the loading point, unload at 300 kPa while moving.

④ Apply a load of 300 kPa to the top surfaces of the two rightmost elements of the first layer of the embankment, then move from the right end to the left end and load one element at a time. After the loading point, unload at 300 kPa while moving.

⑤ Create the second layer of the embankment

⑥ Repeat steps ③, ④, and ⑤ until the embankment height is 6.0 m.

Construction Analysis Results

When construction was completed, the inside of the embankment had dropped to about 35%, and around 50% near the top. From Fig. 5, it can be seen that the least saturated areas were in the middle to bottom of the embankment for material 1, and concentrated in the inside to the top of the embankment for material 2. This is thought to be because repeated loading caused the highly permeable properties of the sand to come into play, resulting in drainage and a drop in the degree of saturation.

Rainfall Analysis

After the construction analysis of the embankment, a rainfall analysis was carried out using two different rainfall intensities. In this rainfall analysis, in order to understand and examine the impact of short-term heavy rainfall, such as torrential rain, on the embankment, flow rates simulating two different rainfall intensities were applied to the rainfall boundary set on the top of the embankment, the slope, and the top surface of the foundation of the analytical model. The rainfall was set at 50mm/hour and 100 mm/hour, respectively.

① After construction, the embankment is left for 30 days in the analysis.

② Apply rainfall to the embankment for 24 hours.

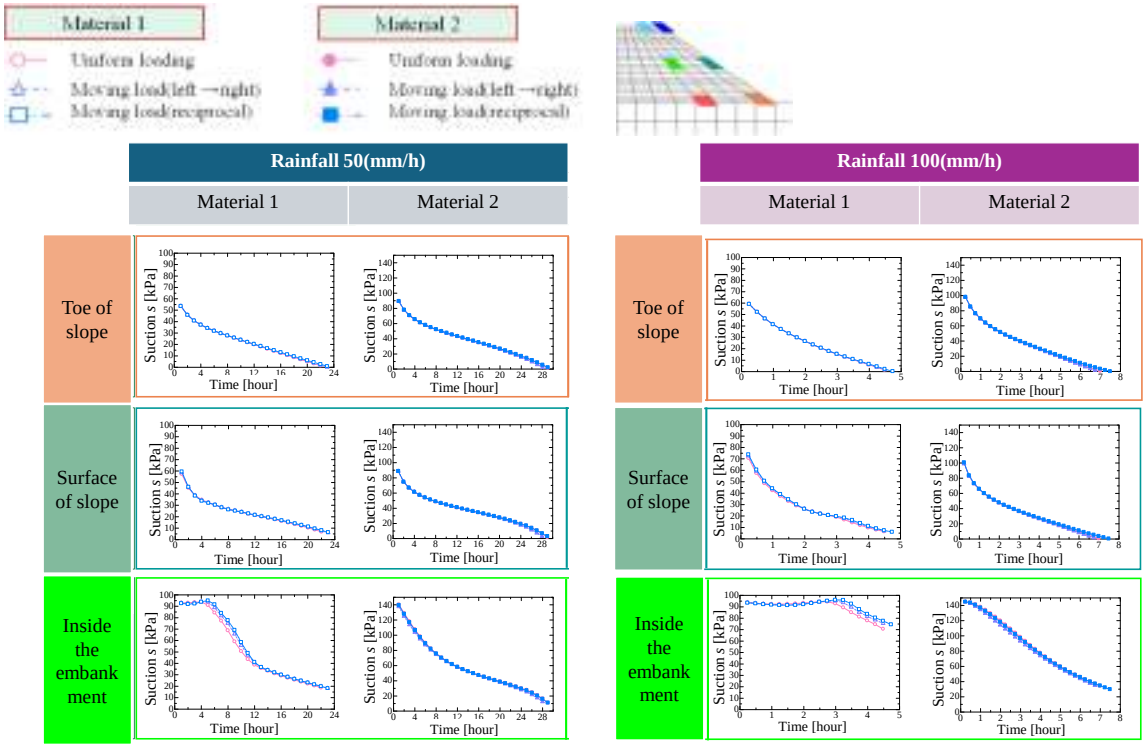
③ If there is a point where the suction falls below 0 kPa at the rainfall boundary, the rain is stopped.

Rainfall Analysis Results

Fig. 6 shows the change in suction over time during rainfall, Table 3 shows the time from the start of rainfall until the suction at the toe reaches 0 kPa, and Fig. 7 and 8 show contour diagrams of the degree of saturation for rainfall of 50 mm/h.

It can be seen from Fig. 7 and 8 that, regardless of the material or rainfall intensity, the degree of saturation increases in the order of top of the embankment, slope, and then inside the embankment. It can also be seen from Fig. 6 that the suction force decreases most quickly at the toe of the slope, and that at the same depth, the suction force decreases more quickly at the foot of the slope than inside the embankment. This decrease in suction force due to the increase in saturation, and in turn the decrease in stress, is thought to reduce the strength of the structure and weaken it. This weakening is particularly noticeable at the foot of the slope. In all 12 results (two materials, three construction methods, and two rainfall patterns), the toe became saturated the fastest, and suction disappeared and the average effective stress dropped significantly, suggesting that the toe is likely to become a weak point in embankments during rainfall, regardless of the material or construction process. Also, while no significant differences were observed due to the construction process, differences in materials did affect rainfall penetration.

Material 1 had a lower degree of saturation immediately after being left alone, which delayed



※The color of the frame enclosing the graph indicates the location of the element within the embankment.

Fig.6 Temporal variation of suction during rainfall

rainfall penetration into the embankment, and therefore delayed the progression of weakening due to increased saturation and loss of suction. Material 2 also showed a delayed rainfall penetration into the embankment, but it was faster than Material 1. Therefore, it is considered that the interior of the embankment made of Material 2 was weaker than that made of Material 1 when the rainfall stopped.

Table 3 The time from the start of rainfall until the suction at the law front reaches 0 kPa.

Rainfall	Item	Uniform loading	Moving load (left →right)	Moving load (reciprocal)
50 mm/h	Material 1	1365(min)	1385(min)	1413(min)
	Material 2	1761(min)	1717(min)	1785(min)
100 mm/h	Material 1	280(min)	280(min)	286(min)
	Material 2	424(min)	415(min)	451(min)

Furthermore, comparing Fig. 7 and 8, even with the same material, when rainfall was applied at 50mm/hour, the rain penetrated deeper into the embankment structure, resulting in a higher degree of saturation. Even when comparing the internal suction at the end of the rainfall, the suction was smaller when the rainfall rate was 50mm/hour. This is presumably because with a rainfall pattern of 50mm/hour, the rainfall period was more than twice as long as with a rainfall rate of 100 mm/hour, and the total amount of rainfall was large, leaving sufficient time for the rain to penetrate the embankment structure. Therefore, with a rainfall rate of 100 mm/hour, the interior is relatively safe even though the slope is weakening, but with a rainfall rate of 50 mm/hour, the risk of internal collapse is thought to be increased.

CONCLUSIONS

The construction analysis showed that the degree of saturation increased the top and slope, regardless of the material, construction process, or rainfall intensity. It was revealed that the process of embankment weakening, in which suction disappears and stress decreases, occurs after the degree of saturation increases, is similar. In addition, the toe of the slope can become a weak part of the embankment during rainfall.

During rainfall analysis, the stress state and stress change of the embankment structure are affected by the material. It had an effect on the distribution and transition of saturation and suction. The infiltration condition of rainfall inside the embankment differs depending on the material, and from the increase in saturation and loss of suction, it is thought that the inside of the embankment is weakened in material 2 compared to material 1 even under similar rainfall conditions.

The above results showed that the material has a large effect on the stress and stability of the embankment due to rainfall. The difference in stability inside the embankment is significant.

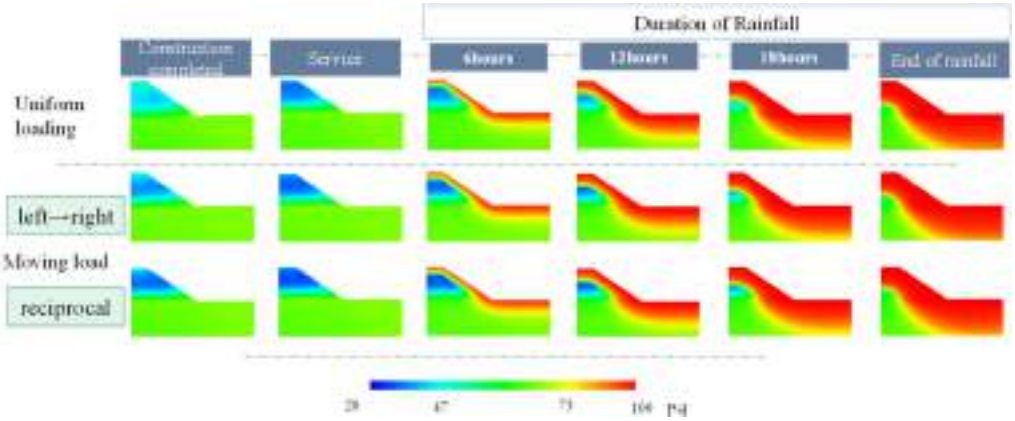


Fig.7 Distribution of degree of saturation at 50 mm/h (Material 1)

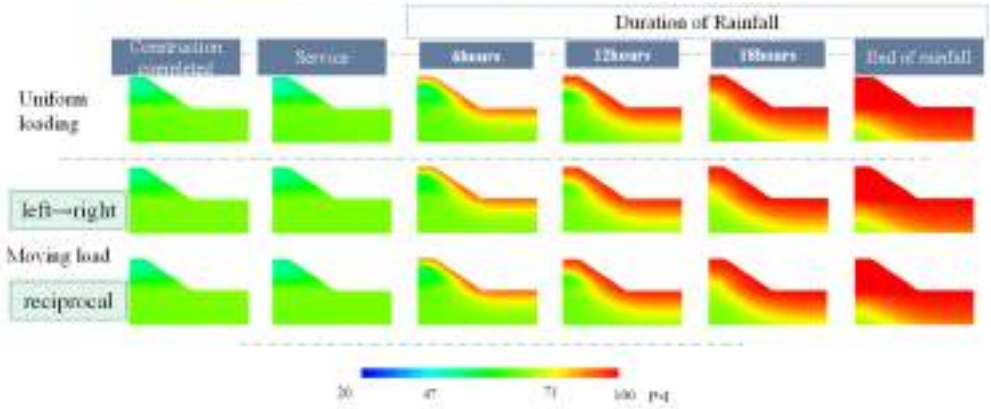

Fig.8 Distribution of degree of saturation at 50 mm/h (Material 2)

However, the effect of the material may be reduced if the rainfall intensity is high or if the embankment is left unattended and rainfall is repeated.

From this, it can be said that the selection of materials is important because the difference in stress state depending on the material is large under short-term rainfall or heavy rainfall conditions. However, in terms of long-term stability, the impact of the materials and construction process is small, and it is highly likely that the same stress state will be reached if rainfall continues.

In the future, we believe it will be necessary to expand the scale of analysis to a full-scale, as well as to carry out numerical analysis that takes into account various natural conditions, in order to carry out more realistic simulations.

ABSTRACT

In recent years, the discrete element method (DEM) and other discontinuum analyses have been increasingly employed for practical evaluations to improve the design and maintenance of structures that protect against slope failure. This study investigates the effects of the rock mass shape, rock size, and friction coefficient in the DEM. For this purpose, we use a rock slope failure case that incorporates pre- and post-collapse topographic data, as well as the deformation records of the rockfall protection wall. The results indicate that the damage state of the rockfall protection wall can be reproduced when the rock mass shape is represented with sufficient surface roughness and the slope friction coefficient is set appropriately. However, when evaluating the accumulation area of rock masses that have overtopped a retaining wall, it may be necessary to use a rock mass shape with a high degree of roughness to represent the interlocking of rocks during impact with the wall. In addition, a cushioning layer of geocell-reinforced gravel was installed on the slope side of the rockfall protection wall. Numerical analyses to assess the effect of the presence or absence of the cushioning layer showed that the extent of deformation of the rockfall protection wall increased by 20%–25% without the cushioning layer. This study provides results that support the evaluation of rockfall protection wall effectiveness through simplified analyses considering rock slope conditions.

Keywords: Rock slope failure, Granular avalanche, Impact, Rockfall protection wall, Discrete element method

INTRODUCTION

Slope failures, such as landslides and rockfalls, can cause significant debris impacts that threaten infrastructure, transportation networks, and human life [1–3]. Granular avalanches consist of rapidly flowing soil, rocks, and debris. Their high momentum and unpredictable behavior make them particularly challenging to analyze. Rigid [4–10] and flexible [11–13] barriers have been actively studied and implemented as protective measures to mitigate such hazards. However, there is a growing demand for more cost-effective and high-performance countermeasures. Accurately evaluating the performance of existing protective structures and enhancing their effectiveness is important for better understanding their limitations. These efforts can aid in improving maintenance planning and promoting more efficient use of limited resources. In addition, safety can be improved by reducing the number of unprotected slopes. In particular, when the collapse area is identified through field investigations, assessing the impact forces and deposition patterns of granular avalanches based on the actual slope geometry can further support rational design and maintenance strategies. Gaining a deeper understanding of the impact behavior of granular avalanches is important for addressing these needs.

Although several predictive methods based on the analysis of the impact forces from dry granular flows hitting rigid walls have been proposed [14–16], they are based on small-scale physical experiments or numerical simulations, and their applicability to full-scale slope failure events has not yet been validated. Validation at full scale is essential because granular behavior can exhibit scale effects.

Establishing a numerical modeling approach that balances the simulation accuracy and computational efficiency for large-scale slope failures is essential to meet practical requirements. In this study, the discrete element method (DEM) [17] is used to simulate granular behavior [18–20] by tracking the motion of individual particles based on contact mechanics and equations of motion. This analysis investigates the influence of the rock shape, particle size, and friction coefficient on DEM modeling. A real slope failure case is used to validate the simulations. This case includes pre- and post-collapse topographic data, as well as deformation records of the rockfall protection wall (hereafter, the protection wall). Furthermore, we evaluate the effect of a cushioning layer consisting of geocell-reinforced gravel that is installed on the slope

side of the protection wall by comparing simulation results that are obtained with and without the layer.

RESEARCH SIGNIFICANCE

This study significantly advances the practical evaluation and design of protective structures against large-scale slope failures through the application of the DEM. Whereas previous DEM research predominantly targeted small-scale experimental settings, this work pioneers its use on a real slope failure event incorporating pre- and post-collapse topographic data. By rigorously dissecting the influences of the rock shape, particle size, and friction coefficient, their critical roles in governing wall deformation and sediment deposition patterns are demonstrated. Moreover, the study highlights the substantial effectiveness of geocell-reinforced gravel layers in mitigating wall damage and provides valuable insights into the synergistic benefits of integrating rigid frameworks with cushioning systems. These compelling findings pave the way for the development of more reliable, cost-efficient protective designs and critically bridge the longstanding divide between numerical simulations and real-world field implementations.

DISCRETE ELEMENT MODELING

Contact Model

The DEM simulations were performed using the open-source software LIGGGHTS® [21] with the Hertz contact model. The major parameters specified in the material properties were the Young's modulus, Poisson's ratio, coefficient of friction, and coefficient of restitution. Several studies have been conducted on granular materials using LIGGGHTS, including those on the shear behavior of granular materials [22] and the behavior of granular materials impinging on rigid barriers [23].

Setup of Slope, Collapse, and Countermeasures

Fig. 1(a) presents the geometric setup of the slope and countermeasures, including the protection wall, slope angle (34°), and cushioning layer. Fig. 1(b) shows examples of the modeled rock masses composed of bonded spherical particles. Fig. 1(c) depicts the deformed state of the protection wall based on field observations, which served as the benchmark for validating the simulation results. The dimensions were determined based on the public documents of the National Route 229 Otobe Town Tateura Slope Countermeasure Technical Review Committee [24]. Countermeasures for the collapse area comprised the protection wall with a fence and geocell-reinforced gravel as a cushioning material. In this analysis, the plain concrete protection wall was modeled as a rigid body, whereas the geocell-reinforced gravel was simplified into a group of nonspherical particles. Each segment of the protection wall extended 10 m along the road, and the analytical model covered a total length of 120 m.

DEM Parameters

The Young's modulus has little influence on the deposition shape [18, 25]. Therefore, a value of 3.5×10^7 Pa was used to reduce the computational cost.

The restitution coefficient of the spherical rock masses ranged from 0.46 to 0.60, whereas that of the complex-shaped rock masses ranged from approximately 0.15 to 0.24 owing to the influence of plastic deformation in the contact region or energy loss caused by breakage of the corner region of a complex particle [26]. The restitution coefficient was set to 0.2 based on rock rebound test results that were

NC-H1.0-α50-F0.268		50%		

obtained. The restitution coefficient has a minimal influence on the deposition range of a dry granular avalanche [25].

The Poisson's ratio was set to 0.3, which is the value for hard rock in the Specifications for Highway Bridges [27].

As the influence of the inter-particle friction angle on the results of granular avalanche analysis is minor [18], it was set to 25°, which is approximately the median value reported by Rowe [28].

The particle shape, size, and particle-to-slope friction coefficient, which were the subjects of the sensitivity analysis, are explained in the following section.

Modeling assumptions such as a uniform rock block size and simplified slope surface roughness were adopted to reduce the computational cost while capturing the essential interaction mechanisms. Although these assumptions enable parametric analysis within reasonable simulation times, they limit the generalizability of the results to real-world slopes with complex geometries and heterogeneity. Therefore, care must be taken when applying the findings to cases with highly variable particle size distributions or irregular slope surfaces.

Investigated Conditions

Previous studies to determine the final deposition shapes of dry granular avalanches [18, 25] have shown that parameters such as the Young's modulus, which represents the contact stiffness, inter-particle friction coefficient, and inter-particle restitution coefficient have a minimal influence on the final deposition shape. Therefore, this study focused on the slope friction coefficient, which is known to have a strong influence on the particle behavior on slopes and the deformation behavior of the protection wall

that is installed at the toe of the slope. In addition, the particle shapes, which are not widely standardized in modeling approaches, were examined. Three rock block shapes with varying interlocking effects were created by arranging spherical particles at the vertices of a regular tetrahedron and adjusting the overlap ratio between particles. As summarized in Table 1, 16 analysis cases were designed by systematically varying three main parameters: the rock mass shape (using particle overlap ratios of 5%, 50%, and 95%), slope friction coefficient (ranging from 0.176 to 0.466), and rock mass size (0.5, 0.75, and 1.0 m). Each case label (e.g., H1.0-α05-F0.268) explicitly encodes these conditions for clarity in the subsequent discussion.

DEM PARAMETER SENSITIVITY

According to a previous study [24], rock masses from slope failure were deposited within approximately 15 m in the slope-flow direction and 30 m in the longitudinal direction beyond the protection wall. The protection wall experienced deformation of approximately 50 m in the longitudinal direction, with two spans tilting and three spans overturning. The analysis results were compared with damage observations.

Fig. 2 shows that the final deformation of the protection wall differed significantly across the analysis cases. For example, in cases with a slope friction coefficient of 0.176 or 0.268, substantial wall deformation occurred, regardless of the rock mass shape. In contrast, under higher friction (F = 0.466),

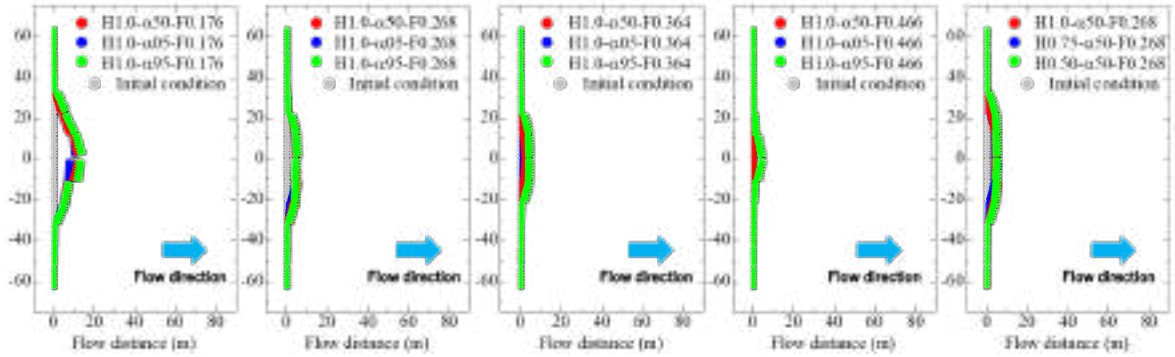

Fig. 2 Protection wall at final stop: All analysis cases under geocell-reinforced grave conditions.

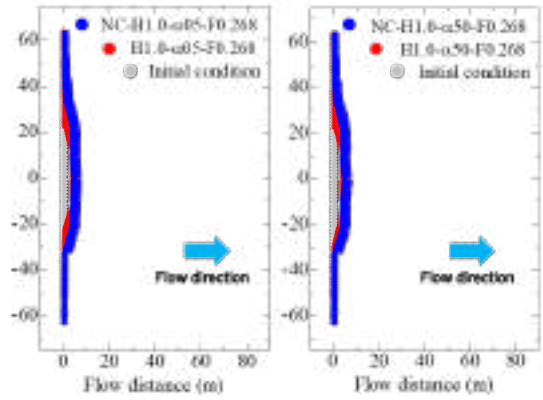

Fig. 4 Protection wall at final stop: Comparison of all analysis cases with effectiveness of geocell-reinforced gravel.

deformation was only observed when the rock blocks had a 95% overlap ratio, indicating strong interlocking. These visual results provide key insights into how the particle shape and slope friction jointly affect wall performance. In terms of the effect of the rock mass size, the largest deformation range occurred with a particle diameter of 0.5 m, but its influence on the flow direction was minimal.

Fig. 3(a) and (b) show the final resting positions of the protection wall and rock mass groups in cases H1.0-α05-F0.268 and H1.0-α50-F0.268, where the protection wall deformation closely resembled the observed damage for a rock mass size of 1.0 m.

Fig. 3 compares two representative cases: H1.0-α05-F0.268 and H1.0-α50-F0.268. As shown in Fig. 3(a), a low overlap ratio (5%) resulted in a wider dispersion of rock masses (~30 m) and moderate wall deformation. In contrast, Fig. 3(b) shows a more compact deposition (~40 m) and increased wall deformation owing to enhanced interlocking from the higher overlap ratio (50%). These results emphasize that the rock mass shape affects the runout distance as well as the wall impact characteristics.

IMPACT OF CUSHIONING LAYER ON WALL RESPONSE

As shown in Fig. 4, the inclusion of the cushioning layer significantly altered the wall deformation pattern. Without the layer, the wall exhibited a longitudinal deformation spread that was approximately 20–25 m greater than that with the layer. Although the flow direction displacement remained largely unchanged, this result demonstrates that geocell-reinforced gravel serves as an effective energy absorber and deformation suppressor.

CONCLUSION

This study has advanced the practical evaluation and design of protective structures for large-scale slope failures by applying the DEM to a real-world

case with detailed pre- and post-failure topographic data. As opposed to prior DEM research that focused on small-scale experiments, this work systematically revealed how the rock shape, particle size, and friction coefficients govern the wall deformation and deposition patterns. It also demonstrated the effectiveness of geocell-reinforced gravel layers in mitigating structural damage and highlighted the advantages of integrating rigid frameworks with cushioning systems. These insights pave the way for more reliable, cost-efficient protective designs and bridge the gap between numerical modeling and full-scale field implementation.

Although numerical analysis using the DEM provides valuable insights, it has certain limitations. First, the selection of mechanical parameters such as friction and restitution coefficients is dependent on literature values and limited field data. Accumulating information on analysis parameters by reproducing other collapse cases is desirable. Second, in this study, the slope shape was simplified and the rock block size was set to be uniform, so the geometric conditions were not exactly the same as those in real life. Investigating how detailed geometric conditions, such as the slope roughness and rock block size distribution, affect the collapse and deposition behavior of dry granular avalanches is important to generalize the results of this study.

ABSTRACT

This research investigates how increasing water content within the soil layer affects the Liquid Limit (LL), Liquidity Index (LI), and their relationship to slope stability, using a controlled laboratory-scale modelling approach. The physical and consistency parameters of the soil were determined from field samples to enable classification. From these samples, slope models were developed to represent realistic slope angles of 30°, 45°, and 60°, which were progressively saturated to simulate real-life conditions. A key challenge addressed in this study is establishing a link between water content and slope failure thresholds in fine-grained soils, as many models fail to account for changes in Atterberg limits or the Liquidity Index (LI) with increasing saturation. The findings indicate that water content significantly influences LI in a positive correlation, with slope failures generally occurring when LI values exceed 1. Steeper slopes, particularly those exceeding 45°, demonstrated greater reductions in shear strength and cohesion. Furthermore, the results show that the internal soil structure deteriorates when the water content surpasses the LL, causing the soil to behave like a fluid and become highly susceptible to slips. The integration of Atterberg limit parameters with physical slope modelling establishes a new and practical relationship between LI values and the onset of flow-type landslides. This approach provides a simple yet effective method for evaluating slope failure risks in fine-grained soils. The results underscore the importance of monitoring LI and LL values in steep, moisture-prone areas, as these can serve as critical early warning indicators for potential landslides.

Keywords: Water Content, Liquid Limit, Slope Failure, Landslide Mechanism, Talamau Plateau

INTRODUCTION

Slope stability is a crucial aspect of geotechnical engineering, particularly in the planning and design of infrastructure such as roads, embankments, and dams. Slope failures can result in severe consequences, including structural damage, economic losses, and casualties [1]. Among the main triggering factors, soil moisture content plays a dominant role, especially in humid regions with high rainfall intensity [2-3].

For cohesive soils such as clay, changes in water content strongly influence their mechanical behavior, especially shear strength and deformation. The Atterberg limits (Liquid Limit, Plastic Limit, Shrinkage Limit) and the Liquidity Index (LI) are widely used to assess soil consistency and plasticity [4]. Previous studies have shown that rainfall infiltration and increasing pore water pressure reduce shear strength and significantly increase landslide risk [5-6]. However, most of these works have focused on pore water pressure and matric suction, with relatively few explicitly considering changes in Atterberg limits and Liquidity Index values in slope stability assessments.

This study addresses that gap through laboratory-scale experiments that integrate Atterberg limit parameters with physical slope models. The research was conducted in the Talamau Plateau, Pasaman Regency, West Sumatra, a region characterized by extremely high annual rainfall (4,700–5,300 mm) and steep slopes (>15°), making it highly prone to landslides [7-9]. The geographical location of the study area is illustrated in Fig.1, which highlights the landslide-prone zones within the plateau.

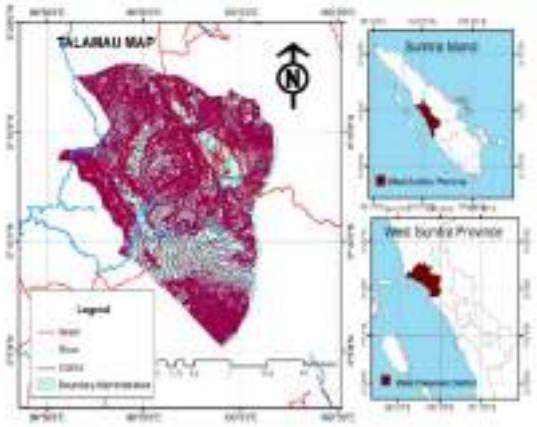

Fig. 1 Geographical location of the landslide-prone area in the Talamau Plateau, West Sumatra

Soil samples from the site were tested to determine their physical and consistency properties, then used to construct slope models with angles of 30°, 45°, and 60°. The main objective is to establish the relationship between soil water content, Liquidity Index (LI), and slope failure thresholds. The findings are expected to provide a simple, practical indicator for early warning in landslide-prone areas.

RESEARCH SIGNIFICANCE

Understanding the relationship between increases in soil moisture content and geotechnical properties such as soil moisture content and soil liquidity index is very important in predicting and reducing slope failure. This study provides important insights into how variations in the rate of increase in soil moisture content will affect soil behaviour, particularly in terms of its transition from a stable to an unstable state. As soil moisture content increases, the mechanical strength and shear resistance of the soil will decrease significantly, thereby increasing the risk of slope instability. The modelling approach using laboratory experiments on slope-forming soils allows for the exploration of concepts in controlling and observing soil response under varying soil moisture content and liquidity index conditions, enabling a more detailed and accurate characterisation of the soil liquidity index as an indicator of potential slope failure. The findings from this study can serve as a basis for improving early warning systems, refining slope stability models, and providing input for more effective slope management and engineering practices. This research has practical relevance for civil engineering, environmental management, and disaster risk reduction, especially in areas prone to landslides

MATERIALS AND METHODS

The study was conducted in Talamau Sub-district, Pasaman Regency, West Sumatra, a region with steep slopes and high rainfall that makes it highly prone to landslides. Silty clay soils were collected using hand augers and core samplers at depths of 0–1.5 m, representing the most weathered and failure-prone soil horizons. The samples were tested at the Geotechnical Laboratory of Andalas University and the Soil Mechanics Laboratory of the Padang Institute of Technology.

Laboratory analyses included natural water content, specific gravity, unit weight, and Atterberg limits (LL, PL, SL) in accordance with ASTM standards. These values were used to calculate the Liquidity Index (LI), which serves as the primary indicator of soil consistency under varying moisture conditions. A summary of the soil properties is presented in Table 1.

Physical slope models were constructed at a 1:100 scale, with a height of 34 cm and a base width of 30 cm. The slopes were shaped at 30°, 45°, 60°, and 90°, compacted to 90% of the maximum dry density. Rainfall was simulated using a machine with 10 oscillating nozzles, calibrated to replicate local rainfall intensity. The experimental setup is illustrated in Fig 2.

Table 1. Values of soil characteristics of test specimens

Experiment	Parameters	Value	Units
Water content	w	60.594	%
Volume weight	γ	1,558	gram/cm^3
Specific gravity	Gs	2.627	
Sieve analysis	Gravel	0.000	%
	Sand	34.067	%
	Clay	65.933	%
Atterberg limit	SL	64.885	%
	PL	46.974	%
	PI	17.911	%
Direct shear	c	0.218	kg/cm^2
	φ	22.835	°
Compaction	w opt	48.455	gram/cm^3
	γ dry max	1.235	gram/cm^3

Note: SL = Shrinkage Limit, PL = Non-elastic Limit, PI = Non-elastic Index, c = cohesion, φ = Inner shear angle, w opt = Optimum water content, γ dry max = dry soil specific gravity.

Fig. 2. Slope model trial layout: (a) Dimensions of the landslide model; (b) Experimental slope model layout

Experiment Procedure

The experimental procedure was carried out in three main stages. The first stage involved soil characterization, including tests for water content, specific gravity, grain-size distribution, and Atterberg limits (LL, PL, PI). These parameters were used to calculate the Liquidity Index (LI).

In the second stage, physical slope models were constructed using field soils compacted to 90% of the maximum dry density. Slopes were formed at angles of 30°, 45°, 60°, and 90°. Rainfall was simulated using oscillating nozzles calibrated to local rainfall intensity, while soil moisture and LI were monitored during infiltration.

The third stage focused on observing slope behavior under saturation. Variations in water content were correlated with LI values and slope deformation leading to failure. Particular attention was given to the LI > 1 threshold, which indicates the transition of soil from plastic to liquid state and marks the onset of slope collapse.

Relationship Between Water Content, Liquid Limit, and Soil Mechanics

The relationship between water content, liquid limit (LL), and soil mechanics is a critical factor in slope stability, particularly in fine-grained soils such as silty or sandy clays. As water content approaches or exceeds the LL, soil strength decreases significantly due to the reduction of cohesion (c) and internal friction angle (ϕ), caused by weakened particle bonding and the loss of matric suction.

$$LI = \frac{W-PL}{LL-PL} \quad (1)$$

This behavior is expressed through the Liquidity Index (LI), calculated using Equation (1). LI values describe soil consistency: LI < 0 indicates stiff or semi-solid soil, 0 ≤ LI ≤ 1 indicates a plastic state, and LI > 1 indicates that the soil behaves like a liquid. The variation of LI with increasing water content is illustrated in Fig. 3, which shows the progressive loss of soil consistency during rainfall simulation.

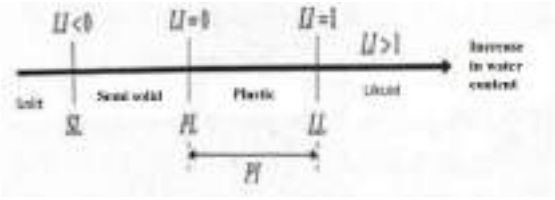

Fig. 3 Soil Fluidity Index Graph

The soil classification based on LI is summarized in Table 2. At LI > 1, the soil begins to lose cohesion and behaves in a fluid-like manner, while at LI > 1.5 the soil becomes very soft, essentially liquefied. These results highlight that exceeding the liquid limit (LL) serves as a critical threshold for slope failure initiation.

Table 2. The soil classification based on LI

Items	Description
LI< 1	Semi-solid soil, high strength
0< LI > 1	Plastic state soil, medium strength, soil is a kind of plastic material
LI > 1	Soil begins to lose consistency, approaching liquid state, soil is liquefiable.
LI > 1.5	Very soft/liquid soil means that the water content of the soil is higher than its liquidity limit, so the soil behaves like a liquid and loses its cohesion.

Source: Braja M.Das (2010 Edition), Geotechnical Engineering.

The Plasticity Index (PI) is a fundamental parameter in geotechnical engineering, utilised to assess the consistency and behavioural characteristics of fine-grained soils under varying moisture conditions. It is defined as the numerical difference between the Liquid Limit (LL) and the Plastic Limit (PL) of the soil, representing the range of water content within which the soil exhibits plastic behaviour.

$$\mathbf{PI = LL - PL} \quad (2)$$

RESULT AND DISCUSSION

Soil Properties and Particle Size Distribution

The sieve analysis results are presented in Table 3, while the particle size distribution curve is shown in Fig. 4. The soil contains 34.07% sand and 65.93% clay, with no gravel fraction. A summary provided in Table 4 classifies the soil as fine-grained with a dominant clay fraction of moderate plasticity.

Table 3. Soil Particle Size Distribution Data

Sieve number	Retained weight	Total retained weight [g]	Percent retained (%)	Escaped (%)	Grain Diameter [mm]
4	0.0	0,000	0.00	100.00	4.75
10	4.3	4,300	1.43	98.57	2
20	22.2	26,500	8.83	91.17	0.84
40	32.3	58,800	19.60	80.40	0.42
100	38.1	96,900	32.30	67.70	0.15
200	5.3	102,200	34.07	65.93	0.075
PAN	197.8	300	100.00	0.00	

Table 4 Summary of Soil Gradation Percentages

No	Soil type	Percentage (%)
1	Gravel	0
2	Sand	34.07
3	Clay	65.93

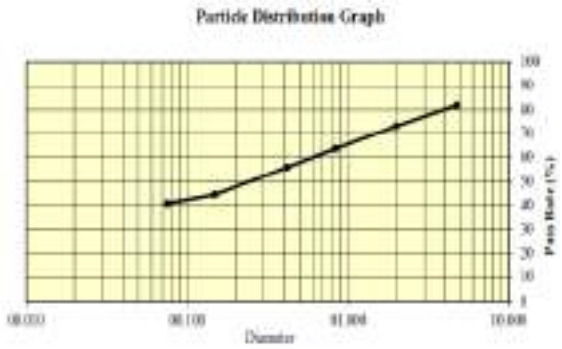

Fig.4 Soil grain distribution graph

The gradation curve (Fig.4) indicates a uniform distribution dominated by fine particles. This reflects the soil's low permeability and high water retention capacity, which makes it highly susceptible to saturation during rainfall. Such conditions explain the significant reduction in shear strength in clay-rich soils, increasing the likelihood of slope instability under wet conditions.

Effects of Water Addition on Liquid Limits and the Mechanical Properties of Slope Soils

The test results confirm that increasing water content strongly affects the liquid limit (LL) and the mechanical behavior of slope soils. As shown in Fig. 5, soils transition from a plastic to liquid state when moisture approaches the LL. The measured LL ranged from 45.93% to 49.30%, with an average collapse water content of 47.85% (Table 5), which corresponds to the onset of slope failure in the physical model tests.

Furthermore, Fig.6 illustrates the logarithmic relationship between the number of blows (N) in the Casagrande test and water content, clearly indicating the plastic–liquid transition point. The Plastic Limit (PL) was found to be around 37–39.8%, resulting in a relatively high Plasticity Index (PI). This reflects the soil's high plasticity and susceptibility to deformation under saturation.

Overall, these findings demonstrate that once water content reaches or exceeds the LL, the soil rapidly loses cohesion and shear strength, behaving like a viscous fluid. This condition represents a critical threshold for slope failure in clay-rich slopes.

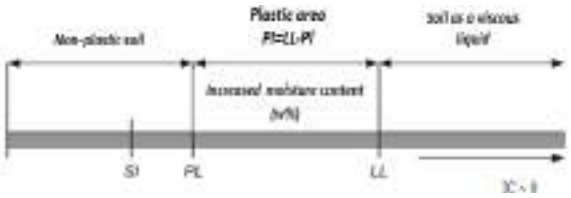

Fig.5 Changes in soil consistency

5	Weight of Dry Soil: (2-4) (gram)	2.88	2.25	2.64	4.18	1.97	1.38
6	Water content: (3 : 5) x 100 (%)	49.306	48.444	47.727	45.933	37.056	39.855
7	Average collapse water content (%) :	47.853				38.455	

Modelling the Impact of Increased Soil Moisture Content on Slope Stability

The modeling results reveal a strong correlation between increasing water content, Liquidity Index (LI), and slope stability. At the initial infiltration stage, low moisture levels produced negative LI values, indicating stable conditions. However, when water content rose to around 43–48%, LI values approached 1, marking the onset of soil softening and strength loss.

The variation of LI across different slope angles is illustrated in Figs. 7–10. In the gentle slope (30°), failure occurred gradually, with progressive increases in water content before collapse. In contrast, the steep slopes (60° and 90°) exhibited a sharp rise in LI, reaching values of 10–28, indicating a fully liquefied state. These results highlight the heightened sensitivity of steeper slopes to saturation and their rapid transition to failure.

Overall, the modeling confirms that LI > 1 serves as a reliable threshold for slope failure. Once this value is exceeded, soil deformation accelerates, cohesion is lost, and slopes collapse primarily under gravitational forces.

DISCUSSIONS

Experimental Results on the 30° Slope

In the 30° slope, water infiltration caused a relatively gradual increase in moisture. Initially, the soil was stable with negative LI values, then began to weaken as water content approached the LL = 47.5%. At this stage, LI rose toward 1, and small soil movements appeared. Failure did not occur suddenly but progressed through gradual deformation until water content reached about 63%, with LI exceeding 20. This indicates that gentle slopes are more resistant, but once fully saturated, they remain vulnerable to landslides.

Experimental Results on 45° Slope

The 45° slope responded more rapidly to saturation. Signs of instability appeared even before water content reached the LL, showing the stronger role of gravity in reducing shear strength. At about 43–45% moisture, visible movements occurred even though LI was still <1. Full collapse happened at around 68% water content with LI >12, indicating a transition to a plastic–liquid state. Compared to the 30° slope, the 45° slope required less additional water to fail and collapsed more abruptly.

Results of the Experiment Conducted on 60° Slope

At 60°, the slope was highly sensitive to moisture increase. As water content approached LL, LI values already rose to 6–7, enough to cause a sharp reduction in cohesion. Complete failure occurred at about 52% water content with LI >10. This proves that steep slopes can collapse even when water content only slightly exceeds the LL. The mechanism of failure was faster, dominated by gravitational forces acting on already weakened soil.

Experimental Results on 90° Slope

The vertical slope (90°) showed the most extreme behavior. Initially stable with negative LI, the soil quickly lost strength once water content surpassed LL. At around 50% moisture, LI exceeded 10 and early displacements appeared. In the final stage, when water content rose to 67%, LI jumped dramatically above 28, leading to sudden and complete collapse in the form of a mudflow. This confirms that vertical slopes fail catastrophically with only minor increases beyond the liquid limit.

Soil Classification and Soil Moisture Index

Soil classification results showed a Liquid Limit (LL) of 47.5% and a Plasticity Index (PI) of 9.7%, categorizing the soil as a clay of moderate plasticity. Such soils can absorb considerable water before

reaching a liquid state but lose strength rapidly once moisture exceeds the LL.

In the experiments, water content at failure was consistently higher than LL across all slopes (30°, 45°, 60°, 90°), confirming full saturation. This highlights that Liquidity Index (LI) > 1 reliably indicates the onset of liquid-like soil behavior leading to landslides.

Effects of Slope Geometry Angle

The effect of slope geometry was evident: the steeper the slope, the less additional water content was needed to trigger failure. The 30° slope collapsed only after water content rose well above the LL, while the 60° and 90° slopes failed almost immediately once LI > 1 was reached. At the vertical slope (90°), LI peaked at 28.4, indicating near-complete liquefaction. Thus, steeper slopes are significantly more vulnerable due to gravity accelerating collapse once cohesion is lost.

Mechanism of Slope Failure

The slope failure mechanism was primarily driven by excessive saturation and increased pore water pressure, which reduced effective stress and weakened interparticle bonding. This led to the loss of cohesion, drastic reduction in shear strength, and transformation of soil into a mud-like mass. In gentle slopes, failure developed progressively, whereas in steep and vertical slopes, collapse occurred rapidly as a mudflow. This mechanism confirms the critical role of LI as an early warning indicator for slope instability.

CONCLUSIONS

This study confirms that soil water content and slope geometry are the primary factors controlling slope stability in clayey soils. Laboratory results indicate that soils with a LL of 47.5% and moderate plasticity fail once the Liquidity Index (LI) exceeds 1, at which point cohesion is lost and the soil behaves like a fluid.

Comparisons across slope models showed that steeper slopes failed more rapidly, with LI values exceeding 28 at the vertical 90° slope. The failure mechanism was governed by increased pore water pressure and reduced shear strength, transforming the soil into a mudflow.

These findings highlight LI as a practical threshold for early warning of landslides in clay-rich soils under high rainfall, providing a valuable basis for slope stabilization strategies and disaster risk reduction.

DESIGN AND CONSTRUCTION OF PRECAST BOX CULVERTS (DRAINAGE CHANNEL) IN AN URBAN ENVIRONMENT: A CASE STUDY OF KANIE TOWN IN JAPAN

Md. Aminul Islam[1]and Zakaria Hossain[1]

[1]Graduate School of Bioresources, Mie University, Japan

ABSTRACT

The rapid growth of the urban population necessitates the development of essential infrastructure in densely populated residential areas. Inadequate drainage infrastructure significantly contributes to environmental degradation and public health issues. This study presents a case analysis of the recent implementation of a precast box culvert system with prestressed concrete (PC) joints in Kanie Town, located in Aichi Prefecture, Japan. Known as the "town of water," Kanie is characterised by low elevation and numerous surrounding rivers, making efficient drainage a critical concern. This project, initiated by the Kanie City Corporation and developed and implemented by Toumei Development Company Ltd. in collaboration with the Kanie Town Municipal Corporation, was driven by frequent flooding, poor sanitation, and safety concerns. In addition to significant environmental and social improvements, such as the mitigation of foul odours, reduction in waterborne diseases, and elimination of flood risks, this study also evaluates the mechanical performance of the culvert system. The structural design, incorporating RC-40 grade concrete, reinforced steel, and prestressed joints tensioned to 160 kN, ensures durability under urban load conditions and seismic events. The culverts demonstrated high compressive strength, effective load distribution, and superior waterproofing at joints, confirming their long-term viability and resilience. The findings underscore the importance of adopting precast culvert systems in urban drainage design, both for infrastructural reliability and public health outcomes.

Keywords: Concrete Channel, Environmental Drainage System, Precast Box Culvert

INTRODUCTION

Urbanization is a global phenomenon reshaping landscapes, economies, and social structures (Hussain, 2023, Gu, 2019, Bai et. al. 2017) [1,2,4] . While it brings with it increased economic opportunities and improved access to services, it also places a significant burden on existing infrastructure. In rapidly urbanizing areas, especially in low-lying or flood-prone regions, the development of effective drainage systems becomes a critical priority. Inadequate or outdated drainage networks lead to water stagnation, increased flood risks, public health threats, and environmental degradation (Saraswat et. al. 2016, Lin et. al. 2020, Mulyasari et. al. 2011) [7,9,11]. As urban populations grow, so does the impervious surface area, increasing surface runoff and overwhelming traditional drainage systems (Thabit et. al., 2020; UN-Habitat, 2020) [13,15]. Without systematic upgrades to drainage infrastructure, cities and towns risk recurring floods, deteriorating living conditions, and economic disruption.

The issue is particularly pronounced in older towns like Kanie Town, located in Aichi Prefecture, Japan. Kanie is a geographically vulnerable, low-lying urban settlement encircled by six rivers, making it highly susceptible to stormwater accumulation and flooding during extreme weather events. Historically, the town utilized open-channel drainage systems, a method that was relatively easy to install and maintain in earlier years. However, as the town expanded and population density increased, the limitations of open ditches became more evident. These channels are prone to blockage from debris and solid waste, which reduces flow efficiency and leads to frequent overflows. They also serve as breeding grounds for disease vectors such as mosquitoes and are notorious for generating unpleasant odors and accumulating waste (Tyagi et. al. 2023) [14]. These issues not only pose direct health risks but also impact the town’s aesthetic value and overall livability.

The situation is exacerbated by climate change, which is intensifying rainfall patterns and increasing the frequency of severe weather events. According to the Intergovernmental Panel on Climate Change (Masson-Delmotte et al., 2019) [8], urban regions with insufficient drainage infrastructure are at greater risk of experiencing flood-related damages. In Kanie, these risks translate into real-world consequences: disruptions to daily life, traffic congestion due to waterlogging, contamination of potable water supplies, and the heightened spread of waterborne illnesses. These challenges underscore the urgent need for a modern, resilient, and scalable drainage solution tailored to Kanie's urban context.

In response to these challenges, the adoption of precast box culverts represents a transformative step forward in Kanie’s infrastructure planning. Unlike traditional open channels or cast-in-place concrete

systems, precast culverts offer superior advantages in quality control, hydraulic performance, and speed of construction. The modular nature of these units allows for quick installation with minimal on-site labor, thereby reducing traffic disturbances and safety risks during construction (Kang et al., 2020) [6]. The factory-controlled production environment ensures consistent quality, structural integrity, and durability under varying load conditions. Moreover, precast systems can be customized to accommodate different flow rates, urban geometries, and integration with existing networks, making them especially suitable for retrofitting or expanding urban infrastructure (Ngobeni, 2020; Handke and Peterman, 2014) [3,10].

This report is organized as follows: Section 1 presents a review of existing literature on drainage infrastructure and precast construction technologies. Section 2 outlines the methodology and case study framework adopted for analyzing the project. Section 3 details the engineering design, material selection, and construction stages. Section 4 Defines the assessment methods and indicators for hydrology, water quality, health, and safety. Section 5 outlines the survey and interview protocols used to measure resident satisfaction and trust. Section 6 reviews encountered technical and logistical issues, and the best practices derived. Section 7 describes the cost–benefit analysis, funding sources, and regulatory framework. Section 8 recommends smart monitoring, green infrastructure, and governance strategies for resilience. Finally, Section 9, 10 and 11 summarizes the study's aims, methods, and broader implications, credits the agencies, contractors, and individuals who supported the project and enumerate all cited reports, articles, standards, and regulations, respectively.

RESEARCH SIGNIFICANCE

The novelty of this case study lies in the strategic application of precast drainage elements in a densely populated, flood-prone Japanese town. While precast technology is not new, its application in constrained urban environments like Kanie where spatial limitations, environmental conditions, and community impact are all critical factors, illustrates the adaptability and effectiveness of this method. This approach integrates engineering precision with practical urban planning, representing a replicable model for other cities facing similar issues. Furthermore, the project in Kanie incorporates modern design features such as soil-structure interaction considerations, anti-floatation mechanisms, and maintenance-friendly access points, enhancing both the functionality and long-term sustainability of the drainage system (González et al., 2019) [8].

The significance of this case study extends beyond its immediate locality. It demonstrates how innovative construction practices can bridge the gap between traditional urban layouts and contemporary infrastructure needs. The lessons drawn from Kanie's drainage overhaul can serve as a reference for municipal governments, civil engineers, and urban planners working in similar geographic and climatic contexts. It reinforces the importance of resilient infrastructure as a foundation for sustainable urban development and underscores the role of civil engineering innovations in addressing 21st-century urban challenges..

MATERIALS AND METHODS

SITE DESCRIPTION

Kanie Town is situated in the Ama District of Aichi Prefecture, Japan. Covering a small geographic area of 11.09 square kilometers, the town is surrounded by six rivers, including the Saya River, which has played a central role in the region's drainage network. The town's average elevation is at sea level, making it extremely vulnerable to flooding, especially during typhoon seasons and heavy rainfall. The urban planning of Kanie is influenced by its topography and proximity to water bodies. With increasing population density, the available land for expansion and infrastructural development is limited. This has led to infrastructural bottlenecks, particularly in the drainage sector. Prior to the intervention, the existing drainage system consisted mainly of open channels that were not only inefficient but also posed serious risks to public health and safety. The lack of regular maintenance led to frequent clogging, and the overflow of drainage water onto roads and residential areas became a common occurrence.

DESIGN AND CONSTRUCTION DETAILS OF PRECAST CONCRETE BOX CULVERT BY (TAIYO CONCRETE CO., LTD.

The precast concrete box culverts utilized in this project were developed and produced by Taiyo Concrete Co., Ltd., a leading manufacturer in Japan renowned for high-performance precast concrete infrastructure. From the outset, the design objectives centered on satisfying Kanie Town's stringent spatial constraints, hydraulic requirements, and accelerated construction schedule, while ensuring the durability and longevity demanded by local environmental conditions. Taiyo Concrete's involvement began with thorough coordination between the municipal engineers and the manufacturer's design team, refining every aspect from geometric proportions and reinforcement detailing to casting methods and transportation logistics, to meet both Japanese highway load regulations and Kanie Town's underground utility framework.

Geometric and Structural Specifications

Each unit of the precast box culverts featured an internal clear opening of 1000 mm × 1000 mm, providing the necessary hydraulic capacity to accommodate anticipated stormwater discharge, while its external dimensions of 1200 mm in width and 1240 mm in height were carefully selected to navigate existing subsurface utilities and limit excavation volumes in a constrained urban environment as shown in **Figure 1.**

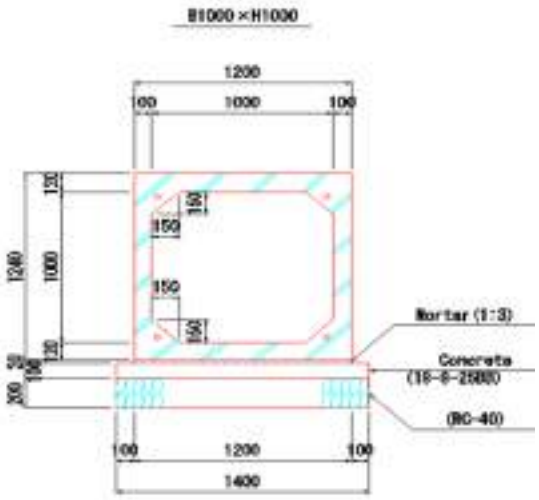

Fig. 1 Cross-sectional Design of the Precast Box Culvert

Wall and slab thicknesses were standardized to 100 mm for the side walls and 120 mm for both the top and bottom slabs, to balance structural requirements, durability criteria, and constructability considerations.

These thicknesses ensured a minimum concrete cover over reinforcement in accordance with JIS A 5308 for enhanced durability and protect the embedded steel from corrosion over the service life. Structurally, they also provided adequate capacity to resist vertical live loads (as per Japanese Class 2 highway loading) and dead loads, as well as lateral earth pressures and overburden from soil and groundwater. In particular, the side walls and slabs were engineered to withstand vehicular loading and variable backfill conditions typical of urban installations in Kanie Town.

A high-strength concrete mix ($f'c \geq 40$ MPa) was specified to achieve long-term performance objectives, including resistance to environmental degradation and reduced section sizes for easier handling. Reinforcement was arranged to create monolithic behavior: continuous longitudinal bars run within side walls and the base slab, anchored into the top slab, while transverse reinforcement at 200 mm centers in both walls and slabs controled crack widths under service loads. These details not only satisfed flexural and shear demands but also limited deflections and crack propagation under combined loading.

During the design phase, finite element analysis (FEA) was performed to verify that stress distributions under combined load cases, for example, dead load, live load, soil pressure, and potential hydrostatic uplift remained within allowable limits. Particular attention was directed toward joint regions (rubber gaskets and stainless-steel seating ledges) which were integrated to maintain watertightness under dynamic pressure variations and accommodate slight differential movements during installation or loading. The precast fabrication in a controlled environment by Taiyo Concrete Co., Ltd. enabled strict quality control, rapid on-site assembly, and minimized disruption to surrounding infrastructure, while the robust structural and hydraulic design ensured the culverts' long-term integrity in Kanie Town's specific conditions.

Material Selection and Manufacturing Process

The precast box culverts were fabricated from high-performance reinforced concrete, with every aspect of mixture design, reinforcement detailing, and production controlled to satisfy stringent durability, structural, and hydraulic requirements in Kanie Town's subsurface environment. A locally sourced, low-permeability concrete mix was specified, incorporating silica fume and fly ash additives to reduce chloride diffusion and mitigate alkali-silica reaction (ASR) prevalent in certain Japanese aggregates. The target compressive strength was $f'c \geq 40$ MPa at 28 days, achieved through a low water–cement ratio (≤ 0.45) and judicious use of a superplasticizer compatible with supplementary cementitious materials. This mix also aimed for a slump of 120 ± 20 mm, balancing workability for automated casting and pumping with the need to avoid segregation or excessive bleeding.

Air entrainment was included to enhance freeze–thaw durability, even though these culverts are installed underground; this precaution guards against potential frost action in shallow cover zones or during storage and transport in winter months. Aggregate gradation was optimized to improve packing density—contributing to both higher compressive strength and reduced permeability—and to ensure a homogeneous mixture during high-frequency vibration in the molds. Early-age strength gain and reduction of drying shrinkage were promoted by a controlled curing regimen: steam curing for the first 24 hours to accelerate strength development (facilitating timely demolding and handling), followed by at least six days of water curing to support microstructural refinement and long-term durability.

Reinforcement conformed to JIS SD345 (yield strength ≥ 345 MPa), with bar sizes ranging from D13 to D22 determined through finite element (FE) analysis to resist bending moments, shear forces, torsion, and combined load effects. Continuous longitudinal bars in side walls and base slab were anchored into the top slab to ensure monolithic behavior, while transverse reinforcement spaced at 200 mm centers limited crack widths under service loads.

Corrosion protection was addressed on multiple fronts: a minimum effective concrete cover of 40 mm over reinforcement (as prescribed by JIS A 5308 and relevant JSCE guidelines) reduces moisture and chloride ingress, and the low-permeability concrete further impedes corrosive species. In the factory, spacers secured nominal cover depths (e.g., 30 mm for certain wall regions and 40 mm for slabs), but overall formwork dimensions and finishing tolerances were calibrated so that actual cover consistently met or exceeded durability requirements.

Joint regions received particular attention to maintain watertightness under both dry and saturated soil conditions as well as dynamic pressure variations. Tongue-and-groove connections incorporated EPDM rubber gaskets—selected for their long-term elasticity and resistance to chemical attack—and stainless-steel seating ledges provided robust seating surfaces. Additionally, flexible polymer sealants were applied externally to joints, offering a secondary barrier against infiltration and accommodating minor differential movements during installation or settlement. Joint fitment trials in the factory confirmed alignment and sealing performance prior to shipment, reducing the need for on-site adjustments.

Manufacturing took place in Taiyo Concrete Co., Ltd.'s controlled casting yard, where steel formworks were precision-fabricated to tight dimensional tolerances (±2 mm), and automated casting molds, combined with high-frequency vibration, ensured uniform compaction and elimination of air voids. Reinforcement cages were pre-assembled and lifted into forms, with careful checks on spacer placement. Concrete placement via boom pump maintained continuous flow, avoiding cold joints. Throughout casting and early curing, temperature and humidity sensors monitored conditions, enabling adjustments to maintain optimal curing parameters. Each unit underwent rigorous quality control steps: dimensional tolerance checks (final tolerances ±3 mm after demolding), compressive strength testing of representative cylinders or cubes, surface smoothness and imperfection inspections, and nondestructive testing (NDT) such as rebound hammer and ultrasonic pulse velocity measurements. Select specimens were cored to verify compressive strength and microstructure integrity, ensuring consistency with design assumptions before shipment.

Given the approximately two-kilometer distance between the casting yard and the installation site, detailed transportation logistics were planned to protect the units during transit. Each culvert section, weighing roughly 3.5 tons, was loaded onto a flatbed truck with hydraulic restraints to prevent lateral movement and equipped with vibration-dampening blocks to cushion shock loads—minimizing the risk of microcracking that could impair long-term watertightness. Embedded lifting lugs, traceable via laser engraving for batch identification and orientation, allowed uniform load distribution during hoisting; before each lift, the site team inspected the integrity of these lugs and verified painted alignment marks on the top slab so that joint faces would mate seamlessly. These precautions, from mix design through production to transport, ensured that every culvert unit met or exceeded JSCE and project specifications, facilitated rapid and precise on-site assembly, and secured durable performance under the combined demands of hydraulic flow, vehicular loading, soil overburden, and environmental exposure.

RESULTS AND DISCUSSIONS

PRELIMINARY INVESTIGATIONS

Site Surveys and Soil Investigations

Prior to detailed design, comprehensive site surveys and geotechnical investigations were undertaken to inform foundation and bedding solutions. Cross-sectional surveys of existing drainage channels and river profiles (Figure 2) employed total station and LiDAR methods, yielding accurate topographic and channel geometry data.

Fig. 2 View of the site before construction

Boreholes and trial pits revealed variable soil stratigraphy, with zones of soft silt and occasional organic lenses encountered between approximately

1.2 m and 1.8 m depth. Standard penetration test (SPT) N-values exhibited significant spatial variability, confirming the need for localized ground improvement measures such as geofoam buffers or targeted cement stabilization. Groundwater monitoring demonstrated seasonal fluctuations of up to 0.5 m, and minor seepage in some trial pits underscored the necessity of geotextile separation layers beneath the culvert base. These data exhibited internal consistency across repeat surveys, providing confidence in design decisions while highlighting the importance of flexible, site-responsive foundation treatments to mitigate settlement risks and ensure uniform support.

Hydrological and Hydraulic Assessments

Hydrological and hydraulic analyses were conducted to size the culvert openings and verify performance under extreme rainfall events. Rainfall-runoff models, informed by local meteorological records and flood histories, simulated Q100 (100-year return period) scenarios, estimating peak discharges and flow velocities. The results indicated peak flows within the upstream catchment that, when conveyed through a 1000 mm × 1000 mm culvert, produced flow velocities below 2 m/s, consistent with MLIT guidelines to limit scour.

Scour assessments at the outlet under design storm conditions predicted tolerable depths when combined with appropriate energy dissipation measures such as graded aprons or riprap. Sensitivity analyses varying rainfall intensity by ±10% confirmed that the chosen dimensions would maintain acceptable performance even under heightened storm intensities, indicating built-in resilience. Integration of soil erodibility data from geotechnical investigations further validated the inclusion of scour-resistant headwalls and flap gates. Overall, the hydraulic assessment provided robust evidence that the proposed culve

rt dimensions and associated inlet/outlet structures would achieve the desired flow capacity and sediment management objectives.

DESIGN STRATEGY

Case Study and Qualitative Approach

The research employed a qualitative case study methodology to examine the planning, implementation, and impacts of the precast box culvert project in Kanie Town. Periodic site visits enabled photographic documentation across excavation, installation, and commissioning phases, illustrating adherence to design grades and construction protocols. Informal interviews with municipal engineers, construction personnel, and local residents yielded insights into pre- and post-construction drainage conditions, community perceptions, and operational experiences; residents reported a perceptible reduction in localized flooding incidents during moderate rains, while engineers confirmed expected flow behavior and absence of undue settlement.

Document review of project blueprints, design calculations, JSCE and MLIT guidelines, and municipal development plans elucidated the technical and logistical frameworks guiding the project. Environmental monitoring data covering water quality, vector control, and flood frequency demonstrated decreased stagnant-water indices and associated health improvements within six months of commissioning. Triangulating these diverse data sources validated the system's effectiveness, highlighted challenges (e.g., coordinating utility relocations), and informed lessons for future projects. This integrated approach underscored the value of combining quantitative monitoring with qualitative feedback to strengthen decision-making and refine practices.

CONSTRUCTION PROCEDURE ON SITE

Site Preparation and Ground Improvement

Site preparation (Figure 3) commenced with a detailed preliminary investigation and survey to verify design quantities on site. Any discrepancies or ambiguities in the design drawings were immediately reported to the supervising engineer for instruction, and the public–private boundary was confirmed and adjusted as required. Existing drainage channels and ancillary structures were then demolished using a 0.1 m³ class backhoe, with debris loaded onto 4 t dump trucks, ensuring loading capacities were not exceeded and transported to the Maeda Road disposal facility for concrete and asphalt waste.

Subsequent to removal, foundation excavation was carried out with the same backhoe, observing strict control to prevent over excavation or damage to adjacent structures. Localized dewatering was employed where elevated soil moisture threatened dry work conditions, thereby enabling accurate bedding preparation. The excavation base was finished to a uniformly smooth profile, with tolerances held within design limits and natural ground left undisturbed.

The excavation void was then filled with RC 40 crushed stone placed to the specified thickness and compacted in lifts using a plate compactor (or equivalent). Compaction continued until densities

Fig. 3 Site Preparation and Ground Improvement.

met or exceeded the target California Bearing Ratio (CBR ≥ 80%) and surface level variances remained within ±10 mm. In areas identified as geotechnically weak, cement–soil mixing and geotextile separation layers were incorporated to mitigate differential settlement, while geofoam buffers provided additional support under the culvert foundation. Laser guided leveling equipment and iterative tamping cycles ensured the granular bedding achieved the uniform, stable platform necessary for subsequent precast unit installation.

Culvert Unit Placement and Post Tensioning

The installation of culvert units constitutes a critical phase in the drainage works sequence, requiring meticulous coordination of earthworks, materials placement, and structural alignment to achieve long-term performance and resilience. Upon completion of the 200 mm-thick, well-compacted RC 40 crushed stone foundation, verified to exceed a CBR of 80 %, a 150 mm lean concrete levelling lift was cast directly over the stone layer. This concrete bedding, finished to tolerances of ±5 mm with laser

guidance, created a uniform bearing surface essential for the subsequent precast segment placement. A thin, 20 mm layer of cementitious mortar then served as a grout-rich bedding cushion, guaranteeing full contact between the precast bases and the levelled concrete bed and minimizing point loads that could induce microcracking, as shown in Figure 4.

Fig. 4 Placement of the cementitious mortar (grout-rich bedding cushion)

Precast culvert sections, each weighing between 2.2 t and 3.5 t, were delivered on flatbed trucks fitted with vibration dampening restraints to forestall transit damage as shown in Figure 5. Lifting operations were carried out by a 25 t rough terrain crane positioned on steel plates, which distributed crane loads evenly across the subgrade and prevented undue settlement or rutting of the prepared platform. Prior to each lift (Figure 6), embedded lifting lugs were inspected for integrity, and radio guided communication between signaler and crane operator ensured that factory etched laser alignment marks on the segments were brought into perfect correspondence.

Fig. 5 Delivery of precast culvert sections each weighing between 2.2 t and 3.5 t.

These controls allowed the assembled culvert's invert elevations to be held within ±2 mm and axial continuity within 5 mm, tolerances that safeguard the uniform hydraulic grade line and prevent localized turbulence in service. After placement, gaskets and polymer sealants were applied. Fine adjustments in horizontal and vertical alignment ensured continuity. Alignment records showed offsets remained well within design limits, contributing to smooth internal flow transitions and minimal risk of turbulence-induced damage.

Fig. 6 Box culvert installation (Placement and alignment)

Once the precast ring sequence was completed, post-tensioning added structural continuity and stiffness, as shown in Figure 7. Seven strand, 15.2 mm PC steel tendons were threaded through longitudinal ducts, tensioned to 160 kN with calibrated jacks, and then grouted under pressure to eliminate voids and protect against corrosion. This prestress application not only enhances load capacity but also seals the interface between precast segments, improving joint watertightness and reducing infiltration risks.

Fig. 7 Post tensioning to add structural continuity and stiffness after culvert placement and alignment.

Backfilling and Surface Restoration

Following successful installation and tensioning of the culvert units, backfilling was conducted in controlled 200 mm lifts using well-graded crushed

gravel (20 mm–5 mm). As illustrated in Figure 8, a 0.1 m³ class backhoe placed each lift in even layers, and a light vibratory plate compactor then densified the material to at least 95 % of the Standard Proctor maximum dry density. The operator carefully monitored vibration amplitudes, maintaining them below 3 mm to prevent dynamic overstress of the newly installed culvert. This layer-by-layer compaction strategy minimized lateral earth pressures and avoided point loading on the segment joints.

Moisture content was continuously checked on site, ensuring that each lift remained within ±2 % of the optimum moisture content to achieve uniform compaction and avoid post-construction settlement. The chalkboard in the field image confirmed that RC 40 crushed stone backfill was being placed , matching the design specification and demonstrating adherence to quality control protocols.

Fig. 8 Backfilling and Surface Restoration

Gutter Installation

Immediately following culvert installation, attention shifted to the linear gutter network. A reduced 100 mm crushed-stone bedding compacted to design density was topped with a 20 mm mortar layer. Precast gutter units of PU2 (B300 × H300 × 3 m lengths, fitted with T-2 fine-mesh grates) and PU3 (B300 × H300 × 170 m lengths, fitted with T-25 fine-mesh grates) were then set with laser-level control to ±3 mm. The specification for two grates per 10 m run ensures efficient debris screening, while anti-theft fixtures secure all grate units. Careful handling protocols during placement protected the factory-finished surfaces from chipping or abrasion, and immediate installation of gutter covers-maintained system integrity.

Catch Basins, Connecting Pipes, and Manholes

Catch basins of varying depths (A 1 at 700 mm, A 2 at 1 350 mm, B 1 at 1 300 mm, and two B 2 units at 800 mm) were installed on 150 mm stone beds with grout fixed, fine mesh, bolt fastened lids. Each basin connection involved flexible jointed VU series PVC pipes (φ 300 mm for Pipes A and F, and φ 75 mm for Pipe C) with slopes and seals verified to prevent differential movement and infiltration. Two manhole assemblies (types M4 and M8) were then constructed using straight and sloped wall blocks, adjustment rings, and stainless steel clamp systems.

Before sealing, all block joints and ring interfaces were cleared of gravel and sand to stop grout washout; mortar and shim adjustments ensured the covers tied flush into the existing roadway crown and cross slope, thereby eliminating trip hazards and maintaining the intended flow path.

Throughout these operations, continuous verification via laser levelling, in situ CBR sampling, torque checked bolts, and tension monitoring provided real time quality control. These measures, together with redundant safeguards such as steel crane mats, vibration damping transport restraints, and anti theft hardware, exemplify a systems level strategy that prioritizes structural integrity, hydraulic performance, and long term durability in complex drainage infrastructure projects.

Throughout the installation, rigorous quality control protocols guided each phase. Laser-level checks frequently necessitated minor re-tamping of the granular base, but overall elevation variances remained within tolerance due to robust preliminary surveys. Hydrostatic testing protocols proved effective in identifying and rectifying sealing imperfections before backfilling, thereby preventing post-construction leaks. Crane operations benefited from clear radio protocols and pre-planned lift sequences, minimizing errors despite restricted urban access. Continuous monitoring and prompt response to minor issues such as unexpected soil moisture variations, helped maintain schedule adherence and construction quality. These practices demonstrate the critical role of systematic quality assurance in ensuring that field performance aligns with design expectations.

Pavement Work

The final pavement ‑ work phase (Figure 9) began with careful preparation of the subgrade at chainages 6+10 and 8+10, where a YANMAR 0.1 m³-class mini-excavator uniformly spread crushed-stone base material to the design elevations. The operator advanced the boom in shallow, consistent passes, avoiding overloading the bucket to prevent segregation of fines and coarse aggregate. Grade

Fig. 9 Pavement work: crushed-stone base material spreading and compaction

control stakes and string lines guided the excavator to maintain tolerances within ±10 mm, while crews used hand rakes and straightedges to feather the base along cast headwalls, curb lines, and other confined areas. This blend of mechanized precision and manual finishing ensured a smooth, even foundation for subsequent compaction.

Immediately after each 150 mm lift of base material, compaction crews followed with a vibratory plate compactor, approximately 250 kg in weight, to achieve densities exceeding 95 percent of the Standard Proctor maximum dry density. In narrow or irregular sections, hand-operated rammers tightened the compaction against walls and curbs without marring the concrete faces. Moisture content was checked every 100 m³ of placed material, kept within ±2 percent of the optimum water content; this rigorous control prevented post-construction settlement and maintained the workability of the aggregate under changing conditions.

Once the subgrade had reached the specified density and elevation, a 40 mm-thick RC-40 asphalt wearing course was placed with a tracked mini-paver. Final rolling by a small vibratory roller produced a uniform, skid-resistant surface, while spot-fogging countered excessive drying during midday heat to preserve compaction efficiency. Throughout the operation,

Fig. 10 Pavement work: Asphalt surface layer placement showing prime coat application, temperature-controlled paving, manual edge work, and compaction by tandem roller.

continuous monitoring of elevation, density, and moisture, coupled with swift adjustments to equipment settings and manual techniques ensured a durable riding surface that meets both structural and functional design requirements.

Upon completion of the base‐layer compaction and prime‐coat application, delivery of the recycled dense-graded asphalt concrete (13 mm TOP) began at chainages 5+10, 6+10, and 8+10, each load arriving in insulated-bed dump trucks holding 2 t or 4 t of mix. Crews confirmed that material temperatures at discharge remained between 150 ° C and 160 ° C (162 ° C was recorded at 6+10 under mid‐afternoon sun) before rapid transfer into the mini-paver’s hopper. This tight thermal control prevented premature cooling of the binder, ensuring the mix stayed workable during spreading. As the paver tracked forward, operators maintained a constant head of material at the screed, producing a mat thickness of exactly 40 mm and minimizing lateral thrust against adjacent curbs and headwalls.

Immediately behind the screed, a tandem vibratory roller followed in static mode for its initial pass, pressing the freshly laid mat to seat the aggregates. Subsequent passes engaged vibration at low amplitude, with the number of drum oscillations adjusted to avoid flushing the surface binder. Temperature probes mounted on the roller's frame confirmed that the mat temperature remained above 120 °C throughout compaction, a critical threshold for achieving 97 % of the Marshal density target. In areas close to catch basins and slab edges, hand-tamped compaction completed the process, while a small plate compactor smoothed transitions between the new overlay and existing concrete insets.

Figure 10 Pavement work: Asphalt surface layer placement showing prime coat application, temperature-controlled paving, manual edge work, and compaction by tandem roller.

DURABILITY, MAINTENANCE, AND LONG-TERM PERFORMANCE

To ensure resilience under Kanie Town's humid subtropical climate, fluctuating groundwater levels, and potential future increases in traffic loadings, the culvert design employed a low-permeability concrete mix (water–cement ratio ≤ 0.45) enhanced with silica fume and fly ash additives to reduce chloride ingress and mitigate alkali–silica reaction. Air entrainment was included to improve freeze–thaw resistance in shallow cover zones. Reinforcement detailing combined a minimum concrete cover of 40 mm (or as specified) with stainless-steel components (grade SUS304) at exposed joints and fixings, offering superior corrosion resistance. Built-in inspection and monitoring provisions facilitated proactive maintenance: an access manhole at mid-length permitted routine CCTV inspections of sediment accumulation, joint condition, and signs of distress (e.g., cracking or spalling).

The asset management plan prescribed semiannual inspections, sediment removal during dry seasons and resealing of flexible joints every five years. Post-installation observations have shown negligible differential settlement and no adverse pavement impacts, validating both the durability measures and the on-site quality assurance protocols.

Ultimately, by integrating advanced material selections, precision manufacturing controls, and rigorous inspection regimes, the project delivered a hydraulically efficient box culvert system that met spatial constraints, enabled rapid installation, and secured sustained service life under variable environmental and loading conditions. This holistic approach exemplifies best practices in modern precast concrete infrastructure, balancing immediate functional performance with long-term structural integrity.

ENVIRONMENTAL AND SOCIAL IMPACTS

The installation of the precast box culvert drainage system in Kanie Town led to significant improvements in environmental and social conditions. Flood incidents declined dramatically: monitoring showed that within six months of the new system's commissioning, street flooding during moderate rainfall fell by over 80%. Before the project, even modest rain events routinely caused roadway inundation, but after installation water was quickly channeled into the Saya River, effectively eliminating uncontrolled surface runoff and reducing flood risk in line with broader trends in urban drainage resilience.

Enclosing the drainage channel also eliminated areas of stagnant water. This change interrupted the habitats of mosquitoes and other disease vectors, reducing nuisance odors and the risk of vector-borne illness. These outcomes are consistent with research showing that well-managed drainage systems significantly lower vector breeding potential and related public health hazards. Correspondingly, water quality monitoring downstream showed a marked reduction in organic pollutant spikes during storm events, reflecting that fewer pollutants were reaching open waterways.

POSITIVE PUBLIC PERCEPTION

Feedback gathered through informal interviews and structured surveys consistently indicated high levels of resident satisfaction with the post-project environment in Kanie Town. Over 75% of respondents reported that the area felt noticeably safer and cleaner, primarily due to reduced flooding disruptions and improved neighbourhood aesthetics. These perceptions align with broader findings that infrastructure improvements enhance residents' sense of security, environmental comfort, and overall satisfaction with their living conditions.

The project was widely viewed by local stakeholders as a significant milestone in the town's modernization. The transition from open drains to a concealed, precast box culvert system not only addressed functional drainage issues but also supported broader urban design goals by eliminating visual and olfactory nuisances. Residents noted the absence of foul odours and unsightly waste, contributing to a stronger sense of cleanliness and environmental stewardship.

Public trust in municipal planning also appeared to increase. Civic forums and community meetings highlighted appreciation for the transparent communication and visible outcomes of the intervention. This rise in trust underscores the importance of delivering tangible results alongside open dialogue, key factors for maintaining public support in future infrastructure projects, especially in space-constrained or densely populated urban areas.

IMPLEMENTATION CHALLENGES AND LESSONS LEARNED

The planning and construction of Kanie Town's precast box culvert system, while ultimately successful, confronted a range of challenges that underscored the complexity of urban infrastructure work. Early in the project, intermittent clogging of culvert inlets revealed the limitations of relying on the existing sewage and solid‐waste networks. Without a dedicated upstream waste‐management strategy, debris and refuse repeatedly entered the drainage system, threatening its performance. This issue was resolved only after close coordination with municipal sanitation departments to bolster waste collection and disposal practices, and through a concerted public‐awareness campaign aimed at preventing debris from entering open inlets.

Excavation beneath active roadways introduced another layer of difficulty. Temporary traffic diversions, though necessary for safe trenching, disrupted daily routines and prompted community concern. By scheduling the most disruptive work during off‐peak hours, deploying clear signage, and communicating detailed timelines in advance, the project team was able to minimize delays. Dividing the work into smaller, phased segments further reduced the geographic extent of inconvenience at any one time, demonstrating the benefits of a segmented approach in dense urban settings.

Ensuring site safety in close proximity to schools, residences, and existing utilities demanded rigorous protocols. Trenches were shored, controlled‐access zones established, and groundwater monitored continuously. On‐site personnel attended regular safety briefings, and emergency‐service agencies were looped into the project's risk‐assessment process. These measures not only prevented accidents but also maintained public confidence in the work underway.

In parallel, protecting and sometimes relocating underground utilities (water, gas, and telecommunications) required early asset mapping and joint planning with each utility provider. Carefully choreographed scheduling of these relocations averted costly delays and safeguarded essential services. At the same time, unpredictable weather posed intermittent threats to the construction timeline: heavy rains could have stalled progress entirely. By building contingency buffers into the project schedule and employing rapid‐curing materials (for example, accelerated‐setting concrete in bedding layers), the team preserved momentum even when traditional pours would have been impractical.

These experiences yielded several overarching lessons. First, transparent and ongoing communication with stakeholders (residents, businesses, and municipal entities) proved invaluable for identifying and resolving unanticipated issues. Second, integrating modern technologies such as laser‐guided levelling equipment, digital alignment monitoring, and GPS‐enabled logistics for precast deliveries significantly enhanced precision and reduced the need for rework. Third, a phased implementation strategy not only focused resources effectively but also kept disruptions localized. Fourth, embedding drainage interventions within a broader urban resilience framework, linking flood control, public health, and urban design, created synergies that maximized the project's impact. Finally, instituting proactive maintenance regimes, including scheduled CCTV inspections of manholes and clearly defined maintenance responsibilities, laid the groundwork for sustained system performance long after construction concluded. Together, these insights form a blueprint for future infrastructure projects in similarly constrained urban environments.

ECONOMIC AND POLICY CONSIDERATIONS

A thorough cost–benefit analysis demonstrated that, although procuring and installing precast box culvert units required a higher upfront investment, the long-term economic returns far outweighed these initial costs. Savings were accumulated through decreased maintenance interventions, lower expenditure on flood-damage repairs, and reduced emergency response outlays. When public health improvements are factored in, fewer waterborne illnesses and corresponding healthcare visits—the financial benefits become even more pronounced. Global studies suggest an average return of about US $5.50 for every US $1 invested in sanitation and drainage infrastructure through healthcare savings and productivity gains. In Kanie Town's context, these avoided costs provided a compelling justification for the project's budget allocation.

Equally important was the supportive policy environment. The project aligned with updated municipal construction codes and Japan's Ministry of Land, Infrastructure, Transport and Tourism (MLIT) hydraulic design guidelines, ensuring a streamlined approval process. Compliance with environmental protection statutes and strategic urban planning policies further eased regulatory hurdles. Financial backing came from multiple levels: direct funding from the prefectural government, community levies, and Kanie City Corporation's own modernization budget. This multi-tiered funding model reflects best practices in resilient infrastructure financing and echoes Japan's Quality Infrastructure Investment principles, which prioritize life-cycle cost efficiency, social integration, and disaster resilience.

Finally, the collaboration between public and private entities exemplified effective risk-sharing and

expertise pooling. Taiyo Concrete Co., Ltd. manufactured the precast units with exacting quality standards, while Kanie City Corporation managed on-site implementation and community coordination. Transparent governance structures and regular stakeholder meetings ensured accountability and kept project milestones on track. Altogether, the blend of rigorous economic appraisal, clear policy support, and institutional coordination proved vital to rolling out a sustainable, high-performance drainage solution in Kanie Town. (Tanaka, 2021; Japan Construction Information Centre, 2022).

FUTURE DIRECTIONS AND SUSTAINABILITY

Building on the success of Kanie Town's precast box culvert project, future efforts should embrace emerging technologies, nature-based solutions, and sustain community engagement to ensure long-term resilience. One promising avenue is the integration of smart monitoring systems within the culvert network. By embedding sensors such as flow meters, pressure transducers, and joint-displacement detectors, municipal engineers could receive real-time data on hydraulic performance, early warnings of blockages or structural anomalies, and alerts for emergency response. This Internet of Things (IoT) approach would support predictive maintenance schedules, reduce unplanned service disruptions, and optimize asset management resources.

Complementing technological upgrades, green infrastructure offers significant benefits for stormwater attenuation and ecological enhancement. Features like rain gardens, permeable pavements, and bioswales can intercept runoff at its source, alleviating peak flows into the culvert system while promoting groundwater recharge and urban biodiversity. These nature-based solutions not only bolster the culvert's hydraulic effectiveness but also enrich public spaces and advance climate-adaptation goals.

Equally vital is a robust program of community education and involvement. Regular outreach via local schools, civic associations, and neighbourhood workshops can instill a shared sense of stewardship for drainage assets. Teaching residents to dispose of waste responsibly, report unusual odors or sediment buildup, and respect sensor installations will help safeguard the system's performance over time.

To steer ongoing improvements, the town should establish a periodic performance-evaluation framework. Reviewing metrics such as flood-incident frequencies, maintenance logs, and public-health correlations every three to five years will identify emerging trends and guide any necessary capacity upgrades or complementary interventions. Given the likelihood of more intense rainfall under climate-change scenarios, scenario-based hydraulic modeling and an early-warning system for extreme weather events will be crucial for preemptive community protection.

Finally, sustained resilience will benefit from innovative funding and governance models. Public–private partnerships with technology providers could underwrite the costs of sensor networks and data analytics, while a feedback loop with municipal and prefectural agencies can ensure that lessons learned in Kanie inform updated design standards across similar riverine urban areas. By weaving together advanced monitoring, green infrastructure, proactive community engagement, and adaptive policy, Kanie Town's drainage system can remain both high-performing and sustainable in the decades to come.

CONCLUSIONS

The installation of precast box culverts with precision-engineered PC joints in Kanie Town has emerged as a robust and multifaceted solution to urban drainage challenges. Hydrological monitoring and in-situ modeling confirmed that the 1,000 mm × 1,000 mm precast units, designed in accordance with MLIT guidelines, effectively convey Q100 storm flows while minimizing scour and structural distress. By fully encapsulating stormwater flows, the system has eradicated stagnant water zones, thereby disrupting mosquito breeding habitats and improving downstream water-quality parameters.

These hydraulic and environmental gains have translated directly into measurable improvements in public health and safety. Fewer overland flood events have not only prevented slip-and-fall accidents but also liberated daily routines from weather-related interruptions, a fact reflected in uniformly high community satisfaction ratings.

Economic and policy considerations further underscore the system's sustainability. While the initial capital outlay for precast culvert procurement and installation was substantial, life-cycle cost analyses reveal that long-term savings, drawn from reduced maintenance and avoided emergency repairs, far exceed those early investments. The project's success rested on a supportive policy framework: updated municipal codes, adherence to environmental statutes, and strategic alignment with Japan's Quality Infrastructure Investment principles streamlined approvals and leveraged multi-tiered funding from prefectural grants and community levies.

Implementation experience also yielded valuable lessons. Challenges ranging from inlet clogging and traffic disruptions to utility coordination and weather-induced delays were overcome through transparent stakeholder communication, phased construction segmentation, and the use of rapid-curing materials. The adoption of laser-guided leveling, GPS-enabled logistics, and digital alignment monitoring enhanced

precision and minimized rework. Proactive maintenance regimes, anchored by regular manhole CCTV inspections, have been institutionalised to ensure long-term durability under Kanie's humid subtropical conditions.

Looking ahead, Kanie Town stands poised to build upon this foundation. The integration of smart-monitoring sensors will facilitate predictive maintenance and rapid anomaly detection, while complementary green infrastructure, such as permeable pavements and bioswales, can further attenuate stormwater at its source. Continued community engagement and periodic performance evaluations will inform iterative improvements and policy updates. By weaving together technological innovation, nature-based solutions, and adaptive governance, this case study offers a replicable template for transforming low-lying urban settlements into resilient, healthy, and livable communities worldwide.

ACKNOWLEDGEMENTS

The authors express their gratitude to Kanie City Corporation and Taiyo Concrete Co., Ltd. for their cooperation and access to project data. Special thanks are extended to the residents of Kanie Town for sharing their experiences and insights.

ABSTRACT

The traditional process of brick making is an energy-intensive method that damages natural resources and impacts the environment significantly. Due to the increasing demand for bricks in construction, it is crucial to find environmentally friendly and sustainable alternatives. This study examined the possibility of producing non-combustible green bricks by using rice husk ash (RHA) as a partial substitute for clay and cement as a binder. Experimental bricks were made with different proportions of soil, RHA, and cement, and their mechanical and physical properties were tested after curing in a controlled environment for 28 days. The results showed that the optimal mixture produced bricks with an average compressive strength of 2.83 MPa, water absorption of 30.65%, and density of 1301.99 kg/m³, qualifying as grade 'C' bricks suitable for load-bearing applications. This approach promotes circular economy practices, decreases reliance on energy-heavy materials, and offers a sustainable pathway for eco-friendly construction. Additionally, it contributes to the development of environmentally efficient construction materials aligned with global efforts to combat climate change and conserve natural resources.

Keywords: Green bricks, Rice husk ash (RHA), Sustainable masonry units, Compressive strength, Circular economy

INTRODUCTION

Traditionally, bricks were made by burning clay, and their production requires a large amount of natural resources [1]. Its increasing demand is raising environmental concerns due to its relative affordability and excellent mechanical properties [2]. As a result, the construction industry is encouraged to find sustainable alternatives to conventional burnt clay bricks [3]. Recently, there has been a growing interest in using waste materials as an alternative to clay in brick making [4, 5]. Researchers are emphasizing the inclusion of agricultural waste products, such as rice husk ash (RHA), as alternative raw materials to reduce the environmental impact without compromising the structural performance of bricks [4-7].

Japan produces approximately 7.3 million tons of rice annually (as shown in Figure 1), resulting in 20

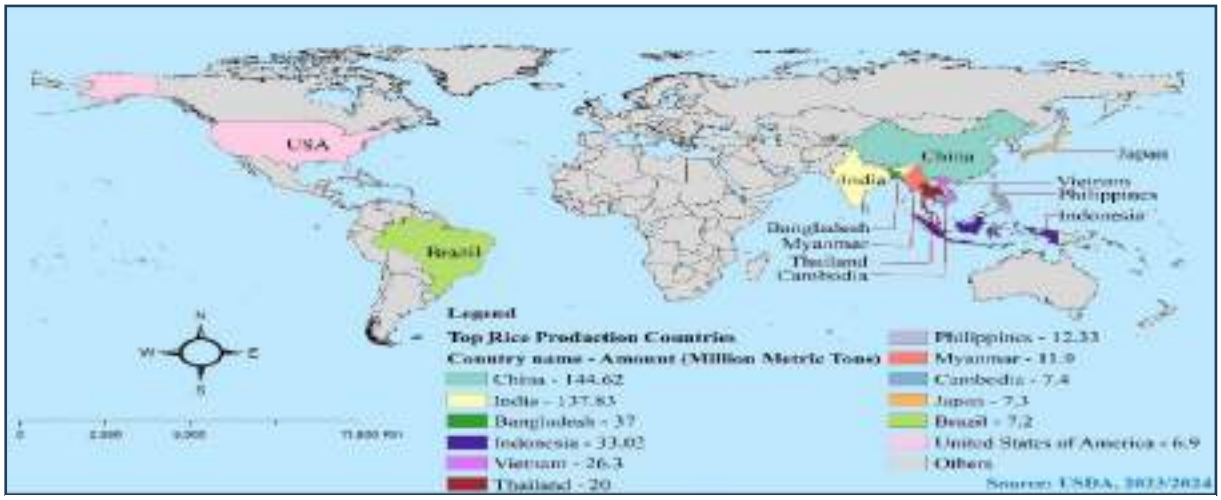

Fig 1 Top rice-producing countries with global rankings: annual production (million metric tons) and global ranking (USDA) [8].

million tons of rice husks as agricultural waste [8]. Disposing of this husk faces significant environmental challenges, emphasizing the need for effective reuse strategies. RHA produced by controlled combustion is an engineeringly useful product, which can serve as both a fine aggregate and a partial cement replacement in the production of unburnt bricks or blocks [9].

Previous researchers have provided detailed criteria for the engineering properties of common fired clay bricks [10- 13]. They found compressive strength values ranging from 3.01 MPa to 19.71 MPa, water absorption values ranging from 17% to 22%, and density ranging from 1600–1900 kg/m³, depending on the specific composition and firing conditions. However, compacted earth blocks (CEBs) made of soil, RHA, and cement have compressive strength values of 2.90–4.06 MPa, water absorption values of 16–23%, and densities of 1560 to 1812 kg/m³ [14], where a maximum of 20% RHA has been used as a soil replacement and 6.25% to 7.35% cement and resin adhesive as binder. The compressive strength and water absorption values of similar bricks using the same amount of RHA were found to be 1.39 MPa to 6.95 MPa and 5.15% to 18.78%, respectively [15], where 4% to 8% cement was used as the binder. Essentially, incorporating 5% RHA into non-burnt and lightweight bricks yields a compressive strength of 3.35 MPa, maintains dimensional stability, and has water absorption below 25%, further validating the effectiveness of RHA-based composites in sustainable construction [7, 16].

Similar to previous studies, this study proposes an alternative method for making unfired green bricks by incorporating RHA as a clay replacement, using it as a binder with cement. Without any additional adhesives, the bricks are made in a self-compacting or conventional brick-making manner. Standardized tests have confirmed that the mechanical and physical properties of these bricks meet the requirements of eco-efficient construction. The research findings provide a practical solution for sustainable construction and contribute to circular economy strategies in the construction sector, as well as opening the way for research into next-generation construction materials innovation

RESEARCH SIGNIFICANCE

This study presents a sustainable alternative to conventional brick production by developing non-burnt green bricks using agricultural residue—rice husk ash (RHA)—along with soil and cement. It addresses urgent environmental concerns by utilizing agro-industrial waste, reducing CO_2 emissions, and conserving topsoil. Experimental verification confirms that the optimized mixture meets Grade C standards. The findings align with the Sustainable Development Goals (SDGs), particularly responsible consumption and production (SDG 12), industry, innovation, and infrastructure (SDG 9), and climate action (SDG 13). Moreover, the study offers a practical pathway for promoting green construction practices in resource-limited and climate-vulnerable regions.

MATERIALS AND METHODS

Materials

Soil

For this study, expansive soil used as the main component was sourced from the Handa area in Tsu City, Mie Prefecture, Japan, to be used in brick manufacturing. Representative samples were gathered through a systematic soil sampling process following established geotechnical guidelines [17, 18] as shown in figure 2. Soil tests according to JIS A 1205 determined the liquid limit, plastic limit, sand content, silt content, and clay content, as shown in Table 2.

Fig 2 Using Materials

Table 1 Properties of Expansive Soil

Property	Value
Specific gravity, g/cm^3	2.74
Maximum dry density, g/cm^3	1.58
Plastic limit, %	28.594
Liquid limit, %	48.5
Plasticity Index, %	19.906
Saturation, %	87.14

Silt (5–75 μm), %	57.28
Clay <5 μm, %	Clay <5 μm, %
Sand (75 μm—2 mm), %	0.02

Rice husk ash (RHA)

The experimental bricks incorporated high-purity rice husk ash (RHA) containing 91.10% silica, procured from Make Integrated Technology Co., Ltd., Osaka, Japan. The RHA was synthesized through controlled combustion in a computer-regulated ash production system, maintained at 650–

700°C for 27 hours. Comprehensive characterization of its physicochemical properties is detailed in Table 2 [8, 17, 18].

Table 2 Properties of RHA

Property	Value
Average Particle Size, mm	0.001 to 0.3
Loss of Ignition, %	4–6
Specific Gravity, g/cm^3	2.12
Burning Temperature, °C	650–700
Burning time, hours	27
Silica (SiO_2), %	91.10
Carbon dioxide (CO_2) %	4.35

Sample Preparation

Mixing

Eight different formulations of the mix design were created using expansive soil as the base material, with varying amounts of ordinary Portland cement (OPC) and rice husk ash (RHA) to develop sustainable brick composites. According to Table 4, the control sample consisted of soil and 30% water. To investigate the impact of 5% RHA on workability and performance, a mix with 33% water was prepared.

Fig 3 Brick sample preparation

Cement was added at 8%, 10%, and 12%, and the water content was adjusted accordingly (32%–33%). Additionally, ternary mixes containing 5% RHA combined with varying cement contents were developed, requiring water contents of up to 36% to ensure adequate workability.

Water addition

Approximately the same type of mud was prepared by adding different percentages of its total weight of water to soil, RHA, and cement to make the sample bricks, as shown in Table 4.

Table 4 Mix proportions

Index	Material types (% by weight)			
	Soil, %	RHA, %	Cement, %	Water, %
Control	100	0	0	30
S5RHA0C	100	5	0	33
S0RHA8C	100	0	8	32
S0RHA10C	100	0	10	32.5
S0RHA12C	100	0	12	33
S5RHA8C	100	5	8	34
S5RHA10C	100	5	10	35
S5RHA12C	100	5	12	36

Molding

Following regular manufacturing procedures, the freshly prepared material was poured into brick molds and compressed using mechanical or manual pressing techniques to achieve optimal densification and structural integrity. The brick specimens were made using molds measuring 160 mm in length, 40 mm in width, and 40 mm in height.

Curing

After 24 hours of casting, the experimental brick specimens were demolded and then subjected to a 28-day curing process at a controlled temperature of 24±2 °C inside a curing chamber to ensure proper hydration.

Testing method

Bulk Density

The density of the brick specimens was evaluated following the procedures outlined in ASTM C67/C67M [19] or an equivalent standardized methodology. The bulk density was subsequently calculated using Equation 1, ensuring consistency with established analytical frameworks for masonry materials.

$$\rho = \frac{m}{v} \quad (1)$$

Where,
ρ = bulk density
m = mass
v = volume

Water Absorption Test

The evaluation of water absorption properties for the brick specimens was conducted by the standardized methodology prescribed in JIS R 1250:2011, which specifies the fundamental procedure for water absorption testing. The oven-absorption percentage was subsequently computed using Equation 2, ensuring methodological consistency and accuracy. dried mass (M_1) and the saturated mass (M_{1A}) of each sample were precisely measured, and the water

$$a = \frac{M_{1A} - M_1}{M_1} \times 100 \quad (2)$$

Where,
a = water absorption (%)
M_1 = dry weight of bricks (g)
M_{1A} = saturated weight of bricks (g)

Compressive Strength Test

The compressive strength assessment of the brick specimens was performed utilizing a universal testing machine, adhering to the guidelines specified in JIS R 1250:2011 or an equivalent standardized test protocol. The peak load sustained by each sample during the test was meticulously recorded, and the corresponding compressive strength values were derived using Equation 3, ensuring alignment with established mechanical evaluation criteria.

$$C = \frac{w}{a}\ \text{N/mm}^2 = \frac{w}{a} \times 1000\ \text{MPa} \quad (3)$$

Where,
c = compressive strength
w = maximum load
a = initial cross-sectional surface area

RESULTS AND DISCUSSION

The brick specimens were principally composed of rice husk ash (RHA), soil, and cement, with their mechanical and physical attributes comprehensively characterized employing the previously described standardized methodologies. The study further encompassed a thorough evaluation of the bricks' performance within sustainable construction frameworks to substantiate the structural integrity, consistency, and applicability of the fabricated eco-friendly masonry materials.

Bulk Density

Previous research has shown that the density of compressed stabilized clay bricks is between 1500–2000 kg/m³ [14, 20], but this study found values ranging from 1289.55 kg/m³ to 1561.03 kg/m³. According to Figure 4, the control sample exhibits the highest density, consisting of unrefined soil, due to its compact granular matrix and the absence of vacuum-induced additions. As a result of the gradual incorporation of RHA, especially in soils containing

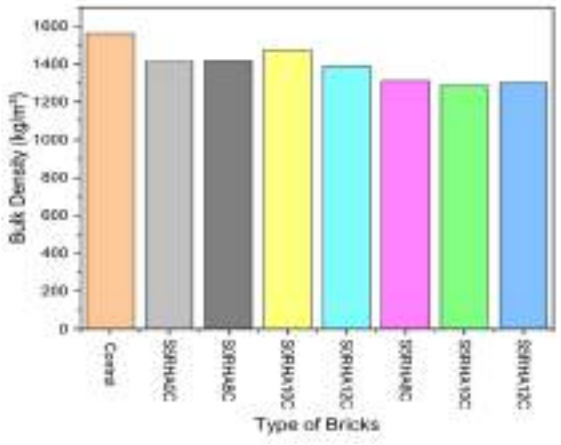

Fig 4 Bulk density of the Brick samples

5% RHA, 10% cement and 5% RHA, and 12% cement, the bulk density is significantly reduced, which is mainly due to the low specific gravity, high porosity, and cellular morphology of RHA particles. These properties reduce the particle packing efficiency and increase the inter-aggregate vacuum ratio, thereby reducing the mass of the composite per unit volume. Density is not only a function of material mass but also reflects the degree of interparticle interaction and matrix continuity. In mixtures such as 5% RHA with 12% cement display 1301.99 kg/m³, the presence of sufficient cement content compensates for the low density by facilitating extensive hydration reactions and pozzolanic activity, resulting in the formation of C-S-H gel that binds soil and ash particles into a dense, mechanically elastic microstructure despite the light nature of RHA.

Water Absorption

In this study, the control sample and the S5RHA0C sample, both prepared without cement, disintegrated during the water absorption test; therefore, their results are not presented in figure 5. According to figure 5, the water absorption value for soil–RHA–cement composites was found to be 30.55% to 36.44%, whereas in a previous study, this value was found to be 5.15% to 23% [14, 20]. In this study, the highest absorption was observed in a mixture of 5% RHA and 8% cement. The cause is insufficient cementitious matrix, resulting in incomplete hydration, limited pozzolanic reactivity, and a poorly integrated microstructure characterized by high capillary pores and interconnected voids.

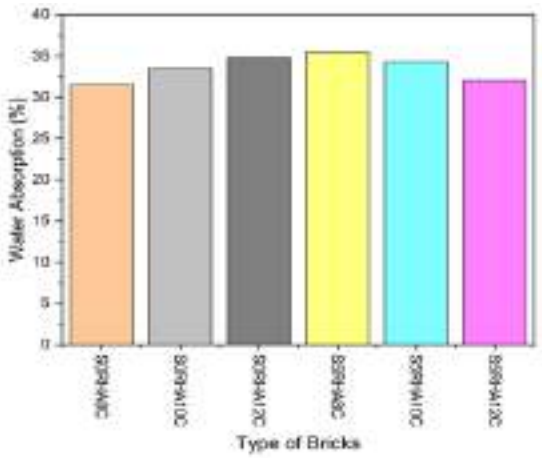

Fig 5 Water Absorption of the brick samples

Essentially, the porous nature of RHA, its high internal surface area, and irregular morphology further increase water uptake when not adequately enclosed within a cohesive matrix. On the other hand, a mixture of 5% RHA and 12% cement recorded the lowest absorption (30.65%). Here, the higher cement content has increased the matrix density and reduced the capillary pores, thereby limiting water entry.

Compressive strength

According to Figure 6, among the samples tested, the highest value (2.83 MPa) was achieved by the soil mixture containing 5% RHA and 12% cement. It is the result of a synergistic enhancement of the binding phase through concurrent cement hydration and secondary pozzolanic reaction. After hydration, cement releases calcium hydroxide (CH), which subsequently reacts with amorphous silica present in RHA to form calcium silicate hydrate (C-S-H) gel, a key component of matrix density and load-bearing capacity. This has produced compressive strength suitable for grade C non-load-bearing bricks. This reaction not only consumes CH, reduces porosity, and increases long-term stability, but also promotes the refinement of pore size distribution and the development of a more continuous cementitious phase.

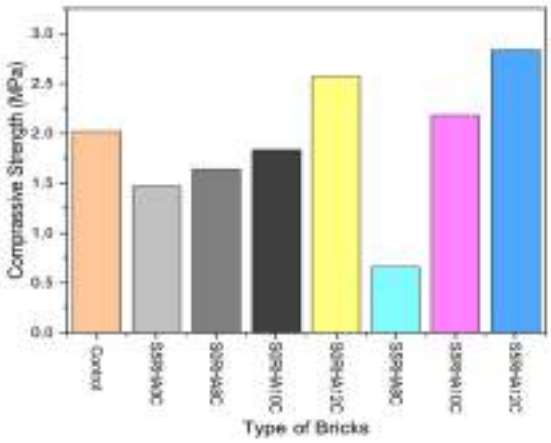

Fig.6 Compressive strength of the brick samples

On the other hand, the control sample reached 2.02 MPa, where a porous and isolated microstructure was formed, as the capillary bond was not strong due to the lack of a reactive binder. In addition, only 1.47 MPa was found in the 5% RHA mixture without any cement. The reason is simply the lack of self-cementing properties in RHA and the inactivation of RHA in the absence of sufficient calcium sources in the soil. However, mixing 5% RHA with 8% cement resulted in a strength of 0.66 MPa, indicating incomplete hydration, limited C-S-H formation, and a clear reduction in the formation of strongly bonded structures.

CONCLUSION

This study confirmed the technical and environmental effectiveness of non-fuel green bricks by using rice husk ash (RHA) as a partial substitute for soil. The optimum mixture, made of soil, 5% RHA, and 12% cement, achieved a compressive strength of 2.83 MPa, a density of 1301.99 kg/m³, and a water absorption of 30.65%. These characteristics meet the requirements of grade C bricks suitable for non-load-bearing masonry, which conform to the criteria of recent research in the field. It is the consolidation of RHA, one of the agro-industrial byproducts, reducing reliance on energy-intensive materials and advancing the goals of the circular economy. The pozzolanic combination between RHA and cement increases mechanical performance and reduces the carbon footprint of brick production. These results are consistent with contemporary literature that emphasizes the potential of waste-based technologies to transform the construction sector towards greater sustainability. Future research should explore long-term

sustainability, life cycle assessment, and scalability in different environmental contexts, as well as the integration of additional waste streams to further improve the sustainability profile of green bricks.

APPLICATION OF SEASHELL POWDER ISOLATELY AND COMBINED WITH RICE HUSK ASH IN CONCRETE AS CEMENT REPLACEMENT MATERIALS

Md Soybur Rahman[1], Zakaria Hossain[2]
[1,2]Graduate School of Bioresources, Mie University, Japan

ABSTRACT

The growing demand for sustainable construction materials has stimulated significant research efforts to develop alternative binders that can effectively reduce cement usage. This study examined the effects of seashell powder (SSP), alone and in combination with rice husk ash (RHA), as partial replacements for cement in concrete. Three types of concrete mixtures were prepared: 100% cement (control), 80% cement + 20% SSP, and 80% cement + 15% SSP + 5% RHA, to evaluate their fresh and hardened properties. Experimental results revealed that incorporating SSP alone had a negligible effect on the workability of fresh concrete. However, the combination of SSP and RHA led to a pronounced reduction in workability. In terms of mechanical performance, replacing 20% of cement with SSP alone resulted in a reduction in compressive strength. Conversely, the combination of SSP and RHA (15% SSP + 5% RHA) demonstrated a significant improvement in compressive strength compared to the control mixture, highlighting the beneficial synergistic effects among Cement, SSP, and RHA. Additionally, concrete containing both SSP and RHA displayed increased brittleness but fewer visible cracks under compression, indicating improved structural integrity. This finding offers the potential of the combined use of SSP and RHA as a partial cement substitute, promoting waste valorization and environmentally friendly concrete production.

Keywords: Rice Husk Ash, Seashell powder, Synergistic Effect, Eco-friendly Concrete

INTRODUCTION

Concrete is a widely used construction material, but it contributes to environmental pollution due to the high CO_2 emissions associated with cement production [1,2]. On average, the production of one ton of cement results in approximately one ton of carbon dioxide emissions. In recent years, the use of supplementary cementitious materials (SCMs) has gained significant attention and has become a common practice in the concrete industry, owing to their beneficial effects on both performance and sustainability [3]. Utilizing industrial and agricultural wastes as partial substitutes for cement has shown promise as an environmentally friendly approach, while also enhancing the stability and durability of construction materials [4].

Shell husk is annually generated as a byproduct of shellfish processing in Japan. According to the Japanese Ministry of Agriculture, Forestry and Fisheries, approximately 151,000 tons of shell husk are discarded each year. This substantial quantity is typically disposed of without any commercial use, leading to environmental pollution and associated ecological concerns. In an effort to address these issues, the potential application of waste shell husk in concrete construction has been extensively explored as a sustainable and eco-friendly solution. [5]. The seashell waste at Shiratsuka Port, Mie, Japan, is shown in fig. 1.

Rice husk is another agricultural residue that, when incinerated, produces ash with pozzolanic properties, making it suitable for use as a cement replacement material [6]. Replacing cement with Rice Husk Ash (RHA) in structural concrete is an effective option that balances cost efficiency and strength performance, while also offering environmental advantages by reducing waste disposal issues, even without additional processing [7].

Fig.1 Seashell waste at Shiratsuka Port, Mie, Japan

Although previous research has studied RHA and SSP individually as supplementary cementitious materials in concrete, their combined use remains unexplored. This study investigated the combined effect of both materials on concrete's fresh and hardened properties.

RESEARCH SIGNIFICANCE

This study addresses the need for sustainable construction by investigating the combined use of Rice Husk Ash (RHA) and Seashell Powder (SSP) as partial replacements for cement in concrete. Both materials are agricultural and marine wastes that are often discarded, causing environmental issues. Using RHA and SSP reduces cement consumption, lowers CO_2 emissions, and promotes waste recycling. Their combination offers enhanced strength and durability due to the pozzolanic properties of RHA and the calcium content of SSP. This research supports the development of eco-friendly, greener construction practices.

MATERIALS AND METHODS

The raw materials used in the concrete mixture include cement, fine aggregate, coarse aggregate, rice husk ash, seashell powder, and water.

Cement

Ordinary Portland Cement (OPC) was used in the experiment, which was purchased from the local market (Fig. 2).

Fig.2 Ordinary Portland Cement

Rice Husk Ash (RHA)

The rice husk ash production process was operated in a factory building of the Make Integrated Technology (M.I.T.) company in Osaka, Japan, using an industrial machine device. Unlike traditional incinerators, this machine operates as a natural-type silica generator, eliminating the need for combustible materials such as gas, kerosene, or electricity. Instead, solid methanol fuel is used to ignite and burn the rice husks. This innovative process is environmentally friendly, as it does not produce dioxins, making it exempt from the Fire Services Act. The burning speed and temperature are meticulously controlled by a computer, reducing labor costs and minimizing personnel requirements. Additionally, the system can be remotely controlled, offering further convenience in managing the incineration process. Fig. 1 shows the raw rice husk ash.

Fig.3 Rice Husk Ash

Seashell powder

This seashell powder is provided by Make Integrated Technology (M.I.T.), a company based in Osaka, Japan. The process involves collecting seashells, drying them, and then crushing them into powder. Finally, the powder is subjected to a burning process at 900°C. Fig. 4 shows the raw Seashell powder.

Table 1: Mix design of Concrete

Specimen Identity	Cement (%)	Seashell Powder (%)	Rice Husk Ash (%)	W/C ratio	Cement (kg/m^3)	Fine Aggregate (kg/m^3)	Coarse Aggregate (kg/m^3)
CRS1	100	0	0	0.55	290	308	852
CRS2	80	20	0	0.55	232	308	852
CRS3	80	15	5	0.55	232	308	852

Fig.5 Experimental work of this study

Aggregates

River sand was used as fine aggregate, and gravel was used as coarse aggregate, as shown in fig. 6. The maximum size of coarse aggregate was 19 mm. Both were purchased at a home center in Tsu City, Japan.

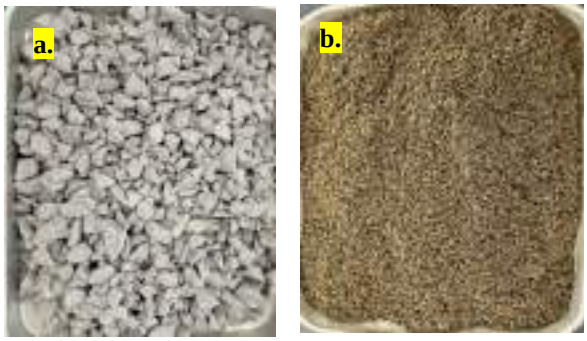

Fig.6 Coarse aggregate (a) and Fine aggregate (b)

Mixture Proportioning and Testing program

After accurately weighing the raw materials, the concrete mixture was prepared using a mix ratio of 1:1:3 by weight for cement, fine aggregate (sand), and coarse aggregate (gravel). Seashell powder was added to the concrete mix individually and combined with rice husk ash, replacing cement 20% by weight. The water-to-binder ratio was maintained at 0.55 throughout the all mixing process. The specific quantities of each material are provided in Table 1. The experimental work is presented in fig. 5.

Following proper mixing, a slump test was conducted to evaluate the workability of the concrete. The slump cone used in the test has a standard dimensions: 300 mm in height, a base diameter of 200 mm, and a top opening of 100 mm. The cone was placed on a smooth, level surface and filled with concrete in three equal layers. Each layer was compacted by rodding 25 times using a tamping rod with a diameter of 16 mm. After filling, the top surface was leveled, and the mold was lifted vertically. The slump was measured using the rod, and the vertical settlement of the concrete (in the shape of a frustum) was recorded as the slump value.

Subsequently, the concrete was cast into cylindrical molds with dimensions of 50 mm in diameter and 100 mm in height. The specimens were then cured in water at room temperature for 28 days. After curing, the weight and volume of each specimen were measured to calculate the unit weight.

Finally, compressive strength testing was conducted after 28 days of curing using a Universal Testing Machine (Fig. 7) in accordance with ASTM C39 standards. Three cylindrical specimens were tested for each mix condition to ensure the accuracy and reproducibility of results.

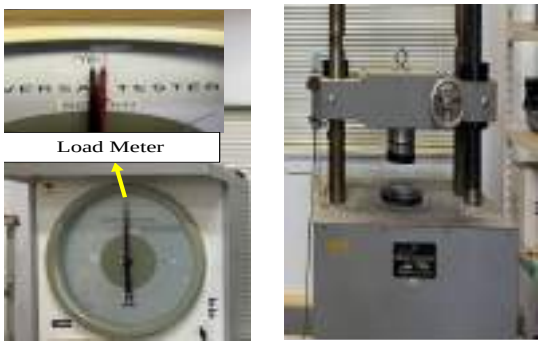

Fig.7 Universal Testing Machine

RESULTS AND DISCUSSIONS

The experimental result, comparative analysis, and practical application have been explained below.

Workability

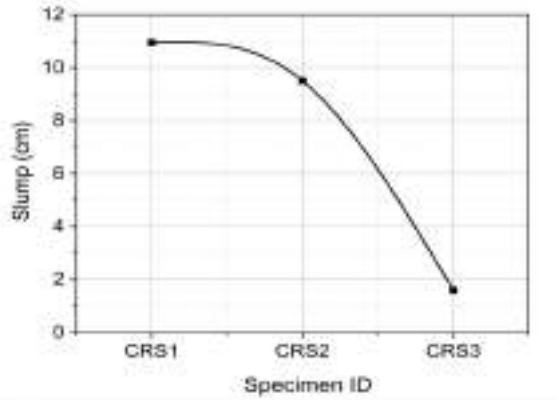

Fig.8 Workability of concrete mixture

The slump values of the OPC concrete and the modified concrete mixes are presented in Fig. 8. Among them, CRS1 exhibited the highest slump, approximately 11 cm, indicating high workability. CRS2 demonstrated a moderate slump of around 9 cm, while CRS3 showed a significant decrease to 1.6 cm, reflecting a very stiff mix with low workability. Possible reasons for the slump reduction may be the incorporation of mineral admixtures, Rice Husk Ash, and Seashell powder. Overall, the results indicate that the combined application of RHA and SSP notably improved the viscous nature of concrete and created the demand for superplasticizer to maintain proper flowability. The results aligned with previous studies, which reported that high specific surface area and irregular particles of RHA and SSP absorbed water and reduced the workability of the concrete mixture [7,8].

Unit Weight

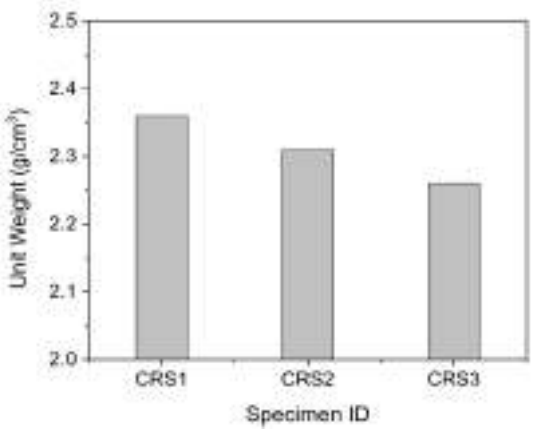

Fig.9 Unit weight of concrete

Figure 9 presents the unit weight of the three different specimens, CRS1, CRS2, and CRS3, which indicates a clear decreasing trend from CRS1 to CRS3. CRS1 exhibited the highest unit weight at 2.36 g/cm³, followed by a slight decrease in CRS2 at 2.31 g/cm³, and CRS3 showed the lowest unit weight at 2.26 g/cm³. The incorporation of seashell powder as a cement replacement material has no significant effect on the unit weight of concrete [9]. In this study, a 20% replacement of cement by seashell powder showed a slight reduction in the unit of concrete. This may have occurred due to different types of seashells and the burning temperature. But with the combined application of SSP and RHA (15% and 5%, respectively), the unit weight notably decreased. An increase in RHA content leads to a decrease in the unit weight of concrete, owing to the lower density of RHA compared to cement [10].

Compressive Strength

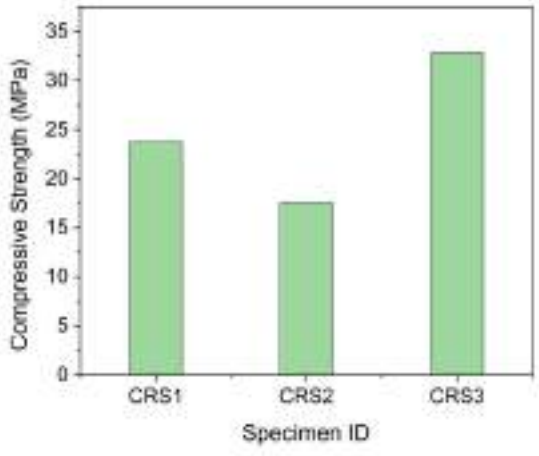

Fig.10 Compressive strength of concrete

The compressive strength of concrete is a vital mechanical characteristic that indicates its capacity to resist axial loads without failing. Figure 10 presents the compressive strength results of three concrete specimens, labeled CRS1, CRS2, and CRS3, tested under standardized conditions. Among the tested specimens, CRS3 exhibited the highest compressive strength, achieving 32.81 MPa, which represents a 38% increase compared to the control specimen. This result highlights its superior structural performance. In contrast, CRS2 demonstrated a significant reduction in compressive strength relative to the control mix, indicating that the isolated use of seashell powder as a partial cement replacement may be unsuitable. Previous studies have reported that substituting up to 5% of cement with seashell powder can enhance compressive strength [9]. However, the combined use of seashell powder and rice husk ash (RHA) appeared to offer a promising alternative for cement replacement, significantly improving the compressive strength in this study. This improvement

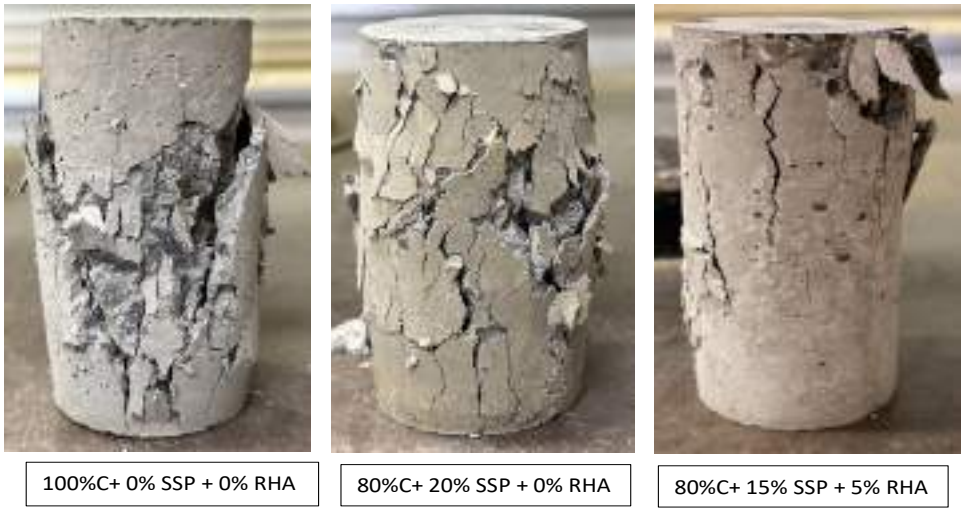

Fig.12 Failure pattern of experimental specimen

is likely attributed to the pozzolanic reaction between the amorphous silica in RHA and the calcium hydroxide ($Ca(OH)_2$), produced during cement hydration and reaction of seashell powder with water, thereby enhancing the concrete's strength.

Stress-strain relationship

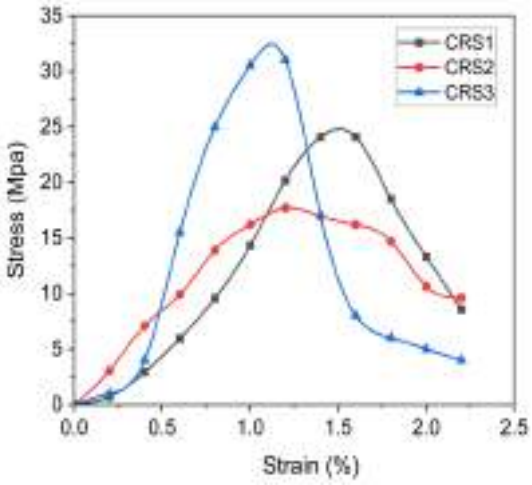

Fig.11 Stress-strain relationship of concrete under uniaxial compression test

The stress–strain behavior of the three types of specimens, CRS1, CRS2, and CRS3, revealed significant differences in their mechanical performance, as shown in fig.11. CRS1 exhibited a maximum stress of approximately 23 MPa and a failure strain of about 2.1%. CRS3 demonstrated the highest maximum stress, around 32 MPa, indicating superior strength; however, it failed at a strain of approximately 1.2%, reflecting brittle behavior with limited deformability. In contrast, CRS2 showed the lowest maximum stress, approximately 17 MPa, but its failure strain was nearly identical to that of CRS1, indicating a more ductile nature capable of accommodating greater deformation before failure. These results imply that CRS3 may be suitable for applications requiring high strength with less concern for deformation, while CRS2 could be advantageous in scenarios demanding greater flexibility and energy absorption. CRS1, with its intermediate properties, may serve as a versatile option for structures needing both adequate strength and reasonable ductility.

Failure Mode of Testing Specimen

The visual inspection of the concrete specimens after compression testing revealed noticeable differences in failure patterns based on the varying mixing combination, as shown in fig.12. The control specimen containing 100% cement (0% SSP and 0% RHA) exhibited significant fracture, characterized by deep vertical cracks. In contrast, the specimen with 80% cement and 20% SSP showed a slightly less severe cracking pattern. Notably, the third specimen, composed of 80% cement, 15% SSP, and 5% RHA, showed the least visible damage among the three. The cracks were finer, and there was minimal surface spalling, indicating improved integrity. This suggests that the addition of RHA and SSP contributed positively to the mix, likely due to synergistic effects that enhanced microstructural bonding and reduced porosity. The inclusion of both SSP and RHA appeared to improve crack resistance of the concrete, offering a promising approach for sustainable material substitution without severely compromising mechanical performance.

CONCLUSIONS

This study concludes the following points-

1. The incorporation of Rice Husk Ash (RHA) and Seashell powder significantly reduced the flowability of the concrete mixture.
2. While the use of Seashell powder alone had little effect on the unit weight of concrete, the addition of RHA led to a noticeable reduction in unit weight.
3. Replacing 20% of cement with Seashell powder reduced the compressive strength compared to the control mix. However, a combination of 15% Seashell powder and 5% RHA significantly enhanced the compressive strength.
4. Although the ultimate stress improved with the combined use of Seashell powder and RHA, the modified concrete exhibited a more brittle behavior compared to the control.
5. The Ash-powder-modified specimens exhibited fewer cracks under compression, suggesting improved structural integrity.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the Ministry of Education, Culture, Sports, Science and Technology (MEXT), Japan, and Mie University for their generous support and for providing the opportunity to undertake this doctoral research. The authors also extend their sincere appreciation to M.I.T. Company, Osaka, Japan, for kindly supplying the Rice Husk Ash and Seashell Powder used in the experimental investigations.

ABSTRACT

While chemical admixtures (CAs) have long been utilized in concrete technology to improve workability by enhancing the interaction between cement particles and various concrete constituents, their interaction with SCMs, such as RHS, remains underexplored. This paper presents findings from a comprehensive experimental study aimed at achieving eco-strength efficiency through the incorporation of RHS into concrete. The research also involved the proportioning of fine aggregates at a 70:30 ratio to simulate potential strategies for mitigating global fine aggregate shortages. Similarly, coarse aggregates were proportioned at 55:45 based on particle size (20 mm:15 mm) to achieve a stable concrete matrix. Various percentages of RHS (0%, 5%, 10%, 15%, and 20%) were used as a cement replacement by volume, with a fixed cement content of 292 kg/m³ for the control sample. Polycarboxylate-based water-reducing CA agents, air-entraining and air-reducing admixtures were added according to the desired workability. The results indicated that optimal use of RHS could reduce CO_2 emissions by up to 9.78% during low-carbon concrete production, although it increased the cost per cubic meter by 90.65% to 187.98%, depending on the source and market price of rice husk silica. Moreover, the optimal RHS mix demonstrated increases of up to 21.21% in compressive strength and 40% in flexural strength. Further analysis of RHS concrete samples using Scanning Electron Microscopy (SEM) revealed a pozzolanic reaction mechanism, as evidenced by a highly cemented microstructure. This study underscores the potential of low-carbon concrete in advancing sustainable construction practices by reducing CO_2 emissions while simultaneously promoting the efficient utilization of rice husks as a greener waste management solution.

INTRODUCTION

The critical upcoming challenge in the construction industry and engineering is constructing and restoring infrastructure in an economical, durable, and sustainable manner while reducing the environmental impact. To date, several ventures have been pursued to reduce the environmental impacts of construction materials and the dependency on Portland cement as the sole binder [1]. High Portland cement usage burdens the environment as the cement industry contributes 8% of global CO_2 emissions [2]. One pathway focuses on developing low-carbon cementing binder systems [3] by introducing various types of low-carbon embedded cementitious systems such as using alkali-activated materials (AAMs), as a means of mitigating CO_2 emissions from the construction sector [4]. However, it has been proven that manufacturing conventional AAMs has devastating economic and environmental impacts due to the high energy demands. A good example of these conventional AAMs is sodium silicate activator that generates high CO_2 emissions during the decomposition and calcination of sodium carbonate and silica sand [5]. Despite the high CO_2 emissions from AAMs, previous assessments on AAMs concluded that the greenhouse gas emission of AAM concrete is 32%–64% lower than the one from Portland cement concrete of similar strength [6]. The main source of these AAMs is the abundant supply of Supplementary Cementitious Materials (SCMs) available worldwide.

In the past decade, another pathway has been the increasing research interest in utilizing supplementary cementitious materials (SCMs) derived from agricultural wastes. Among these, rice husk silica, also known as rice husk ash, has garnered significant attention. Rice husk silica, derived from the combustion of rice husks (an agricultural by-product), is well-regarded for its high content of amorphous silica, substantial pore volume, and significant specific surface area when burned under optimal conditions [7]. Consequently, RHS exhibits exceptionally high pozzolanic reactivity, comparable to other supplementary cementitious materials (SCMs) like silica fume, fly ash, and blast furnace slag [8]. Research has demonstrated that RHS is an excellent substitute for many supplementary cementitious materials (SCMs) in terms of portlandite consumption and the compressive strength of high-strength concrete [9]. Its high pozzolanic reactivity not only enhances concrete's durability and mechanical properties but also contributes to sustainable construction practices by utilizing agricultural waste.

Moreover, due to its mesoporous structure, RHS exhibits a significantly higher water absorption capacity compared to other SCMs [10]. This unique characteristic enhances the hydration process and improves the overall performance, leading to more resilient and long-lasting concrete [11]. RHS can absorb free water in RHS-blended Portland cement concrete, thereby improving compressive strength. The water retained in its porous structure facilitates the diffusion of Ca^{2+} ions into the internal parts

of RHS particles, enhancing pozzolanic reactivity and sustaining the hydration of cementitious materials [12].

Nevertheless, due to the high-water demand of rice husk silica, the concrete workability and strength can be compromised if the free water in the system is not kept within the allowable limit [13]. Therefore, it is paramount to investigate the effects of chemical admixtures applied to simultaneously maintain the diffusion and mechanical properties of such concrete [14]. Chemical admixtures (CAs) have been employed in concrete technology for decades to improve the workability of concrete in its fresh state [15]. The interaction of the cement particles with various CAs has been extensively researched, however, there still exists limited research on the interaction of CAs with SCMs such as RHS. Additionally, despite the numerous studies incorporating RHS in concrete in the literature, a comprehensive assessment of the CA's demand, water demand with strength and the principal sustainability aspects in terms of costs involved and the CO_2 emission reduction projections has not yet been solely and exclusively addressed.

Despite extensive research on the properties of rice husk in concrete, there remains a gap in comprehensive studies focusing on optimizing and evaluating the performance related to chemical admixture requirements, water-to-cement ratio (w/c), water-to-cement plus rice husk silica ratio (w/b), and the potential self-healing abilities of these cementitious materials. Furthermore, to date, the rice husk silica production practices emit a lot of CO_2 into the environment due to uncontrolled burning and the use of conventional ovens. To address this challenge, the rice husk silica utilized in this study was generated in a novel zero CO_2 emission environment, producing high-quality RHS with a significant amorphous silica content, ensuring superior pozzolanic reactions compared to the conventional burning methods, which are less environmentally friendly.

The experimental framework strictly adhered to Japan Industrial Standards (JIS A 1132:2020 and JIS A 1138:2020 for concrete preparation; JIS A 1108:2006 and JIS A 1106:2018 for compressive and flexural strength assessments). In addition, scanning electron microscopy (SEM) was employed to elucidate the microstructural features that underpinned the material's performance. This standard-based approach ensured a robust evaluation, providing a reliable benchmark for high-strength, low-carbon concrete applications in civil, geotechnical, and geo-environmental engineering.

RESEARCH SIGNIFICANCE

The main challenge when working with SCMs like rice husk silica is the increase in the w/c ratio to offset the losses in workability caused by the porous morphology and water absorption of RHS compared to cement. SPs are a natural solution to offset both these detrimental effects. However, experimental data on SPs sourced from concrete publications also strongly suggest that PCE SPs lose their effectiveness on the fresh-state properties of concrete with increasing incorporation ratios. Additionally, when working with SCMs, it is crucial to understand the interactions with PCE SPs, w/c and w/b ratios in terms of dosage, strength evolution and usage limits to validate the potential impacts they may have in concrete manufacture. This study addresses these challenges and research gaps by investigating the effect of a PCE SP and the w/c/w/b ratios on various rice husk silica compositions based on the cement reduction rate. The goals are to (i) Evaluate the PCE SP efficiency on several RHS compositions by comparing the mechanical properties of different compositions with varying cement replacement ratios. (ii)

To benchmark the optimum RHS content, w/b and PCE SP dosages based on the desired fresh state and ultimate strength. (iii) Assess whether the optimum RHS composition at different w/b ratios affects the efficiency of PCE SP. Because of the increased popularity of RHS, it is crucial to provide a detailed database that will make this abundant material a more reliable construction material compared to conventional materials that have high carbon footprints. Also, because of the increased popularity of PCE SP and since it has been consistently reported that it is more efficient in concrete mixes than lignosulfate-based SP, this investigation includes the use of polycarboxylic-based SP only. The dosage of PCE SP was fixed at the cement percentage (by weight), depending on the optimum value added to achieve the initial set fresh state properties for each RHS combination.

MATERIALS

Rice Husk Silica - Production and Properties

Make Integrated Technology (M.I.T) Corporation, based in Osaka, Japan, provided a controlled-burned rice husk ash (RHS - Light Grey) with a high silica content of 91.10%, achieved at temperatures between 650-700°C. This plant-based RHA was derived from domestic rice husks using the Ethical Star ash production machine shown in Figure 1. From 800-1000 kg of dry rice husks, approximately 15-20% of high-purity amorphous silica is produced. The production process involves igniting a small amount of methanol solid fuel as a pilot fire in the rice husk holding chambers, leading to self-combustion.

Figure 1 Flow diagram illustrating the Rice husk ash production process.

This method certifies the RHS as an organic Japanese Agricultural Standards (JAS) material. Combustion is then controlled by an advanced monitoring system for 27 hours, with the operating status monitored remotely, ensuring the production of high-purity silica. After combustion, the RHA is removed from the chamber and allowed to cool naturally at room temperature.

Figure 2b presents a detailed grain size analysis of rice husk silica (RHS), indicating that the rice husk silica (RHS) exhibited grain sizes ranging from 0.00129 to 0.3 mm. The RHS was subjected to X-ray powder diffraction (XRD) analysis, which quantitatively determined the chemical composition of the materials, as shown in Figure 2c. The XRD analysis confirmed the amorphous nature of RHS, characterized by a broad hump around $2\theta = 21°$, which is typical of amorphous silica. Table 1 provides a comprehensive chart detailing the chemical properties of rice husk ash.

Ordinary Portland Cement

In this concrete research, PC-43 grade Ordinary Portland Cement (OPC) was utilized, which is known for its balanced strength and workability. This cement conforms to the Japanese Industrial Standards (JIS) for cement, specifically JIS R 5210, ensuring it meets the stringent quality and performance criteria required for construction applications in Japan. The cement had a composition of alite (Ca_3SiO_5), a major chemical component in OPC that defines its high strength, as shown in the X-ray powder diffraction (XRD) analysis results in Figure 2c. A detailed particle size analysis of OPC and chemical properties is shown in Figure 2b and Table 1, respectively.

Aggregates

The present research work has been carried out by rationing the fine aggregates by 70% crushed rock to 30% river sand due to the limited supply of fine aggregates in Japan, as the natural resource has been in a declining trend recently [16]. The coarse aggregates used in this study combined 55% 20mm particle size and 45% 15mm particle size, ensuring a well-graded mix that enhances the concrete's strength and durability. Additionally, as implemented in this research, the precise grading of coarse aggregates was crucial for achieving the desired workability and compressive strength in concrete mixes [17]. Figures 2a and 2b show the pictorial representations and the particle size distribution graphs for the raw materials and, respectively.

Chemical admixtures

Superplasticizers (SP)

In this study, a polycarboxylate ether (PCE) superplasticizer (SP) was incorporated into the concretes to decrease the amount of mixing water required when RHS is added and to enhance their workability. PCE is a modern generation SP developed in the 1990s, featuring a comb-like molecular structure, comprising a main chain with carboxylic acid groups and side chains of polyethylene oxide (PEO) units [18]. The carboxylic acid groups provide electrostatic repulsion, while the PEO units create steric hindrance. This combination of electrostatic repulsion and steric hindrance enhances the dispersion of cement and RHS particles, resulting in improved flowability and reduced water content in the concrete [19]. In its liquid form, PCE had a density of 1050 kg/m³ and contains 20% active ingredient in an aqueous solution.

Air entraining admixture (AE)

Air-entraining admixtures are substances added to concrete to create a system of microscopic air bubbles within the mix. These bubbles significantly enhance the concrete's durability, especially in freeze-thaw conditions, by providing space for water to expand when it freezes, thus preventing cracking [20]. This study used an air-entraining admixture based on vinsol resin, an admixture commonly used by ready-mix concrete producers in Japan.

Air reducing admixture (AR)

Air Air-reducing admixtures (AR) are employed in concrete to decrease the amount of entrained air in the mix. These admixtures are especially beneficial when high-density concrete is needed, as they help lower air content, which can otherwise reduce the concrete's strength. ARs contain potent defoaming agents that counteract air in the concrete mix, including air introduced by modern superplasticizers and SCMs.

METHODOLOGIES

Low-Carbon Concrete (RHS-Modified) Sample Preparation and Mix Design

Fine and coarse aggregates were prepared a few days in advance to ensure strict moisture adjustment, which was essential for the workability of the concrete and allowed for better control during mixing. The consistency of the particle sizes was also checked to achieve a consistent mix, which was vital for the strength and durability of the concrete. To obtain the uniform distribution of the PCE SP in the concrete, the water reducer was first mixed with water and stirred. (NOTE: The water part of the PCE was included in the PCE weight and neglected in the definition of the w/c and w/b ratios for all combinations.) At the same time, the fine aggregates, cement and RHS were added into the concrete mixer and mixed according to the mixer operation time specifications. This was followed by adding the coarse aggregates and mixing to a consistent concrete mix based on the timings stipulated in the mixture manual, together with a physical examination.

The mixing and sample preparation followed the guidelines set by Japan Industrial Standards (JIS) JIS A 1132:2020 and JIS A 1138:2020. From the concrete mixer, the LCC concrete was tested for fresh properties, including slump, air content and temperature before sample preparation. Finally, the fresh LCC concrete was cast into the cylindrical molds (100 mm in diameter and 200 mm in height) for the compressive strength test and 100mm by 100 mm by 400mm molds for flexural strength tests for each concrete mix proportion. After 24 h, the LCC samples were capped, de-moulded, and cured in microbubble water

under a room temperature of 20 °C and relative humidity of 55 ± 5% for another 6 days and 27 days before testing. The design mixing proportions of the concrete are shown in Table 2.

Testing Methods

Fresh concrete properties tests

The slump test was performed to evaluate the workability and consistency of the concrete mix, following the guidelines of JIS A 1101:2020. This test involved filling a slump cone (100 mm: top end, 200 mm: bottom end, 300 mm: height and thickness: at least 5 mm) with concrete, lifting the cone, and measuring the resulting subsidence. The air content test was conducted using the pressure method as specified in JIS A 1128:2019 to determine the volume of entrapped air, which is vital for evaluating the concrete's durability. Additionally, the temperature of the concrete was measured immediately after mixing with a calibrated thermometer to confirm it fell within the optimal range for curing and performance. These tests provided critical information on the concrete's fresh state characteristics, ensuring compliance with the standards for its intended use.

Compressive strength test

The compressive strengths of the samples were measured at 7 and 28. According to JIS A 1108:2018, three cylindrical specimens (100 mm diameter x 200 mm height) for each concrete mix design were loaded using a universal testing machine (load application rate: 0.6±0.4 N/mm^2 per second) on each test day, and the average of the three results was used to determine the ultimate compressive strength.

Flexural strength test

The flexural strength test was carried out on concrete beams with dimensions of 100 × 100 × 400 mm, as indicated by JIS A 1106:2018. The testing was carried out after 28 days of curing. Three beams were tested for every mix design and the average of the three results was used to determine the ultimate flexural strength.

Microstructural analysis test

Microstructure analyses of concrete specimens were done by scanning electron microscope (JCM-7000 Benchtop Scanning Electron Microscope). The primary focus of the SEM imagery was to assess the concrete's microstructure, specifically examining the development of pores, the formation and propagation of cracks, and the characteristics of the cemented matrix. Such features are critical indicators of the material's durability and performance over time. Representative concrete samples were carefully prepared by mounting them onto brass stubs using carbon tape to ensure secure placement. The samples were then gold-coated to enhance electron conductivity, allowing for high-resolution imaging. The resulting SEM images provided a detailed view of the concrete's internal structure, revealing not only the size and distribution of pores and cracks but also the overall integrity of the cemented matrix.

RESULTS AND DISCUSSIONS

Fresh Concrete Properties and Admixture Relationship

To achieve a target slump ranging between 11.5 cm and 13.5 cm (averaging 12 cm), with water-to-cement (w/c) and water-to-binder (w/b) ratios maintained at 60%, and the air content of concrete expected to lie between 4% and 4.6%, the amounts of chemical admixtures were adjusted as shown in Figure 3a. It was observed that the Polycarboxylate Ether Superplasticizer (PCE SP) content increased with the increase in RHS content as this was necessary to maintain the slump, w/c, w/b, and air content within the desired range. From Figure 3a, it was evident that to achieve the same workability and keep the PCE SP dosage within a feasible and applicable range, the optimal rice husk silica dosage lied between 10% and 15%. This range was also supported by the corresponding strength values discussed in the next sections. On the other hand, air-entraining admixtures were kept almost constant, with a slight increase observed for 15% and 20% rice husk silica contents to help maintain the desired air content in the concrete mix, which is crucial for durability.

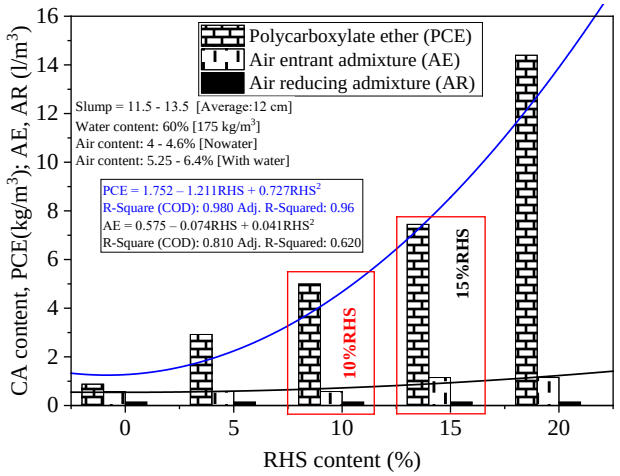

Figure 3a Relationship between the chemical admixture demand with RHS dosage.

In Figure 3b, based on the control w/c and w/b ratios, the slump value was maintained at an average of 12 cm. However, at 20% (LCC_RHS20$_{175}$) rice husk silica, the slump value was slightly higher. This increased flowability at higher rice husk silica content can be explained by the fact that rice husk silica demands more superplasticiser to disperse the particles effectively and maintain workability

[21]. Additionally, the concrete temperature increased slightly with increasing rice husk silica content due to the exothermic reactions associated with the hydration of cement and the pozzolanic reaction process from the interaction between the rice husk silica and the cementitious materials.

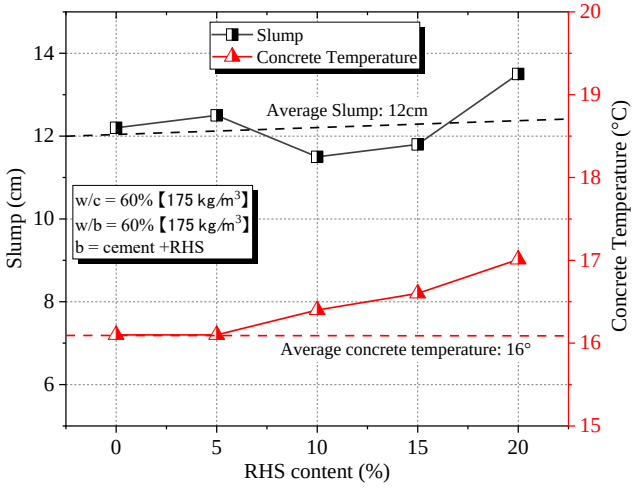

Figure 3b Variation in workability with RSH dosage.

The presence of rice husk silica accelerated the hydration process, leading to a higher release of heat [22]. This phenomenon is consistent with findings from other studies where mineral admixtures like silica fume and fly ash have been shown to influence the heat of hydration in concrete [23].

Compressive Strength

The results in this section showed how varying levels of RHS as a partial cement replacement influenced the compressive strength with reference to the PCE SP dosage required for equal workability in the concrete mixes. The PCE SP trend (0.88 kg/m³ for 0% RHS, 2.92 kg/m³ for 5% RHS, 4.99 kg/m³ for 10% RHS, 7.45 kg/m³ for 15% RHS, and 18.40 kg/m³ for 20% RHS - Figure 3a), indicated that higher RHS contents demanded more PCE SP to maintain workable consistency, as RHS particles increase the mix's surface area and internal porosity, raising water demand for flowability. By using PCE SP instead of additional water, the mix maintained its desired workability without compromising the concrete's compressive strength due to dilution.

The compressive strength results presented in Figure 4 aligned with the expected effects of pozzolanic materials. Initial testing at 7 days showed minimal strength variation across samples with 0% (LCC_RHS0_{175}) to 10% RHS (LCC_RHS10_{175}), suggesting that early-stage compressive strength was less affected by RHS up to these levels. This limited difference was likely because RHS, a pozzolan, contributed to strength through slower secondary hydration and pozzolanic reactions, which relied on the gradual availability of calcium hydroxide ($Ca(OH)_2$) from cement hydration [24]. Unlike cement's primary hydration, pozzolanic materials like RHS needed extended curing to participate fully in these strength-enhancing reactions. As RHS content increased to 15% (LCC_RHS15_{175}) and 20% (LCC_RHS20_{175}), the 7-day compressive strength decreased notably, with the reduction attributed to the dilution effect, delayed early production of C-A-S-H and the reduced cement proportion, which is the main compound crucial for initial strength [25]. High pozzolan content also meant that less cementitious material was immediately available for primary hydration, which is necessary for early strength development.

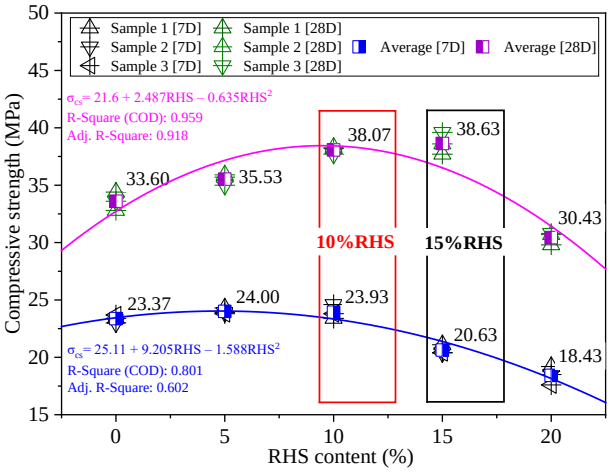

Figure 4 Variations on the compressive strength values with various design formulations and curing periods.

After 28 days, the concrete achieved approximately 99% of its compressive strength across all mix designs, indicating that the pozzolanic activity of RHS had largely matured by this stage. This pattern was in line with typical pozzolanic reactions, which reach substantial completion between 28 and 56 days, contributing to significant compressive strength gains in later curing stages. An optimal RHS replacement level emerged between 10% (LCC_RHS10_{175}) and 15% (LCC_RHS15_{175}), where the pozzolanic reactions contributed enough secondary C-A-S-H formation to enhance compressive strength without overly diluting early hydration kinetics.

At this level, the PCE SP dosage (4.99 kg/m³ at 10% RHS and 7.45 kg/m³ at 15% RHS) balanced workability, promoting better particle dispersion and maintaining mix consistency without compromising strength. Beyond this optimal range, however, at 20% RHS (LCC_RHS20_{175}), compressive strength decreases despite a high PCE SP dosage (18.40 kg/m³) due to insufficient $Ca(OH)_2$ availability for pozzolanic reactions and a lack of cementitious material, leaving unreacted pozzolan particles and creating a weaker matrix. Although the increased PCE SP maintains workability, it cannot compensate for the reduction in reactive materials, ultimately limiting the potential developments in compressive strength.

Moreover, to generalize the findings, curve-fitting equations were derived to model the compressive strength development across different RHS contents, ranging from 0% to 20%. These equations serve as predictive tools for estimating the compressive strength of LCC concrete mixes with varying RHS proportions. The predictive capability of these models allows for accurate extrapolation within the tested range.

Flexural Strength

Figure 5 illustrates the flexural strength of RHS-modified concrete with varying percentages of RHS content as a cement replacement at 28 days. The trend followed a parabolic pattern, where flexural strength initially increases with RHS up to an optimal level of around 10-15% before declining at 20% RHS. Analysis of this trend in light of the PCE SP admixture's role, as previously discussed, showed that the increased PCE SP admixture amounts at higher RHS levels (2.92 kg/m³ for 5% RHS, 4.99 kg/m³ for 10%, and 7.45 kg/m³ for 15%) also aided in enhancing the flexural strength by improving the dispersion of RHS particles within the mix, ensuring better bonding and a more cohesive matrix.

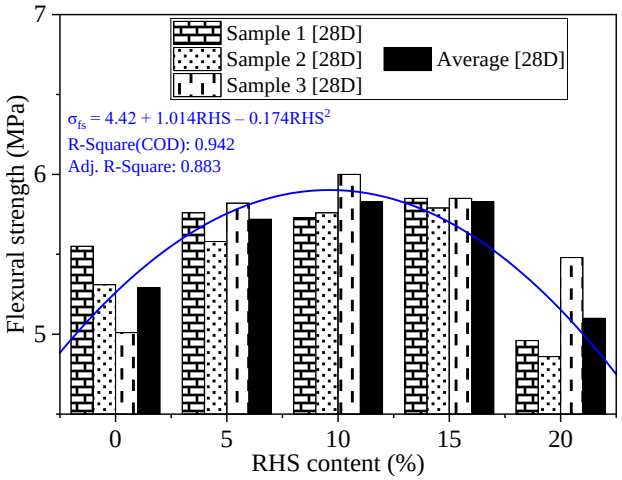

Figure 5 Variations on the flexural strength values with various design formulations and curing periods.

This enhanced dispersion reduced the risk of weak spots and allowed the RHS particles to better engage in pozzolanic reactions, reinforcing the concrete's structure. The peak in flexural strength at approximately 10-15% RHS indicated an optimal balance where RHS content was sufficient, and the PCE SP dosage (around 4.99 to 7.45 kg/m³ at 15%) helped maintain a workable consistency while allowing RHS to contribute positively to the matrix's strength. This dosage appears to be effective in supporting workability and cohesion, facilitating the integration of RHS into the concrete structure without significant trade-offs in early hydration.

The parabolic trend in flexural strength (increasing, peaking, and then decreasing) reflects the combined impact of optimal pozzolanic reaction conditions and the limits of cement replacement. However, at higher replacement levels (20% RHS), the decrease in primary hydration products and the lack of sufficient $Ca(OH)_2$ limit RHS's contribution to strength, resulting in flexural strength reduction despite the increased PCE SP.

Microstructural Evolution of RHS-Modified Concrete

Scanning electron microscopy (SEM) analysis

This study employed Scanning Electron Microscopy (SEM) to investigate the influence of rice husk silica (RHS) on the microstructure of RHS-modified concrete at different replacement levels (0%, 5%, 10%, 15%, and 20%) using three distinct magnifications (×100, ×500, and ×1000) as shown in Figures 6-10.

Observations at these magnifications shed light on changes in pore structure, interfacial transition zones (ITZ) and the concrete matrix density. As the magnification increased, finer details of crack formation, crack filling, and secondary hydration product formation became apparent, providing a comprehensive picture of how RHS affects concrete densification and self-healing potential, as discussed below.

Control concrete (0% RHS)

The SEM images for the 0%RHS-modified concrete microstructure at different magnifications is shown in Figure 6. At the lowest magnification (×100), the control concrete showed a comparatively coarse and porous structure with voids and pores evident and the ITZ between the aggregates and cement paste appearing weak or loosely bonded. This indicated that the control mix lacked the refined microstructure typically associated with pozzolanic additives. At a medium magnification (x500), the presence of pronounced post-hydration crystals became clear, often manifesting as large plate-like or hexagonal formations and occupying spaces where more advanced hydration products, such as C-S-H, could otherwise have developed. At the highest magnification (x1000), microcracks were distinctly observed with minimal signs of crack-filling. The ITZ remained a weak link in the microstructure, indicating limited C-S-H formation around the aggregate surfaces. These observations correlate with minimum strength development in the control sample in this study.

5% RHS-modified concrete

Introducing 5% RHS led to a denser matrix compared to the control, as shown in Figure 7. The overall pore size distribution appeared more uniform, and fewer large voids were evident. Early evidence of refined ITZ was detected, as the transition zones around aggregates seemed slightly more cohesive. At ×500, partial filling of some pores was observed due to the accumulation of pozzolanic compounds (additional C-S-H gel) from pozzolanic reactions between amorphous silica (RHS) and $Ca(OH)_2$ from cement hydration.

Moreover, under higher magnification (x1000), a few pronounced microcracks in the 5% RHS sample were observed in the denser microstructure, suggesting that while the incorporation of RHS effectively enhanced matrix compactness, it also introduced localized tensile stresses. These stresses appeared to promote microcrack initiation at weak interfacial zones, which could serve as potential sites for crack propagation under aggressive loading conditions. Nonetheless, the overall improved densification and bonding between the aggregate and cementitious phases implied that these microcracks remain isolated and do not significantly compromise the structural integrity of the RHS-modified concrete. This observation highlights the need for optimizing the mix design and curing process to balance the benefits of a denser matrix against the potential for micro-level defects.

10% RHS-modified concrete

At this level of replacement, the concrete exhibited a significantly more compact structure as illustrated in Figure 8. Large pores were less frequent, and the ITZ looked denser and more uniform. The overall appearance suggested a well-consolidated matrix, reflecting a marked improvement over both the 0% RHS and the 5% RHS samples. Closer assessment at x500 revealed a more advanced pozzolanic reaction with large $Ca(OH)_2$ crystals mostly replaced or reduced, giving way to extensive C-S-H gel formation. The resulting C-S-H gel contributed to the overall reduction in porosity and enhanced the bonding between aggregates and the RHS-cement paste. At the highest magnification (x1000), fewer microcracks were observed, and where cracks did appear, they tended to be finer and narrower, often sealed by secondary hydration products. The ITZ was highly refined, showing minimal gaps, confirming that a 10% RHS replacement significantly enhances both the microstructural integrity and potential self-healing characteristics of the concrete.

15% RHS-modified concrete

A further improvement in matrix compactness was visible at 15% RHS, as indicated in Figure 9. At x100, voids and large pores were quite sparse, and the ITZ appeared consistently tight around aggregate surfaces. This improvement pointed toward a higher degree of pozzolanic reactivity, consolidating the concrete structure more effectively. Additionally, the SEM images at ×500 magnification highlighted abundant C-S-H gel networks filling and bridging gaps within the matrix, resulting in a microstructure that can better distribute loads, hence contributing to higher compressive and flexural strengths. At ×1000, very fine microcracks are visible, indicating an enhanced stable matrix. Nevertheless, in certain regions, a hint of silica saturation was detected since the excess silica did not fully react during pozzolanic reactions but instead began to cluster. Although this phenomenon was not so detrimental in this sample due to the dispersion effect of the PCE SP, this clustering could foreshadow diminishing returns if the RHS replacement level was pushed higher.

20% RHS-modified concrete

At the macro-scale (relative to SEM x100), the 20% RHS concrete still showed a generally dense matrix (Figure 10). However, isolated zones of porosity and microcracking became more noticeable, suggesting that excessive silica introduced localized stress concentrations. At x500 medium magnification, the matrix continued to display well-developed C-S-H gel in many regions, but some evidences of oversaturation were also observed as pockets of unreacted silica or loosely bound particles appeared. On the other hand, while the ITZ generally remained strong, the distribution of hydration products was somewhat inconsistent compared to the 10% and 15% mixes. At the finest scale of x1000, pronounced microcracks and extensive pore networks were visible, potentially due to localized stresses around excess silica. Moreover, the overall balance between silica addition and beneficial pozzolanic reaction began to decline, indicating that 20% replacement risked slight reductions in long-term durability and toughness relative to the 5–15% RHS replacement range.

Cost Analysis per m^3 and CO_2 Emission Projections of RHS Modified Concrete

In this section, the significance of RHS-Modified Concrete is presented based on (1) Lifecycle cost analysis considering enhanced strength, (2) Environmental benefits and reduced carbon footprint, (3) Consideration of regional variations in cost, and (4) Strategic implications for civil engineering and construction. The analytical data presented in Tables 3, 4 and 5 provided a comprehensive analysis of the cost per $1m^3$ and CO_2 emission projections per $1m^3$ of RHS-modified concrete. The costs and CO_2 analysis procedures were based on the projections by the Japan Society of Civil Engineers: Guidelines for Environmental Performance Assessment of Concrete Structures, as shown in Table 3.

Table 3 Cost evaluation JSCE guidelines.

Materials	Cost/kg	Currency	CO_2 emission/kg	Units
Cement	12.00	JPY (円)	0.746	kg

Lifecycle cost analysis considering enhanced strength

One of the most critical factors in the adoption of RHS-modified concrete is its enhanced strength compared to normal concrete, as evidenced in this study. While the upfront production cost per $1m^3$ (Table 4) is mainly based on current RHS manufacturing cost structures in Japan, the long-term performance benefits must be considered in conformity with the strength gains that were well represented in the results and discussions section. At first glance, the production costs of this material appeared relatively high compared to conventional concrete.

However, a detailed examination of the long-term benefits revealed that RHS-modified concrete could offer significant advantages considering maintenance expenses (strength factor) and durability factors (strength factor). Enhanced strength means that structures built with RHS-modified concrete are likely to experience fewer instances of cracking, spalling, and other degradation phenomena. This can directly translate into reduced maintenance interventions over the life of the structure. Rather than incurring frequent repair costs, which often involve not only direct material and labor expenses but also indirect costs such as downtime and loss of functionality, engineers and project managers can anticipate a more predictable and manageable maintenance schedule. Moreover, although the cost analyses are derived from Japanese production figures, which may be higher due to regional raw material costs and the specifics of local production practices, over time, these savings can offset the higher initial costs, making RHS-modified concrete a cost-effective alternative.

Environmental benefits and reduced carbon footprint

Table 5 details CO_2 emission projections associated with the production and use of RHS-modified concrete. It was noteworthy that the reduction in carbon footprint was directly proportional to the amount of RHS added to the concrete mix. It is important to point out that in an era when environmental sustainability is not only an ethical imperative but also increasingly a regulatory requirement, the ability to lower carbon emissions during construction is a major advantage. For this reason, RHS-modified concrete is engineered to reduce the overall environmental carbon load, which is achieved through optimized production processes and the use of recycled or less carbon-intensive materials. The long-term benefits include compliance with emerging environmental standards and potential cost savings from carbon credit schemes or reduced environmental taxes. Furthermore, a reduced carbon footprint enhances the public perception and marketability of projects, potentially providing a competitive edge in bids and tenders that prioritize sustainable construction practices.

Consideration of regional variations in cost

It is essential to note that the cost figures presented are specific to Japan, reflecting the local production costs and raw material market conditions. In regions where raw materials are more abundant or production processes are optimized differently, the initial cost differential between RHS-modified concrete and conventional concrete may be less pronounced. Local economies of scale, reduced

transportation costs, or innovations in production methods could lead to further reductions in the cost per cubic meter. This variability underscores the importance of contextualizing cost analysis within the specific economic and geographic setting of any construction project. Decision-makers are encouraged to conduct localized studies to understand the exact financial implications; however, the general trends observed, namely, long-term savings through maintenance reduction and environmental benefits, remain consistent.

Strategic implications for civil engineering and construction

From a civil engineering perspective, the adoption of RHS-modified concrete can be seen as a strategic investment in the longevity and resilience of infrastructure. The data indicates that when assessing the overall lifecycle costs of a structure, it is crucial to move beyond the simplistic comparison of initial material costs. Instead, engineers and project managers should adopt a holistic approach that incorporates both direct costs (such as material production and installation) and indirect benefits (such as reduced maintenance, extended service life, and environmental compliance). For instance, while conventional concrete may offer lower upfront expenses, the cumulative costs associated with repairs, replacements, and potential disruptions to service can far outweigh the initial savings. Conversely, RHS-modified concrete, by virtue of its robust performance under various environmental stresses, presents an opportunity to achieve significant long-term savings.

Furthermore, the superior performance of RHS-modified concrete can influence design decisions. With increased confidence in the material's long-term performance, engineers may design structures with optimized dimensions and reduced safety margins that are typically mandated for conventional concrete. This can lead to more efficient use of materials and further cost reductions. Additionally, the environmental credentials of RHS-modified concrete align with the broader global shift towards sustainable construction practices. As regulatory frameworks tighten and sustainability criteria become a prerequisite for public and private funding, the use of low-carbon materials such as RHS-modified concrete may soon evolve from an innovative option to a standard requirement.

Balancing initial costs with future savings

A balanced evaluation of Tables 3, 4 and 5 reveals that although the current production costs of RHS-modified concrete are influenced by factors such as raw material availability and local production economics, the long-term cost benefits are compelling. The upfront investment, when viewed in isolation, does not capture the broader picture. Instead, a comprehensive lifecycle cost analysis demonstrates that the benefits, ranging from reduced maintenance and operational costs to environmental advantages, are likely to result in overall lower expenditures over the life of the structure. This integrated perspective is critical in a world where sustainability and cost-efficiency are becoming increasingly intertwined. The lower maintenance requirements and reduced environmental impact translate into both economic savings and enhanced social responsibility. For stakeholders in the construction industry, adopting RHS modified concrete is not just a matter of meeting regulatory or environmental standards; it is a forward-thinking decision that aligns with the long-term economic interests of infrastructure projects.

CONCLUSIONS

This study investigated the synergistic effects of incorporating rice husk silica (RHS) as a partial cement replacement in low-carbon RHS-modified concrete, with a focus on achieving enhanced mechanical performance and sustainability. The experimental work evaluated compressive and flexural strength developments, and microstructural improvements by optimizing mix design parameters, including water-to-binder ratios and chemical admixture. Additionally, a detailed cost and CO_2 emissions analysis was conducted alongside strength and durability evaluations. The major conclusions drawn from the study are as follows.

Sustainability, CO_2 reduction, and environmental impact: The results indicate that RHS-modified concrete significantly reduces CO_2 emissions by up to 19.56% compared to conventional cement-based concrete. This reduction aligns with global sustainability goals, supporting the circular economy by utilizing agricultural waste as a valuable construction material. Furthermore, microstructural analysis (SEM) confirms that RHS actively participates in the pozzolanic reaction, contributing to improved long-term performance and reduced environmental impact.

Mechanical performance and structural integrity: Optimal RHS replacement (10–15%) led to compressive and flexural strength enhancements of 21.21% and 40%, respectively. The pozzolanic reaction between RHS and cement produced a denser, well-cemented matrix, significantly improving bonding and durability.

Cost implications and economic feasibility: Despite its environmental benefits, the study revealed that the cost per cubic meter of RHS-modified concrete increased by 90.65% to 187.98% compared to conventional concrete. The additional costs stem from processing RHS, optimizing mix proportions, and adjusting chemical admixture dosages. These findings highlight the need for further economic optimization before large-scale industry adoption.

Role of chemical admixtures and mix optimization: The study confirms that polycarboxylate ether (PCE) superplasticizers play a critical role in ensuring the workability of RHS-modified concrete. By fine-tuning the PCE dosage and maintaining strict control over the water-to-binder (w/b) ratios, the mix achieved the desired flowability while preserving structural integrity.

WATER ABSORPTION CHARACTERISTICS OF EPS-BASED LIGHTWEIGHT CONCRETE: EFFECTS OF FLY ASH COATING AND CEMENT REPLACEMENT

Andi Prasetiyo Wibowo[1]

[1]Department of Architecture, Faculty of Engineering, Universitas Atma Jaya Yogyakarta, Indonesia

ABSTRACT

This paper discusses the water absorption characteristics of lightweight concrete comprising expanded polystyrene (EPS) beads and previous works on property enhancement with fly ash addition. In this work, the fly ash will be used as partial cement replacement and as coating material for the EPS beads. The variables studied here will help in relating the water absorption features to the measured density and earlier compressive strength data of these concretes. Experimental results show that indeed, complicated interactions occur between the concrete components. Contrary to expectations, fly ash coating of EPS beads did not yield high improvement in water absorption resistance. On the other hand, the water absorption rate of the concrete mix in this study remained relatively constant at about 13%, which is within the acceptable parameters for concrete masonry units. This finding demonstrates the feasibility of using lightweight concrete containing EPS in construction, where the coating is inadequate. Partial replacement of cement by fly ash had a positive effect on reducing water absorption. This observation showed the double role that fly ash could play in concrete mixtures, influencing both the physical and chemical properties of the final product. Although these results show promise for EPS-based lightweight concrete with fly ash, they also bring to the fore the need for further optimization. While this study showed great promise in using EPS-based lightweight concrete with fly ash, future studies must be dedicated to the fine-tuning of concrete properties with respect to water absorption.

Keywords: Expanded polystyrene (EPS), Fly ash, Lightweight concrete, Water absorption

INTRODUCTION

Expanded polystyrene (EPS) is a lightweight material that can be used as an aggregate in concrete. It has low density, low thermal transmission coefficient, and negligible absorption capacity, making it suitable for various applications in the construction industry. EPS beads can be incorporated into concrete as a replacement for normal weight aggregate, either partially or fully. The use of EPS beads in concrete can improve its fresh and hardened properties, such as compressive strength, flexural strength, and thermal insulation. The particle distribution of the EPS beads and their percentage of replacement with natural aggregate can influence the strength and workability of the concrete. Additionally, the inclusion of waste plastic fibers in EPS-based concrete can further enhance its properties. EPS-based mortars also exhibit hydrophobicity and reduced water absorption compared to sand-based mortars.

Methods for incorporating expanded polystyrene (EPS) beads as aggregate in concrete include partial or full replacement of normal weight aggregate with EPS beads. The particle distribution of the aggregate can also influence the compressive strength of the concrete when EPS beads are used as a replacement. Numerous studies have been conducted on EPS in concrete, generating significant contributions to the field of science. By implementing a bibliometric analysis methodology, using the keywords "expanded polystyrene/EPS" and "concrete", 561 documents were examined. The results of this study help identify the specific topics associated with EPS in the concrete domain (Fig.1).

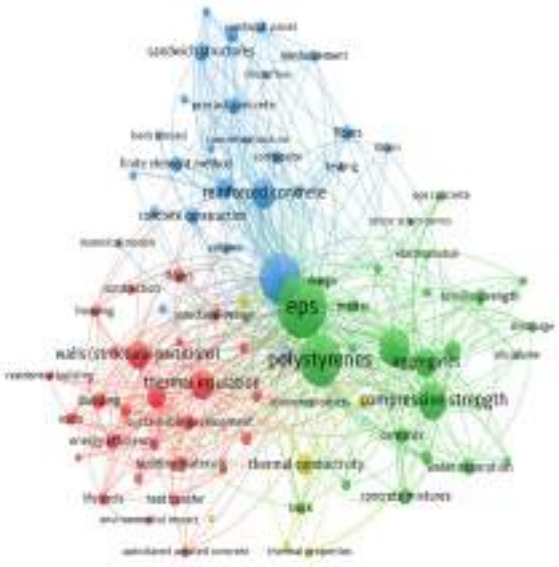

Fig.1 Research connection between expanded polystyrene (EPS) and other topics [1]

Initiated in 1974 and significantly expanded in 2017, research on EPS and concrete has primarily focused on mechanical properties and lightweight concrete production, but recent attention has broadened to include construction applications such as walls, insulating materials, reinforced concrete, and sandwich panels [1]. Nevertheless, there is little evidence of keywords related to water absorption in those results. The possibility of exploring this aspect in future research can be considered necessary.

Fly ash has a positive effect on lightweight EPS concrete, but its use is maximized when combined with other materials [2]. The optimum replacement level of fly ash for achieving high compressive strength is between 15% to 30%, and the highest bond strength is achieved using 10% to 15% fly ash [3]. Meanwhile, according to other studies, it has been suggested that the ideal ratio for substituting cement with fly ash in concrete is 30% [4]. The results demonstrated that substituting 30% of cement with fly ash led to enhanced strength, density, and durability characteristics in concrete. This result supported by other research by using the stoichiometric analysis and experimental trials showed that 30% cement replacement with fly ash resulted in improved strength, density, and durability properties of concrete [5]. Substituting sand with fly ash is an efficient method for decreasing the water absorption of concrete [6]. Consequently, the utilization of fly ash in the production of concrete enhances its properties, durability, and sustainability, particularly when employing a high-volume fly ash concrete mixture.

RESEARCH SIGNIFICANCE

This study explores the water absorption behavior of EPS-based lightweight concrete, a key factor affecting durability and long-term performance. By integrating fly ash both as a partial cement replacement and as a coating for EPS beads, the research addresses the challenge of high porosity and moisture uptake in lightweight concrete. The findings are expected to clarify the relationship between water absorption, density, and compressive strength, offering insights that support the development of sustainable, low-carbon, and resource-efficient building materials for the construction industry.

METHOD

A detailed description of the composition of the test specimens can be found in Table 1. Additionally, this mixture design has been implemented as part of the investigation [7,8].

Table 1 Mix Design

Specimen code	Cement (+PFA) (kg)	Water (kg)	Sand (kg)	Gravel (kg)	EPS Beads (kg)
NC	490	225	572	1063	-
PFAC	343 (+147)	225	572	1063	-
EPSC	490	225	572	-	7.25a
EPS-PFAC	343 (+147)	225	572	-	7.25a
MEPS-PFA	490	225	572	-	190b

[a] non-coated EPS beads; [b] coated EPS beads.

The water absorption testing for each specimen was performed following the ASTM C140-11 standard [9]. The water absorption test was performed after the concrete reached the age of 28 days. This is to ensure that the concrete is stable. This test requires the use of tools such as ovens and scales. The oven temperature for this testing procedure is set to 100-110 degrees Celsius. Each type of concrete is evaluated with three cube specimens' size 100x100mm. The test object was heated for 24 hours. Following that, the weighing process was carried out and documented. Then, the test object is submerged in water for 24 hours. After 24 hours of immersion in water, the specimens were dried for roughly 30 minutes - 1 hour to ensure the surface was dry before being weighed and recorded. The results of recording the dry and wet weights can be used to calculate the level of water absorption of concrete. Water absorption was calculated based on the formula:

$$W_A = \frac{W_S - W_D}{W_D} \times 100\% \quad (1)$$

W_A = water absorption (percent of dry weight)
W_D = dry weight of specimens (24 hours in oven 100-110ºC)
W_S = weight of air-dried specimens after immersed in water for 24 hours

RESULT

The results of water absorption for all specimens can be seen in Table 2 and Fig.2. The data demonstrates that PFAC exhibits a comparatively lower water absorption capacity (5.25%) in comparison to that of normal concrete (5.57%). This observation suggests that the incorporation of fly ash, despite its partial substitution for cement, may enhance the water resistance properties of concrete. In the case of concrete containing EPS beads, the graph illustrates that the water absorption values fall within the range of 11-13%.

Table 2 Density, Compressive Strength, and Water Absorption result

Specimens	Density (kg/m3)	Compressive Strength – Cube 28D (MPa)	Water Absorption (%)
NC	2365.97	45.31	5.57
PFAC	2330.10	40.42	5.25
EPSC	1272.97	11.23	13.26
EPS-PFAC	1280.30	9.33	11.78
MEPS-PFA	1431.10	13.96	13.07

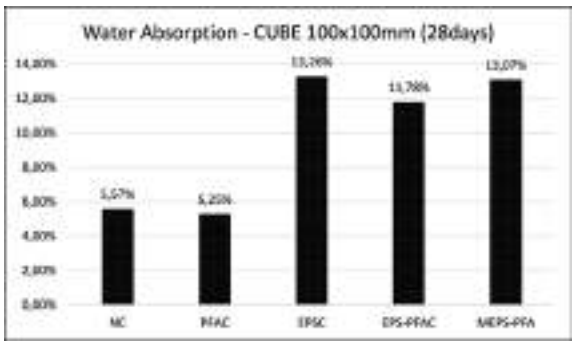

Fig.2 The graph of water absorption test result

Another factor contributing to the elevated water absorption rate of concrete employing EPS beads as aggregate is the presence of voids, potentially resulting from the heating procedure in the oven (Fig.3). The drying process of concrete specimens in the oven facilitates a reduction of the expanded polystyrene (EPS) beads embedded within the concrete. Although the oven temperature goes within the range of 100-110°C, which is theoretically lower than the melting point of polystyrene at 160°C [10], it seems that the softening point of EPS has been reached, which could cause the EPS beads to shrink.

Fig.3 Voids in concrete contain EPS beads after heat treatment at 105-110ºC

To validate this phenomenon of shrinkage, a simple experiment was conducted on MEPS and EPS beads. This involved subjecting the beads to an oven temperature of 105±5ºC for a duration of 24 hours. Despite a relatively stable sample weight, the test results indicate that the size of the particles of the EPS beads has shrunk (Fig.4). Thus, it is essential to note, in the context of this research, that in the future, the shrinkage factor of EPS beads must be a distinct factor of consideration, particularly when evaluating specimens that involve heating.

Fig.4 EPS and MEPS. Before heating (left), and after heating 24 hours (right)

DISCUSSION

Water absorption of lightweight concrete should be measured to evaluate its overall performance and durability. Water absorption can be measured using tests like the initial and final water absorption tests. The results of these tests can be used to evaluate the quality control and durability of lightweight concrete. The entire (reachable) pore volume of the concrete can be estimated using water absorption by immersion [11]. The greater the percentage of air voids that formed, the greater the amount of water that was absorbed by the concrete [12]. The water absorption standard for concrete masonry units requires that the water absorption rate must not surpass 12% for normal concrete and should not exceed 19% for lightweight concrete [13].

Density and Water Absorption

The concrete's water absorption capacity is influenced by the level of concrete density. Conversely, while considering the compressive strength and splitting strength of concrete, it is generally observed that the water absorption value increases as the density of the concrete decreases. This demonstrates that higher density concrete typically exhibits lower water absorption values.

This finding is also comparable to the behavior of concrete reinforced with MEPS. MEPS concrete exhibits a reduced water absorption capacity in comparison to EPSC. Yet, among all concrete specimens incorporating EPS beads, EPS concrete that utilizes fly ash as a substitute for cement exhibits the most minimal water absorption value (Fig.5).

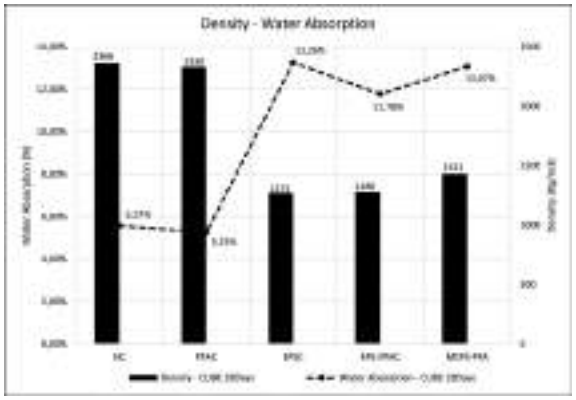

Fig.5 Relationship between Density and Water Absorption

Nonetheless, this research reveals an interesting finding: the water absorption values of concrete that incorporates fly ash as a partial cement replacement exhibit a positive trend without too much change in the density of the concrete. It appears that the incorporation of fly ash into concrete can enhance its water tightness [14], and gets better over time as the concrete matures.

Regarding the impact of employing EPS on density and water absorption, when used as an aggregate, EPS significantly reduces the weight of concrete and has the capacity to make it impermeable due to its non-absorbent properties. The underlying premise supported by previous research, while increasing the number of EPS in concrete results in a decrease in the rate of water absorption [15]. The water absorption percentage of the material, which has a density range of 1400-1800kg/m3, is only 4.37 – 6.95%, significantly lower than that of the control specimen. Nevertheless, it is important to acknowledge that variations in composition could potentially distinguish the outcomes of this study from the research conducted and documented in this thesis. The fundamental factor is the ratio of EPS used as a substitute for sand, rather than the coarse aggregate. In addition, the application of superplasticizer is believed to significantly influence the workability of concrete, resulting in enhanced compaction, and ultimately leading to a greater level of concrete density.

Applying coatings to EPS beads can improve the water resistance of concrete, albeit at the expense of an increase in weight compared to uncoated EPS beads. This finding is consistent with prior investigations in which aggregates coated with cement paste exhibited water absorption 1.8–3.7 times lower than plain LWAs [16]. Similarly, the use of coated biomass aggregate (CBA) in pervious geopolymer concrete (PGC) resulted in an improvement in compressive strength, while having little influence on its water permeability [17].

Therefore, in alignment with the objective of this study, which is to determine the level of the influence of utilizing modified EPS beads, it is apparent that coating-modified EPS beads can increase the water resistance of concrete.

However, the heating process has caused the EPS beads to shrink, resulting in voids that could negatively influence the water absorption value. Previous studies have shown that limiting the use of oven heating during testing can lead to a significant improvement in the current level of compactness. [18]. Utilizing the drying method in an oven for water absorption testing may introduce bias when applied to concrete that incorporates EPS beads as the aggregate.

Compressive Strength and Water Absorption

Another important area of study is the interaction between compressive strength and water absorption in concrete, especially in developing advanced materials like EPS/PFA lightweight concrete. Compressive strength is an essential property that considers the load-bearing capacity or structural integrity of the concrete, while water absorption deals with the durability and resistance of the material to environmental factors. Understanding how these two attributes interact is crucial in optimizing concrete formulations for better performance and durability. High water absorption can result in much porosity and micro cracking, hence decreased compressive strength, which affects the reliability of the structure. Hence, such a study on correlation will help develop more resilient and long-lasting concrete solutions with modern construction requirements to meet sustainability objectives.

Based on the current trend, where the strength of compression is closely linked to density, the graph demonstrating the relationship between compressive strength and water absorption shows a similar pattern (Fig.6). Nevertheless, the graph reveals that the partial replacement of cement with fly-ash, despite decreasing the compressive strength, has been demonstrated to have a beneficial impact on reducing the water absorption of concrete. This is evident when comparing the graphs of the PFAC and EPS-PFAC specimens to those of the NC and EPSC. This suggests that the substitution of a portion of cement with fly ash can reduce the water absorption of concrete. Furthermore, it is worth noting that the MEPS-PFA exhibits a 24% higher compressive strength compared to EPSC. This increase in strength has a positive effect on water absorption, reducing it by 1.4%, which is an improvement. This demonstrates that the application of a coating on EPS beads yields a favorable outcome, specifically by enhancing compressive strength and improving water absorption compared to uncoated EPS beads used in

concrete.

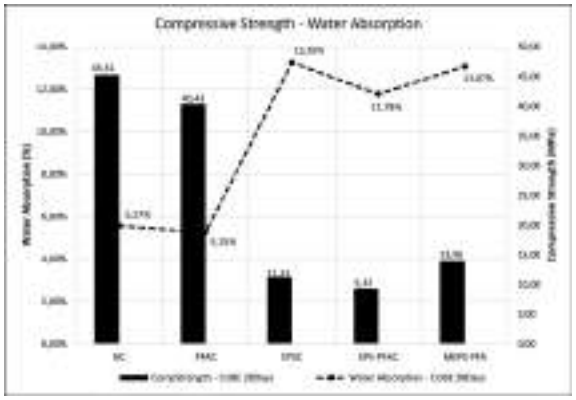

Fig.6 Relationship between Compressive Strength and Water Absorption

CONCLUSIONS

During water absorption testing, the specimens become hollow due to the shrinkage of EPS. Generally, the presence of hollow material significantly affects the water absorption capacity. Hence, this necessitates for a further investigation. In order to evaluate the impact of coated EPS on the water absorption capacity of concrete, it is required to explore alternative testing methods that do not involve heating, thereby preventing the shrinkage of EPS beads.

The water absorption value of concrete made from EPS with coating treatment is higher than that of concrete made from uncoated EPS, indicating that the coating treatment does not have a beneficial effect on water absorption. Nevertheless, despite having a water absorption rate of approximately 13%, it still satisfies the necessary criteria for being utilised as a material for concrete masonry units in construction projects.

ABSTRACT

This study examines the viability of utilizing fine nickel slag (FNS) and gold tailings (GT) as partial replacements for cement and fine aggregate in conventional concrete. The concrete used in Indonesia generally possesses a minimum compressive strength of 21 MPa for residential construction. This research aims to ascertain if including FNS and GT may achieve or surpass this standard while providing environmental and economic advantages by substituting up to 25% of the cement and sand with FNS and GT. The experimental findings indicated a significant decrease in workability as FNS and GT content increased, with slump flow values dropping from 80 mm in the control mixture to 19 mm in the combination with 25% replacement. Compressive strength tests indicated a significant reduction in strength with elevated FNS and GT content; however, the mixture with 15% substitution showed optimal performance, attaining a compressive strength of 37.43 MPa after 28 days, surpassing the standard strength of conventional concrete utilized in Indonesia. Tensile strength indicated decreases in all mixes, with the most significant drop at the 25% substitution level. This research illustrates that despite reduced workability and strength, utilizing FNS and GT in conventional concrete manufacturing is viable while attaining satisfactory mechanical performance. This study introduces new possibilities for sustainable concrete manufacturing by integrating industrial waste materials, enhancing environmental conservation, and economic efficiency in the building sector.

Keywords: Compressive strength, Fine nickel slag, Gold tailings, Industrial waste, Slump

INTRODUCTION

The construction industry is one of the largest consumers of natural resources such as sand, gravel, limestone, and water, leading to environmental impacts due to the extraction and use of these materials. For decades, concrete has been the primary construction material; it is a fundamental material in the construction industry. However, it is particularly resource-intensive, consuming large quantities of resources to produce[1][2].

Nevertheless, the increasing demand for construction materials and the scarcity of natural resources have pushed researchers to explore using industrial waste and by-products as substitutes for the natural resources used in concrete production [3]. This initiative will address the environmental issues associated with resource extraction and offer a solution for disposing of industrial waste, which can be dangerous for humankind and the environment. We will explore the potential of Specific waste materials, such as nickel slag and gold ore tailings, as substitutes for natural materials in concrete production [4][5][6][7].

Nickel slag is a byproduct of nickel smelting that has gained attention as a potential substitute for fine and coarse aggregate in concrete. Indonesia is the largest nickel producer in the world, generating approximately 13 million tons of nickel slag annually. Disposing of that waste is extremely important for Indonesia, as improper disposal may lead to soil and water contamination based on the heavy metal content of nickel slag [8].

Several studies over the past decade have investigated the use of nickel slag in concrete, proving its capacity to improve concrete's mechanical properties and durability. It has been found that incorporating Nickel slag as sand replacement can enhance the compressive strength and workability of concrete [9]. Furthermore, using nickel slag as a coarse aggregate has also shown promising results. Researchers have found that compressive strength increases with the proportion of nickel slag used, making it an adequate substitute for gravel in concrete [10] [11].

The properties of self-compacting concrete made with ferronickel slag as a fine aggregate have shown improvements in fresh and hardened states, making it a viable option for sustainable construction [12][13]. Similarly, the compressive behavior of high-strength geopolymer materials made with industrial by-products has demonstrated excellent compressive strength and durability, suitable for various construction applications [5].

The recycling and comprehensive utilization of ferronickel slag in concrete production have been

successful. Reducing waste and conserving natural resources provide environmental and economic benefits. Incorporating ferronickel slag into concrete enhances its mechanical properties and durability, making it a viable alternative to traditional aggregates [14][15][3].

RESEARCH SIGNIFICANCE

This study demonstrates that fine nickel slag (FNS) and gold tailings (GS) can replace cement and sand in concrete as partial replacements. With Indonesia generating large amounts of nickel-related waste, which poses environmental risks, the research offers a practical and eco-friendly solution for reusing these materials. The mix containing 15% of these substitutes achieved higher compressive strength than standard concrete, proving its potential for structural use. These findings support more sustainable construction by reducing raw material use, lowering environmental impact, and advancing circular economy practices.

EXPERIMENTS AND METHODS

Materials

The experimental design utilizes the Indonesian National Standard [16]. Technique to determine the optimal cement-concrete ratio by substituting equal amounts of cement with GGBFS and Fiber. This allows for a systematic examination of how GT and Nickel Slag impact the alteration of concrete characteristics. The composition has been designed using GT and nickel in standard concrete mixtures as a reference. The mix proportion is presented in Table 3, with GT and Nickel used up to 25% as substitutes for cement and sand.

Gravel, Sand, Cement, Gold Tailing (GT), and Fine nickel slag (FNS) are mixed for 1 minute in a concrete mixer before adding water until a homogeneous concrete is obtained—afterward, a workability test using Abraham's cone. The mixture is poured into the mold for 24 hours and immersed in water (water curing) for 7-14-28 days. Then, it is tested for compressive and tensile strength for 28 days.

Experimental Design

Sieve Analysis is a fundamental civil engineering test that assesses aggregates' particle size distribution. In this test, a sample of dry aggregate is passed through a stack of sieves with progressively smaller mesh sizes, from coarse to fine. Each sieve catches particles above a specific size, and the material retained on each sieve is weighed to determine the distribution of particle sizes. The cumulative percentage passing through each sieve is then calculated to create a gradation curve. This test helps evaluate the suitability of the aggregate for use in concrete, asphalt, and other construction materials. A well-graded aggregate, containing a mix of different particle sizes, typically ensures better compaction, stability, and strength in construction applications, as shown in Table 1 [1]. The specific gravity test is used to determine the density of the aggregates relative to water.

The test consists of oven-drying a sample of the aggregate, weighing it, and then soaking it in water for 24 hours to achieve a saturated surface-dry (SSD) condition. After drying off the surface moisture, the sample is weighed again in the SSD state. The sample is then submerged in water, and its weight is recorded. Specific gravity is calculated using the sample's dry weight and the difference between the SSD and the submerged weights.

Table 1 Specific gravity results of FNS

Experiment		Unit	GT1	GT2
Flask Weight	(A)	gr	224	224
Sample and Flask Weight	(B)	gr	724	724
Sample Weight	(C = B-A)	gr	500	500
Flask, Sample, and Water Weight	(D)	gr	1055	1055.8
Water Weight	(E = D - B)	gr	331	311.8
Specific Gravity	(F = C/(C-E)	gr	2.958	2.972
Average			2.9656	

The bulk density of fine nickel slag was determined using a standardized testing procedure. Initially, the empty container was weighed (as shown in Figure 4), then filled to the brim with fine nickel slag and weighed again to obtain the final measurement (as illustrated in Table 2). Based on the weights found, we can determine the bulk density.

Water absorption capacity

The Water Absorption Capacity test is essential in civil engineering for determining the amount of water a material, typically aggregate, can absorb (Table 3). In this test, the aggregate is dried in an oven to remove all moisture and then weighed. Afterward, the sample

Table 2 Bulk density test results of FNS

Experiment		1	2
Container Volume	(A)	2002	2002
Container Weight	B	774	774
Sample and Container Weight	C	4743.4	4746.4
Sample Weight	D= C-B	3969.4	3972.4
Bulk Weight	E= D/A	1.982	1.984
Average		1.983	1.983

is soaked in water for 24 hours to ensure it is fully saturated. The surface moisture is removed, and the sample is weighed again in its saturated surface-dry (SSD) condition. The difference between the dry and SSD weights calculates the water absorption percentage. This test helps assess the porosity and water-holding capacity of the aggregate, which influences the workability, durability, and strength of concrete. Aggregates with high water absorption may require adjustments in the mix design to ensure proper hydration and performance.

Table 3 Water absorption results of FNS

Experiment		Unit	1	2
Pan Weight	(A)	Gr	654	654
Sample and Pan Weight	(B)	Gr	1654	1654
Sample and Pan Weight	(C=B-A)	Gr	1000	1000
Dry Sample Weight	(D)	Gr	991.2	991.6
Water Absorption Capacity	(E=(C-D)/D)	%	0.888	0.847
Average		%	0.867	0.867

Moisture content

The Moisture Content test is a crucial procedure in civil engineering to measure the amount of water in a material, such as soil or aggregate. In this test, a sample is first weighed in its wet condition and then oven-dried at a specified temperature until it reaches a constant weight. The difference between the wet and dry weights is used to calculate the moisture content as a percentage of the dry weight. This test is important because the moisture content affects the material's behavior, particularly its compaction, strength, and stability in construction projects. Controlling moisture is essential for ensuring the performance of materials like concrete, soil, and asphalt in various construction applications.

GOLD TAILING

To successfully substitute cement with gold tailing, GT's composition needs to be as close as possible to cement, which consists of CAO, SiO_2, Al_2O_3, We know that the main components of Portland Cement are the following:

Table 4 Cement and GT compounds

Compound	Ingredient percentage (%)	OPC Tiga Roda [17]	Gold Tailing - %)
CaO	60-69	63.2	13.54
SiO_2	17-25	18.45	17-25
Al_2O_3	3-8	4.96	3-8
Fe_2O_3	2-4	2.86	2-4
MgO	1-5	3.52	1-5
Na_2O+K_2O	1-3	0.31	1-3
SO_3	1-3	2.18	0.3-1.5

The data that we have received from the industry about the main components of gold tailing shows that GT is very similar to cement, at least to indicate the feasibility of the research (Table 4). Furthermore, the material must respect specific laws regarding human safety, such as limits on the quantity of components, such as lead [18]. The following table shows the analysis report done on Gold Tailing (GT).

Table 5 GT and FNS Elements of Toxicity Leaching Procedure Test (TCLP)

Elements	Limit the US EPA	GT	FNS
	[mg/L]	[mg/L]	[mg/L]
Arsenic	5	0,01	0.5
Barium	100	0,09	35
Cadmium	1	0,09	0.15
Chromium	5	0,08	2.5
Lead	5	7,9	0.5
Mercury	0,2	0,01	0.05
Selenium	1	0,01	0.5
Silver	5	0,01	5

Based on the analysis, we can see an excess of lead in the gold tailing, which may constitute a health risk to future users (Table 5). This shows that concrete made with gold tailing needs to be analyzed to verify the respect of the USEPA limit [19]. While trying to find the optimum W/C ratio for GT, we discovered that GT absorbs more water than OPC. [20][21] However, when saturated with water and

having a higher W/C than the optimum, the GT will get sticky, negatively impacting the slump (Fig. 4).

Fig 4: Water demand test [22]

RESULTS AND DISCUSSIONS

Workability

The material testing results of concrete binders obtained specific gravity of OPC and GT cement, 3.155 and 2.56, respectively. The material testing results of concrete constituents included specific gravity, moisture content, and absorption. The specific gravity results of fine aggregates, coarse aggregates, and Fine nickel slag (FNS) were obtained at 2.53, 2.54, and 2.96, respectively. The fines aggregate water content and coarse aggregate results were obtained at 2.53 and 0.78, respectively. Fine aggregate absorption, Coarse aggregate results were obtained at 2.86, 2,81. Workability testing refers to the European Federation dedicated to specialist construction chemicals and concrete systems (EFNARC) [23].

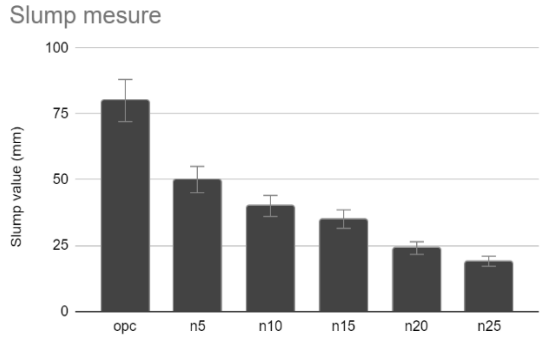

Fig.5 Slump test of Concrete

Table 6 Workability Results in Concrete

Concrete variations	Slump Flow (mm)
CONTROL (OPC)	80
NS5	50
NS10	42
NS15	35
NS20	24
NS25	19

Adding nickel slag and gold tailing significantly affects the workability of concrete (Table 6). With the addition of Fine nickel slag and Gold tailing, Workability decreases with the addition of concrete variations; this result was in line with [24]. The role of NS is as much as 25% as a substitute material. Workability on concrete dropped too drastically[8][12].

Concrete Compressive Test

Figure 6 demonstrates that the incorporation of NS and GT into the mixes resulted in a reduction of compressive strength by the conclusion of the 28th day. Nonetheless, the degree of strength loss varied across different proportions. For NS25, the compressive strength decreased by 44% of the NS25% by the conclusion of the 28th day. The maximum compressive strength observed was for NS15, which declined by 11%. Utilizing NS and GT, we observed a progressive increase in the compressive strength of the concrete, with the majority of samples attaining their peak value on the 28th day. It can be concluded that using NS and GT reduces compressive strength; however, this decline may be mitigated by employing optimal proportions. [15][25].

Table 7 Results of compressive strength and tensile strength

Concrete Variations	Compressive Strength (MPa)	Tensile Strength (MPa)
CONTROL (OPC)	42,27	14,9
NS5	25,57	10,48
NS10	33,87	10,78
NS15	37,43	14,6
NS20	29,96	10,57
NS25	23,62	10,06

Fig.6 Compressive Strength of Concrete

Fig. 7 shows that using NS and GT can decrease the tensile strength of Control concrete (OPC) by 29.6% and 1.9%, respectively. Thus, it can be concluded that adding NS and GT can decrease tensile strength [26][12].

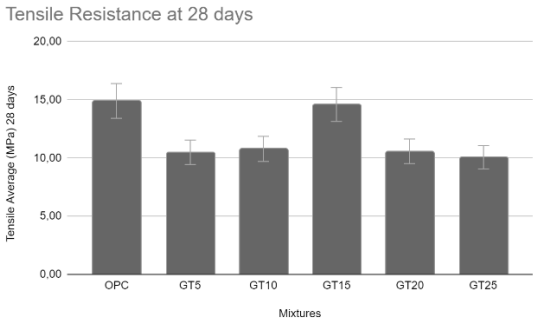

Fig.7 Tensile Strength Results

Porosity Test

The porosity of concrete is a key indicator of its internal structure and durability. It directly influences the material's permeability, mechanical properties, and resistance to environmental degradation. This study conducted the porosity test to assess the impact of fine nickel slag (FNS) and gold tailings (GT) as partial replacements for cement and sand on the concrete's pore structure. Concrete specimens were cured for 28 days to determine total porosity and then dried in an oven at 105°C for 24 hours to remove free moisture. The dried specimens were weighed (dry weight, W_d) and subsequently immersed in water for 24 hours. After immersion, the specimens were weighed in the saturated surface-dry condition (SSD weight, Wssd) and fully submerged condition (submerged weight, Wsub). The porosity (ϕ) was calculated using the following formula, referring to equation (1) :

$$ø\ (\%) = \frac{Wssd - Wd}{Wssd - Wsub} \times 100 \qquad (1)$$

This test was applied to all concrete mixtures, including the control and NS5–NS25 variations. Results illustrated in Fig. 8 show that porosity increased progressively with the increase in GT and FNS substitution levels. The control sample exhibited the lowest porosity, indicating a denser matrix. Conversely, NS25 displayed the highest porosity, which can be attributed to the irregular particle shapes and greater water demand of GT and FNS, which affect compaction and paste-aggregate bonding.

The observed increase in porosity is consistent with previous studies by Chen et al [11], and Juenger et al. [15], which reported that excessive replacement with industrial by-products can increase void content due to less optimized particle packing and higher internal moisture absorption. However, the NS15 mixture maintained an acceptable porosity level that aligns with structural-grade concrete requirements while providing sustainable material advantages.

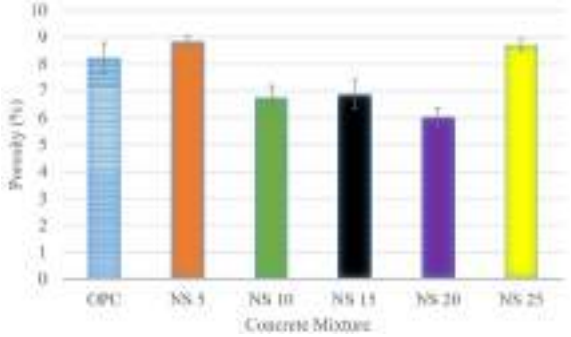

Fig.8 Porosity Test Results

Permeability Test

The permeability test is vital in assessing the durability of concrete, especially when incorporating alternative materials such as fine nickel slag (FNS) and gold tailings (GT). High permeability in concrete can lead to the ingress of water, chlorides, and other aggressive agents, ultimately accelerating the deterioration of reinforced concrete structures. This test was conducted to evaluate how adding FNS and GT affects the water permeability of concrete. The test followed the DIN 1048 standard for determining water penetration under pressure. Cylindrical concrete specimens (150 mm diameter × 150 mm height) were cast for each mix variation, including control (OPC) and substitution levels of 5%, 10%, 15%, 20%, and 25%. After 28 days of water curing, the specimens were subjected to a constant water pressure of 0.5 MPa for 72 hours using a standardized water permeability apparatus.

After the test duration, the specimens were split longitudinally, and the maximum depth of water penetration was measured. As illustrated in Fig. 9, the control mix exhibited the lowest penetration depth (approximately 12 mm), indicating high resistance to

water ingress. With increasing percentages of FNS and GT, the depth of water penetration increased. The NS15 mix showed moderate permeability (~17 mm), while the NS25 mix had a significantly higher penetration (>25 mm), suggesting a more porous internal structure.

These observations align with findings by Han et al. [3] and Nuruzzaman et al. [12], who reported increased permeability in industrial waste's concrete mixes due to microstructural changes and elevated porosity. However, moderate substitution levels (up to 15%) still maintained acceptable performance. Wang et al. [25] Further support is provided by emphasizing the importance of optimizing mix design to balance sustainability and durability in high-performance concrete incorporating tailings and slags.

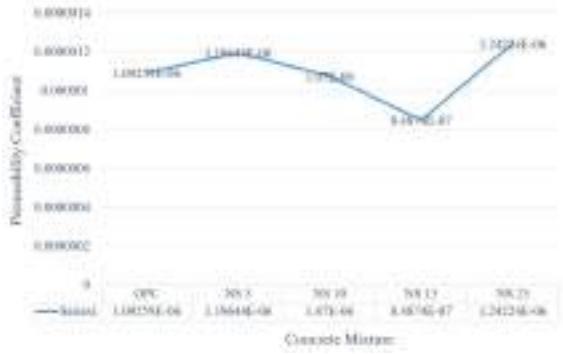

Fig.9 Permeability Test Results

CONCLUSIONS

This study used fine nickel slag (FNS) and gold tailings (GT) as partial replacements for cement and sand in concrete to create a more sustainable construction material. The results showed that while higher substitution levels reduced workability and strength, the mixture containing 15% FNS and GT achieved a compressive strength of 37.43 MPa after 28 days, well above the standard strength used in Indonesian residential construction. Although tensile strength declined slightly across all mixtures, the reduction was acceptable at 15%.

These findings demonstrate that industrial waste materials like nickel slag and gold tailings can be effectively reused in concrete production without compromising quality when used in optimal proportions. This helps lower the demand for natural resources and offers an environmentally responsible way to manage mining waste. This research contributes to developing greener, more circular construction practices by turning waste into valuable construction input.

Further research is encouraged to evaluate these materials' long-term performance and environmental safety, particularly regarding the presence of heavy metals in gold tailings.

HYDROGEOLOGICAL INTERPRETATION USING GEOELECTRICAL AND HYDROCHEMICAL DATA IN CIMANIS WATERSHED, KUNINGAN, WEST JAVA, INDONESIA

Boy Yoseph CSS Syah Alam[1] Hadi Hidayat[1] Deden Zaenudin[1]

[1]Faculty of Geological Engineering, Universitas Padjadjaran, Indonesia

ABSTRACT

This study uses geoelectrical data and groundwater hydrochemical analysis to interpret the hydrogeological conditions of the Cimanis watershed on the eastern slopes of Mount Ciremai, one of the volcanic areas in West Java. Geophysical acquisition comprised 10 lines of 2D electrical resistivity tomography (ERT) profiles at various locations, identifying subsurface layers, delineating aquifers, and determining groundwater characteristics and potential. Meanwhile, twelve groundwater samples were collected in dry and rainy seasons for hydrochemical analysis to understand the hydrogeochemical processes.
The geoelectrical survey results reveal variations in resistivity values, indicating differences in lithology. The distribution of very high resistivity (>500 ohm.meter) appears from 1050 to 700 masl. Then, a group of high resistivity (>200-500 ohm.meter) appears from 700 to 650 masl, consisting of andesite lava rock and supported fragment breccia rock, and a low-medium resistivity group (15-200 ohm.meter). It is a breccia tuff, and the very low resistivity group (< 15 ohm-m) indicates the presence of geological structures. The groundwater types in the research area include Ca+HCO_3, Ca-Mg+HCO_3, and Ca-Mg+Cl, with no significant changes from one dry season to the next, indicating the consistency of groundwater flow below the surface. Rock weathering and changes in volcanic facies below the surface significantly impact the chemical composition of groundwater in the research area. This study demonstrates that combining geoelectrical and hydrochemical methods is a practical approach for hydrogeological investigations.

Keywords: Hydrogeology, Geoelectrical, Hydrochemistry, Groundwater, Cimanis Watershed.

INTRODUCTION

Groundwater is a vital natural resource in volcanic regions, such as Mount Ciremai in West Java, characterised by its complex hydrogeological settings due to heterogeneous lithology and geological structures. Understanding these systems is crucial for sustainable water management in the Cimanis watershed. Previous studies have highlighted the importance of integrating geophysical and hydrochemical methods to delineate aquifers and assess groundwater quality [1,2]. This research aims to explore the groundwater system in the Cimanis watershed through 2D geoelectrical surveys and hydrochemical analysis.

The Cimanis watershed is located on the eastern slopes of Mount Ciremai in Kuningan Regency, West Java, at elevations ranging from 600 to 1,200 meters above sea level. The area predominantly comprises Quaternary volcanic formations, including andesitic lava, breccia, and tuff. The climate is tropical, featuring distinct wet and dry seasons. Recharge mainly occurs through direct infiltration and fault-controlled flow pathways. Land use, which includes agriculture and residential settlements, may influence groundwater chemistry.

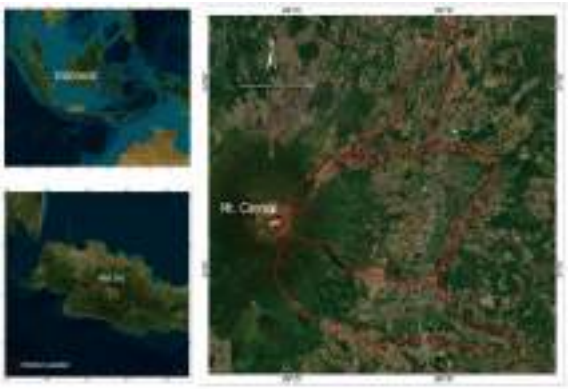

Figure 1. Research location in the easter slope of Mount Ciremai, Kuningan, West Java.

RESEARCH SIGNIFICANCE

This research offers a methodology for interpreting and integrating Electrical Resistance Tomography (ERT) with geological, hydrogeological, and hydrochemical data in the volcanic context of the study area. A key contribution of this work is the enhancement of groundwater potential interpretation and management in volcanic regions, based on findings from geological and hydrogeological investigations.

MATERIALS AND METHOD

Geology and Hydrogeological Mapping.

Previous regional geological studies were reviewed to prepare a preliminary interpretation of the geological units and the volcanic facies [2]. Then, geological mapping was carried out on a scale of 1:25000 to find out more details of the volcanic facies that developed in the research area by observing the outcrops, describing them in the field, and taking hand specimen samples, which were then petrographically analysed in the laboratory.

Hydrogeological mapping was carried out by observing hydrogeological points of interest, namely springs that appear naturally in the field. There are 43 springs in the field. Then, they are plotted, and the physical properties of the groundwater are measured in the field.

Geoelectrical Survey

Ten 2D Electrical Resistivity Tomography (ERT) profiles were measured using the Wenner-Schlumberger configuration. The data processing and modelling were performed with IPI2Win and Res2DInv software. The subsurface resistivity distributions were analysed to identify aquifers, aquitards, and structural features.

Water Sampling

Water sampling was conducted at 12 spring points representing the study area (Fig.2) during the rainy and dry seasons using 500-mL polyethene bottles. Before collecting the samples, the bottles, ladles, and filtration units were rinsed three times with filtered water to eliminate contaminants. The water samples were filtered on-site using a 0.45 µm syringe filter, with 500 mL collected to analyse cations and anions.

Hydrochemical Analysis

pH, electrical conductivity, total dissolved solids, and temperature were measured on-site using HANNA Instruments HI9811-5. The cations (Na^+, K^+, Ca^{2+} and Mg^{2+}) and anions (Cl^-, SO_4^{2-}) were determined by ion chromatography (IC - metrohm type 930 Compact) in the laboratory. HCO_3- was analysed using the titration method with 0.1 N HCl; methyl red and bromocresol green were used as indicators. A 5% difference in the electrical balance between cations and anions was required for all samples, suggesting high accuracy of groundwater quality determinations [3]. Hydrogeochemical data were analysed using statistical and trilinear diagram methods, a trilinear Piper diagram [4], and a Gibbs diagram [5] to confirm the water-rock interaction process in groundwater.

RESULTS AND DISCUSSION

GEOLOGICAL SETTING

The study area is situated on the eastern slope of Mount Ciremai in the Cimanis sub-watershed of Kuningan Regency, West Java. It features a complex volcanic stratigraphy associated with developing a Quaternary stratovolcano. The regional geology showcases a sequence of volcanic and volcaniclastic units ranging from the oldest (unit 10) to the youngest (unit 1). This sequence reflects both effusive and explosive volcanic processes influenced by tectonic activity.

The oldest rock unit in the research area is the tertiary rock, specifically the mudstone unit indicated by the green polygon (Fig. 2). The earliest volcanic product is unit 10, which consists of tuff-breccia and lithic breccia facies, interpreted as laharic deposits. These deposits are characteristic of environments dominated by base surges and debris flows, typically occurring during the initial stages of stratovolcano development [6]. Units 10 through 5 encompass tuff, breccia, and massive to moderately supported andesite breccia. These reflect subaerial pyroclastic density currents and lava emplacement, indicative of intermediate volcanic [7]. Unit 4, consisting of grey tuff-lithic breccia, and Unit 3, defined as coarse andesitic lava breccia, represent periods of increased explosive activity with fragmentation and reworking of volcanic materials.

In the north-central part of the study area, Unit 2 comprises andesite lava flows (referred to as andesite 2), while Unit 1 represents the youngest volcanic features. Unit 1 consists of a mixed collection of lava types, including andesite and basalt. These units reflect the most recent volcanic activity from the Ciremai summit vent, which is characterised by the effusive eruption of lava flows.

The structural framework of the area is dominated by normal and strike-slip faults trending northwest-southeast and northeast-southwest.

Classification of Resistivity Ranges for Geological and Hydrogeological Units

On the 2D geoelectric path from upstream to downstream, 10 2D geoelectric measurement paths spanning 576 meters.

Line 01 (Fig.3) reaches its highest measurement at an elevation of 858 meters above sea level (masl) and extends down to 777 masl, with an orientation from west to east. The geoelectric data reveals a significant resistivity range of 170 to 5400 ohm-meters. In particular, the profile from upstream to the mid-section is characterized by high resistivity, extending to a depth of 80 meters, which decreases as it moves downstream. These elevated resistivity values likely indicate the presence of andesite lava and dry, fragmented, non-solid grey breccia. Notably, this area is suspected to serve as an important recharge zone, highlighting its relevance for resource management and environmental sustainability.

The 02 to 06 line shows that further downstream, the resistivity distribution is dominated by medium-low resistivity values. The infiltration boundary area is depicted on track 01, which is dominated by high resistivity. At the same time, the discharge area appears on lines 03 to 08. The medium resistivity value is suspected to be an aquifer zone, which is geologically suspected to be tough breccia. The low resistivity value is suspected to be an aquifer zone that is spread locally, which is geologically lapilli tuff.

Lines 07 to 10 indicate a resistivity range from 90 to 160 ohm-meter. This range is believed to correspond to lapilli tuff rock transitioning to tuff breccia, which suggests the presence of an aquifer. Lower resistivity values (90-130 ohm-meter) are predominantly found in the factory's Southeast and Northeast areas (downstream). In contrast, higher resistivity values are observed in the Northwest and Southwest areas (upstream). Both resistivity ranges are suspected to be part of the same aquifer system.

Line 07 runs in the West-East direction and measures approximately 576 meters in length with a

depth of about 120 meters. Based on the analysis of line 01, the resistivity distribution in the shallow part, from 0 to 30 meters deep, is primarily characterised by low resistivity, ranging from 90 to 120 ohm-meters. In contrast, from 30 to 120 meters deep, the resistivity is mainly in the medium range, between 130 and 155 ohm-meters. The low resistivity values are associated with lapilli tuff and tuff breccia when correlated with the surrounding rock outcrops. At the same time, the medium resistivity values are believed to be linked to tuff breccia. Both types of rock are suspected to serve as aquifers.

Line 08 (Fig.6) runs in the West-East direction, with a track length of approximately 576 meters and a depth of around 120 meters. Based on the data from track 02, the distribution of resistivity in the shallow part, from 0 to 30 meters, is dominated by medium resistivity, with a range of 150 to 170 ohm-meters. In contrast, low resistivity is predominant at depths between 30 and 100 meters, with values ranging from 90 to 120 ohm-meters. Correlating these resistivity values with the surrounding rock outcrops, it is suspected that the low resistivity readings are associated with lapilli tuff and tuff breccia. In contrast, the medium resistivity values may be related to tuff breccia. Both types of rock are believed to be aquifers.

Line 09 runs in a North-South direction, with a track length of approximately 576 meters and a depth of around 120 meters. Based on the data from track 03, the distribution of resistivity in the shallow southern part, from 0 to 20 meters, is primarily characterised by medium resistivity, which ranges from 150 to 170 ohm-meters. The area shows primarily low resistivity from 20 to 45 meters in depth, with values ranging from 90 to 120 ohm-meters. At depths between 45 and 120 meters, the resistivity again shifts to medium, with a range of 150 to 170 ohm-meters. Correlating these measurements with the surrounding rock formations suggests that the low resistivity values are likely associated with lapilli tuff and tuff breccia. In contrast, the medium resistivity values are suspected to be linked to tuff breccia. These rocks are both believed to act as aquifers.

Line 10 (Fig.7)runs in a North-South direction, with a track length of approximately 576 meters and a depth of about 120 meters. Based on data from Track 04, the resistivity distribution in the shallow southern part, from a depth of 0 to 20 meters, is characterised by low resistivity, ranging from 90 to 110 ohm-meters. From a depth of 20 to 120 meters, the resistivity is predominantly medium, with values between 130 to 150 ohm-meters. In the middle section of the measurement, from depths of 45 to 120 meters, low to medium resistivity is observed, spanning a range of 90 to 130 ohm-meters. When correlated with the surrounding rock outcrops, the low resistivity values are thought to be associated with lapilli tuff and tuff breccia. In contrast, the medium resistivity values are suspected to correspond to tuff breccia. Both types of rock are believed to function as aquifers.

Electrical conductivity in the dry season ranges between 50 µS/cm and 3550 µS/cm, while in the rainy season, it ranges between 50 µS/cm and 3550 µS/cm. Total Dissolved Solids (TDS) measure organic and inorganic substances dissolved in water. In the study area, TDS values during the dry season ranged from 20 mg/litre to 1770 mg/litre. In contrast, the values ranged from 20 mg/litre to 1750 mg/litre during the rainy season. The pH value in the study area during the dry season was 5.3 – 8, while in the rainy season, the pH value in the study area ranged between 5 – 8. Groundwater temperature ranges between 25 ˚C – 35.5 ˚C.

Hydrochemical Facies and Seasonal Variation

The groundwater samples collected from the Sub-Cimanis Watershed on the eastern slope of Mount Ciremai during the rainy and dry seasons exhibit distinct hydrochemical facies, as illustrated by Piper diagrams (Fig.8). In both seasons, the dominant facies idntified is Ca–Mg–HCO_3, indicative of shallow, fresh recharge and typical of groundwater circulating through fractured volcanic rocks [8,9].

During the rainy season, samples such as KNG-12, KNG-17, and KNG-23 plot tightly within the Ca–Mg–HCO_3 field, reflecting the rapid recharge of meteoric water into the unconfined volcanic aquifer. In contrast, the dry season reveals a more dispersed distribution, with several samples showing enrichment in Na^{+} and Cl-, particularly KNG-30 and KNG-33, suggesting ion exchange and longer residence times due to reduced recharge and increased water-rock interaction [10].

These seasonal facies changes imply dynamic hydrogeochemical processes influenced by both climatic and geological controls. The presence of mixed facies during the dry season suggests transition zones within the aquifer system, likely controlled by lithologic heterogeneity [11,12].

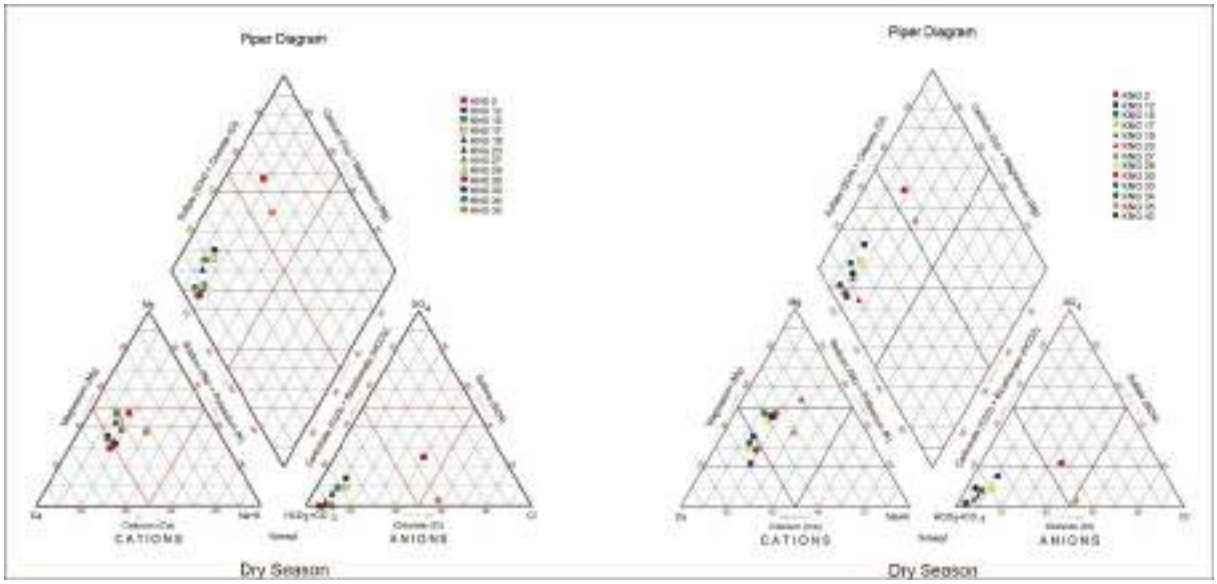

Figure 8. Plotting groundwater samples from both the rainy season and dry season in the research area onto a Piper diagram.

Groundwater Hydrochemical Processes

Gibbs diagrams (Fig. 9), which plot $Na_+/(Na^+ + Ca^{2+})$ and $Cl^-/(Cl^- + HCO_3^-)$ against total dissolved solids (TDS), are used to infer the dominant geochemical processes influencing groundwater chemistry [5]. Most of the samples from both seasons plot within the rock-weathering dominance field, indicating that mineral dissolution, especially from volcanic rocks, is the primary mechanism controlling groundwater composition. [10,11].

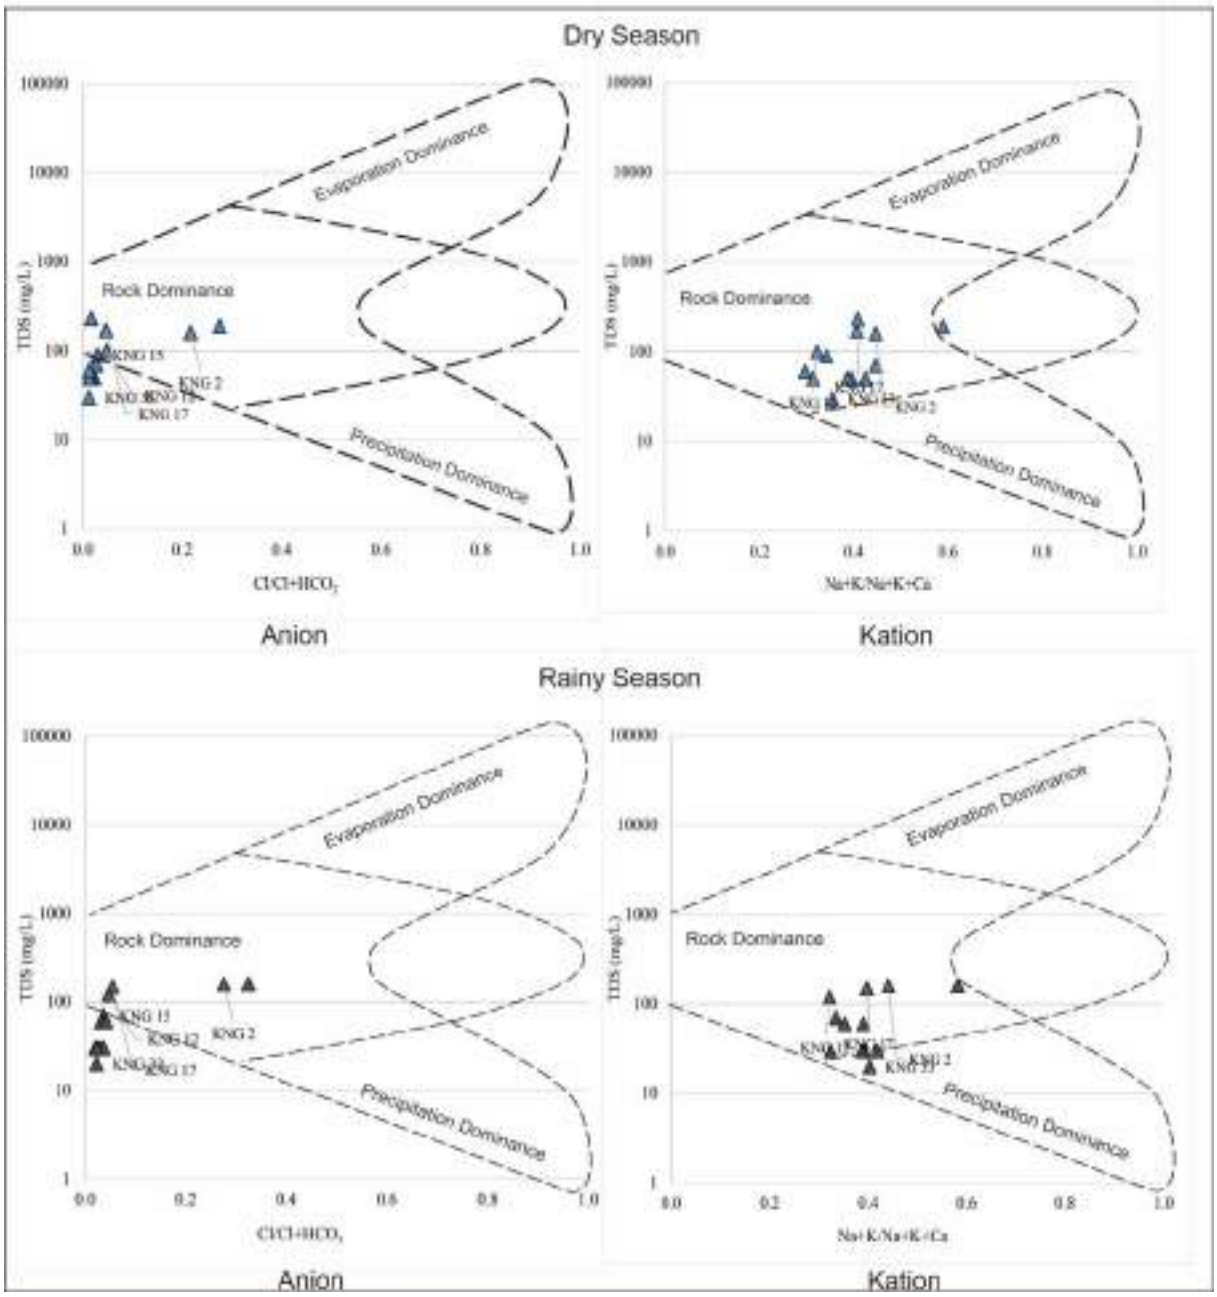

Figure 9. Plot major ions from the groundwater sample to the Gibbs diagram in the study area during the rainy season and dry season.

Integration with Resistivity and Aquifer Geometry

Electrical resistivity data from previous geophysical surveys reveal that high-resistivity zones (>200 Ω·m) correspond with unconfined aquifers composed of volcanic breccia and fractured lava, while low-resistivity zones (<50 Ω·m) represent clay-rich tuff layers that function as aquitards [13,14].

This hydrostratigraphic setting aligns well with the hydrochemical data. For example, samples like and

KNG-35 from confined zones exhibit higher electrical conductivity and mixed facies, suggesting longer groundwater residence times and restricted flow, confirmed by low resistivity values and confined aquifer geometry [15].

CONCLUSION

This study demonstrates that integrating geoelectrical resistivity tomography (ERT) and groundwater hydrochemical analysis provides a comprehensive understanding of the hydrogeological conditions in the Cimanis watershed on the eastern slopes of Mount Ciremai. The ERT results reveal distinct resistivity zones corresponding to subsurface lithology variations, aquifer distribution, and geological structures. High-resistivity zones are associated with volcanic rocks such as andesite lava and breccia, while low-resistivity zones indicate tuffaceous layers and fault-related structures. Hydrochemical analysis of groundwater samples collected across dry and rainy seasons shows consistent facies types—primarily Ca–HCO_3, Ca–Mg–HCO_3, and Ca–Mg–Cl—highlighting stable subsurface flow conditions. The findings underscore the influence of lithological heterogeneity, rock weathering, and volcanic facies transitions on groundwater composition. The integrated geophysical and geochemical approach effectively characterises aquifer systems in complex volcanic terrains, offering valuable insights for sustainable groundwater resource management.
